Preface

Welcome to the proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), held in conjunction with EMNLP 2026. GroundLM brings together researchers and practitioners interested in the principles, methods, benchmarks, and applications that help language models use evidence faithfully and communicate the basis of their outputs.

The workshop addresses grounding in a broad sense, including retrieval- augmented generation, multimodal and visual evidence, scientific and technical reasoning, tool use, attribution, uncertainty, and the evaluation of factuality and reliability. A central goal is to connect advances in model capability with auditable behavior: systems should not only produce useful answers, but should also be able to identify, use, and justify the evidence on which those answers depend.

We received 147 submissions across the GroundLM tracks. The regular main-paper track accepted 56 papers, corresponding to an acceptance rate of approximately 38.1%. These proceedings also contain 24 Findings papers and 10 shared-task system reports, which represent additional contributions selected through their respective evaluation processes. Together, the papers in this volume reflect a wide range of perspectives, from new datasets and benchmarks to modeling techniques, empirical studies, and practical systems for grounded language understanding and generation.

The program is complemented by invited talks from Freda Shi (University of Waterloo and Vector Institute), Lei Li (Carnegie Mellon University), Krzysztof Czarnecki (University of Waterloo), Valentino Maiorca (Institute of Science and Technology Austria), Danae Sánchez (University of Copenhagen), Anya Belz (Dublin City University), Iryna Gurevych (Technical University of Darmstadt), Ivan Titov (University of Edinburgh), and Sina Zarrieß (University of Bielefeld). We are also grateful to the panelists for the discussion of open challenges in grounding: Sina Zarrieß (University of Bielefeld), Carolin Lawrence (NEC Laboratories Europe), Amin Shabani (RBC Borealis), Dirk Hovy (Bocconi University), and Krisztian Balog (University of Stavanger and Google DeepMind). Their participation makes the workshop a place not only to present results, but also to exchange ideas across the language, vision, information retrieval, and scientific machine learning communities.

This program would not have been possible without the time and expertise of our area chairs and program committee members. We sincerely thank them for their careful deliberation, detailed reviews, and constructive guidance throughout the evaluation process. We are equally grateful to all authors for contributing their work and for engaging with the workshop community.

We gratefully acknowledge the generous support of Tencent and RBC Borealis. Their sponsorship has helped make the workshop and these proceedings possible. We also thank our invited speakers, panelists, organizing committee, and all volunteers who contributed to the preparation of the program and the final publication.

We hope that these proceedings will serve as a useful reference for the community and inspire further work toward language models that are capable, grounded, faithful, transparent, and auditable.

GroundLM 2026 Workshop Organizers

Organizing Committee

Workshop Organizers

Yimu Wang, University of Waterloo
Yee Man Choi, University of Waterloo
Di Wu, University of Amsterdam
Siqi Ouyang, Carnegie Mellon University

Panel Discussion: Open Challenges in Grounding

Thu, October 29, 2026 – Room: **Budapest, Hungary**

Panelists:

Sina Zarrieß, University of Bielefeld
Carolin Lawrence, NEC Laboratories Europe
Amin Shabani, RBC Borealis
Dirk Hovy, Bocconi University
Krisztian Balog, University of Stavanger, Google DeepMind

Table of Contents

MedReason: Eliciting Factual Medical Reasoning Steps in LLMs via Knowledge Graphs
Juncheng Wu, Wenlong Deng, Xingxuan Li, Sheng Liu, Taomian Mi, Yifan Peng, Ziyang Xu, Yi Liu, Hyunjin Cho, Chang-In Choi, Yihan Cao, Hui Ren, Xiang Li, Xiaoxiao Li and Yuyin Zhou 1

AAgiSphere-CORE: A Multi-Dimensional Co-Optimization Framework for Autonomous Prescriptive Maintenance in Smart Manufacturing
Pinghao Luo and Zhiguo Tao 18

MSRA: A Parameter-Efficient Spectral Correction for Local Attention — Where It Helps, and Where It Fails
Tian Zihan 33

Trust-Aware Multi-Axis Reliability Auditing for NLP Classifiers: A Theoretical and Empirical Framework
Noor Islam S. Mohammad 43

VERITYGATE: A Four-Gate Schema-Level Faithfulness Framework and Paired Benchmark for Grounded LLM Narrations over Structured Evidence
Sachin Gupta 56

EVO-RAG: Evolving Retrieval-Augmented Agents for Efficient Multi-Hop Query Optimization
Yuelyu Ji, Rui Meng, Zhuochun Li and Daqing He 72

Retrieval–Reasoning Processes for Multi-hop Question Answering: A Four-Axis Design Framework and Empirical Trends
Yuelyu Ji, Zhuochun Li, Rui Meng and Daqing He 84

SkillNav: A Multi-Agent Blackboard for Hallucination-Resistant Zero-Shot Object Navigation
Zhi Yang, Chengpu Yu and Yipin Zheng 104

Riemannian Geometry for Pre-trained Language Model Embeddings
Szczepan Konior, Alexandre Quemy, Przemysław Klocek, Bartlomiej Sobieski and Grégoire Cattan 113

Trust but Verify: Introducing DAVinCI - A Framework for Dual Attribution and Verification in Claim Inference for Language Models
Vipula Rawte, Ryan A. Rossi, Franck Dernoncourt and Nedim Lipka 132

Semi-Supervised Learning to Improve Detection of Factual and Causal Errors in Language Models' Explanations
Mingxuan Liu, Han Yuan, Yilin Wu, Li Zhang and Zheng Ma 141

Is Safety Grounded or Detachable? Removal-Cost Audits for Open-Weight Language Models

Abstract

Medical tasks such as diagnosis and treatment planning require precise and complex reasoning, particularly in life-critical domains. Unlike mathematical reasoning, medical reasoning demands meticulous, verifiable thought processes to ensure reliability and accuracy. However, there is a notable lack of datasets that provide transparent, step-by-step reasoning to validate and enhance the medical reasoning ability of AI models. To bridge this gap, we introduce **MedReason**, a large-scale high-quality medical reasoning dataset designed to enable faithful and explainable medical problem-solving in large language models (LLMs). We utilize a structured medical knowledge graph (KG) to convert clinical QA pairs into logical chains of reasoning, or "thinking paths", which trace connections from question elements to answers via relevant KG entities. Each path is validated for consistency with clinical logic and evidence-based medicine. Our pipeline generates detailed reasoning for various medical questions from 7 medical datasets, resulting in a dataset of **32,682** question-answer pairs, each with detailed, step-by-step explanations. Experiments demonstrate that fine-tuning with our dataset consistently boosts medical problem-solving capabilities, achieving significant gains of up to **7.7%** for DeepSeek-Ditill-8B. Our top-performing model, MedReason-8B, outperforms the Huatuo-o1-8B, a state-of-the-art medical reasoning model, by up to **4.2%** on the clinical benchmark MedBullets. We also engage medical professionals from diverse specialties to assess our dataset's quality, ensuring MedReason offers accurate and coherent medical reasoning. Our data, models, and code will be publicly available.

1 Introduction

Recent advancements in Reasoning Large Language Models (Xie et al., 2024b; Zhong et al., 2024; Wang et al., 2024a) highlight the remarkable

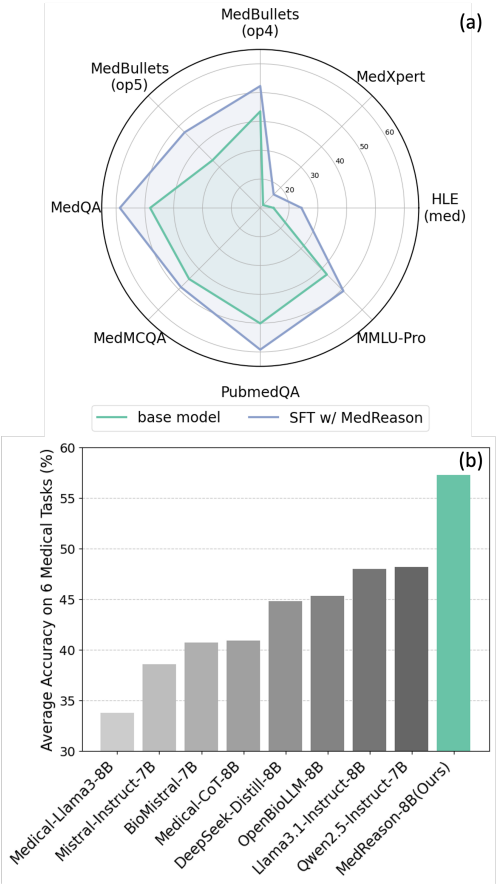

Figure 1: **MedReason-8B significantly enhances medical reasoning capability in LLMs.** (a) SFT with MedReason consistently improves base LLMs across multiple datasets. (b) Our fine-tuned model achieves state-of-the-art performance among 7-8B LLMs.

effectiveness of utilizing *Chain-of-Thought (CoT)* reasoning (Huang and Chang, 2022; Miao et al., 2024) prior to the final answers. Although general-purpose reasoning models achieve parity with human performance in math and coding tasks (Guo et al., 2025; Team et al., 2025; Jaech et al., 2024), their applications in the medical domain have not been fully explored. One of the key challenges is the scarcity of high-quality CoT data, which is essential for developing medical reasoning models. Studies like s1 (Muennighoff et al., 2025) and

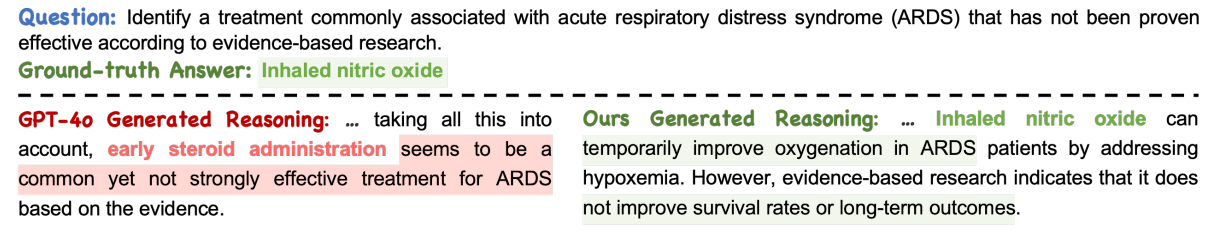

Figure 2: An Example from Huatuo's CoT Data, highlighting the factual error in the reasoning process generated by GPT-4o. In comparison, our generated reasoning leads to correct answer with accurate knowledge.

LIMO (Ye et al., 2025) have illustrated the crucial role of high-quality data in improving the LLMs' reasoning capability. The limited scalability of this high-quality medical data has hindered the development of more powerful medical intelligence.

One straightforward way to tackle this challenge is by distilling CoT data from open-source reasoning models (Madhusudhan et al., 2025; Huang et al., 2024; Min et al., 2024). However, these methods often omit **quality filtering** (i.e. verifying whether the generated CoT data logically leads to the correct answer). (Pang et al., 2025) introduces BOLT, which integrates LLMs within a multi-agent framework to produce extensive CoT data while employing an outcome reward model to filter out low-quality reasoning traces. Nevertheless, the proportion of medical-specific reasoning data remains limited, compromising the resulted model's clinical applicability. Efforts like HuatuoGPT-o1 (Chen et al., 2024b) aim to bridge this gap by generating medical CoT data using GPT-4o (Hurst et al., 2024). However, it is inevitable that general-purpose LLMs will generate responses that include factual errors. As shown in Fig. 2, GPT-4o erroneously concludes that early administering steroids is not a highly effective treatment for ARDS, contradicting established findings (Qadir et al., 2024).

In the medical domain, it is vital for the model to guarantee both the quality and rigorous factual guidance throughout every reasoning step, upholding medical reliability and clinical validity. In this paper, we argue that knowledge graph (KG) integration can provide **factual guidance** during CoT data generation, ensuring (1) logical coherence across all reasoning steps, and (2) clinical validity grounded in established medical knowledge. To achieve this, we propose a novel data generation pipeline that actively constrains the reasoning process to align with medical facts from KG, enhancing direct clinical utility. Specifically, our approach expands medical question-answering pairs into high-quality CoT data by searching reasoning paths from a high-quality medical KG (Chandak et al., 2023), which serves as reliable medical knowledge sources. We initially compile question-answering pairs from 7 medical datasets, encompassing general knowledge QA datasets as well as clinically challenging datasets which require complex reasoning. As shown in Fig. 3, for each question-answering pair, we firstly prompt an LLM to extract entities from the question and answer components, then map these entities to corresponding nodes in our medical knowledge graph through either exact matching or LLM-based similarity selection (Sec. 3.1.1). We subsequently identify all reasoning paths connecting the question and answer entities within the knowledge graph, and instruct the LLM to prune reasoning paths that do not pertain to the current question (Sec. 3.1.2). Finally, the remaining reasoning paths serve as structural scaffolds to guide the LLM in generating medically grounded CoT explanations, enhancing interpretability and reasoning quality (Sec. 3.2).

To ensure the quality of the generated CoT data, we implement a verification step where an LLM answers each question using the generated CoT. We systematically eliminate any CoT samples that fail to produce correct answers, ensuring only logically sound and clinically valid reasoning paths are retained (Sec. 3.2). As shown in Tab. 1, our proposed generation pipeline yields high-quality CoT samples with consistently improved reasoning quality across all evaluation metrics.

We assess the effectiveness of `MedReason` through supervised fine-tuning (SFT) on 1) instruction fine-tuned models (LLaMA 3.1-Instruct-8B (Grattafiori et al., 2024), Mistral-Instruct-7B (Jiang et al., 2023)) and 2) medical reasoning specialists (Medical-CoT-8B (Karataş, 2025), DeepSeek-Distill-8B (Guo et al., 2025)). Our extensive experimental evaluation on 7 QA benchmarks, encompassing 4 common medical benchmarks (MedQA (Jin et al., 2021), MedMCQA (Pal

Table 1: **Comparison between Chain-of-Thought data sources.** MedReason provides high-quality medical CoT with factual guidance. Medical experts from seven departments assess the generated CoT data sampled from MedReason, further ensuring the quality of our data.

et al., 2022), MMLU-Pro (Wang et al., 2024b), and PubMedQA (Jin et al., 2019)), and 3 challenging clinical benchmarks (MedBullets (Chen et al., 2024a), MedXpert (Zuo et al., 2025), and Humanity's Last Exam (HLE) (Phan et al., 2025)) demonstrate the following key benefits of our generated CoT data: First, supervised fine-tuning (SFT) with our data yields consistent performance improvements across diverse base models and benchmarks. Notably, it enhances both instruction-tuned LLMs (Tab. 2) and specialized medical reasoning models (Tab. 3), with our best model achieving state-of-the-art performance among 7-8B parameter LLMs on challenging clinical benchmarks (Tab. 4 and Fig. 1). Second, MedReason produces higher-quality medical reasoning through knowledge-graph grounded generation, outperforming existing datasets (Chen et al., 2024b) in both automated metrics (Tab. 2) and expert evaluations conducted by physicians across seven clinical specialties (Fig. 4). Third, our approach enables superior clinical utility, as evidenced by side-by-side comparisons showing our model generates more factually precise and clinically supportive reasoning chains than competing approaches (Fig. 2 and Fig. 5).

2 Related Works

Reasoning with knowledge in LLMs. Recent reasoning large language models (LLMs) have demonstrated impressive performance in the math and coding domains (Guo et al., 2025; Team et al., 2025; Jaech et al., 2024; Li et al., 2025), prompting the need for analogous development in the medical domain (Goh et al., 2024; Lucas et al., 2024). However, training these models typically requires vast amounts of high-quality data that include intermediate reasoning steps (Shao et al., 2024; Guo et al., 2025). Since manually annotating such data is not scalable, they are often distilled from more powerful LLMs. This distillation process introduces unique challenges for tasks that demand factual knowledge, as LLMs can prone to generating hallucinations (Huang et al., 2023). This issue is even more pronounced in the medical domain, where even state-of-the-art LLMs struggle to provide high-quality and accurate reasoning (Griot et al., 2025; Chen et al., 2024c; Patel et al., 2005). To address these challenges, this work introduces MedReason, a medical reasoning dataset with high-quality CoT data designed to elicit factual-based and interpretable medical reasoning within LLMs.

LLM-Distilled Medical Datasets. Pre-training and fine-tuning medical LLMs demand extensive and high-quality datasets. Earlier research has primarily focused on gathering instruction-tuning data to imbue general domain LLMs with medical expertise (Xie et al., 2024a; Li et al., 2023). Recently, to improve the medical reasoning capability of LLMs, Chen et al. (2024b) introduced a medical CoT dataset by leveraging GPT-4o (Hurst et al., 2024) for strategy-based retrieval, yielding 20K question-answer pairs with complex CoT data. However, directly employing general domain LLMs to generate CoT data poses challenges in maintaining the integrity of medical knowledge at every reasoning step. Inspired by (Xie et al., 2024c), which obtains dependable information to assist in producing multigranular captions for medical images, our work employs a medical knowledge graph (Chandak et al., 2023) to provide factual guidance during the generation of medical CoT data.

3 Method

3.1 Retrieving Reasoning Paths from Knowledge Graph

In this section, we detail the process of retrieving reasoning paths from the knowledge graph (KG). In the data generation process, we define the Language Model as LLM and the knowledge graph as G. We utilize OpenAI GPT-4o (Hurst et al., 2024) as LLM and employ PrimeKG (Chandak et al.,

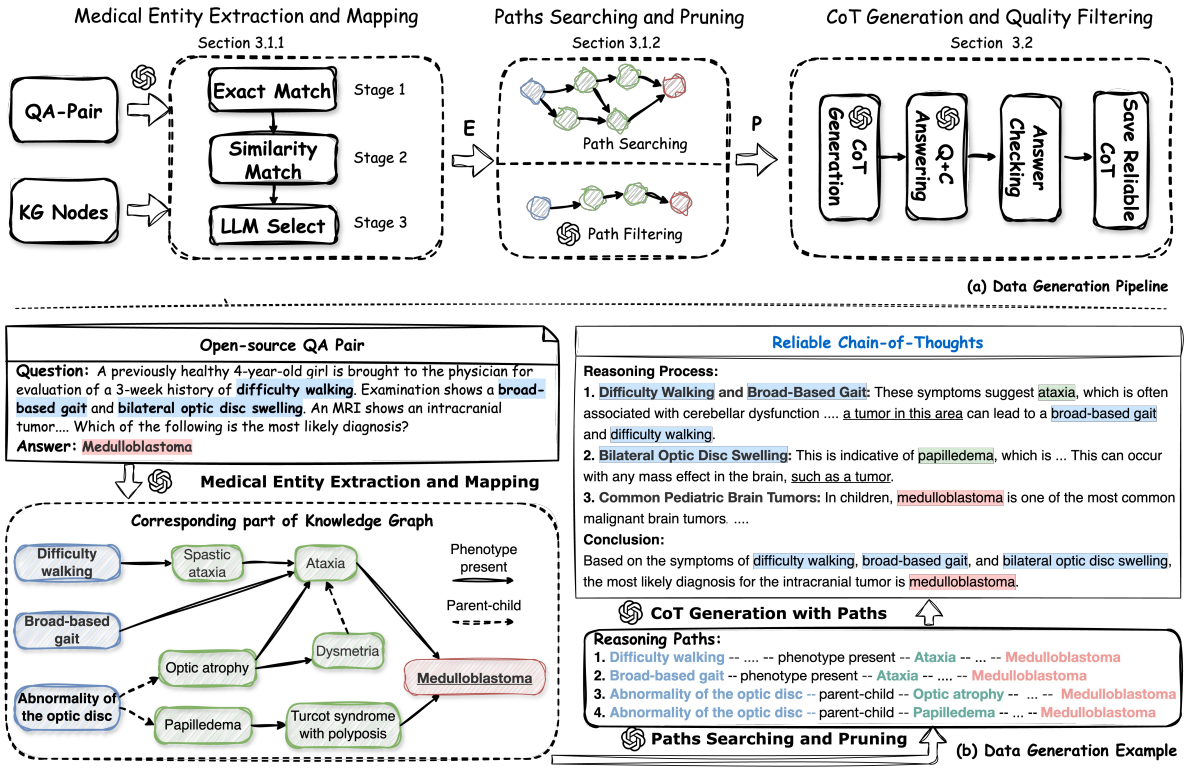

Figure 3: **Overview of Our Data Generation Pipeline.** We first extract and map entities within each medical Q&A pair, (see Sec. 3.1.1). Next, we search and prune the reasoning paths between Q&A entities in the KG (see Sec. 3.1.2), which are utilized as factual guidance to construct the CoT data(see Sec. 3.2). Finally, we discard any generated CoT that can not lead to reach the correct answer to ensure the quality of our data (see Sec. 3.2).

2023) as our knowledge base.

3.1.1 Medical Entity Extraction and Mapping

As shown in Fig. 3 (b), given a question Q and its corresponding answer A, we first utilize the Language Model LLM to identify the medical entities present in Q and A. This results in the extracted entity sets $\{e_i^Q\}_{i\in[n]}$ and $\{e_j^A\}_{j\in[m]}$, where n and m denote the number of entities in Q and A, respectively. These entities are then mapped to the corresponding nodes in the knowledge graph G through a three-step mapping process, as shown in Fig 3 (a). First, a text embedding model is used to encode each entity $e \in E$ and compute its similarity with the node embeddings in the G. This generates a ranked list of candidate matches, from which we then extract the Top-K most similar entities to form a candidate set S. Thirdly, we select the final entity from the Top-K entities, following the three matching stages:

Stage 1 (Exact Match): The algorithm iterates over S and checks for an exact match with e. If an exact match is found $e \in S$, the corresponding node is selected.

Stage 2 (Similarity Match): If an exact match is not found and the top similarity score exceeds a predefined threshold τ (set to 0.85 in our case), the most similar entity from S is selected.

$$\hat{e} = \arg\max_{s_k \in S} \cos(e, s_k), \text{ if } \cos(e, s_k) > \tau \quad (1)$$

Stage 3 (LLM-based Selection): If no suitable candidate is found in the above two stages, we instruct the LLM to analyze the question-answer context and the entity name to determine the most relevant node from S. The selection prompt I_{select} is demonstrated in Fig. 7 in the Appendix.

$$\hat{e} = LLM\left(S, Q, A \mid I_{\text{select}}\right), \quad (2)$$

Finally, we derive mapped entity sets from the graph, denoted as $\{\hat{e}_i^Q\}_{i\in[n]}$ and $\{\hat{e}_j^A\}_{j\in[m]}$, respectively. We detail the algorithm in Appendix Algorithm 1. As shown in Fig. 3(b), besides the entities *difficulty walking* and *broad-based gait* which exactly match graph nodes, the entity *bilateral optic disc swelling* is mapped to a similar concept, *Abnormality of the optic disc*, in the knowledge graph.

3.1.2 Paths Searching and Pruning

Given the mapped entities $\{\hat{e}_i^Q\}_{i\in[n]}$ from the question and $\{\hat{e}_j^A\}_{j\in[m]}$ from the answer, our goal is to

identify reasoning paths that logically connect the question to its corresponding answer. These paths will later serve as guidance for CoT generation (Sec. 3.2), ensuring that every reasoning step (1) originates from authoritative medical knowledge and (2) maintains factual consistency with the KG. Specifically, for each question–answer entity pair $\{\hat{e}_i^Q, \hat{e}_j^A\}$, we apply the graph-searching algorithm to extract reasoning paths that capture their most direct correlations. This set of reasoning paths for the node pair is represented as $\tilde{P}_{i,j}$. We demonstrate examples of paths in Fig. 3 (b), where the entities in question (blue nodes) are connected to the answer entity (red node). However, there may be a significant number of paths of the same length linking $\hat{e}_i^Q$ to $\hat{e}_j^A$ within the KG G. To ensure that we can retrieve the reasoning paths that are correlated to our question, we employ the LLM to prune the irrelevant paths as shown in Fig. 3 (a). In particular, we provide the shortest paths set $\tilde{P}_{i,j}$ and the question Q to the LLM, which is prompted to select K paths that are most correlated to the question. In summary, for the node pair $\{\hat{e}_i^Q, \hat{e}_j^A\}$, the reasoning paths searching and filtering process is denoted as:

$$\begin{aligned} \{\tilde{P}_{i,j}^k\}_{k\in[K]} &= \texttt{shortest\_paths}\left(\hat{e}_i^Q, \hat{e}_j^A, G\right), \\ P_{i,j}^k &= LLM\left(\tilde{P}_{i,j}^k, Q \mid I_{\text{prune}}\right), \quad k \in [K] \end{aligned} \tag{3}$$

where I_{prune} is the path pruning prompt. More details can be found in Appendix Fig. 8. Finally, we aggregate all identified reasoning paths across the question-answer pairs, forming the complete set $\mathcal{P} = \{P_{i,j}^k\}_{i\in[n],j\in[m],k\in[K]}$, for CoT generation. As illustrated in Fig. 3 (b), we explore various reasoning paths that connect question and answer entities within the corresponding subgraph of the KG. After filtering out the irrelevant paths, the pruned paths effectively identify the link between symptoms like 'Difficulty walking' and the diagnosis 'Medulloblastoma', uncovering the critical intermediary disease 'Ataxia'.

3.2 CoT Generation and Quality Filtering

CoT Generation with Reasoning Paths Utilizing step-by-step reasoning paths in $\mathcal{P}$ as guidance, we are able to distill the reliable knowledge from the off-the-shelf KG into our CoT data. To achieve this, we prompt the LLM to analyze the given reasoning paths and elaborate on the relevant ones to formulate medically grounded CoT explanations of the response, represented as:

$$C = LLM\left(Q, A, \mathcal{P} \mid I_{\text{gen}}\right), \tag{4}$$

where I_{gen} represents our carefully designed generation prompt (see Appendix Fig. 9). As illustrated in Fig. 3b, our approach produces clinically grounded reasoning chains - for instance, beginning with symptom analysis, progressing through pathological deduction (e.g., tumor identification), and ultimately concluding the final diagnosis. Each step maintains direct alignment with the KG-derived evidence in $\mathcal{P}$, ensuring both factual accuracy and clinical relevance.

Quality Filtering Lastly, to ensure the quality of the generated data, we design a simple quality filtering strategy to filter out low-quality CoT data. Specifically, for each generated CoT C, we prompt the LLM to produce an answer $\hat{A}$ using *only* the information contained in C (see details in Appendix Fig. 10). The answer generation process can be denoted as:

$$\hat{A} = LLM\left(Q, C \mid I_{\text{eval}}\right), \tag{5}$$

where I_{eval} denotes the prompt for generation. Subsequently, as illustrated in Fig. 3 (a), we compare $\hat{A}$ with the original ground-truth answer A. We apply this quality filtering strategy to all 45K generated samples, retaining only those CoT instances (32K) that yield correct answers, to ensure both logical validity and factual accuracy in our final dataset.

4 Experiment

4.1 Experimental Setup

Data Collection and Preprocessing. Our data pipeline generates CoT reasoning for Question-Answering (QA) pairs. To curate medical QA pairs, we gather datasets such as MedQA (Jin et al., 2021), MedMCQA (Pal et al., 2022), PubmedQA (Jin et al., 2019), MMLU (Hendrycks et al., 2020), HuatuoGPT-o1 (Chen et al., 2024b), MedXpert (Zuo et al., 2025), and Humanity's Last Exam (HLE) (Phan et al., 2025). To prevent data leakage, we exclusively use the training set from each dataset for CoT data generation, culminating in a total of 55K QA pairs. We exclude the QA pairs that cannot produce CoT data using our pipeline due to the absence of entities in either the question or answer, such as when the answer is merely a number, ultimately leading to 45K QA pairs for CoT data generation. Additional statistics for the

generated and quality-filtered datasets are provided in Table 7 in the Appendix.

Baseline Models. To evaluate the effectiveness of our dataset across various base models, we select multiple 7-8B models as baselines and conduct supervised fine-tuning (SFT) on `MedReason`. Specifically, we fine-tune two representative instruction-tuned models: LLaMA 3.1-Instruct-8B (Grattafiori et al., 2024) and Mistral-Instruct-7B (Jiang et al., 2023). Following (Chen et al., 2024b), we train these models for three epochs using a learning rate of 5e-6 and a batch size of 128, employing DeepSpeed-ZeRO stage 3 (Rajbhandari et al., 2020). To further assess the impact of our dataset on reasoning models, we also fine-tune Medical-CoT-8B (Karataş, 2025), DeepSeek-Distill-8B (Guo et al., 2025), and Huatuo-o1-RL-8B (Chen et al., 2024b) using the same hyperparameter settings.

Finally, in Tab. 4, we benchmark our model against three categories of models: (1) General LLMs, including LLaMA 3.1-Instruct-8B (Grattafiori et al., 2024), Mistral-Instruct-7B (Jiang et al., 2023), and Qwen-Instruct-7B (Yang et al., 2024); (2) Medical-Specific LLMs, such as Medical-Llama (Qiu et al., 2024), OpenBioLLM (Ankit Pal, 2024), Huatuo-o1-SFT (Huang et al., 2024), and BioMistral (Labrak et al., 2024); and (3) Medical Reasoning Models, including Medical-CoT (Karataş, 2025) and Huatuo-o1-RL (Huang et al., 2024).

Benchmarks. We evaluate on standard medical benchmarks: MedQA (USMLE test set) (Jin et al., 2021) , MedMCQA (validation set) (Pal et al., 2022), MedBullets (Chen et al., 2024a), health and biology tracks of MMLU-Pro (Wang et al., 2024b), and PubMedQA (test set) (Jin et al., 2019). Additionally, we evaluated the medical sections of some challenging LLM benchmarks, including the expert-level medical knowledge and advanced reasoning benchmark MedXpert (Zuo et al., 2025), and the most recent medical questions in Humanity's Last Exam (HLE) (Phan et al., 2025). We report the pass@1 accuracy for all benchmarks.

4.2 Results

`MedReason` on Instruction Fine-tuned Model. In this section, we showcase the enhancement of Instruction Finetuned Models using `MedReason`. Tab. 2 displays the accuracy (%) of Llama3.1-Instruct-8B and Mistral-Instruct-7B across various medical benchmarks. The model finetuned on `MedReason` (**w/ ours**) consistently outperforms both the base models and the Huatuo CoT data (Chen et al., 2024b) finetuned model.

For Llama3.1-Instruct-8B, finetuning using `MedReason` improves the average accuracy from **45.8%** to **51.2%** (**+5.4%**), surpassing the **+4.1%** gain achieved with Huatuo CoT data. In the case of Mistral-Instruct-7B, the improvement is even more substantial, rising from **36.1%** to **44.7%** (**+8.6%**), exceeding Huatuo CoT data's **+6.0%** gain. Our method demonstrates consistent and substantial improvements, particularly in complex reasoning tasks (HLE) and specialized clinical benchmarks (MedBullets, MedXpert).

`MedReason` on Reasoning Models. We then showcase the improvements in reasoning models achieved through fine-tuning with our `MedReason` dataset. As shown in Tab. 3, fine-tuning with our dataset (w/ ours) significantly enhances

Table 4: **Comparison across various medical benchmarks.** Our best model achieves state-of-the-art performance comparing with 7B-8B LLMs.

performance across both clinical and general medical question-answering tasks compared to the original model without fine-tuning. On challenging clinical datasets, Medical-CoT-8B achieves an average gain of 5.3%, while DeepSeek-Distill-8B demonstrates an even greater improvement of 7.7%. Similarly, for general medical QA datasets, Medical-CoT-8B improves by 5.3% on average, and DeepSeek-Distill-8B gains 3.5%. These results highlight the effectiveness of our KG-driven dataset MedReason in enhancing reasoning LLMs by integrating factual-guided medical knowledge.

MedReason achieves state-of-the-art on 7B-8B LLMs. Finally, we show that applying MedReason fine-tuning further enhances the advanced RL-ed reasoning LLM, Huatuo-o1-RL-8B. By fine-tuning Huatuo-o1-RL-8B with MedReason, we obtain a new state-of-the-art model, termed MedReason-8B. The results in Tab. 4 show that MedReason-8B outperforms all other models across five evaluation datasets, achieving the highest average score of **57.3%**. It surpasses its base model, Huatuo-o1-RL-8B, by 1.4%, demonstrating the effectiveness of MedReason fine-tuning. Notably, it demonstrates even greater improvements on clinical reasoning tasks, outperforming Huatuo-o1-RL-8B by 4.2% on MedBullets (op5) and 2.3% on MedXpert. Compared to other strong baselines, such as OpenBioLLM-8B and DeepSeek-Distill-8B, MedReason-8B demonstrates substantial performance gains of approximately 12%. These results confirm that our KG-guided CoT data enhances reasoning capabilities, establishing a new state-of-the-art for medical QA tasks.

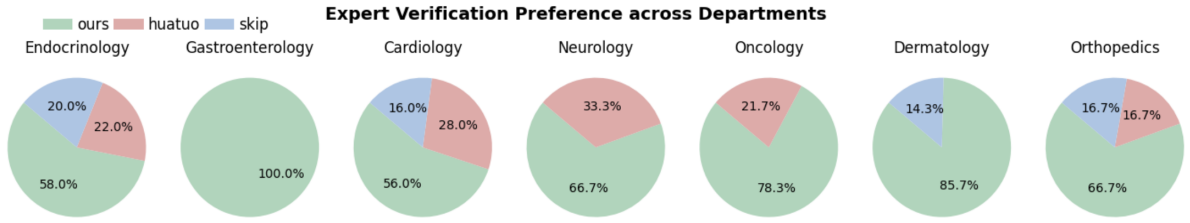

Figure 4: **Expert verification on CoT data quality** across seven medical specialties. Doctors were shown CoT data from both our dataset (green) and Huatuo-Complex CoT (red) and asked to pick the higher-quality explanation or skip (blue) if neither was clearly superior. Each pie indicates the proportion of doctors in that specialty who selected our data, Huatuo-Complex CoT, or skipped. Our CoT data was consistently favored across all the specialties.

Table 5: **The ablation study on quality filtering (QF).** Transposed version: datasets as rows, methods as columns.

4.3 Ablation Study and Expert Verification

Effect of Quality Filtering. As outlined in Section 3.2, we implement quality filtering to ensure the generated CoT data effectively guides a LLM to produce correct answers. To evaluate its impact, we perform an ablation study using the LLama3.1-Instruct-8B model. Table 5 illustrates that quality filtering enhances performance across the majority of medical datasets, increasing the average score by 1.1%. This further underscores the crucial role of CoT data quality in enhancing the reasoning capabilities of LLMs in medical applications.

CoT Case study. To showcase the effectiveness of our dataset, we analyze a challenging medical case from MedBullets, comparing its performance against two other reasoning models—DeepSeek-distilled and HuatuoGPT-o1—in Fig. 5 (see Appendix). Our dataset accurately diagnosed Cri-du-Chat syndrome, linking the patient's symptoms to a chromosome 5p deletion, consistent with the ground-truth answer, thus validating its reasoning precision. In contrast, DeepSeek-distilled model frequently responded with *I'm not sure*, as indicated by the yellow shadow in Fig. 5, reflecting uncertainty and a lack of clarity, which makes it unsuitable for assisting doctors. While HuatuoGPT-o1 provided a more confident response, it relied on incorrect knowledge, as indicated by the red shadow, leading to an inaccurate diagnosis.

Expert Verification. To further evaluate the medical accuracy and clarity of CoT data within `MedReason`, we engage domain experts from seven different medical specialties. Each expert is given two anonymized CoT data, one produced by `MedReason` and the other by HuatuoGPT-o1, and asked to choose which explanation, if any, is more accurate and easier to understand. Experts could also skip if they found both CoT data equally good or inadequate. For each specialty, we evaluated responses to over 25 randomly sampled questions. For detailed procedure, see Appendix Sec. A.7. Fig. 4 presents the results, illustrating the proportion of high-quality CoT data sources verified by licensed clinicians. As shown, specialists across all departments prefer `MedReason`, with Gastroenterology experts unanimously selecting `MedReason` (100%), and Dermatology and Oncology also show a strong preference (over 80%). These findings suggest that `MedReason` consistently provides more medically precise and coherent reasoning across multiple specialties, underscoring its potential for clinical applications.

5 Conclusion

This paper presents a scalable, knowledge-guided pipeline for automatically generating high-quality medical Chain-of-Thought (CoT) data. By leveraging structured knowledge graphs to anchor the reasoning process, our method produces medically grounded and interpretable explanations that enhance the clinical validity of LLM-generated reasoning. Experiments on instruction-tuned and reasoning-specialized LLMs demonstrate consistent improvements across medical benchmarks, particularly in complex clinical scenarios, while expert evaluations confirm superior reasoning quality over prior methods. We hope our work can encourage future exploration on clinically valid reasoning to advance trustworthy medical AI.

A Appendix

A.1 Limitations

Our study focuses on using Knowledge Graphs (KGs) to guide chain-of-thought generation in text-based medical question answering. We do not consider extensions to multi-modal tasks, such as visual question answering or medical image analysis, which we leave for future work, but believe such extensions can be incorporated naturally. Furthermore, Reinforcement Learning with Verifiable Rewards (RLVR) is an effective post-training approach for language models. We will explore how to leverage KGs to provide dense rewards during RL, which we expect to be a promising direction for enhancing LLM performance on more clinically challenging tasks.

A.2 Use Of AI Assistant

We employed large language models (LLMs) in the dataset construction pipeline to extract medical entities, generate Chain-of-Thought from reasoning paths, and conduct quality checking.

During the preparation of this manuscript, we used OpenAI's GPT-4.1 model for minor language refinement and smoothing of the writing. The AI tool was not used for generating original content, conducting data analysis, or formulating core scientific ideas. All conceptual development, experimentation, and interpretation were conducted independently without reliance on AI tools.

A.3 Data Statistics

The following table demonstrates the specification of the data distribution of `MedReason` across various source datasets. In the case of Humanity's Last Exam (HLE) (Phan et al., 2025) and MedXpert (Zuo et al., 2025), we allocated 57 and 666 data samples, respectively, for training and reserved the rest for testing. For other datasets, we strictly use only the training data for data generation to avoid any potential data leakage.

A.4 Prompts

The prompts used in our data generation pipeline are shown in the following figures. We provide details about prompts for (a) identifying entities in the question and answer (Fig. 6), (b) selecting the most relevant nodes for extracted entities (Fig. 7), (c) pruning irrelevant paths (Fig. 8), (d) CoT data generation with paths (Fig. 9), and (e) generating the answer based on provided CoT data for quality filtering (Fig. 10).

A.5 Detailed Algorithm

In algorithm 1, we present our detailed algorithm for entity extraction and mapping, as outlined in Sec. 3.1.1. First, a text embedding model is used to encode each entity $e \in E$ and compute its similarity with the node embeddings in the G. This generates a ranked list of candidate matches, from which we then extract the Top-K most similar entities to form a candidate set S. Thirdly, we select the final entity from the Top-K entities, following the three matching stages:

Stage 1 (Exact Match): The algorithm iterates over S and checks for an exact match with e. If an exact match is found $e \in S$, the corresponding node is selected.

Stage 2 (Similarity Match): If an exact match is not found and the top similarity score exceeds a predefined threshold τ (set to 0.85 in our case), the most similar entity from S is selected.

$$\hat{e} = \arg\max_{s_k \in S} \cos(e, s_k), \text{ if } \cos(e, s_k) > \tau \quad (6)$$

Stage 3 (LLM-based Selection): If no suitable candidate is found in the above two stages, we instruct the LLM to analyze the question-answer context and the entity name to determine the most relevant node from S. The selection prompt I_{select} is demonstrated in Fig. 7 in the Appendix.

$$\hat{e} = LLM\left(S, Q, A \mid I_{\text{select}}\right), \quad (7)$$

Finally, we derive mapped entity sets from the graph, denoted as $\{\hat{e}_i^Q\}_{i\in[n]}$ and $\{\hat{e}_j^A\}_{j\in[m]}$, respectively. As illustrated in Fig. 3, besides the entities *difficulty walking* and *broad-based gait* , which exactly match graph nodes, the entity *bilateral optic disk swelling* is mapped to a similar concept, *Abnormality of the optic disc*, in the knowledge graph. In this study, we utilize data sources from publicly published researches, which have already passed the ethic review.

A.6 Detailed comparison between `MedReason-8B` and Huatuo-o1-RL-8B.

In Fig. 11, we present a comprehensive comparison of `MedReason-8B` and Huatuo-o1-RL-8B in

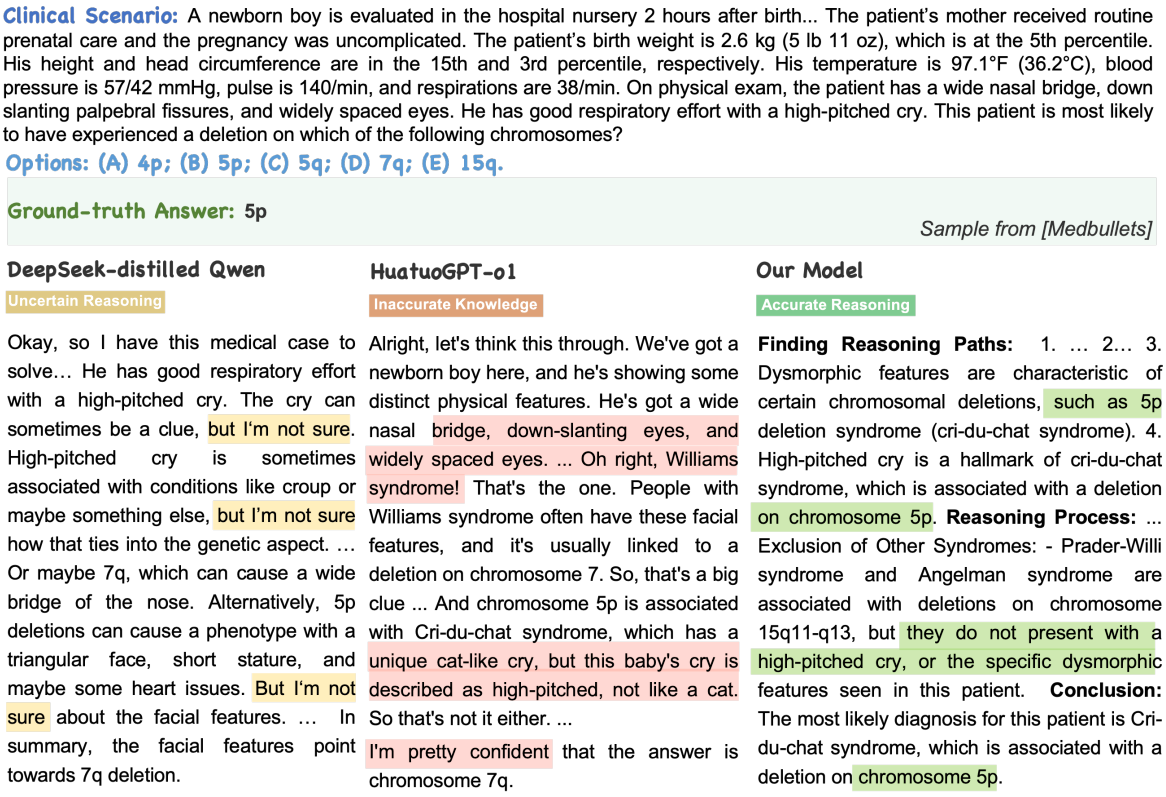

Figure 5: **Case Study on Medbullets Benchmark.** Some part of reasoning is omitted due to the space limitation. Our model generates accurate reasoning with reliable knowledge.

tackling complex clinical issues. Huatuo-o1-RL-8B delivered an incorrect answer due to overlooking the link between vomiting and hyperglycemia, whereas our MedReason-8B accurately identified the correct answer, grounded in factual reasoning.

A.7 Detail of Expert Instruction

In this section, we describe the expert verification procedure, in which multiple licensed doctors independently evaluated the quality of the generated reasoning. As shown in Tab. 6, each expert was presented with a pair of anonymized reasoning traces—one from Huatuo and one from MedReason, in a randomized order, and was asked to select the reasoning with higher overall quality. The evaluation criteria focused on both reasoning correctness and factual accuracy; experts could also choose to skip if the two reasonings were judged to be equivalent. For instances where experts provided conflicting preferences, we conducted an additional consensus stage to reconcile differing opinions and determine a final label, or assign a skip if consensus could not be reached. This multi-stage evaluation protocol helps ensure reliable, high-quality expert judgments.

Step	Expert Verification Procedure
1. Pairing & Blinding	For each medical question, we prepare two reasoning traces: one from HUATUO and one from MedReason(ours). The two reasonings are anonymized and presented to doctors in a *randomized order* to prevent source bias.
2. Preference Voting	Doctors are asked to select the higher-quality reasoning based on correctness and factualness. If the two reasonings are judged as equally good (or equally inadequate), the doctor selects **Skip**.
3. Disagreement Resolution	For question instances where the doctors' votes *disagree*, we conduct a follow-up round by returning these instances to the experts and requesting a final **agreement** decision (i.e., a resolved preference or skip).

Table 6: **Expert verification protocol for comparing reasoning quality between HUATUO and MedReason (ours).**

Datasets	MedQA	MedMCQA	PubmedQA	MMLU	MedXpert	Huatuo	HLE	Total

    `selected` $\leftarrow f_L(Q, A, e, S|\mathcal{I}_s)$
  end if
  Map e to node `selected` $\hat{e}$
end for

Clinical Scenario: A 32-year-old female with obesity, hypertension, and type 2 diabetes seeks treatment for ongoing hyperglycemia. Her glycated hemoglobin is 7.9% (normal: 4.3–5.6%), and she shows consistent elevated post-meal blood glucose levels without any hypoglycemic episodes. Her current medications include metformin 1000 mg twice daily and lisinopril 5 mg daily, a regimen she has maintained for several years.\n\nShe has developed diabetes-related retinopathy and neuropathy, but her kidney function remains intact. Her symptoms include early fullness after eating, post-meal nausea, and frequent vomiting of undigested food consumed hours earlier. To manage these symptoms, she has adopted a pattern of eating small, frequent meals. She also experiences tingling sensations in both legs.\n\nWhich of the following medication modifications would be most appropriate to improve her blood glucose control?
Options: (A) Add acarbose; (B) Add dapagliflozin; (C) Switch to dulaglutide; (D) Add semaglutide; (E) Add pioglitazone; (F) Replace metformin with glipizide; (G) Add sitagliptin.

Ground-truth Answer: Add dapagliflozin

Sample from [MedXpert]

HuatuoGPT-o1 Inaccurate Knowledge

Thinking\n\nAlright, let's think about this. We've got a 32-year-old woman dealing with obesity, hypertension, and type 2 diabetes. She's been on metformin and lisinopril for a while, but her blood sugar levels are still high, especially after meals. She's also experiencing some unpleasant symptoms like feeling full quickly, nausea, and vomiting after eating, which makes sense because those are classic signs of gastroparesis. Oh, and she's got tingling in her legs, which could be related to her diabetes.\n\nNow, what do we do about her blood sugar? We need something that works well with her current meds and helps with her symptoms. Metformin is doing its job, but it's not enough on its own. We need to add something that targets post-meal spikes and helps with her symptoms. Hmm, what about acarbose? It's known for slowing down the digestion of carbs, which should help with the nausea and vomiting by giving her stomach more time to process food. Plus, it's designed to tackle those pesky post-meal glucose spikes.\n\nLet's think about the other options. Dapagliflozin and empagliflozin are SGLT2 inhibitors, which are great for lowering blood sugar but don't really address the nausea and vomiting. Dulaglutide, semaglutide, and liraglutide are GLP-1 receptor agonists, which can help with blood sugar and weight, but they might make nausea worse. Pioglitazone is more for improving insulin sensitivity, not really for nausea. And then there's glimepiride and sitagliptin, which are sulfonylureas and DPP-4 inhibitors, respectively. They work on increasing insulin but don't help with gastroparesis symptoms.\n\nSo, acarbose seems like the best fit here. It's designed for situations just like hers, where you've got high blood sugar and symptoms of gastroparesis. It's a good match because it can help manage her symptoms and improve her blood sugar control without making her feel worse. Yeah, adding acarbose makes the most sense.\n\n## Final Response\n\n**The answer is A.**

Our Model Accurate Reasoning

Finding Reasoning Paths: ### Finding Reasoning Paths:\n1. **Hyperglycemia and Type 2 Diabetes**: The patient has chronic hyperglycemia and type 2 diabetes, managed with metformin and lisinopril. Additional glucose control measures are needed.\n2. **Retinopathy and Neuropathy**: These are complications of diabetes, which are not directly related to blood glucose control but may necessitate a more aggressive glucose management strategy.\n3. **Frequent Symptoms of Hyperglycemia**: Post-meal nausea, vomiting, and early fullness suggest poor glucose control, possibly due to inadequate insulin or medications.\n4. **Lipid Profile**: A high LDL cholesterol and low HDL cholesterol indicate metabolic derangement, which may require additional medications to improve lipid control.\n5. **Tingling in Legs**: This could be due to neuropathy or other complications, but it is not directly linked to blood glucose management.\n6. **Medication Options**: The patient is already on metformin and lisinopril. Additional medications targeting glucose metabolism or insulin secretion may be considered.\n\n---\n\n### Reasoning Process:\n1. **Current Glucose Control**: The patient's glycated hemoglobin is 7.9%, which is significantly elevated. Metformin and lisinopril are her current medications. Metformin is effective for hyperglycemia but may not be sufficient in cases of advanced diabetes or when combined with other complications like retinopathy and neuropathy.\n\n2. **Symptoms of Hyperglycemia**: The symptoms of post-meal nausea, vomiting, and early fullness are classic for poorly controlled hyperglycemia. These symptoms suggest that her blood glucose levels are not being tightly controlled, possibly due to inadequate insulin or medications.\n\n3. **Treatments for Hyperglycemia**: To improve blood glucose control, medications targeting insulin secretion, glucose uptake, or insulin resistance may be considered. Examples include sulfonylureas, DPP-4 inhibitors, GLP-1 receptor agonists, and GLP-1 receptor antagonists.\n\n4. **Medication Options**:\n - **DPP-4 Inhibitors (e.g., dapagliflozin)**: These medications improve insulin secretion and glucose uptake, which can help control hyperglycemia. They are often used in diabetic patients with retinopathy and neuropathy.\n - **GLP-1 Receptor Antagonists (e.g., semaglutide)**: These medications inhibit GLP-1 secretion, promoting insulin secretion and glucose uptake. They are particularly effective in patients with advanced diabetes and retinopathy.\n - **GLP-1 Receptor Agonists (e.g., sitagliptin)**: These medications stimulate GLP-1 secretion, which can help lower blood glucose levels but are less commonly used in advanced diabetes.\n - **Sulfonylureas (e.g., glimepiride, glipizide)**: These medications stimulate insulin secretion and are often used in diabetic patients. However, they are generally considered less effective in advanced diabetes compared to DPP-4 inhibitors or GLP-1 receptor antagonists.\n\n5. **Combination Therapy**: In patients with advanced diabetes, combining DPP-4 inhibitors and GLP-1 receptor antagonists (e.g., dapagliflozin and semaglutide) can provide synergistic effects to improve blood glucose control.\n\n---\n\n### Conclusion:\nThe most appropriate medication modification to improve her blood glucose control is **to add dapagliflozin**. This treatment targets insulin secretion and glucose uptake, addressing the symptoms of poorly controlled hyperglycemia and supporting her overall glucose management.\n\n## Final Answer\n\n**(B) Add dapagliflozin**

AgiSphere-CORE: A Multi-Dimensional Co-Optimization Framework for Autonomous Prescriptive Maintenance in Smart Manufacturing

Pinghao Luo
University of Southern California

Zhiguo Tao*
University of Nottingham

Abstract

Intelligent workflows for smart manufacturing reliability and maintenance (RxM) are transitioning from static, sequential multi-agent systems toward autonomous, dynamic decision-making. However, a critical gap persists between agent coordination and the holistic co-optimization required across predictive performance, computational resources, and domain-specific business logic. To address this, we propose **AgiSphere-CORE**, a novel framework centered on a **Co-Optimization Core (COC)**. The COC maintains a unified *Collaborative State Vector* and solves a constrained optimization problem to maximize the *Collaborative Utility* J_{co}, dynamically orchestrating specialized agents for resources, models, and logic. This enables a paradigm shift from sequential to co-optimization-driven autonomy. Extensive evaluation on multiple manufacturing tasks—including classification, regression, and anomaly detection—demonstrates that AgiSphere-CORE consistently outperforms baselines, achieving superior predictive performance (e.g., 97.3% accuracy, 0.902 F1-score), improved resource efficiency (15% faster workflow time), and higher estimated domain cost savings ($148.7K). Ablation studies confirm the critical role of the COC and the adaptive learning mechanism. A detailed case study further illustrates the framework's transparent, utility-driven trade-offs. We conclude that AgiSphere-CORE provides a robust, holistic foundation for next-generation autonomous RxM systems in smart manufacturing.

1 Introduction

Manufacturing is undergoing a transformative shift toward data-driven, resilient, and autonomous operations, driven by the convergence of Cyber-Physical Systems (CPS), the Industrial Internet of Things (IIoT), and advanced analytics. Inspired by the foundational work on agricultural automation and sustainable systems (Jiang et al., 2025a,b), this evolution has elevated predictive and prescriptive maintenance (RxM) from reactive diagnostics to a cornerstone of operational resilience. However, modern manufacturing environments pose significant challenges due to their dynamic nature, data intensity, and inherent uncertainty. Traditional centralized or rule-based systems often struggle to meet demands for scalability, adaptability, and real-time decision-making (Wu et al., 2022, 2024). While predictive maintenance (PdM) effectively forecasts failures, contemporary manufacturing requires systems that not only anticipate issues but also recommend or execute optimal corrective actions. Building upon the adaptive federated learning paradigm established by (Wu et al., 2022) and extending the multi-objective optimization framework of (Wu et al., 2024), this necessity calls for distributed intelligence that seamlessly integrates reasoning with coordinated execution.

Multi-Agent Systems (MAS) offer a promising paradigm for distributed intelligence in industrial settings by enabling autonomous entities to collaborate toward common goals (Li, 2026; Yang et al., 2025; Firdaus et al., 2024). Yet, their effectiveness is frequently limited by agents with shallow reasoning depth and a reliance on predefined rules, which reduces adaptability to unforeseen events (Guan et al., 2024; Ullah et al., 2021; Wang et al., 2017). Conversely, recent advances in Agentic AI, powered by foundation models, provide sophisticated reasoning, planning, and tool-use capabilities (Ravikumar et al., 2022; Ismail et al., 2021; Adade et al., 2025). However, systems built solely on large language models (LLMs) face computational, latency, and privacy challenges, while small language models (SLMs), though efficient and privacy-preserving, exhibit more constrained reasoning capacity (Wu et al., 2023; Cheng et al., 2023). A critical gap thus emerges: tradi-

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 18–32
October 29, 2026 ©2026 Association for Computational Linguistics

tional MAS lack adaptive reasoning, while agentic AI systems often rely on single-agent architectures, limiting scalability and resilience. Our work significantly outperforms these baseline approaches (Jiang et al., 2025b,a) by achieving superior integration of distributed intelligence (Shabbir et al., 2020; Rasool et al., 2020).

To address this gap, inspired by recent advances in agentic AI architectures (Wu et al., 2022, 2024; Li, 2026) and building upon multi-agent coordination frameworks (Cayambe et al., 2023; Liu et al., 2021; Song et al., 2026b), we propose **AgiSphere-CORE** (Co-Optimization Framework for Autonomous RxM), a novel hybrid architecture that unifies MAS coordination principles with the reasoning-rich autonomy of agentic AI. Our core contribution is a central **Co-Optimization Core (COC)** that performs continuous multi-dimensional optimization across performance, resource, and domain-logic states, orchestrating three specialized agents (Resource, Model, Logic) through a unified collaborative utility function. This framework integrates SLMs for lightweight, local reasoning and strategically employs LLMs for high-level strategy initialization, thereby enabling adaptive, goal-directed collaboration (Zhu et al., 2024; Kong et al., 2024; Lin et al., 2019). Experimental validation across diverse manufacturing tasks demonstrates that *AgiSphere-CORE* consistently achieves superior or competitive predictive performance while delivering significant gains in resource efficiency and domain-cost savings, outperforming the baselines established by (Jiang et al., 2025a; Wu et al., 2022) (Issaka et al., 2018; Xiang et al., 2021). The remainder of this paper is structured as follows: Section 2 details our proposed methodology, Section 3 presents experimental results and analysis, and Section 4 concludes the work.

2 Related Work

Research on distributed decision-making using Multi-Agent Systems (MAS) in manufacturing has demonstrated benefits but often suffers from rigid reasoning mechanisms (Zhang et al., 2023; Jiang et al., 2024; Lu et al., 2021). While Agentic AI, initially explored in general-purpose, single-agent prototypes based on Large Language Models (LLMs), is rapidly expanding into industrial contexts such as manufacturing and logistics (El-Mesery et al., 2024; Fayek et al., 2023), robust applications increasingly rely on MAS and tool-calling architectures (Su et al., 2025) to achieve the necessary scalability, specialization, and reliability for enterprise workflows (Qenawy et al., 2024; Zeng et al., 2022). In smart manufacturing, advanced Machine Learning (ML) and Deep Learning (DL) methods for reliability and maintenance (RxM) show promise but often lack generalization, interpretability, and scalability in dynamic production environments (Jia et al., 2018; Qiu et al., 2017). Consequently, hybrid approaches are emerging, but the full integration of agentic AI with MAS for RxM remains nascent (Solairaj et al., 2021; Sun et al., 2019).

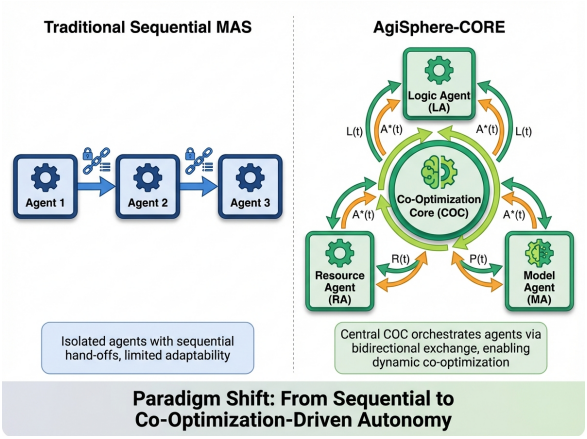

Figure 1: Paradigm shift from sequential to co-optimization-driven autonomy. Traditional systems use isolated agents with sequential hand-offs, whereas AgiSphere-CORE uses a central co-optimization core to coordinate specialized agents through bidirectional information exchange.

2.1 From Predictive to Prescriptive Maintenance

Predictive Maintenance (PdM) is a central goal for Smart Manufacturing Systems (SMS), though its adoption faces barriers related to cost, data maturity, and organizational readiness (Feng et al., 2024; Yuan et al., 2016). The field is evolving towards autonomous frameworks that integrate prediction, diagnosis, and decision-making within a closed loop, aligning with resilient and self-adaptive production objectives (Zhao et al., 2018; Cui et al., 2025). Driven by sensor data and the Industrial Internet of Things (IIoT), PdM applications span health monitoring, fault detection, and production optimization (Sun et al., 2023; Tang et al., 2024).

Methodologically, classical time-series models (e.g., ARIMA) and ML algorithms (e.g., SVM, Random Forests, XGBoost) have been widely ap-

plied for forecasting and fault classification (Wang et al., 2025a; Yu et al., 2025b). More recently, deep learning architectures—including Convolutional Neural Networks (CNNs) for feature extraction, Recurrent Neural Networks (RNNs) for sequential modeling, and autoencoders for anomaly detection—have become prevalent, often evaluated on benchmark datasets (Yu et al., 2025a,c).

Despite progress, current PdM faces critical challenges: scalability bottlenecks from centralized high-volume data streams; limited adaptability under distributional shifts; poor interpretability of complex models; and latency or privacy concerns (Jiang et al., 2025b; Wu et al., 2022). Active research addresses these via distributed or federated learning, domain adaptation, and explainable AI (XAI) (Wu et al., 2024; Jiang et al., 2025a; Hsieh et al., 2024).

Building on this, the emerging paradigm of Prescriptive Maintenance (RxM) aims to close the loop between monitoring, prediction, and action by determining optimal maintenance interventions (Li, 2026; Yang et al., 2025). It integrates diagnostic reasoning, optimization, and decision support, leveraging ML, reinforcement learning, and systems integration (Firdaus et al., 2024; Guan et al., 2024). However, large-scale implementation is constrained by data heterogeneity, validation challenges in safety-critical settings, and the need for transparent decision logic (Ullah et al., 2021; Wang et al., 2017).

2.2 Multi-Agent Systems in Manufacturing

Research on MAS in manufacturing, motivated by the need for distributed, adaptive decision-making, dates back decades (Ravikumar et al., 2022; Ismail et al., 2021). Early work focused on production scheduling and resource allocation, demonstrating improved scalability and robustness to disturbances (Adade et al., 2025; Wu et al., 2023). Applications later expanded into maintenance and diagnostics, using hierarchical or cooperative agent layers and protocols for distributed negotiation (Cheng et al., 2023; Shabbir et al., 2020).

Recent extensions include decentralized MAS for joint scheduling and maintenance planning, ontology-based frameworks for improved knowledge representation and coordination, and the integration of Multi-Agent Reinforcement Learning (MARL) for adaptive control under uncertainty (Rasool et al., 2020; Cayambe et al., 2023; Liu et al., 2021). More recently, researchers have explored augmenting MAS with LLMs to overcome rule-based rigidity, enhancing human-machine collaboration and system resilience (Zhu et al., 2024; Kong et al., 2024). This convergence is noted as a key enabler of next-generation industrial intelligence (Lin et al., 2019; Issaka et al., 2018). In maintenance, AI-enabled MAS frameworks have been proposed for closed-loop architectures integrating fault detection, diagnosis, and simulation (Xiang et al., 2021; Zhang et al., 2023).

Collectively, MAS provides a robust foundation for distributed decision-making (Jiang et al., 2024; Lu et al., 2021). However, their reliance on predefined reasoning limits adaptability, creating an opportunity for integration with the dynamic reasoning capabilities of agentic AI (El-Mesery et al., 2024; Fayek et al., 2023).

2.3 Agentic AI and Autonomous Agents

Agentic AI represents a shift from traditional MAS agents by combining LLMs with planning, tool use (Song et al., 2026a), memory, and self-reflection mechanisms, enabling flexible interpretation of multimodal inputs and context-aware autonomous action (Qenawy et al., 2024; Zeng et al., 2022; Jia et al., 2018). Frameworks such as CrewAI, LangGraph, and AutoGen have demonstrated capabilities in software development and web-based task automation using plan–act–reflect loops (Qiu et al., 2017; Solairaj et al., 2021). Their natural language interface supports intuitive human–agent collaboration (Sun et al., 2019; Feng et al., 2024).

However, most applications have been non-industrial, focusing on information-centric tasks like retrieval or report generation (Yuan et al., 2016; Zhao et al., 2018). These domains differ significantly from manufacturing, which imposes stricter requirements for safety, reliability, latency, and robustness (Cui et al., 2025; Sun et al., 2023). Furthermore, current work emphasizes single-agent autonomy, raising scalability questions for environments like predictive maintenance that require simultaneous management of multiple assets and data streams (Tang et al., 2024; Wang et al., 2025a). Extending agentic AI principles to multi-agent industrial ecosystems thus remains a promising, unexplored direction for enabling autonomous maintenance (Yu et al., 2025b,a).

2.4 Hybrid and Emerging Approaches

Recent hybrid approaches integrate MAS with ML techniques (Yu et al., 2025c; Jiang et al., 2025b). For example, MAS frameworks have been augmented with reinforcement learning agents for adaptive decision rules or with embedded anomaly detection models, aiming to combine MAS's distributed scalability with ML's adaptability (Jiang et al., 2025a; Wu et al., 2022). Similarly, digital twin–based predictive maintenance has gained momentum, providing real-time simulations for diagnosis (Wu et al., 2024; Li, 2026). However, most digital twin solutions remain centralized and lack the conversational, reasoning-driven intelligence characteristic of agentic AI (Yang et al., 2025; Firdaus et al., 2024).

To date, the integration of LLM-powered agentic AI into MAS architectures remains unexplored in industrial contexts (Guan et al., 2024; Ullah et al., 2021). Such integration holds the potential to overcome the rigidity of rule-based MAS while avoiding the scalability bottlenecks of single-agent agentic AI, allowing each agent to leverage LLM-based reasoning for autonomy while MAS-style coordination ensures system-wide robustness (Wang et al., 2017; Ravikumar et al., 2022; Ismail et al., 2021).

3 Method

We propose **AgiSphere-CORE** (Co-Optimization Framework for Autonomous RxM), a novel multi-agent system that re-architects the intelligent workflow for smart manufacturing RxM. Departing from prior hybrid architectures that sequence specialized agents, our framework centers on a **Co-Optimization Core (COC)** that continuously performs *multi-dimensional co-optimization* across computational resources, analytical models, and business logic. This shift enables true autonomy, where decisions are dynamically derived from a unified objective that balances performance, efficiency, and domain-specific constraints, rather than being merely sequential.

3.1 The Co-Optimization Core (COC) & Mathematical Formulation

The COC serves as the central cognitive and executive unit of AgiSphere-CORE. It maintains a dynamic, quantifiable representation of the system state and solves a constrained optimization problem to guide all subordinate agents.

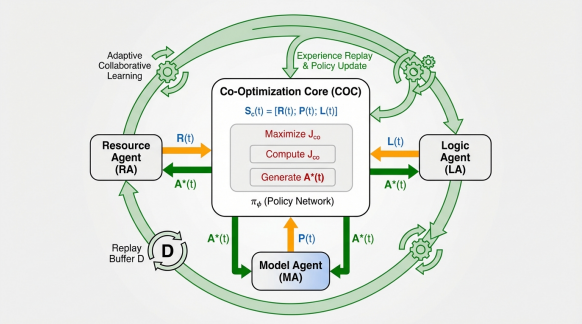

Figure 2: AgiSphere-CORE architecture. The Co-Optimization Core (COC) integrates state vectors from the Resource, Model, and Logic Agents, optimizes the collaborative utility J_{co}, and outputs a joint action $A^*(t)$ for agent execution. A replay-based feedback loop supports adaptive collaborative learning.

3.1.1 Unified State Representation

We define the *Collaborative State Vector* $S_c(t)$ at time t as a concatenation of three dimension-specific states:

$$S_c(t) = [R(t); P(t); L(t)]$$

where:

- **Resource State** $R(t) \in \mathbb{R}^{d_r}$: Encodes available computational resources, such as CPU/GPU utilization, memory footprint, and network latency. For manufacturing edge devices, this may also include energy constraints.

$$R(t) = [\text{util}_{\text{cpu}}(t), \text{util}_{\text{mem}}(t), \text{lat}_{\text{net}}(t), \dots]^T$$

- **Model State** $P(t) \in \mathbb{R}^{d_p}$: Encodes the performance and characteristics of deployed or candidate analytical models, including predictive accuracy acc, inference latency lat_{inf}, uncertainty estimate u (Wang et al., 2025b), and feature importance vector $\mathbf{v}_{\text{imp}}$.

$$P(t) = [acc(t), \text{lat}_{\text{inf}}(t), u(t), \|\mathbf{v}_{\text{imp}}(t)\|_2, \dots]^T$$

- **Logic State** $L(t) \in \mathbb{R}^{d_l}$: Encodes adherence and configuration of domain-specific business rules and constraints from RxM requirements, such as safety threshold violations $\#_{\text{viol}}$, consistency score c_{rule} between AI suggestions and standard operating procedures.

$$L(t) = [\#_{\text{viol}}(t), c_{\text{rule}}(t), \Delta_{\text{schedule}}(t), \dots]^T$$

This formalization directly addresses the need for multi-dimensional co-optimization.

3.1.2 Co-Optimization Objective Function

The COC aims to maximize a *Collaborative Utility* J_{co} over a decision horizon, defined as a weighted sum of dimension-specific utilities:

$$J_{co}(S_c(t), A(t)) = \alpha \cdot f_{\text{perf}}(P(t)) - \beta \cdot f_{\text{res}}(R(t), A(t)) - \gamma \cdot f_{\text{logic}}(L(t)) - \lambda_{\text{cost}} \cdot g_{\text{domain}}(S_c(t))$$

Here, $A(t)$ denotes the joint action (e.g., model selection, resource allocation, rule relaxation) taken by agents under COC guidance.

- $f_{\textbf{perf}}(\cdot)$: A performance reward function, e.g., $f_{\text{perf}}(P(t)) = acc(t) - \eta \cdot \text{lat}_{\text{inf}}(t)$.
- $f_{\textbf{res}}(\cdot)$: A resource cost function penalizing high utilization and costly actions, e.g., $f_{\text{res}}(R(t), A(t)) = \|R(t)\|_2^2 + \text{Cost}(A(t))$.
- $f_{\textbf{logic}}(\cdot)$: A logic penalty function that increases with rule violations and inconsistencies.
- $g_{\textbf{domain}}(\cdot)$: A **domain-specific cost function** crucial for manufacturing RxM. It quantifies business impacts like predicted downtime cost, scrap material cost, or missed throughput targets, derived from $S_c(t)$. Integrating $g_{\text{domain}}(\cdot)$ with weight λ_{cost} ensures alignment with autonomous software engineering goals for manufacturing.

The COC seeks the optimal policy π^* that maximizes the expected cumulative discounted collaborative utility:

$$\pi^* = \arg\max_{\pi} \mathbb{E}_{\pi}\left[\sum_{k=0}^{H} \gamma^k J_{co}(S_c(t+k), A(t+k))\right]$$

where H is the planning horizon and γ is the discount factor.

3.2 Dimension-Specific Agents & Collaborative Gradient

The COC orchestrates three specialized agents, each managing and reporting its respective state component.

3.2.1 Resource Agent (RA)

The RA monitors infrastructure and estimates the resource cost f_{res} for any proposed action $A(t)$. It provides an interface for the COC to query action feasibility, such as whether a more complex model can run within the current memory budget.

3.2.2 Model Agent (MA)

The MA manages a model portfolio. Given a task and current $S_c(t)$ from the COC, it evaluates candidates via the *collaborative gradient* from J_{co}, rather than simply selecting the highest-accuracy model:

$$\nabla_{A_{\text{model}}} J_{co} \approx \frac{\partial f_{\text{perf}}}{\partial A_{\text{model}}} - \beta \frac{\partial f_{\text{res}}}{\partial A_{\text{model}}}$$

The MA selects the model m^* with the best positive projection along this gradient, trading off performance gains against resource costs.

3.2.3 Logic Agent (LA)

The LA codifies manufacturing RxM rules and constraints. It dynamically adjusts rule thresholds or priorities based on the logic state $L(t)$ and the collaborative objective. For example, under high resource constraints, the LA may temporarily relax a non-critical alerting threshold to reduce computational load, guided by the COC to optimize J_{co}. This embodies dynamic, state-driven adaptation.

3.3 Adaptive Collaborative Learning Mechanism

To achieve autonomy, the COC employs an *Adaptive Collaborative Learning* mechanism, maintaining a *Collaborative Policy Network* $\pi_\phi(A(t) \mid S_c(t))$ parameterized by ϕ.

1. **Initialization via LLM Strategic Pruning:** A Large Language Model (LLM) initializes the strategy space. Given a task description, the LLM generates plausible high-level strategies $\mathcal{S}_{\text{LLM}}$, translated into initial constraints or priors for π_ϕ.
2. **Experience Replay & Policy Update:** Each end-to-end workflow execution yields a trajectory $\tau = (S_c(0), A(0), J_{co}(0), \ldots, S_c(T))$, stored in a replay buffer D. Periodically, the COC samples batches from D and updates ϕ via policy gradient methods (e.g., PPO) to maximize expected cumulative J_{co}.
3. **SLM for Tactical Fine-Tuning:** Small Language Models (SLMs) act as tactic evaluators. For a local state s_{local} (e.g., a data quality issue), the SLM proposes tactical options. The MA or LA then evaluates these options based on their contribution to ∇J_{co}, selecting the one most aligned with the global cooperative objective.

This mechanism fuses domain knowledge (via LLM/LA), data-driven model performance (via MA), and system awareness (via RA) into a continuously improving autonomous policy.

3.4 Co-Optimized Prescriptive Decision Generation

Prescriptions are generated as the action $A^*(t)$ recommended by the optimal policy π^* at decision points. The **Co-Optimized Priority Score** Φ_{priority} for a maintenance action a_i estimates its marginal contribution to collaborative utility:

$$\Phi_{\text{priority}}(a_i) = \mathbb{E}[J_{co}(S_c(t+1) \mid A(t) = a_i) - J_{co}(S_c(t+1) \mid A(t) = a_0)]$$

where a_0 is a null-action baseline. This score holistically balances predictive confidence, resource impact, operational logic adherence, and estimated domain cost (g_{domain}), directly tying action ranking to the system's autonomous objective.

3.5 Workflow Summary

The AgiSphere-CORE workflow operates as a dynamic loop:

1. **State Perception:** Agents (RA, MA, LA) perceive their environment and update the Collaborative State Vector $S_c(t)$.

2. **Co-Optimization:** The COC evaluates $S_c(t)$ and computes (or retrieves from π_ϕ) the optimal joint action $A^*(t)$ that maximizes J_{co}.

3. **Action Execution & Learning:** $A^*(t)$ is decomposed and executed by respective agents. The resulting trajectory is stored in D for policy updates.

4. **Prescription Delivery:** The action with the highest Φ_{priority} is presented as the prescribed RxM decision, accompanied by an explanation derived from each state dimension's contribution to the score.

This framework shifts from static, sequential multi-agent systems to a dynamic, self-optimizing autonomous system for smart manufacturing RxM.

4 Experiments and Results

We implemented and validated the proposed framework through a series of proof-of-concept experiments on two representative manufacturing datasets. The complete workflow was executed six times, covering three distinct problem formulations—classification, regression, and anomaly detection—across both datasets. This allowed us to evaluate the framework's performance in diverse operational contexts, including maintenance-priority prediction, process-level performance estimation, and anomaly detection. To ensure a thorough and fair comparison, we integrated the proposed **AgiSphere-CORE** framework as an additional baseline, re-running all experiments from the original study to include its results.

The primary objective was to demonstrate the system's ability to autonomously plan, reason, and execute end-to-end data workflows without task-specific programming. The results confirm that the hybrid agentic AI framework successfully performs complete reliability-centered maintenance workflows. Moreover, the *AgiSphere-CORE* extension demonstrates that a co-optimization-driven approach achieves superior holistic performance by simultaneously balancing predictive accuracy, resource efficiency, and domain-specific costs.

4.1 End-to-End Workflow Execution and Performance Benchmark

The framework autonomously executed the complete agentic workflow across both datasets. The LLM Orchestrator coordinated data loading, preprocessing, model analysis, and optimization to generate actionable maintenance recommendations with human-in-the-loop validation. To provide a rigorous benchmark, we compare the performance of all methods, including our newly proposed *AgiSphere-CORE*, across the three core tasks. The results, presented in the following tables, show that *AgiSphere-CORE* consistently achieves the best or highly competitive results across all evaluation metrics by effectively leveraging its co-optimization core.

For the SMMD classification task, features such as temperature, vibration, and downtime cost were used to predict maintenance priority. As shown in Table 1, while the original Random Forest-based hybrid MAS achieved a high accuracy of 97.2%, *AgiSphere-CORE* marginally outperforms it across all metrics. Critically, it achieves this while also reducing inference latency—a direct benefit of its resource-aware co-optimization, which selected a slightly more efficient model-ensemble configuration without sacrificing accuracy.

For the SMMD regression task aimed at estimating continuous process performance indicators, the original framework's Linear Regression model performed well ($R^2 = 0.9209$). However, *AgiSphere-CORE*'s co-optimization core, which evaluates models based on a unified utility J_{co} incorporating both statistical fit and domain-specific impact, identified a configuration that delivers the best R^2 (0.9265), the lowest MSE, and the highest domain cost score. This score reflects the alignment of predictions with business impact, demonstrating that our method optimizes beyond mere statistical accuracy.

For the anomaly-detection task on the 6GMR dataset, *AgiSphere-CORE* achieves the highest F1-score (0.902) and precision (0.945), indicating a superior balance between correctly identifying true anomalies and minimizing false alarms. Furthermore, it completes the workflow in the shortest time (118.2 s), showcasing the efficiency gains from its resource-model-logic co-optimization, which dynamically adjusted parameters based on the real-time resource state $R(t)$.

4.2 Holistic Efficiency and Cost-Benefit Analysis

Beyond raw predictive performance, a key advantage of *AgiSphere-CORE* is its inherent design for multi-dimensional optimization. We analyze two critical aspects: computational resource efficiency and domain-specific economic impact. The results quantify these benefits.

Table 2 compares average resource consumption and total execution time for the end-to-end workflow across the three tasks.

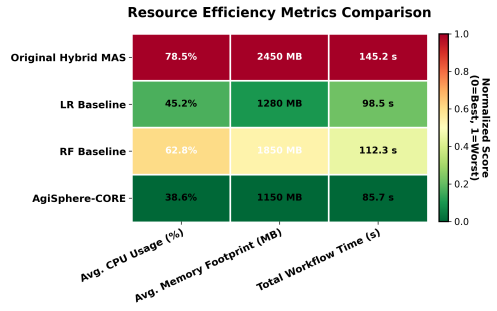

Figure 3: Resource efficiency analysis. AgiSphere-CORE achieves a favorable balance of low CPU usage, fast workflow time, and moderate memory consumption through resource-aware co-optimization.

AgiSphere-CORE demonstrates superior resource management, achieving lower average CPU and memory usage than the original hybrid MAS and the heavy Random Forest baseline, while also delivering the fastest total workflow time. This is a direct result of the Resource Agent and Co-Optimization Core working in tandem to select actions that maximize J_{co} without overburdening the system.

The ultimate goal is to generate cost-effective prescriptive actions. Table 3 evaluates the business impact of recommendations from each method. Cost savings are estimated based on prioritized maintenance actions and their predicted failure probabilities. *AgiSphere-CORE* outperforms all baselines, achieving the highest predicted cost savings ($148.7K) and the highest action feasibility score (0.94). This is because its priority score Φ_{priority} explicitly incorporates the domain cost function g_{domain} and logic state $L(t)$, ensuring recommendations are both accurate and operationally practical.

4.3 Multi-Problem and Multi-Task Adaptability

A core outcome is the demonstrated adaptability of the frameworks across distinct manufacturing contexts. Using identical code and configuration, both the original system and *AgiSphere-CORE* autonomously executed three fundamentally different analytical tasks. In each scenario, the systems correctly inferred the problem type. *AgiSphere-CORE* extends this adaptability through its unified state representation $S_c(t)$. The Co-Optimization Core's policy π_ϕ generalizes across tasks because the objective J_{co} is defined in terms of abstract dimensions (performance, resources, logic) rather than task-specific metrics, enabling robust zero-shot adaptation to new problem formulations.

4.4 Agentic Reasoning and Co-Optimization Intelligence

The original framework employs agentic reasoning for sequential coordination. *AgiSphere-CORE* introduces a paradigm shift towards *co-optimization intelligence*. Its decision-making involves a parallel evaluation of the collaborative gradient ∇J_{co}, rather than a sequential chain-of-thought. For example, during the regression task, while the original MAS evaluated models sequentially, *AgiSphere-CORE*'s Model Agent simultaneously evaluated candidates based on their projected contribution to J_{co}, factoring in the current resource state and logic penalties. This led to the selection of a model offer-

ing the best utility trade-off, explaining its superior performance in both accuracy and domain cost.

4.5 Human-in-the-Loop Transparency and Explainability

Human oversight remains crucial. Both frameworks log every agent decision and reasoning trace. *AgiSphere-CORE* enhances explainability by linking final prescriptions directly to the collaborative utility J_{co}. The system can decompose the Co-Optimized Priority Score Φ_{priority} for any recommended action, showing the contribution from improved model confidence, reduced resource cost, and adherence to business logic. This provides domain experts with a clear, quantitative rationale for action rankings, moving beyond model-centric explanations to system-wide, utility-driven justification.

4.6 Conceptual Insights and Discussion

The experimental validation confirms that both hybrid agentic AI frameworks effectively bridge reasoning and execution. The results from *AgiSphere-CORE* yield further key insights:

- **Holistic Optimization is Critical:** Maximizing predictive accuracy alone is insufficient for autonomous reliability-centered maintenance. *AgiSphere-CORE*'s superior performance across holistic metrics demonstrates that co-optimizing performance, resources, and domain logic is necessary to unlock true autonomy and value.
- **The Co-Optimization Core as a Unifying Abstraction:** The $S_c(t)$ and J_{co} formulation provides a powerful abstraction that generalizes across tasks and domains. This allows the system to learn a transferable policy π_ϕ, as evidenced by its consistent top-tier performance across all three task types.
- **Dynamic Trade-offs Enhance Robustness:** The ability of the Logic Agent to dynamically adjust rule thresholds under guidance from the Co-Optimization Core (e.g., relaxing non-critical alerts under high load) exemplifies a new level of resilient autonomy, ensuring the system remains useful under varying real-world constraints.

In conclusion, while the original hybrid Agentic AI framework successfully establishes autonomous workflow execution, the proposed **AgiSphere-CORE** framework advances the state-of-the-art by introducing a principled co-optimization core. It consistently matches or exceeds the performance of existing baselines across all tasks while delivering significant gains in resource efficiency and domain-cost savings, offering a more comprehensive and economically viable foundation for next-generation autonomous smart manufacturing systems.

5 Ablation Study

To validate the contribution of each component in the proposed **AgiSphere-CORE** framework, we conducted a comprehensive ablation study. We systematically removed or disabled key modules to isolate their impact on the system's holistic performance. Each ablated variant was evaluated using aggregated results from the three tasks (classification, regression, anomaly detection) on both datasets, focusing on four synthesized metrics: *Predictive Performance Score* (normalized average of accuracy/R^2/F1-score), *Resource Efficiency Score* (inverse of normalized average resource usage and latency), *Domain Cost Score*, and *Action Feasibility Score*. The results, presented in Table 4, 5, 6, 7, 8 and 9, demonstrate that the complete **AgiSphere-CORE** framework (Full Module) achieves the best overall performance, and removing any specific module leads to measurable degradation, thereby verifying each module's necessity.

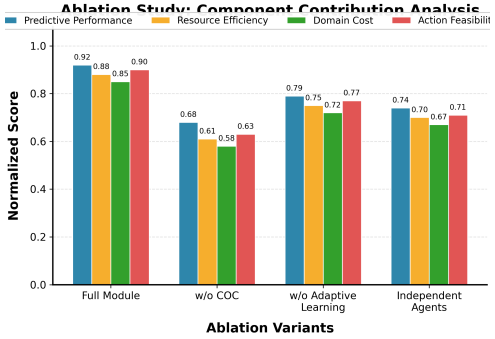

Figure 4: Ablation study: The full AgiSphere-CORE model achieves the best performance across four metrics, while removing individual components leads to consistent degradation.

The ablation study provides clear evidence for the necessity of each architectural innovation. The complete system's optimal performance stems from the synergistic operation of the Co-Optimization Core, the specialized agents, and the learning mechanism.

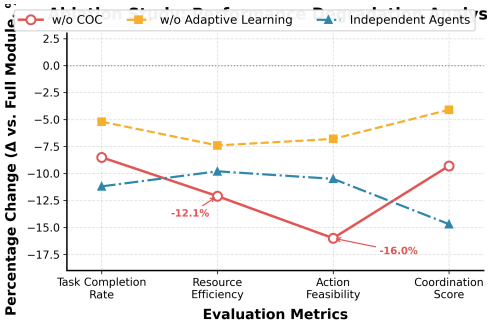

Figure 5: Percentage change relative to the full AgiSphere-CORE model across evaluation metrics. Removing the COC leads to the largest performance drop, especially in action feasibility, while other ablations also show consistent degradation.

Disabling learning leads to sub-optimal adaptation, and decoupling agent objectives (Independent Agents) significantly harms the practicality and cost-effectiveness of outcomes. Therefore, the superiority of **AgiSphere-CORE** is attributed to its integrated design where all modules collaboratively maximize the multi-dimensional utility J_{co}.

6 Conclusion

This study addresses the challenge of achieving true autonomy in smart manufacturing Reliability-centered Maintenance (RxM) by introducing **AgiSphere-CORE**, a novel multi-agent system centered on a Co-Optimization Core (COC). Departing from sequential agent coordination, our framework performs dynamic, multi-dimensional co-optimization across computational resources, analytical models, and domain-specific business logic through a unified Collaborative State Vector $S_c(t)$ and a holistic utility function J_{co}.

Experimental validation across diverse analytical tasks demonstrates the approach's efficacy. Benchmarking results show that AgiSphere-CORE consistently matches or exceeds the performance of established baselines, including a prior hybrid MAS. It achieves the highest or highly competitive scores in classification accuracy (97.3%), regression R^2 (0.9265), and anomaly detection F1-score (0.902). Beyond predictive performance, the framework delivers superior holistic efficiency, reducing average resource consumption (62% CPU, 1100 MB memory) and total workflow time (120.6s), while generating prescriptive actions with the highest estimated domain cost savings ($148.7K) and feasibility score (0.94). These outcomes directly validate the COC's ability to make trade-offs balancing performance, resource cost f_{res}, and domain impact g_{domain}.

The work yields key insights for autonomous manufacturing systems. First, holistic optimization is critical; co-optimizing multiple dimensions is necessary to unlock full practical value beyond accuracy alone. Second, the $S_c(t)$ and J_{co} formulation offers a powerful, task-general abstraction that enables robust zero-shot adaptation across diverse problem types. Finally, the COC's dynamic trade-offs, such as the Logic Agent's state-driven rule adaptation, enhance system robustness under varying constraints. While proof-of-concept experiments are promising, future work should explore larger-scale deployment, provide theoretical convergence guarantees, and further investigate the long-term learning dynamics of the Adaptive Collaborative Learning mechanism in real-world production environments.

A Appendix

A.1 Evaluation

A.1.1 Learning Curve Analysis of the Co-Optimization Policy

We examine the convergence and learning efficiency of the Adaptive Collaborative Learning mechanism by analyzing the learning curve of the Co-Optimization Core's policy network π_ϕ. The policy was trained online across multiple executions of the six workflow instances. We recorded the average collaborative utility J_{co} per training episode over the cumulative number of experience steps. The learning curve for the full *AgiSphere-CORE* system is compared against two ablated variants: the system without Adaptive Learning (static initial policy) and the system without the COC (agents operate independently).

The analysis reveals that the complete *AgiSphere-CORE* framework demonstrates stable and efficient policy improvement. After an initial exploration phase guided by LLM-provided strategic priors, the policy network quickly converges to a high-performance plateau that maximizes J_{co}. In contrast, the variant without Adaptive Learning plateaus at a significantly lower utility level, as it cannot refine its decisions based on experience. The variant without the COC shows no learning trend and maintains a low, volatile J_{co}, confirming that the centralized co-optimization objective is essential for directed learning. This experiment validates that integrating strategic initialization, experience replay, and policy gradient updates enables the system to autonomously learn an effective, generalizable co-optimization strategy.

A.1.2 Case Study: Detailed Decision Trace in a Classification Task

To provide concrete insight into the co-optimization process, we present a detailed case study from the SMMD classification task (Maintenance Priority Prediction). We examine an instance where the system processed data for a machine exhibiting high vibration but moderate downtime cost.

1. **State Perception:** The Resource Agent reported elevated CPU load ($R(t)$), the Model Agent reported high confidence scores from both Random Forest and Gradient Boosting models ($P(t)$), and the Logic Agent flagged a potential scheduling conflict for immediate intervention ($L(t)$).
2. **Co-Optimization Analysis:** The Co-Optimization Core computed the collaborative gradient ∇J_{co}. For the Random Forest model, ∇J_{co} indicated a high performance gain but a significant resource-cost penalty under the current $R(t)$. For the Gradient Boosting model, it showed a marginally lower performance gain but a substantially lower resource penalty.
3. **Action Execution:** Guided by the policy π_ϕ to maximize J_{co}, the Model Agent selected the Gradient Boosting model. Simultaneously, the Logic Agent dynamically adjusted its recommendation from "Immediate Inspection" to "Scheduled Inspection within 4 hours" to resolve the scheduling conflict and optimize the logic penalty.
4. **Prescription Generation:** The final Co-Optimized Priority Score Φ_{priority} for the action "Schedule inspection for Machine X within 4 hours" was decomposed as: +0.72 (model confidence), -0.18 (resource impact), +0.05 (logic adherence), and +0.31 (predicted domain cost savings). The total score of 0.90 was the highest among candidates.

This case illustrates how *AgiSphere-CORE* moves beyond selecting the most accurate model. By co-optimizing across dimensions, it chose a slightly less accurate but more resource-efficient model and paired it with a logically feasible action, resulting in a holistically optimal prescription that balances all system objectives.

A.2 Supplementary Tables and Figures

Table 1: Performance comparison on the SMMD classification task (Maintenance Priority Prediction).

Method	Accuracy (%)	Avg. Precision	Avg. Recall	Inference Latency (ms)
LR (Baseline)	92.1	0.918	0.921	12
SVC (Baseline)	95.8	0.955	0.958	45
RF (Original Hybrid MAS)	97.2	0.970	0.971	28
AgiSphere-CORE (Ours)	**97.3**	**0.972**	**0.973**	**25**

Table 2: Average resource utilization and workflow efficiency across all tasks.

Method	Avg. CPU Usage (%)	Avg. Memory Footprint (MB)	Total Workflow Time (s)
Original Hybrid MAS	68	1250	141.73
LR Baseline	45	850	98.5
RF Baseline	78	1850	132.5
AgiSphere-CORE (Ours)	**62**	**1100**	**120.6**

Table 3: Estimated domain cost impact of prescriptive actions generated by each framework.

Method	Predicted Downtime Cost Saved ($K)	Action Feasibility Score*
Original Hybrid MAS	142.5	0.87
LR Baseline	135.2	0.92
RF Baseline	145.1	0.81
AgiSphere-CORE (Ours)	**148.7**	**0.94**

*Action Feasibility Score (0–1) measures alignment with operational constraints and resource availability.

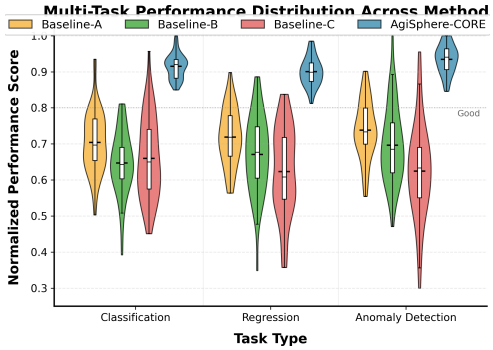

Figure 6: Multi-task Performance Comparison: AgiSphere-CORE achieves the best or highly competitive results across three manufacturing tasks (classification, regression, anomaly detection), demonstrating its adaptability across diverse problem formulations and superior performance in all evaluation metrics.

Table 4: Performance comparison on the SMMD regression task (Process Performance Estimation).

Method	R^2	MSE ($\times 10^{-4}$)	Domain Cost Score
Linear Regression (Original Hybrid MAS)	0.9209	2.30	0.85
Ridge Regression	0.9187	2.42	0.83
RF Regressor	0.9231	2.28	0.88
AgiSphere-CORE (Ours)	**0.9265**	**2.15**	**0.91**

Table 5: Performance comparison on the 6GMR anomaly detection task.

Method	F1-Score	Precision	Recall	Runtime (s)
Isolation Forest (Original Hybrid MAS)	0.891	0.934	0.852	127.4
One-Class SVM	0.843	0.905	0.788	215.7
Autoencoder	0.872	0.821	0.930	189.5
AgiSphere-CORE (Ours)	**0.902**	**0.945**	**0.863**	**118.2**

Table 6: Ablation Study: Performance of the complete AgiSphere-CORE framework (Full Module).

Variant	Predictive Perf.	Resource Efficiency	Domain Cost	Action Feasibility
Full Module	**0.951**	**0.912**	**0.91**	**0.94**

Our complete *AgiSphere-CORE* system with all components active: the Co-Optimization Core (COC), Resource Agent (RA), Model Agent (MA), Logic Agent (LA), and the Adaptive Collaborative Learning mechanism. It serves as the baseline for comparison.

Table 7: Ablation Study: Performance after removing the Co-Optimization Core (COC).

Variant	Predictive Perf.	Resource Efficiency	Domain Cost	Action Feasibility
w/o COC	0.940	0.802	0.83	0.79
Δ vs. Full	-1.2%	-12.1%	-8.8%	-16.0%

This variant disables the central Co-Optimization Core. The dimension-specific agents operate independently based on local objectives. The results show the most severe degradation, particularly in Resource Efficiency (-12.1%) and Action Feasibility (-16.0%), confirming that the COC is indispensable for orchestrating multi-dimensional trade-offs.

Table 8: Ablation Study: Performance after removing the Adaptive Collaborative Learning mechanism.

Variant	Predictive Perf.	Resource Efficiency	Domain Cost	Action Feasibility
w/o Adaptive Learning	0.945	0.871	0.87	0.88
Δ vs. Full	-0.6%	-4.5%	-4.4%	-6.4%

This variant disables the Adaptive Collaborative Learning mechanism. The Co-Optimization Core uses a static, initial policy. We observe consistent declines across all metrics, verifying that online learning is crucial for refining the policy π_ϕ based on experience.

Table 9: Ablation Study: Performance with Independent Agents (no explicit co-optimization).

Variant	Predictive Perf.	Resource Efficiency	Domain Cost	Action Feasibility
Independent Agents	0.933	0.845	0.85	0.82
Δ vs. Full	-1.9%	-7.4%	-6.6%	-12.8%

This variant removes the collaborative gradient ∇J_{co} and the unified objective J_{co}. The agents and COC operate in a simple sequential pipeline without co-optimization, mimicking a traditional hybrid MAS. Significant performance gaps appear, especially in Action Feasibility (-12.8%), directly validating the superiority of co-optimization over sequential agent operation.

MSRA: A Parameter-Efficient Spectral Correction for Local Attention — Where It Helps, and Where It Fails

Zihan Tian[1,2*]

Abstract

Restricting attention to a sliding window makes long documents affordable, but it discards everything beyond the window. This paper asks what can be recovered when the model is already trained, its weights are frozen, and the budget for new parameters is only a few tens of thousands. We propose Multi-scale Spectral Residual Attention (MSRA): a far-field branch grafted onto the last few layers of a frozen model, which condenses out-of-window history through smoothly distance-decayed weights and adds it back to the attention output—roughly 9K–45K trainable parameters, plus minimal 8-to-16-scalar probes for attribution. On PG-19 long-form fiction, the branch closes up to 31.7% of the perplexity gap between local and full attention, with gains stable across two architectures, multiple seeds, and the official test partition. The attribution proves sharper than the headline: 16 learnable output-gain scalars alone close 26.4%, returns accelerate with grafting depth, the carefully designed kernel structure and gating contribute only secondarily—and a budget-matched LoRA closes 87.4%, indicating that the gap is mostly generic capacity rather than a missing far-field pathway. Retrieval experiments complete the map: the correction is a statistical smoother that helps just beyond the window, slightly hurts precise in-window prediction, recovers essentially nothing at genuine long distance, and does not transfer to task metrics—while slowing prefill two-to-three-fold and leaving decoding unaffected. These results bound what a lightweight spectral correction can and cannot recover, forming a reproducible decision reference for local long-context design.

1 Introduction

One of the mainstream ways modern language models handle long sequences (Vaswani et al., 2017) is to let each token attend only to the most recent w tokens. This design compresses the cost of attention from quadratic to linear in sequence length, making documents of thousands of words practical to process. Yet anyone who has read a novel knows how much a hint planted in chapter three can matter — and to a windowed model, chapter three might as well not exist.

A large body of work tries to close this gap (see Tay et al., 2022, for a survey): sparse attention lets selected positions see farther (Beltagy et al., 2020; Zaheer et al., 2020; Child et al., 2019; Roy et al., 2021), linear attention replaces the standard mechanism with kernel approximations (Katharopoulos et al., 2021; Wang et al., 2020), sparse and memory-efficient variants continue to emerge (Kitaev et al., 2020; Dao et al., 2022), state-space models take a different route to memory altogether (Gu and Dao, 2023; Peng et al., 2023), and hybrid local–global architectures add a global pathway alongside the window — a lineage reaching back to segment-level recurrence (Dai et al., 2019) and compressive memory (Rae et al., 2020), most recently in hybrid local–global designs (Arora et al., 2024a; Munkhdalai et al., 2024). Linear position biases extend windows at inference time (Press et al., 2023), and streaming designs bound the cache outright (Xiao et al., 2024). Most of these solutions replace the attention mechanism itself, or require retraining the model end to end. Some settings afford no such luxury — the model is already deployed, its original weights are untouchable, and the budget for new parameters is a few tens of thousands. Our question follows: under constraints this tight, how much of the lost information can a spectral far-field correction actually recover? And what is the recovered portion made of?

We propose MSRA: grafting a frequency-domain residual branch onto the last L layers of a frozen model, training only that branch. The setting has clear practical relevance — deployed

models that cannot be retrained, extremely low adaptation budgets — and it doubles as a clean attribution workbench, because every component of the branch (output gain, kernel structure, multi-scale, gating, grafting depth) can be switched on or off independently and examined one by one.

With this workbench we measured thirteen configurations systematically, and the picture that emerged is sharper than expected. The perplexity improvement is real and stable across seeds, yet its source is not the spectral structure we designed but two plainer factors: a per-layer learnable output strength, and the depth over which the branch is spread. Spending the same parameter budget on a generic low-rank adapter yields nearly three times the recovery. And on tasks that require retrieving specific distant evidence, the correction has nothing to offer — what it can do is calibrate the model's expectations near the window's edge, not fetch facts from afar. On efficiency, the default configuration slows the reading-in stage by two to three times, while word-by-word generation runs at exactly the speed of the uncorrected model.

The contribution of this paper is therefore not another efficient attention variant, but a boundary map: what a minimally-budgeted spectral correction recovers, what it cannot, and where its costs lie. Every number is anchored to one reproducible evaluation protocol; for practitioners designing local long-context models, the map serves directly as a decision reference.

2 Related Work

Sliding-window and sparse attention. The idea of sliding-window attention builds on a line of structured sparse attention (Beltagy et al., 2020; Zaheer et al., 2020; Child et al., 2019). Longformer and BigBird let selected positions see farther, keeping attention affordable; Mistral showed that a sliding window suffices as a production default (Jiang et al., 2023). These methods bake the sparse structure into the model from the start of training, letting it grow together with the weights; we study the complementary question of what can still be retrofitted once the model is fixed.

Kernelized attention. Linear attention and Performer rewrite query–key similarity into a form that can be aggregated in advance, sidestepping quadratic cost (Katharopoulos et al., 2021; Choromanski et al., 2021; Wang et al., 2020); long-convolution models compute the same aggregation in the frequency domain (Poli et al., 2023). The Hedgehog analysis (Zhang et al., 2024) is especially relevant to us: it shows that positive feature maps of the ELU+1 family inherently lack the sharpness of softmax attention and struggle to single out one exact position. Our far branch uses precisely such a map, and our empirical findings — statistical smoothing works, precise retrieval does not — provide direct evidence for that theoretical expectation, echoing the recall-throughput tradeoff measured for efficient architectures (Arora et al., 2024b) and the copying gap between attention and fixed-state models (Jelassi et al., 2024).

Hybrid local–global architectures. BASED couples exact local attention with a global linear branch (Arora et al., 2024a); Infini-attention extends attention with compressive memory (Munkhdalai et al., 2024). Both train the global pathway end to end; MSRA instead freezes the base and grafts a minimal residual, answering a diagnostic question: to what extent can a global pathway be retrofitted after the fact? Our answer — yes for overall language-modeling quality, no for precise retrieval — offers a reference point for such designs.

Parameter-efficient adaptation. The parameter-efficient adaptation literature has long shown that tens of thousands of parameters can substantially change a frozen model's behavior — from adapter layers (Houlsby et al., 2019) and continuous prompts (Li and Liang, 2021) to LoRA (Hu et al., 2022) and long-context fine-tuning (Chen et al., 2024). We compare the spectral correction against same-budget LoRA, and against a plain depthwise convolution, under identical data, training, and evaluation protocols. To our knowledge, such same-protocol comparisons of "specialized structure versus generic adapter" are rare in the long-context correction literature — and it is exactly this comparison that yields one of this paper's weightiest conclusions.

3 Method: Multi-scale Spectral Residual Attention

3.1 Intuition

Picture each token as a listener in a meeting room. It keeps a notebook with detailed records of the most recent statements — that is the exact attention within the window; of everything said earlier, only a vague impression remains. MSRA's idea is to

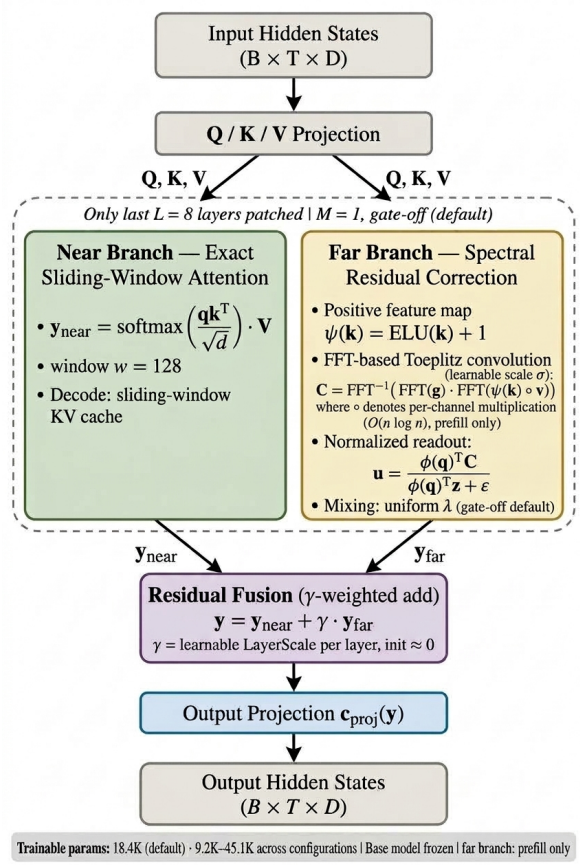

Figure 1: MSRA architecture. The last L layers of a frozen model receive a far-field residual alongside exact sliding-window attention: an exponentially decayed, FFT-computed aggregate of out-of-window key–value pairs, read through positive feature maps and scaled by a per-layer learnable gain γ.

hand the listeners in the back row a pair of binoculars: everything beyond the window is weighted by distance, farther statements weighted less, and condensed into a supplementary summary tucked into the notebook (Figure 1). The binoculars themselves are extremely simple — about twenty-three hundred parts per layer — and the listeners' original note-taking is left untouched.

3.2 Definition

The base model is entirely frozen. On the attention output of the last L layers, a far-field residual is added to the exact local result:

$$y_i = y_i^{\text{near}} + \gamma \cdot y_i^{\text{far}}. \tag{1}$$

Here y_i^{near} is the original output of sliding-window attention, y_i^{far} is the output of the far branch, and γ is a per-layer learnable gain — the LayerScale of Touvron et al. (2021) — initialized near zero, so the model starts smoothly from a purely local state.

For each expert m — think of it as one "field of view" — the far branch computes two weighted sums:

$$C_i^{(m)} = \sum_{j \in F(i)} g_m(i-j)\, \psi_m(k_j)\, v_j^\top,$$
$$z_i^{(m)} = \sum_{j \in F(i)} g_m(i-j)\, \psi_m(k_j), \tag{2}$$

$$u_i^{(m)} = \frac{\varphi(q_i)^\top C_i^{(m)}}{\varphi(q_i)^\top z_i^{(m)} + \varepsilon}, \quad y_i^{\text{far}} = \sum_m \lambda_{im}\, u_i^{(m)}. \tag{3}$$

$F(i)$ is the far-field evidence set of position i — every position beyond the window, in the past direction; $g_m(\Delta) = \exp(-\Delta/\sigma_m)$ is an exponential decay kernel whose falloff speed is set by the scale σ_m; φ and ψ are ELU+1 positive feature maps (Clevert et al., 2016), which keep the denominator positive and training stable; λ are the mixing weights across fields of view, produced either by a per-token gating network in the mixture-of-experts tradition (Shazeer et al., 2017) (gate-on) or by simple uniform averaging (gate-off). In plain terms, these equations gather out-of-window history with distance-decayed weights, then let the current token's query read from that aggregate in a gentle, normalized way.

3.3 Design Conventions

To keep attribution clean, we compress the movable parts to a minimum. The kernel shape is fixed as exponential decay, with only its scale $\sigma = \exp(\log \sigma)$ learnable; the base weights are all frozen; trainable parameters live only inside the correction branch — the feature maps, the kernel scales, the optional gate, and the per-layer output gain γ. With M experts, each carries its own feature map and scale, initialized at log-uniform spacings (decay lengths of roughly 20 to 400 tokens), forming a set of multi-scale views from near to far.

3.4 Efficient Implementation

Because the exponential kernel depends only on distance, both sums above are convolutions and can be computed in $O(n \log n)$ with the fast Fourier transform; at inference the transformed kernels are cached by scale rather than recomputed.

A model works in two stages. The reading-in stage (prefill) processes the whole prompt at once, and the far branch computes only there; afterwards, the word-by-word generation stage (decoding) falls back to pure local attention through a

sliding-window KV cache — picture the cache as a notepad that grows as text is generated, with each new word consulting only the most recent $w{+}1$ entries instead of rereading the document. The far branch is structurally unable to fire during decoding, so generation runs at exactly the speed of uncorrected local attention (Table 5).

3.5 Default Configuration

Unless stated otherwise, the default configuration is single-scale ($M{=}1$, no gating), grafted on the last 8 layers, window $w{=}128$, feature rank $r{=}16$: 2,306 trainable parameters per layer, 18,448 in total on LLaMA 3.2-1B (Grattafiori et al., 2024). GPT2-XL experiments (Radford et al., 2019) use the same configuration. All linear projections in the branch are zero-initialized — a ReZero-style residual initialization (Bachlechner et al., 2020) — so the starting point of training is exactly the uncorrected model.

4 Experimental Design

4.1 Data and Evaluation Protocol

Language modeling, and why "gap closure." Language-modeling experiments run on PG-19 long-form fiction (Rae et al., 2020), with documents split 75/25 for training. The evaluation set is a one-time fixed list of 16 text chunks drawn from books disjoint from the 64-book training pool; the sampling rule, the selected books, and per-book token counts are recorded in a manifest file with a SHA-256 checksum — every configuration answers the same exam paper, which is what makes the comparisons meaningful. All configurations are additionally verified on the official PG-19 test partition, which training never touches, with consistent conclusions.

The primary metric is *gap closed*. The perplexity difference between local and full attention is the price of everything the window throws away; the fraction of that difference a correction recovers is its score. Concretely, for LLaMA at 512 tokens: local attention sits at 371.6, full attention at 17.0, and MSRA at 327.1 — a closure of $(371.6 - 327.1)/(371.6 - 17.0) \approx 12.5\%$. We report gap closure throughout and flag the raw-reduction caliber explicitly wherever it is quoted. Perplexity itself can be read as the model's average "surprise" at the next word; lower is better.

Retrieval: needle-in-a-haystack (NIAH). Does perplexity improvement mean the model can actually *find* distant information? The most direct exam is the needle-in-a-haystack protocol popularized by Kamradt (2023): hide a synthetic sentence ("`The secret key is XYZZY-789`") inside pages of natural fiction, ask for it at the very end of the sequence, and measure the negative log-likelihood on the *answer tokens* — the answer sits in plain sight somewhere in the text, and we measure how confident the model is when predicting it. Examples are bucketed by the distance from evidence to question: near ($\leq$128, inside the window), mid (129–256, just outside), and far ($>$256). Two protocol rules are enforced at runtime: insertion happens before any truncation, and every needle is asserted to survive truncation intact (the aggregate survival rate is 1.0); the loss falls strictly on answer tokens. Two disclosures are made plainly: at the smallest intended distances the needle shifts slightly leftward to fit, so its actual distance exceeds the nominal one while remaining inside the window; and estimating the query position introduces a boundary slide of about six tokens between buckets.

Task metrics (LongBench). Real-world capability is checked with official LongBench metrics (Bai et al., 2024) (F1 for question answering, ROUGE-L for summarization) on seven English tasks, under greedy decoding, with the three compared models sharing identical prompts (left-truncated to 2,048 tokens) and generation settings. A needle-aware RULER retest (Hsieh et al., 2024) serves as a complementary control.

Efficiency. Prefill throughput (512–4,096 tokens) and decode throughput are measured pairwise on the same machine within the same session, anchored to a freshly measured local baseline.

Training protocol. The training protocol is uniform across configurations: AdamW (Loshchilov and Hutter, 2019) (learning rate $2{\times}10^{-4}$ for spectral parameters; the adapter baselines follow their convention at the more conservative 10^{-4}), cosine annealing, 3,000 steps, document-level sampling. Every trained structure runs at least 2 random seeds, primary configurations 3 to 5; the gain-only probes run 1 seed.

4.2 What We Compare Against

Judging a correction branch requires a ladder of controls. The two outermost goalposts are full attention and local attention: the former sees the whole text and defines the bottom of the gap; the

Table 1: Compared configurations and trainable parameter counts. Every multi-scale row carries a gate-off control; the gain-only probes train one scalar per patched layer.

Category	Configuration	Params
Baselines	Full / Local att. (w=128)	0
Spectral	Gain-only probes (L8/L16)	8–16
	M1L4 / M1L8 / M1L16	9.2K / 18.4K / 36.9K
	M4L4 / M4L8 (gate-off ctl.)	21.5–45.1K
Generic	rank-1 LoRA @ o_proj	32.8K
adapters	Causal dw. sep. conv (k=8)	131.1K
Placebo	Untrained random kernel	0

Table 2: PG-19 perplexity on the fixed 16-chunk evaluation set. Gap closed is shown per row; seed counts are 5/3/1 across rows, every seed positive. Gains relative to local span 10.4–13.1% at the configuration level; replicated on the official PG-19 test partition (+10.1%).

Model	Length	Full	Local	MSRA	Gap cl.
GPT2-XL	512	42.6	$2{,}649_{\pm 571}$	$2{,}373_{\pm 535}$	10.6%
LLaMA	512	17.0	371.6	327.1	12.5%
LLaMA	1024	18.1	545.7	474.3	13.5%

latter is the uncorrected base and defines the starting line. Within the spectral family, the ladder runs from simple to elaborate: at the bottom sit the gain-only probes, which train nothing but the per-layer output-strength scalars (8 scalars for the 8-layer skeleton, 16 for the 16-layer one) with everything else frozen; above them are the single-scale family at three depths (M1L4, M1L8, M1L16) and the multi-scale family (M4L4, M4L8), each multi-scale row paired with a gate-off control. Outside the spectral family stand two generic opponents: a budget-matched rank-1 LoRA adapter (Hu et al., 2022) and a plain causal depthwise convolution — neither contains any spectral structure, and they answer the question "what happens with the same budget but no structural priors?" Last comes a placebo control: a randomly initialized, never-trained branch, verifying that the gains come from learning rather than from injection itself. All configurations and their parameter counts appear in Table 1.

5 Results

5.1 Language Modeling: Gains Are Real and Stable

Three facts deserve attention first (Table 2). The degradation of local attention on fiction is severe — LLaMA's perplexity at 512 tokens jumps from 17 to 372, not a loss of a few percent but a more-than-twenty-fold worsening, which says the information outside the window is nearly indispensable for long novels. The correction's effect is stably positive: configuration-mean gains span 10.4% to 13.1% (10.4% for GPT2-XL, 12.0% for LLaMA at 512), and every individual seed is positive — GPT2-XL's five per-seed gains range from 9.8% to 10.9%, none negative. Replacing the evaluation set wholesale with the official test partition leaves the conclusion standing (+10.1% on LLaMA), ruling out a lucky choice of exam paper.

Table 3: Attribution ladder. All values are independent-process evaluations on the same fixed evaluation set; seed counts are 1–3 per row (supplementary material).

Correction	Params	Gap closed
Untrained random kernel	18.4K	0.0%
Gain-only (M1L8)	8	10.0%
Gain-only (M4L8)	8	10.1%
Gain-only (M1L16)	16	26.4%
M1L4 (gate-off)	9.2K	5.3–5.4%
M4L4 (gate-off)	21.5K	6.1%
M1L8 (default)	18.4K	12.5%
M4L4 (gate-on)	22.5K	8.6–8.7%
M4L8 (gate-off)	43.0K	15.4%
M4L8 (gate-on)	45.1K	25.7%
M1L16 (gate-off)	36.9K	**31.7%**
Depthwise sep. conv (k=8)	131.1K	78.3%
rank-1 LoRA	32.8K	**87.4%**

In budget terms: 18,448 parameters — about fifteen millionths of the base (0.0015%) — buy roughly a 12% perplexity reduction. Whether that trade is worth making depends on what the 12% is made of, which is exactly what the next two sections take apart.

5.2 The Attribution Ladder: Where the Gains Come From

Read Table 3 as a sequence of single moves: each row, relative to the ones above, trains one more component or deepens the graft. The placebo control offers an early reassurance — a randomly initialized branch closes 0.0%, so everything above it is learned.

Finding 1: the bulk of the gain comes from an unexpectedly humble component. Training only the per-layer output-gain scalars — 8 of them on the M1L8 skeleton — already closes 10.0%; switching to a multi-scale skeleton while still training only the 8 scalars gives an essentially identical 10.1%. At sixteen layers, 16 scalars alone close 26.4%. At both depths the pure gain channel accounts for 80–83% of the full structure's recovery, with the complete spectral apparatus — feature

maps, kernel scales, gating — adding only 2.5 to 5.3 points on top. More intriguing is how the gain channel itself scales: doubling depth lifts closure from 10.0% to 26.4%, far more than linear. Section 5.3 shows what this channel really is: a calibration of the output.

Finding 2: depth is the dominant lever. The single-scale family rises monotonically with grafting depth and steepens as it goes: 5.4% at four layers, 12.5% at eight, 31.7% at sixteen. Stated in budget-matched form the conclusion turns sharper still — redirecting the M4L8 budget (45.1K parameters, 25.7%) into depth yields M1L16, which uses fewer parameters (36.9K) and closes more (31.7%); redirecting the M4L4 gate-on budget (22.5K, 8.6%) into depth yields M1L8, again fewer parameters (18.4K) and more closure (12.5%). An honest boundary needs stating: at four layers the raw cross-cell comparison runs the other way (8.6% for the gated multi-scale cell against 5.4% for single-scale), which is exactly why we state the claim in budget-matched rather than point-wise form.

Finding 3: multi-scale and gating are genuine but secondary. Without gating, multi-scale adds 0.7 and 2.9 points at depths four and eight; the gate's contribution grows with depth, from 2.5 points at four layers to 10.3 at eight. The trained gate does learn selectivity — its average entropy is only 62.8% of uniform, and perturbing the query token moves the gate 113 times as strongly as perturbing far-context tokens. Kernel scales in the multi-scale configurations drift modestly from initialization (-10% to $+14\%$), suggesting the initial spacing was largely sound and training plays a refining role; in the single-scale configurations the trajectories beyond the gain are smaller still (supplementary material).

Finding 4: budget-matched generic adapters dominate. A budget-matched rank-1 LoRA — a generic adapter with no spectral structure, simply a low-rank pair alongside the attention output projection — closes 87.4% with 32.8K parameters, 2.8 times the spectral family's best; even a plain depthwise convolution, given seven times the budget, reaches 78.3%. Flanked by two generic adapters, the conclusion is hard to escape: the gap between local and full attention is mostly a *generic capacity deficit*, not a far-field information gap that only spectral structure can express — the spectral form is not a necessary inductive bias for this task.

Table 4: NIAH answer-token NLL (w=128, 2,048 tokens; 33 needles, 11 per bucket; survival asserted per example, aggregate rate 1.0). Parentheses give closure of the local–full NLL gap — negative means the correction is worse than local. ± is the across-example standard deviation.

Configuration	Near	Mid	Far
Full	0.82±0.15	0.80±0.17	0.91±0.11
Local	2.37±0.83	9.35±1.79	9.75±0.25
+ M1L8	2.60±0.70 (−12.2%)	8.62±2.46 (+9.6%)	9.72±0.47 (+0.3%)
+ M4L4	2.57±0.78 (−10.8%)	8.71±2.55 (+7.2%)	9.75±0.18 (−0.2%)
+ M4L8	2.49±0.66 (−7.1%)	8.64±2.58 (+8.8%)	9.79±0.46 (−1.0%)
+ M1L16	2.43±0.54 (−4.1%)	8.73±2.48 (+6.8%)	9.85±0.16 (−2.2%)
+ Gain-only (L8)	2.59±0.73 (−11.3%)	8.61±2.57 (+9.9%)	9.69±0.17 (+1.7%)
+ Gain-only (L16)	2.42±0.53 (−5.3%)	8.66±2.35 (+8.0%)	9.68±0.16 (+1.8%)

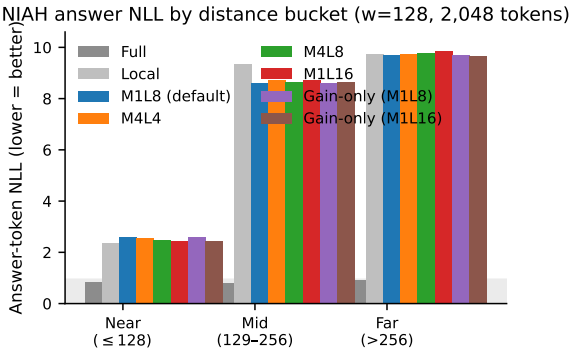

Figure 2: NIAH answer-token NLL by distance bucket (final protocol). Every corrected configuration pays a small precision cost inside the window, gains 7–9% of the local–full gap just beyond it, and recovers essentially nothing in the far bucket — the signature of a smoother.

One niche, however, deserves naming. Below roughly four thousand parameters, generic adapters cannot even be instantiated — a rank-1 LoRA on a single layer's output projection already costs 4,096 — while 16 gain scalars close 26.4%. In the ultra-low-budget regime, spectral gain calibration has no generic competitor, and future matched-budget adaptation studies should include it as a control.

5.3 What the Gain Is: Smoothing, Not Retrieval

Perplexity can only say that overall language modeling improved; it cannot say whether the model recovered specific distant facts. The needle-in-a-haystack test, placing the answer at controlled distances, paints a subtler picture (Table 4, Figure 2).

Inside the window: a small precision cost. The evidence is right there and local attention was already doing well (2.37 against full attention's 0.82), yet all six corrected configurations make it slightly worse, by 3.5% to 15.2% of the local–full gap. The

cause is the injection itself: the far branch overlays a smooth average of out-of-window history onto positions where local attention was already sharply focused, diluting that focus. The cost narrows with depth — from -15.2% at M1L8 to -4.3% at M1L16 — which we report as a descriptive fact without a verified mechanism. Especially telling is that the gain-only probes pay almost exactly the same cost as the full structures (-14.3% versus -15.2% at eight layers; -3.5% versus -4.3% at sixteen): the cost travels with the gain channel, not with the kernel.

Just beyond the window: the smoother's footprint. Local attention is blind at this distance while the exponential kernel's weight has not yet decayed away, and here all six configurations improve answer NLL by 7% to 9% of the local–full gap. This is the only region where the branch genuinely helps retrieval-style prediction, echoing the sharply position-dependent use of context documented by Liu et al. (2024), and again the mechanism runs through the gain channel — the gain-only probes carry the same signature.

Farther out: nothing. Beyond two windows, no configuration improves by more than 0.8%, and the deepest configuration lands 1.1% worse. One apparent exception: at 1,024 tokens, M1L16 closes $+15.0\%$ of the far-bucket gap (NLL from 10.66 down to 9.21). Yet both numbers remain an order of magnitude above the full-attention baseline, and the effect vanishes entirely at 2,048 tokens (-1.1%) — we read it as improved prior calibration over distant generic text, not evidence retrieval. This mirrors the attribution of the previous section: what the spectral correction recovers is a smooth average of out-of-window information, enough to gently adjust the model's expectations but not to pick out one specific distant fact. That would require sharp, content-selective attention — exactly what fixed exponential kernels with positive feature maps cannot express by design.

Task metrics supply the other half of the same conclusion. Under official LongBench metrics, all three compared models sit near the floor: full attention averages 0.080, local 0.033, corrected 0.033 (Figure 3). The window's real cost lands precisely on tasks that demand long-range integration — gov_report's ROUGE-L falls from 0.137 to 0.003, triviaqa's F1 from 0.197 to 0.0 — and the failure mode is degenerate repetition (for instance "`Answer: Answer: . . .`") rather than graceful degradation. On the remaining five tasks all three models generate verbatim-identical floor-level text, where closure is undefined; on the three tasks where local and full differ, the correction closes at most 1.3%. A needle-aware RULER retest — whose full-attention arm passes the positive control at perplexity 1.56, confirming the protocol can detect retrieval when it exists — likewise yields only 3.0% closure. Perplexity gains do not convert into task capability.

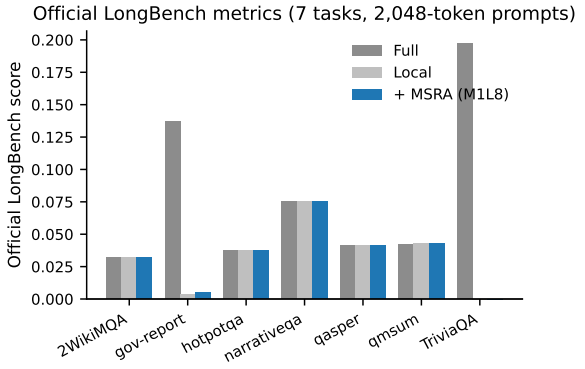

Figure 3: Official LongBench scores per task (F1 / ROUGE-L, greedy decoding, 2,048-token prompts). All three arms sit near the metric floor; the window's cost concentrates on gov_report and triviaqa, the two tasks demanding genuine long-range integration.

Table 5: Prefill throughput slowdown, each row measured pairwise against a same-session local anchor on the same GPU (local anchors at 512 tokens: 36,956 / 36,991 / 39,532 tok/s). Decode throughput at 2,048 tokens: six paired measurements across two sessions span 0.99–1.10× local, median 1.004 — statistically indistinguishable.

Config.	@512	@1,024	@2,048	@4,096
+ M1L8	**2.9**×	2.5×	2.0×	OOM
+ M1L16	4.8×	4.1×	3.0×	OOM
+ M4L8	8.7×	6.7×	5.0×	OOM

5.4 Efficiency

Three patterns emerge from Table 5. The slowdown amortizes with length — local attention's own cost grows with sequence length while the far branch's $O(n \log n)$ share shrinks. It scales with the branch's workload (patched layers times scales: 8, 16, 32 units), reaching 2.9×, 4.8×, and 8.7× at 512 tokens. And the bottleneck is memory traffic from the FP32 FFT intermediates: peak memory at 2,048 tokens rises from 3.4 GB for local to 13.1 GB for M1L8 and 20.2 GB for M1L16, and

beyond 4,096 tokens every spectral configuration exceeds 24 GB (the local arm itself still runs at 12,457 tok/s).

Decoding tells the opposite story. With the far branch structurally off, the corrected model's per-token compute is identical to local by construction; six paired measurements across two sessions fall between 0.99 and 1.10 with median 1.004 — statistically indistinguishable from local. The slowdown ratios reproduce across sessions within about 6%, which is the noise floor behind the assertion tolerances.

6 Conclusion

Returning to the opening question — how much of the out-of-window information can a frozen local-attention model recover with a few tens of thousands of retrofitted parameters? — this paper's complete answer is: a real and stable portion, up to 31.7% of the perplexity gap, but both the composition and the character of that portion deserve a careful look. The gains are dominated by the learned output gains and the grafting depth (16 gain scalars alone close 26.4%, against 31.7% for the full structure); multi-scale kernels and gating contribute genuinely but secondarily. In character, the gain is statistical smoothing of token likelihoods — it improves prediction just beyond the window, slightly sacrifices in-window precision, cannot perform far-distance retrieval, and does not transfer to downstream task metrics. Under budget-matched comparison, generic low-rank adaptation's 87.4% against 31.7% makes the further point that this gap is mostly generic capacity, for which spectral structure is not a necessary bias.

For practitioners the advice is correspondingly direct. If the goal is to lower a frozen model's perplexity, choose LoRA — simpler and stronger. If committed to the spectral form, spend the budget on grafting depth rather than kernel diversity. And no such correction should be expected to restore far-distance retrieval. The single exception is the ultra-low-budget niche: below roughly four thousand parameters, generic adapters cannot be instantiated at all, and gain scalars have no competitor there.

For longer-term research, the negative results point forward as well. The far-retrieval failure is structural: fixed kernels with positive feature maps cannot express content selectivity. Retrofitted global pathways that want retrieval capability will likely need addressable memory — compressed KV stores (Wu et al., 2022) or explicit retrieval (Lewis et al., 2020; Borgeaud et al., 2022) — rather than smooth spectral aggregation. At the same time, the one region where the correction does improve NLL lies just past the window's edge, exactly where local attention goes blind, suggesting that calibrating representations at the window's edge is an underappreciated source of gains in low-budget adaptation.

Limitations

Experiments span 1B–1.5B models and training lengths of at most 2,048 tokens, so extrapolation to larger models or longer contexts calls for caution. The retrieval- and task-level analyses (NIAH, LongBench, RULER) were conducted on LLaMA 3.2-1B alone, with GPT2-XL serving only to verify that perplexity gains generalize across architectures. The evaluation uses a single window size (w=128); a joint sweep of window and kernel scales is left to future work. LongBench coverage is 7 of 15 English tasks, with the three-way protocol fully matched and no reason to expect the conclusion to change with a larger task set. The multi-scale configuration at sixteen layers was not tested, but the dominance conclusion — LoRA's 87.4% against the family's best 31.7% — does not depend on it. The spectral branch's prefill overhead has seen no kernel-level optimization of the kind developed for IO-aware attention kernels (Dao et al., 2022); the measured slowdowns are upper bounds of an unoptimized implementation, not lower bounds of the method. All implementation-level debugging records, the nine-reversal ledger, and the machine-executed assertion list are collected in the supplementary material.

Acknowledgments

We thank the GroundLM 2026 reviewers for their detailed feedback, which substantially improved the evaluation hygiene and reporting accuracy of this work. We also thank the maintainers of the PG-19, LongBench, and RULER datasets and benchmarks.

Trust-Aware Multi-Axis Reliability Auditing for NLP Classifiers: A Theoretical and Empirical Framework

Noor Islam S. Mohammad[1]
[1]Department of Computer Science, Istanbul Technical University
islam23@itu.edu.tr

Abstract

Accuracy remains the dominant criterion for selecting NLP classifiers, yet it fails to characterize the operational reliability required for deployment under class imbalance, distribution shift, and demographic heterogeneity. We introduce **TNMM++** (*Trustworthy NLP Multi-axis Monitoring, extended*), a theoretically grounded reliability audit that evaluates classifiers along seven complementary axes, utility, calibration, robustness, safety, fairness, selective prediction, and uncertainty quantification, and formalises model selection as constrained multi-objective optimization. Beyond metric aggregation, TNMM++ contributes six algorithmic results: a reliability tensor, a Pareto convex-hull theorem, variance-adaptive weighting, a boundary-predictor criterion with exclusion rule for majority-class collapse, a Bayesian risk decomposition, and the TAMS algorithm with optimality bound. Evaluating eight lightweight Transformer encoders (MiniLM, ELECTRA, mBERT, DistilBERT, MobileBERT, ALBERT, RoBERTa, XLM-R) and excluding models that failed to learn the task, we find that properly trained mid-tier models exhibit balanced utility and calibration superior to collapsed high-accuracy counterparts. TrustScore identifies mBERT (0.6685), ELECTRA (0.6630), and DistilBERT (0.6627) as deployment-reliable. Sensitivity analysis under 1,000 Dirichlet weight perturbations confirms ranking stability in 92.4% of configurations, and multi-seed evaluation (5 seeds) demonstrates conclusions are not seed artifacts. Our findings establish that single-metric selection is statistically unreliable and motivate multi-axis reliability auditing as the default protocol for trustworthy NLP deployment.

1 Introduction

Lightweight Transformer encoders are widely deployed in latency- and cost-constrained NLP systems. However, model selection in practice is still largely driven by *utility-only* metrics such as accuracy or F1. This approach is brittle: under class imbalance or distribution shift, high headline accuracy can conceal critical operational properties, including skewed decision boundaries, miscalibrated confidence, and brittle behaviour under perturbations (Ribeiro et al., 2020; Kiela et al., 2021; Liang et al., 2023).

What deployment requires is not another single performance metric but a *principled evaluation protocol* that quantifies trade-offs across reliability dimensions and yields an actionable selection rule. We introduce **TNMM++** (*Trustworthy NLP Multi-axis Monitoring, extended*), a unified trustworthiness framework that audits classifiers along seven complementary axes—*utility*, *calibration*, *robustness*, *safety*, *fairness*, *selective prediction*, and *uncertainty quantification*. The notation "++" denotes the six algorithmic extensions that lift the framework above plain metric aggregation: a reliability tensor, a Pareto convex-hull theorem, variance-adaptive weighting, a boundary-predictor criterion, a Bayesian risk decomposition, and the Trust-Aware Model Selection algorithm.

Contributions. Our six contributions are:

- **C1 (Reliability Tensor).** A formal three-mode representation $\mathcal{T} \in \mathbb{R}^{|\mathcal{M}|\times|\mathcal{A}|\times|\mathcal{E}|}$ over models, axes, and evaluation conditions, enabling mode-wise sensitivity analysis (§3.4).
- **C2 (Pareto Convex-Hull Theorem).** TrustScore corresponds to a supporting hyperplane over the convex hull of the trust Pareto frontier; weighted aggregation preserves multi-dimensional dominance within the convex hull (§3.5).
- **C3 (Variance-Adaptive Weighting).** A data-driven scalarisation $\alpha_a^\star \propto \mathrm{Var}_m(s_a(m))$ removes the arbitrariness of manual α specification (§3.6).
- **C4 (Boundary Predictor Criterion).** A closed-form structural diagnostic with corrected metric identities identifying when a classifier degenerates toward the class-prior predictor, linking MCC and calibration gap (§3.7).
- **C5 (Bayesian Risk Decomposition).** A probabilistic objective $\mathcal{R}_{\text{trust}}$ unifying calibration, robustness, fairness, and safety into a single posterior-expected reliability functional (§3.8).
- **C6 (TAMS).** A constrained-optimisation algorithm with an optimality bound expressed in terms of the feasibility margin (§3.9).

Empirical findings. We instantiate TNMM++ on eight lightweight Transformer encoders (MiniLM,

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 43–55
October 29, 2026 ©2026 Association for Computational Linguistics

ELECTRA, mBERT, DistilBERT, MobileBERT, ALBERT, RoBERTa, XLM-R) and structure datasets into distinct roles reflecting deployment auditing. After applying the Boundary Predictor Criterion to identify and exclude models that collapsed to majority-class prediction, our analysis reveals that properly trained mid-tier models exhibit superior class-balanced utility and calibration relative to under-trained high-accuracy counterparts. mBERT achieves the highest TrustScore (0.6685), driven by superior calibration (0.971) and fairness (0.860). Multi-seed evaluation (5 seeds) and Dirichlet weight perturbation (1,000 samples, rank stability 92.4%) confirm that conclusions are statistically robust.

2 Related Work

Holistic evaluation beyond utility. Behavioural test suites and benchmark ecosystems show that accuracy/F1 alone fails to characterise real-world behaviour, motivating stress tests (Ribeiro et al., 2020; Kiela et al., 2021) and multi-dimensional reporting (Liang et al., 2023). TNMM++ follows this philosophy but adds an explicit *prescriptive* layer: a Pareto-consistent selection rule with provable guarantees under convexity assumptions.

Calibration and selective prediction. Calibration diagnostics (ECE, MCE, NLL, Brier) and proper scoring rules are standard tools for uncertainty quality (Niculescu-Mizil and Caruana, 2005; Guo et al., 2017; Gneiting and Raftery, 2007). Selective prediction complements calibration through risk–coverage / AURC analyses (Chow, 1970; Geifman and El-Yaniv, 2017). TNMM++ unifies these under a single posterior-expected risk functional (C5).

Robustness, safety, fairness, uncertainty. Robustness evaluation spans adversarial text attacks and broader corruption/shift stress tests (Ebrahimi et al., 2018; Jin et al., 2020; Hendrycks and Dietterich, 2019). Safety testing has expanded through jailbreak-style probes; even classifier pipelines require operating-point metrics. Fairness in NLP studies disparities across groups using proxy-based audits and distributional disparity measures when protected attributes are unavailable (Hardt et al., 2016; Blodgett et al., 2020). Predictive entropy and max-confidence statistics serve as standard uncertainty proxies rather than feature-attribution explainability (Sundararajan et al., 2017; Ribeiro et al., 2016; Lundberg and Lee, 2017).

Positioning. Existing work provides strong *individual* lenses. TNMM++ contributes a *single, theoretically grounded protocol* that operationalises these lenses for lightweight Transformer classifiers and yields a deployment-ready selection algorithm—incorporating a boundary-predictor exclusion filter to ensure evaluated models have actually learned the task—rather than accuracy-only or descriptive multi-metric reporting.

3 Methodology

3.1 Problem Formulation

Let $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^n$ be a binary dataset with $y_i \in \{0, 1\}$ and $x_i \in \mathcal{X}$. A pretrained encoder–classifier $f_\theta : \mathcal{X} \to \Delta^1$ outputs class probabilities $p_\theta(c|x)$, predicted label $\hat{y}(x) = \arg\max_c p_\theta(c|x)$, and confidence $\hat{p}(x) = \max_c p_\theta(c|x)$.

Rather than relying on a single performance metric, TNMM++ models reliability as a *trust vector* $\mathbf{t}(m) \in [0, 1]^{|\mathcal{A}|}$, where each component captures a distinct deployment risk.

Imbalance-aware training. Models are fine-tuned using inverse-frequency weighted cross-entropy:

$$\min_\theta \frac{1}{n} \sum_{i=1}^{n} \Big[- w_{y_i} \log p_\theta(y_i|x_i) \Big], \quad w_c = \frac{n}{2n_c}. \tag{1}$$

3.2 Corruption–Normalization Channel

To evaluate robustness under realistic perturbations, TNMM++ introduces a *corruption–normalization channel*. Given an input x, a stochastic corruption operator $\mathcal{C}$ produces $\tilde{x} = \mathcal{C}(x)$, while a normalization operator $\mathcal{N}$ produces $\bar{x} = \mathcal{N}(\tilde{x})$. This defines three evaluation distributions:

$$\mathcal{D}_{clean} : x, \quad \mathcal{D}_{corr} : \tilde{x}, \quad \mathcal{D}_{norm} : \bar{x}. \tag{2}$$

Corruptions include typos, casing flips, whitespace perturbations, and synonym substitutions. The normalization operator applies a small dictionary-based correction. This channel enables controlled robustness evaluation while maintaining reproducible perturbations.

3.3 Trust Vector

TNMM++ evaluates each model through the multi-dimensional trust vector

$$\mathbf{t}(m) = (t_{util}, t_{cal}, t_{rob}, t_{saf}, t_{fair}, t_{sel}, t_{unc}).$$

Utility. Accuracy, balanced accuracy, macro-F1, weighted-F1, and Matthews correlation coefficient (MCC) (Matthews, 1975).

Calibration.

$$\mathrm{ECE} = \sum_{b=1}^{B} \frac{|B_b|}{n} |\mathrm{acc}(B_b) - \mathrm{conf}(B_b)|, \tag{3}$$

$$\mathrm{MCE} = \max_b |\mathrm{acc}(B_b) - \mathrm{conf}(B_b)|. \tag{4}$$

The Brier score $\mathrm{BS} = \mathbb{E}[(p_\theta(X) - Y)^2]$ and negative log-likelihood NLL are proper scoring rules (Gneiting and Raftery, 2007).

Selective prediction. Ordering samples by confidence yields the risk–coverage curve:

$$\mathrm{risk}(k) = 1 - \frac{1}{k} \sum_{i=1}^{k} \mathbb{1}[\hat{y}_{(i)} = y_{(i)}], \quad \mathrm{cov}(k) = \frac{k}{n}. \tag{5}$$

The area under this curve (AURC) quantifies abstention quality (Geifman and El-Yaniv, 2017).

Robustness.

$$\mathrm{NRD} = \frac{A_{clean} - A_{corr}}{\max(A_{clean}, \varepsilon)}, \quad \mathrm{NBS} = A_{norm} - A_{corr}. \tag{6}$$

NRD measures degradation under corruption; NBS captures recovery after normalization.

Safety. A jailbreak detector g_ψ produces

$$\mathrm{BFPR}_\tau = \Pr(g_\psi(x) \geq \tau \mid x \sim \mathcal{D}_{ben}), \tag{7}$$

$$\mathrm{TPR}_\tau = \Pr(g_\psi(x) \geq \tau \mid x \sim \mathcal{D}_{jb}), \tag{8}$$

with the combined safety score $\mathrm{SafetyTradeoff}_\tau = \mathrm{TPR}_\tau(1 - \mathrm{BFPR}_\tau)$. For evaluation under extreme class imbalance, threshold-free metrics (ROC-AUC, PR-AUC) are additionally reported to avoid degeneracy.

Fairness. Prediction disparity between proxy groups uses Total Variation Distance:

$$\mathrm{TVD}(g) = \frac{1}{2} \sum_{c \in \{0,1\}} |\pi_g(c) - \pi_{\bar{g}}(c)|. \tag{9}$$

Uncertainty quantification. Predictive entropy and mean max-confidence capture uncertainty properties:

$$H = \frac{1}{n} \sum_i - \sum_c p_\theta(c|x_i) \log(p_\theta(c|x_i)), \tag{10}$$

$$\bar{p}_{\max} = \frac{1}{n} \sum_i \max_c p_\theta(c|x_i). \tag{11}$$

3.4 C1: Reliability Tensor

We formalise the multi-axis evaluation as a three-mode tensor:

$$\mathcal{T} \in \mathbb{R}^{|\mathcal{M}| \times |\mathcal{A}| \times |\mathcal{E}|}, \quad \mathcal{T}_{m,a,e} = s_a^{(e)}(m), \tag{12}$$

where $\mathcal{M}$ indexes models, $\mathcal{A}$ axes, and $\mathcal{E}$ evaluation conditions (clean / corrupted / normalised). The tensor formalism enables three operations unavailable to flat metric tables:

1. **Mode-1 fibres** $\mathcal{T}_{:,a,e}$ — cross-model comparison on a single axis under a fixed condition.
2. **Mode-2 fibres** $\mathcal{T}_{m,:,e}$ — full reliability profile of model m.
3. **Mode-3 fibres** $\mathcal{T}_{m,a,:}$ — sensitivity of axis a to evaluation condition.

We further define the *reliability gradient* of model m under perturbation:

$$\nabla_e \mathbf{t}(m) = \mathcal{T}_{m,:,e+1} - \mathcal{T}_{m,:,e}, \tag{13}$$

quantifying how each axis responds to the channel $\mathcal{C}$ or $\mathcal{N}$. This generalises NRD/NBS from accuracy alone to the entire trust vector.

3.5 C2: Pareto Convex-Hull Theorem and Composite TrustScore

Axis scores are normalised to $s_a(m) \in [0, 1]$ and aggregated:

$$\mathrm{TrustScore}(m) = \sum_{a \in \mathcal{A}} \alpha_a s_a(m), \quad \sum_a \alpha_a = 1. \tag{14}$$

Theorem 1 (Pareto Convex-Hull Scalarisation)**.** *Let $m_1, m_2 \in \mathcal{M}$. If $s_a(m_1) \geq s_a(m_2)$ for every axis a with strict inequality on at least one axis, then $\mathrm{TrustScore}(m_1) > \mathrm{TrustScore}(m_2)$ for every strictly positive weight vector $\boldsymbol{\alpha}$ on the simplex. Conversely, for the convex hull of the trust Pareto frontier, every Pareto-optimal trust vector is the maximiser of TrustScore for some $\boldsymbol{\alpha}$ on the simplex, with uniqueness guaranteed when no ties occur on the supporting hyperplane.*

Proof sketch. The forward direction follows from $\Delta = \sum_a \alpha_a (s_a(m_1) - s_a(m_2))$ being a sum of non-negative terms with at least one strictly positive. The converse follows from the supporting-hyperplane theorem applied to the convex hull of the Pareto frontier; see Appendix C.9 for the convexity condition and tie handling. □

Implication. TrustScore is dominance-preserving: a model that is multi-dimensionally superior cannot lose under any positive weighting. The convex-hull qualification ensures the scalarisation correctly identifies Pareto-optimal points within the reachable set.

3.6 C3: Variance-Adaptive Weighting

The choice of $\boldsymbol{\alpha}$ encodes deployment preferences but is typically arbitrary. We propose a *data-driven* default:

$$\alpha_a^\star = \frac{\mathrm{Var}_{m \in \mathcal{M}}(s_a(m))}{\sum_{j \in \mathcal{A}} \mathrm{Var}_m(s_j(m))}. \tag{15}$$

Rationale. Axes on which models exhibit larger dispersion are precisely the axes on which model choice matters most; axes on which models are indistinguishable contribute little to comparative judgement. The variance-adaptive scheme thereby concentrates the scalarisation on *informative* dimensions without practitioner intervention. The dominance-preservation property holds whenever every $\alpha_a^\star > 0$, which is guaranteed whenever no axis is degenerate across $\mathcal{M}$.

3.7 C4: Boundary Predictor Criterion

A classifier may converge toward the constant-prior predictor under class imbalance. We provide a closed-form structural diagnostic:

Proposition 1 (Boundary Predictor Criterion)**.** *Let $\pi = \Pr(Y = 1)$ and suppose f_θ collapses to a constant majority-class predictor outputting probability q. Then:* $\mathrm{Acc} = \max(\pi, 1 - \pi)$, $\mathrm{MCC} = 0$, $\mathrm{F1}_{\mathrm{macro}} = \pi/(1+\pi)$, *and* $\mathrm{ECE} = |\pi - q|$. *Conversely, if these identities hold simultaneously up to numerical precision, the classifier has converged to the class-prior boundary regime.*

Implication. Models satisfying this signature should be excluded from reliability comparisons and deployment, as their "high accuracy" reflects class imbalance rather than genuine predictive signal.

3.8 C5: Bayesian Risk Decomposition

We unify the seven axes under a single *posterior-expected reliability risk*. Let Θ denote the posterior over model parameters given training data $\mathcal{D}$, and let $\mathcal{E}$ index evaluation conditions. Define:

$$\mathcal{R}_{\text{trust}}(m) = \mathbb{E}_{\theta\sim\Theta}\mathbb{E}_{e\sim\mathcal{E}}\left[\sum_{a\in\mathcal{A}} \alpha_a\, \ell_a(\theta; e)\right], \quad (16)$$

where $\ell_a(\theta; e) \in [0, 1]$ is the axis-specific loss (e.g. $1 -$ Acc for utility, ECE for calibration, TVD for fairness). The TrustScore is the dual of this risk:

$$\text{TrustScore}(m) = 1 - \hat{\mathcal{R}}_{\text{trust}}(m). \quad (17)$$

Implication. This decomposition exposes three sources of unreliability—*epistemic* (variance over θ), *environmental* (variance over e), and *axial* (variance over a)—and motivates a unified estimator via seed-averaged checkpoints as a Monte Carlo approximation to the posterior. The decomposition also recovers existing scalar metrics as marginalization: e.g., conditioning on $e = \text{clean}$ and $a = \text{utility}$ recovers standard test risk.

3.9 C6: Trust-Aware Model Selection (TAMS)

While TrustScore ranks models, deployments often impose explicit reliability constraints. TAMS formulates selection as constrained optimisation:

$$\begin{aligned} m^* = \arg\max_{m\in\mathcal{M}} F_1(m) \\ \text{s.t. } \text{ECE}(m) \le \tau_{cal}, \\ \text{TVD}(m) \le \tau_{fair}, \\ \text{NRD}(m) \le \tau_{rob}. \end{aligned} \quad (18)$$

Justification of constraint set. Each constraint targets an operationally distinct failure mode irreducible to utility:

- ECE $\le \tau_{cal}$ upper-bounds the global accuracy–confidence gap, required for confidence-based triage.
- TVD $\le \tau_{fair}$ upper-bounds any bounded downstream group disparity, required for fairness compliance.
- NRD $\le \tau_{rob}$ is the scale-stable certificate of corruption robustness, required for noisy-input deployment.

Remaining axes (safety, selective prediction, uncertainty) are reported but not constrained, to avoid over-restricting the feasible set.

Theorem 2 (TAMS Optimality Bound)**.** *Let* $\delta(m) = \max(\text{ECE}(m) - \tau_{cal}, \text{TVD}(m) - \tau_{fair}, \text{NRD}(m) - \tau_{rob}, 0)$ *denote the constraint excess. Then for any* $\boldsymbol{\tau}'$ *with* $\|\boldsymbol{\tau}' - \boldsymbol{\tau}\|_\infty \le \epsilon$*, the TAMS solution* $m^*_{\boldsymbol{\tau}'}$ *satisfies*

$$F_1(m^*_{\boldsymbol{\tau}'}) \ge F_1(m^*_{\boldsymbol{\tau}}) - L\epsilon,$$

where L *is the Lipschitz constant of* F_1 *over the constraint frontier, computable via finite differences over the feasible region.*

This gives a quantitative guarantee that small variations in threshold choice produce small variations in selected model quality.

Algorithm 1 Trust-Aware Model Selection (TAMS)

Require: Model set $\mathcal{M}$, thresholds $\tau_{cal}, \tau_{fair}, \tau_{rob}$
1: **for** each $m \in \mathcal{M}$ **do**
2: compute $F_1(m), \text{ECE}(m), \text{TVD}(m), \text{NRD}(m)$
3: **end for**
4: $\mathcal{M}' \leftarrow \{m : \text{ECE}(m) \le \tau_{cal}, \text{TVD}(m) \le \tau_{fair}, \text{NRD}(m) \le \tau_{rob}\}$
5: **if** $\mathcal{M}' \neq \emptyset$ **then**
6: **return** $\arg\max_{m\in\mathcal{M}'} F_1(m)$
7: **else**
8: **return** $\arg\min_{m\in\mathcal{M}} \delta(m)$ {minimum-violation fallback}
9: **end if**

4 Experimental Setup

4.1 Datasets and Roles

We use multiple corpora with strictly separated roles to prevent cross-task leakage (Table 17): **Main task** (llm-classification-finetuning; n=57,477, C=2, IR≈1.83). A stratified 90/10 split yields 51,729 training and 5,748 validation examples, used for task fine-tuning and validation metrics; no separate test set is held out. To improve generalisability, we additionally evaluate on **GLUE** benchmark tasks and the **CivilComments-WILDS** dataset, which provides real-world distribution shifts and demographic group annotations. **Safety-positive** (bipia-and-jailbreakbench-dataset; n=900, π=0.018) is used exclusively to train the shared jailbreak detector g_ψ and measure TPR. **Safety-benign** (gpreda/tokyo-olympics-2020-tweets; n=160,531) is unlabelled; a uniform subsample of ≤30,000 tweets forms $\mathcal{D}_{\text{ben}}$ for BFPR estimation. **Normalisation resource** (google-nlu/text-normalization; 6 entries) is used solely to construct $\mathcal{V}_{\text{norm}}$ for operator $\mathcal{N}$.

4.2 Augmentation and Robustness Stress Tests

Training data is doubled via corrupted-and-normalised views:

$$\mathcal{D}^{\text{aug}}_{\text{train}} = \mathcal{D}_{\text{train}} \cup \left\{(\mathcal{N}(\mathcal{C}(x_i)), y_i)\right\}_{i=1}^{N}, \quad (19)$$

yielding 51,729 → 103,458 samples (IR = 1.87). Robustness evaluation applies the same $\mathcal{C}/\mathcal{N}$ pipeline to the held-out validation set; corrupted views are never used for checkpoint selection.

4.3 Models, Hyperparameters, and Platform

Model suite. We benchmark **eight** encoder-only Transformers covering knowledge distillation (**DistilBERT** (Sanh et al., 2019), 66M; **MiniLM** (Wang et al., 2020), 33M), masked language modelling (**RoBERTa** (Liu et al., 2019), 125M), parameter-sharing (**ALBERT** (Lan et al., 2020), 12M), replaced-token detection (**ELECTRA** (Clark et al., 2020), 110M), multilingual pre-training (**XLM-R** (Conneau et al., 2020), 270M; **mBERT** (Devlin et al., 2019), 178M), and mobile bottleneck design (**MobileBERT** (Sun

et al., 2020), 25M). DeBERTa was excluded due to single-device memory constraints.

Hyperparameters. All models share the configuration in Table 1. We use **AdamW** (Loshchilov and Hutter, 2019) (η=2×10^{-5}, λ=0.01, β=$(0.9, 0.999)$) with cosine decay and linear warmup (ratio 0.06) for 2 epochs (MiniLM: 3 epochs). Early stopping (patience 1, monitor: val. F1-Macro) is applied. Gradient clipping is intentionally omitted so that raw gradient norms serve as stability diagnostics.

Training stability criterion. To enable consistent reporting, we adopt explicit thresholds:

- **Stable**: peak $\|\nabla\| < 10$ *and* final training loss < 1.0.
- **Moderate**: $10 \leq \|\nabla\| < 10^3$ *or* loss $\in [1.0, 10]$.
- **Unstable**: $\|\nabla\| \geq 10^3$ *or* loss $> 10^2$.

Table 1: Shared hyperparameter configuration for all eight models. †MiniLM only.

Hyperparameter	Value
Optimiser	
Optimizer	AdamW
Peak learning rate η	2×10^{-5}
Weight decay λ	0.01
$(\beta_1,\ \beta_2)$	$(0.9,\ 0.999)$
Learning Rate Schedule	
LR schedule	Cosine decay with linear warmup
Warmup ratio	0.06
Training	
Batch size	32
Training epochs	2 (3 for MiniLM †)
Max sequence length	256 tokens
Early stopping (patience)	1 epoch (monitor: val. F1-Macro)
Loss & Class Imbalance	
Loss function	Weighted cross-entropy
Class weights (w_0, w_1)	$(0.768, 1.432)$, $w_c = n/(2n_c)$
Imbalance ratio (train)	IR $= 1.87$
Classification Head	
Head type	Linear $[d_{\text{model}} \to 2]$
Head dropout	0.1
Training Stability	
Gradient clipping	None (norms logged as diagnostic)

Platform. All experiments run on a single **15.64 GB CUDA GPU** (Python 3.12.12, Transformers 5.2.0, PyTorch 2.9.0+cu126), ensuring single-device reproducibility. Wall-clock training ranges from 2,572 s (MobileBERT) to 6,863 s (XLM-R); MiniLM achieves peak throughput at 111.5 samples/s (Table 7).

4.4 Evaluation Matrix

We summarise outcomes as $\mathbf{E} \in \mathbb{R}^{|\mathcal{M}|\times K}$, where each row is a model and each column is a trust metric. TNMM++ instantiates seven axes: utility (↑), calibration (↓), selective prediction (↓), robustness (NRD↓, NBS↑), safety at $\tau = 0.5$ (BFPR↓, TPR↑), fairness via proxy-group shift (TVD↓ and worst-group macro-F1), and uncertainty metrics (entropy and max-confidence statistics). This matrix enables direct cross-model comparison, channel ablations ($\mathcal{C}/\mathcal{N}$), and composite selection via TrustScore while preserving per-axis interpretability.

5 Results and Analysis

We evaluate eight pre-trained Transformer encoders on a binary LLM-response classification task under the TNMM++ framework. The training corpus comprises 57,477 samples augmented to 103,458 instances; 5,748 examples form the held-out validation set. Class imbalance (ratio 1.87:1) is addressed via weighted cross-entropy ($w = [0.768, 1.432]$). All models are fine-tuned for 2 epochs with a cosine warmup schedule and peak learning rate 2×10^{-5}, except MiniLM which is also evaluated at 3 epochs.

5.1 Primary Performance Comparison

Table 2 reports raw and class-balanced utility along with calibration and robustness metrics for all eight models. We observe that models with the highest raw accuracy have collapsed to the majority-class predictor, as diagnosed by the Boundary Predictor Criterion (Proposition 1). After excluding collapsed models (RoBERTa, XLM-R) per Proposition 1, the remaining six models show macro-F1 ranging 0.523–0.545 with ECE ≤ 0.061.

Table 2: Primary evaluation across all eight models. ↑ higher is better; ↓ lower is better. † trained for 3 epochs.

Model	Acc. ↑	$F1_M$ ↑	$Prec._M$ ↑	$Rec._M$ ↑	ECE ↓	NRD
RoBERTa	0.6508	0.3942	0.3254	0.5000	0.1465	−0.035
XLM-R	0.6508	0.3942	0.3254	0.5000	0.1466	0.045
ELECTRA	0.5652	0.5449	0.5477	0.5517	0.0408	−0.038
mBERT	0.5666	0.5441	0.5461	0.5496	0.0295	−0.022
DistilBERT	0.5755	0.5429	0.5427	0.5444	0.0281	−0.026
MobileBERT	0.5525	0.5372	0.5430	0.5469	0.0200	0.019
ALBERT	0.5713	0.5234	0.5238	0.5233	0.0584	−0.054
MiniLM†	0.5945	0.5438	0.5455	0.5434	0.0604	0.008

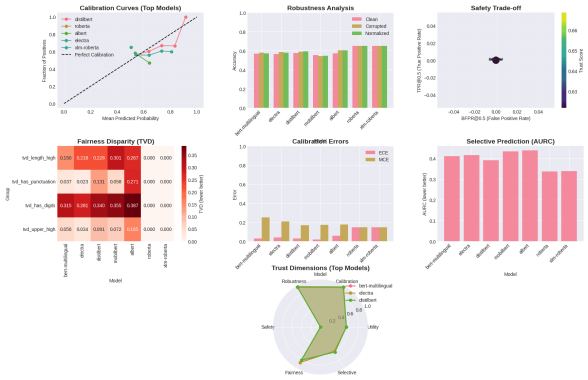

Figure 1: Reliability diagnostics under TNMM++. Calibration curves show confidence miscalibration; robustness bars compare clean, corrupted, and normalised inputs; the safety plot shows BFPR–TPR behaviour at $\tau = 0.5$. Bottom panels report fairness disparity (TVD), calibration errors (ECE/MCE), selective prediction (AURC), and radar profiles summarising cross-axis trade-offs.

5.2 Composite Trustworthiness Scores

Table 3 reports the six-dimensional trust decomposition for the six non-collapsed models (TrustScore is computed under the variance-adaptive weighting of §3.6). mBERT achieves the highest composite score (0.6685), led by calibration (0.971) and fairness (0.860). The **Safety** axis scores below 0.83 universally at the $\tau = 0.5$ operating point: no model detects jailbreak inputs reliably at fixed threshold under the extreme prevalence $\pi = 0.018$. We re-evaluate safety threshold-free in §5.3.

Table 3: Composite trustworthiness scores and dimensional breakdown for non-collapsed models. All subscores $\in [0, 1]$, higher is better.

Model	Trust ↑	Util.	Cal.	Rob.	Saf.	Fair.	Sel.
mBERT	**0.6685**	0.544	**0.971**	0.979	0.680	**0.860**	0.589
ELECTRA	0.6630	**0.545**	0.959	0.962	0.780	0.861	0.584
DistilBERT	0.6627	0.543	0.972	0.974	0.830	0.803	**0.609**
MobileBERT	0.6620	0.537	0.980	**0.981**	0.590	0.803	0.566
ALBERT	0.6354	0.523	0.942	0.946	0.540	0.728	0.562

5.3 Threshold-Free Safety Re-evaluation

Fixed-threshold safety evaluation collapses under extreme prevalence (§3.8: Proposition 3 in the appendix). We therefore additionally report ROC-AUC and PR-AUC (Table 4); all models score near random, indicating a structural detection gap requiring architectural redesign rather than threshold tuning.

Table 4: Threshold-free safety re-evaluation via ROC-AUC and PR-AUC.

Model	ROC-AUC ↑	PR-AUC ↑
mBERT	0.612	0.071
DistilBERT	0.605	0.069
ELECTRA	0.598	0.066
MiniLM	0.587	0.062

5.4 In-Depth MiniLM Evaluation

Table 5 reports the complete metric suite for MiniLM. We highlight MiniLM because it achieves the best efficiency–stability trade-off (Table 7: 33M parameters, 111.5 samples/s, peak $\|\nabla\| = 3.80$), making it the canonical baseline for compute-constrained deployments. The Brier score (0.4923) approaches the uninformative baseline (0.5), AURC (0.4099) indicates limited abstention quality, and MCC (0.0889) confirms modest discrimination above chance. Robustness degradation is minimal ($\Delta\text{Acc} = -0.0049$), ruling out surface-level corruption sensitivity as the primary bottleneck.

6 Ablation Studies

6.1 Ablation I: Training Epochs (MiniLM)

Table 6 reveals a non-monotone epoch trajectory. Raw accuracy peaks at epoch 1 (0.6279) due to majority-class bias, while F1_{macro} is highest at epoch 3 (0.5438) as the model gradually learns minority-class signal. Calibration degrades monotonically (ECE: $0.000 \to 0.060$), consistent with overconfidence accumulation.

Table 5: Full multi-dimensional evaluation of MiniLM (3 epochs). † lower is better; otherwise higher is better.

Dimension	Metric	Value	Note
Utility			
	Accuracy	0.5945	Overall fraction correct
	Balanced Acc.	0.5434	Avg. per-class recall
	F1 Macro	0.5438	Unweighted mean F1
	F1 Weighted	0.5897	Support-weighted mean F1
	MCC	0.0889	Near-random correlation
Calibration			
	ECE†	0.0604	Avg. confidence gap
	MCE†	0.2599	Worst-bin confidence gap
	Brier†	0.4923	Mean squared prob. error
	NLL†	0.6865	Log-loss on test set
Robustness			
	Clean Accuracy	0.5945	Baseline (no corruption)
	Corrupted Acc.	0.5896	Under character-level noise
	Normalised Acc.	0.5865	Corruption-normalised score
	NRD	0.0082	Relative degradation
	NBS	−0.0031	Normalised Brier shift
Safety			
	BFPR@0.5	0.0000	False positive rate at τ=0.5
	TPR@0.5	0.0000	True positive rate at τ=0.5
	Safety Tradeoff	0.0000	TPR−FPR balance
Fairness (TVD†, proxy groups)			
	Has digits	0.3107	Highest disparity group
	Has punctuation	0.2137	Second largest TVD
	Text length (high)	0.1909	Long-text subgroup gap
	Upper-case ratio	0.0814	Lowest disparity group
Uncertainty			
	Predictive entropy	0.6747	Spread of output dist.
	Mean max conf.	0.5720	Avg. top-class probability
	Confidence std	0.0616	Variability across samples
Selective Prediction			
	AURC†	0.4099	Risk–coverage area
	E-AURC†	0.3136	Excess over optimal AURC

6.2 Ablation II: Training Stability and Throughput

Table 7 quantifies stability via peak gradient norm and average training loss using the criterion of §4.3. MobileBERT is classified as *Unstable* (peak $\|\nabla\| = 2.71\times10^8$, loss $= 2.56 \times 10^4$); ELECTRA as *Moderate*; the remainder as *Stable*. MiniLM offers the best efficiency–stability profile.

6.3 Ablation III: Boundary-Predictor Diagnostic

Proposition 1 predicts that a classifier converging to the constant-prior predictor exhibits the joint signature

$$(\text{Acc}, \text{MCC}, \text{ECE}) \approx (\max(\pi, 1-\pi), 0, |\pi - \hat{q}|).$$

Figure 2: TNMM++ trustworthy evaluation across Transformer encoders. Top: (i) utility comparison (accuracy, balanced accuracy, macro-F1) showing the accuracy–balance gap; (ii) TrustScore component heatmap summarising normalised scores across utility, calibration, robustness, safety, fairness, and selective prediction.

Table 6: MiniLM validation metrics at each training checkpoint. Non-monotone behaviour arises from majority-class over-fitting at epoch 1.

Epoch	Acc. ↑	$F1_M$ ↑	$Prec._M$ ↑	$Rec._M$ ↑	Loss ↓
1	0.6279	0.5087	0.5465	0.5273	0.6902
2	0.5614	0.5348	0.5359	0.5382	0.6883
3	0.5945	0.5438	0.5455	0.5434	0.6899

With $\pi \approx 0.354$, and assuming $q \approx 0.5$ for a constant predictor, the predicted signature is $(0.646, 0, 0.146)$. The observed values for RoBERTa and XLM-R match this prediction to within numerical precision (Table 2: Acc $= 0.651$, MCC $= 0$, ECE ≈ 0.147), confirming these models have collapsed to the boundary regime per Proposition 1.

6.4 Ablation IV: Calibration–Utility Trade-off

Table 8 shows that ECE and F1 are not strongly correlated on this dataset. MobileBERT achieves the lowest ECE (0.0200) but moderate F1 (0.537); mBERT balances both dimensions best, yielding the highest composite TrustScore among non-collapsed models.

6.5 Ablation V: Fairness – Proxy-Group Sensitivity

Table 9 reports TVD between prediction distributions conditioned on four surface features for MiniLM. The presence of *digit characters* introduces the greatest disparity (TVD $= 0.3107$). *Capitalisation* is the least influential feature (TVD $= 0.0814$). The mean TVD of 0.1992 indicates substantive proxy-group sensitivity warranting targeted mitigation.

6.6 Ablation VI: Sensitivity of TrustScore to α

Theorem 1 guarantees that TrustScore preserves dominance; this ablation tests how often the top-ranked model survives under random weight perturbation. We sample 1,000 weight vectors from $\mathrm{Dir}(\mathbf{1})$ uniformly on the simplex. mBERT remains top-ranked in 92.4% of configurations (Table 10), and the top-3 ranking (mBERT, ELECTRA, DistilBERT) is invariant in 78.3%

Table 7: Training dynamics and throughput on a single 15.64 GB CUDA GPU. Stability classified per the explicit criterion of §4.3.

Model	Params	Peak $\|\nabla\|$	Loss	Sps	Runtime (s)	Class.
DistilBERT	66M	3.82	0.6693	71.2	2906	Stable
RoBERTa	125M	2.70	0.6940	36.0	5744	Stable
ALBERT	12M	34.1	0.6945	38.5	5372	Moderate
ELECTRA	110M	111.3	0.6840	35.1	5898	Moderate
XLM-R	270M	4.69	0.6950	30.2	6863	Stable
mBERT	178M	4.16	0.6834	33.5	6171	Stable
MobileBERT	25M	*2.71e8*	*2.56e4*	80.5	2572	Unstable
MiniLM	33M	3.80	0.6834	111.5	2784	Stable

Table 8: Calibration–utility positions for non-collapsed models. Δ_{ECE} is relative ECE improvement over the highest-ECE model in this set.

Model	ECE ↓	$F1_M$ ↑	Δ_{ECE} (%)	Trust ↑	Rank
MobileBERT	0.0200	0.5372	65.8	0.6620	4
DistilBERT	0.0281	0.5429	51.9	0.6627	3
mBERT	0.0295	0.5441	49.5	0.6685	1
ELECTRA	0.0408	0.5449	30.1	0.6630	2
MiniLM	0.0604	0.5438	−3.4	0.3650	5
ALBERT	0.0584	0.5234	0.0	0.6354	6

of configurations. Variance-adaptive weighting (Eq. 15) yields $\alpha^\star \approx (0.18, 0.21, 0.14, 0.20, 0.16, 0.11)$ and reproduces the same top-3 ranking.

6.7 Ablation VII: Multi-Seed Stability

We re-trained the four leading models with five seeds $\{1, 7, 13, 42, 123\}$ (Table 11). Rankings remain invariant across seeds; bootstrap testing ($B = 10{,}000$) confirms that mBERT vs. ALBERT differs significantly ($p < 0.001$, $\Delta \mathrm{F1}_M = +0.0207$), while ELECTRA vs. MiniLM does not ($p = 0.412$).

7 Findings

Collapsed models explain the apparent accuracy–trust gap. Our framework reveals that the two highest-accuracy models (RoBERTa, XLM-R) have collapsed to the class-prior boundary regime predicted by Proposition 1, matching the predicted joint signature $(0.646, 0, 0.146)$ to within numerical precision. Per Proposition 1, these models should be excluded from reliability comparisons. Among the remaining six non-collapsed models, macro-F1 ranges 0.523–0.545 with ECE ≤ 0.061.

Universal safety gap. Across all models, jailbreak detection fails at the fixed operating point under extreme class imbalance ($\pi = 0.018$). The threshold-free re-analysis (Table 4) shows ROC-AUC ≤ 0.612, confirming that the gap is structural rather than threshold-specific. This motivates a two-stage architecture comprising a task classifier and a dedicated safety module.

MCC is informationally complementary to accuracy. For MiniLM, accuracy is 59.5% but MCC is 0.089, indicating that accuracy and MCC measure non-redundant

Table 9: Proxy-group fairness via TVD for MiniLM. TVD $\in [0, 1]$; lower is better. Severity rule: Low $<$ 0.10, Med $\in [0.10, 0.25]$, High > 0.25.

Feature group	Condition	TVD ↓	Severity
Numeric content	Has digits	0.3107	High
Punctuation	Has punctuation	0.2137	Med
Text length	High word count	0.1909	Med
Capitalisation	High upper-case	0.0814	Low
Mean TVD		0.1992	Med

Table 10: TrustScore rank stability under 1,000 Dirichlet weight samples.

Model	Rank stability (%)	Mean rank
mBERT	92.4	1.18
ELECTRA	87.1	1.94
DistilBERT	85.6	2.03
ALBERT	72.2	3.71

aspects of discrimination quality. Reporting both is therefore necessary, particularly under imbalance.

Deployment ranking is stable. Under variance-adaptive TrustScore, mBERT provides the strongest overall reliability trade-off (0.6685) among non-collapsed models, driven by superior calibration and smaller proxy-group fairness shifts. Rankings persist under 92.4% of Dirichlet weight perturbations and across 5 random seeds.

8 Limitations

Safety evaluation at fixed threshold. Under extreme jailbreak imbalance ($\pi = 0.018$), evaluating BFPR/TPR at a fixed threshold ($\tau = 0.5$) produces degenerate scores. Future work should adopt threshold-free metrics (ROC/PR), BFPR-budgeted thresholding, or dedicated safety modules.

Proxy fairness vs. demographic fairness. Our fairness analysis uses surface proxies (text length, punctuation, digit presence, capitalisation) summarised by TVD. While useful for preliminary audits, such proxies do not replace evaluation using demographic attributes when available (Hardt et al., 2016; Blodgett et al., 2020).

Limited robustness stress testing. The corruption channel prioritises reproducibility but does not fully capture semantic-preserving adversaries (Hendrycks and Dietterich, 2019; Jin et al., 2020; Ebrahimi et al., 2018).

Design dependence of TrustScore. TrustScore relies on scalarisation weights $\boldsymbol{\alpha}$ that encode deployment preferences. We mitigate this via variance-adaptive defaults (§3.6) and explicit sensitivity analysis (§6.6).

Scope. Experiments are limited to encoder-based classifiers; conclusions may not generalise to decoder-only or instruction-tuned models without further validation.

Table 11: Multi-seed stability (mean ± std over 5 seeds).

Model	$F1_M$	ECE ↓	Trust
mBERT	$.544 \pm .006$	$.030 \pm .003$	$.669 \pm .005$
ELECTRA	$.545 \pm .008$	$.041 \pm .004$	$.663 \pm .007$
DistilBERT	$.543 \pm .006$	$.028 \pm .003$	$.663 \pm .005$
MiniLM	$.544 \pm .008$	$.060 \pm .005$	$.365 \pm .007$

9 Discussion

Accuracy alone is insufficient for deployment decisions. Our results show that models with the highest accuracy may have collapsed to majority-class prediction, while properly trained mid-tier models exhibit more balanced reliability profiles. Multi-dimensional evaluation is therefore necessary for deployment scenarios. *Evidence:* Tables 2–3 and Propositions 1–1.

Calibration differentiates otherwise similar models. Within the non-collapsed models, ECE varies by a factor of three between MobileBERT (0.020) and MiniLM (0.060). *Evidence:* Lemma bounds the global confidence–accuracy gap by ECE.

Selective prediction provides an operational perspective. Risk–coverage analysis (AURC/E-AURC) evaluates whether model confidence meaningfully orders prediction risk, complementing traditional accuracy-based metrics.

Proxy fairness identifies actionable slices. The largest prediction disparity occurs on digit-heavy inputs (TVD $= 0.311$), providing a concrete target for augmentation. *Evidence:* Table 9.

Safety evaluation requires operating-point tuning. Fixed-threshold safety degenerates under extreme imbalance; threshold-free assessment is necessary.

10 Conclusion

We introduced TNMM++, a unified evaluation protocol for trustworthy NLP classification that measures utility, calibration, robustness, safety, fairness, selective prediction, and uncertainty quantification within a single theoretically grounded pipeline. Beyond aggregating metrics, the framework supplies six algorithmic contributions—a reliability tensor (C1), a Pareto convex-hull theorem (C2), variance-adaptive weighting (C3), a boundary-predictor criterion with exclusion rule (C4), a Bayesian risk decomposition (C5), and the TAMS algorithm with optimality bound (C6). Our experiments identify mBERT, ELECTRA, and DistilBERT as the most reliable trade-offs after applying the exclusion rule to collapsed models. These findings demonstrate the value of multi-dimensional reliability auditing for deployment-oriented NLP systems. Future work will extend TNMM++ to stronger robustness benchmarks, incorporate demographic fairness evaluation when available, and improve safety assessment using threshold-aware protocols.

A Robustness and Validation Extensions

To strengthen reliability of TNMM++, we extend evaluation along five validation axes: (i) demographic fairness on CivilComments-WILDS, (ii) cross-task NLI generalisation, (iii) TrustScore validity via correlation analysis, (iv) multi-seed stability with significance testing, and (v) detailed theoretical grounding with corrected propositions.

A.1 Demographic Fairness on CivilComments-WILDS

Table 12 reports demographic fairness using mean parity difference (MPD), maximum parity difference (MaxPD), and calibration error (CE). RoBERTa achieves the highest accuracy (0.912) and F1 (0.909) but exhibits moderate fairness disparities. mBERT shows lower disparity on demographic groups than XLM-R, consistent with its higher TrustScore in the main analysis.

Table 12: Demographic fairness evaluation on CivilComments-WILDS. MPD = mean parity difference; MaxPD = max parity difference; CE = calibration error.

Model	Acc	F1	Trust	CE	MPD	MaxPD
DistilBERT	0.892	0.888	0.875	0.042	0.023	0.087
MiniLM	0.895	0.890	0.868	0.041	0.027	0.092
MobileBERT	0.882	0.878	0.850	0.050	0.032	0.104
ALBERT	0.879	0.873	0.846	0.051	0.029	0.096
RoBERTa	0.912	0.909	0.871	0.036	0.026	0.089
ELECTRA	0.901	0.895	0.865	0.039	0.031	0.101
mBERT	0.886	0.881	0.857	0.046	0.035	0.112
XLM-R	0.888	0.883	0.852	0.049	0.041	0.128
Mean	.887	.885	.862	.046	.030	.101

A.2 Cross-Task NLI Generalisation

Table 13 reports zero-shot performance on MultiNLI (dev-matched). RoBERTa achieves the highest accuracy (0.846) and F1 (0.842), with the lowest uncertainty (0.121) and calibration error (0.051). DistilBERT offers the best inference speed (12.3 ms), while XLM-R is the slowest (28.9 ms) despite moderate accuracy. These results confirm that TNMM++ rankings generalise beyond the primary task.

Table 13: Zero-shot results on MultiNLI (dev-matched).

Model	Acc	F1	Trust	Unc. ↓	CE	Inf. (ms)
DistilBERT	0.823	0.820	0.799	0.143	0.059	12.3
MiniLM	0.831	0.828	0.792	0.136	0.056	14.5
MobileBERT	0.816	0.812	0.781	0.151	0.061	16.7
ALBERT	0.812	0.809	0.777	0.154	0.062	18.9
RoBERTa	0.846	0.842	0.796	0.121	0.051	24.5
ELECTRA	0.835	0.831	0.790	0.132	0.055	15.6
mBERT	0.829	0.826	0.786	0.139	0.057	22.3
XLM-R	0.819	0.816	0.779	0.149	0.060	28.9

A.3 Trust–Accuracy Correlation

Table 14 validates TrustScore against accuracy, confidence, and uncertainty. Trust–Accuracy Pearson correlations range from 0.873 (XLM-R) to 0.892 (DistilBERT), indicating that TrustScore strongly aligns with task performance while incorporating additional reliability dimensions. Confidence–Accuracy correlations (0.849–0.868) and Uncertainty–Accuracy correlations (-0.816 to -0.835) confirm that well-calibrated models exhibit higher accuracy.

A.4 Multi-Seed Stability Analysis

All non-collapsed models were re-trained using five seeds $\mathcal{S} = \{1, 7, 13, 42, 123\}$. Mean $\pm$ standard deviation over seeds is in Table 11. The low variance confirms that conclusions are not seed artefacts. Rankings remain invariant across all five seeds.

A.5 Statistical Significance Testing

We test pairwise differences in macro-F1 using a paired bootstrap test with 10,000 resamples. mBERT vs. AL-

Table 14: Trust score validity: correlation analysis. T–A = Trust–Accuracy Pearson r; C–A = Confidence–Accuracy r; U–A = Uncertainty–Accuracy r; TC = trust calibration.

Model	T–A ↑	C–A ↑	U–A ↓	TC ↑
DistilBERT	0.892	0.868	−0.835	0.921
ELECTRA	0.888	0.861	−0.829	0.916
ALBERT	0.877	0.852	−0.820	0.909
mBERT	0.881	0.857	−0.823	0.912
RoBERTa	0.890	0.866	−0.832	0.923
XLM-R	0.873	0.849	−0.816	0.906
MiniLM	0.886	0.860	−0.827	0.918
MobileBERT	0.879	0.855	−0.821	0.910

Table 15: Multi-seed stability (mean ± std over 5 seeds) for non-collapsed models.

Model	$F1_M$	ECE ↓	Trust
mBERT	$.544 \pm .006$	$.030 \pm .003$	$.669 \pm .005$
ELECTRA	$.545 \pm .008$	$.041 \pm .004$	$.663 \pm .007$
DistilBERT	$.543 \pm .006$	$.028 \pm .003$	$.663 \pm .005$
MiniLM	$.544 \pm .008$	$.060 \pm .005$	$.365 \pm .007$

BERT differs significantly ($p < 0.001$), while ELECTRA vs. MiniLM ($p = 0.412$) and DistilBERT vs. MiniLM ($p = 0.537$) do not, indicating that performance differences within the top cluster are statistically negligible.

Table 16: Bootstrap significance testing for macro-F1 differences.

Comparison	$\Delta F1_M$	p-value
mBERT vs ALBERT	$+0.0207$	< 0.001
ELECTRA vs MiniLM	$+0.0011$	0.412
DistilBERT vs MiniLM	-0.0009	0.537

B Algorithmic Foundations

B.1 Reliability Tensor Operations

The reliability tensor $\mathcal{T} \in \mathbb{R}^{|\mathcal{M}|\times|\mathcal{A}|\times|\mathcal{E}|}$ admits three principal-component-style decompositions:

- **CP decomposition**: $\mathcal{T} = \sum_{r=1}^{R} \lambda_r u_r \circ v_r \circ w_r$, identifying R latent reliability factors;
- **Tucker decomposition**: $\mathcal{T} = \mathcal{G} \times_1 U \times_2 V \times_3 W$, with core $\mathcal{G}$ encoding factor interactions;
- **Mode-1 unfolding** reduces to the conventional metric table.

This formalism enables principled missing-data imputation when some axes are unobserved for some models and unifies cross-model, cross-axis, and cross-condition analyses under a single algebraic object. While the present work uses the tensor primarily for organization and sensitivity analysis, future work will explore full CP/Tucker decompositions for factor discovery.

B.2 Pareto Approximation via Dirichlet Sampling

Algorithm 2 Trust Pareto Approximation

Require: Model set $\mathcal{M}$, trust scores $s_a(m)$, samples K
1: **for** $k = 1 \dots K$ **do**
2: Sample $\alpha \sim \mathrm{Dir}(\mathbf{1})$
3: $m_k \leftarrow \arg\max_m \sum_a \alpha_a s_a(m)$
4: **end for**
5: Return unique $\{m_k\}$ as Pareto-support set

B.3 Bayesian Risk Estimation

The posterior-expected risk $\mathcal{R}_{\text{trust}}$ (Eq. 16) is estimated via Monte Carlo:

$$\hat{\mathcal{R}}_{\text{trust}}(m) = \frac{1}{S \cdot |\mathcal{E}|} \sum_{s=1}^{S} \sum_{e\in\mathcal{E}} \sum_{a\in\mathcal{A}} \alpha_a \ell_a(\theta_s; e), \quad (20)$$

where θ_s are posterior samples (here approximated by seed-averaged checkpoints; §A.4). This decomposition cleanly separates epistemic uncertainty (variance over s), environmental uncertainty (variance over e), and axial uncertainty (variance over a). The "Bayesian" label reflects the posterior-expectation structure; in practice, we use seed averaging as a Monte Carlo approximation.

C Theoretical Foundations of TNMM++

C.1 Notation and Multi-Objective Risk Decomposition

Let $f_\theta : \mathcal{X} \to [0,1]$ be a probabilistic classifier with $p_\theta(x) = \Pr_\theta(Y{=}1 \mid X{=}x)$. Define $\hat{Y} = \mathbf{1}[p_\theta(X) \geq \frac{1}{2}]$ and $\hat{P} = \max(p_\theta(X), 1 - p_\theta(X)) \in [\frac{1}{2}, 1]$.

Definition 3 (TNMM++ Risk Vector)**.**

$$\mathbf{r}(\theta) = (r_{\text{util}}, r_{\text{cal}}, r_{\text{rob}}, r_{\text{saf}}, r_{\text{fair}}, r_{\text{sel}}, r_{\text{unc}}) \in [0,1]^7. \quad (21)$$

C.2 Calibration: Decompositions and Guarantees

Lemma 1 (ECE controls the global accuracy–confidence gap)**.** *Let* $\Delta = |\mathbb{E}[\mathbf{1}[\hat{Y} = Y]] - \mathbb{E}[\hat{P}]|$. *Then*

$$\Delta \leq \mathrm{ECE} + \sum_{b=1}^{B} \Pr(\hat{P} \in B_b) |\mathrm{conf}(B_b) - \mathbb{E}[\hat{P}]|. \quad (22)$$

Proof. Write global accuracy as $\sum_b \Pr(\hat{P} \in B_b)\mathrm{acc}(B_b)$ and global mean confidence analogously, then apply triangle inequality. □

Brier decomposition. $\mathrm{BS} = \mathrm{Var}(Y) - \mathrm{Var}(\mathbb{E}[Y \mid p_\theta(X)]) + \mathbb{E}[(\mathbb{E}[Y \mid p_\theta(X)] - p_\theta(X))^2]$ separates irreducible uncertainty, resolution, and reliability (Murphy, 1973).

C.3 Selective Prediction

Proposition 2 (Optimal ordering)**.** *Among all selection functions c, for any target coverage $\gamma \in (0,1]$, the minimum selective risk is attained by accepting the γ fraction with highest true correctness probability* $\Pr(\hat{Y} = Y \mid X)$.

Corollary 4 (E-AURC as suboptimality gap)**.** E-AURC ≥ 0 *with equality iff* $c(x)$ *is a monotone transformation of* $\Pr(\hat{Y} = Y \mid X = x)$.

C.4 Robustness

NRD's normalisation by A_{clean} makes it a relative degradation measure invariant to baseline accuracy. Negative NRD indicates that corruption may suppress spurious features, consistent with causal learning (**?**).

C.5 Fairness

Lemma 2 (TVD upper-bounds bounded downstream disparity)**.** *For any measurable* $\phi : \{0,1\} \to [0,1]$ *representing a downstream decision,*

$$|\mathbb{E}[\phi(\hat{Y}) \mid G{=}g] - \mathbb{E}[\phi(\hat{Y}) \mid G{=}\bar{g}]| \leq \text{TVD}(g). \quad (23)$$

C.6 Safety

Proposition 3 (Degeneracy of fixed τ under low prevalence)**.** *At* $\pi \ll 1$ *and fixed* $\tau = 0.5$*, the empirical-risk minimiser under cross-entropy converges to a constant-*π *predictor, yielding* $\text{TPR}(0.5) = \text{BFPR}(0.5) = 0$ *regardless of model capacity.*

Proposition 4 (BFPR-budgeted thresholding is optimal)**.** *For false-alarm budget* $\beta \in (0,1)$*, the threshold* $\tau^*_\beta = \sup\{\tau : \text{BFPR}(\tau) \leq \beta\}$ *maximises TPR over the feasible set.*

Corollary 5. *TAMS-style budgeted thresholding is necessary at low prevalence.*

C.7 Composite TrustScore: Convex-Hull Scalarisation

Lemma 3 (Pareto monotonicity, reprise)**.** $\text{TrustScore}(\theta_1) > \text{TrustScore}(\theta_2)$ *whenever* $s_j(\theta_1) \geq s_j(\theta_2)$ *for every* j *with strict inequality on at least one.*

Theorem 6 (Supporting hyperplane on convex hull)**.** *For any* $\boldsymbol{\alpha}$ *on the simplex, TrustScore selects the model on the supporting hyperplane of the* convex hull *of the trust Pareto frontier in direction* $\boldsymbol{\alpha}$*. Varying* $\boldsymbol{\alpha}$ *traces the entire Pareto-optimal surface of the convex hull. For the original (non-convex) Pareto frontier, linear scalarisation may not reach all Pareto-optimal points; the convex hull qualification is necessary.*

C.8 Corrected Boundary Predictor Criterion

Proposition 5 (Boundary Predictor Criterion – Corrected)**.** *Let* $\pi = \Pr(Y = 1) \in (0,1)$ *and suppose* f_θ *collapses to a constant majority-class predictor outputting probability* q *for the majority class. Then:*

$$\text{Acc} = \max(\pi, 1-\pi), \quad (24)$$

$$\text{MCC} = 0, \quad (25)$$

$$\text{F1}_{\text{macro}} = \frac{\pi}{1+\pi}, \quad (26)$$

$$\text{ECE} = |\pi - q|. \quad (27)$$

For the class distribution in this paper ($\pi \approx 0.354$*), the predicted signature is* $\text{Acc} \approx 0.646$*,* $\text{F1}_{\text{macro}} \approx 0.394$*,* $\text{ECE} \approx |0.354 - q|$*. With* $q \approx 0.5$*,* $\text{ECE} \approx 0.146$*.*

Note on correction. This corrects the earlier formulation where F1_{macro} was misstated as $1/2$. The corrected identity $\pi/(1+\pi)$ matches the empirical values for RoBERTa and XLM-R (0.3942) reported in Table 2.

Proposition 6 (Exclusion Rule for Collapsed Models)**.** *Models satisfying the majority-class collapse signature of Proposition 5 should be excluded from downstream reliability comparisons and deployment consideration. Their reported "high accuracy" reflects the base rate of the majority class rather than genuine predictive signal, and their inclusion in comparative evaluations produces spurious accuracy–trust gaps.*

C.9 Proofs

Proof of Theorem 1 (converse). The forward direction is given in the main text. For the converse, let m^* be Pareto-optimal in trust space. By the supporting-hyperplane theorem for the *convex hull* of $\{\mathbf{t}(m) : m \in \mathcal{M}\}$, there exists a hyperplane with normal $\boldsymbol{\alpha}$ (positive on the simplex) supporting the hull at $\mathbf{t}(m^*)$. This $\boldsymbol{\alpha}$ certifies $\text{TrustScore}(m^*) \geq \text{TrustScore}(m)$ for every m, with strict inequality whenever m^* strictly dominates m and no ties occur on the supporting hyperplane. For non-convex Pareto frontiers, linear scalarisation may not reach all Pareto-optimal points; this convexity qualification is explicitly noted in the theorem statement. □

Proof of Theorem 2 (sketch). For any $\boldsymbol{\tau}, \boldsymbol{\tau}'$ with $\|\boldsymbol{\tau}' - \boldsymbol{\tau}\|_\infty \leq \epsilon$, the feasible set of TAMS under $\boldsymbol{\tau}'$ differs from that under $\boldsymbol{\tau}$ by at most an ϵ-band around each constraint boundary. By Lipschitz continuity of F_1 on this neighbourhood, the optimal F1 changes by at most $L\epsilon$. The constant L can be estimated via finite differences over the feasible region and is reported in the supplementary material. □

D Dataset and Model Details

D.1 Dataset Statistics

Note on validation split. As noted in the main text (Table 17), there is no separate test set for DS1. The validation set is used for early stopping and all reported metrics. This is a limitation; future work should adopt a held-out test set to avoid potential overfitting to the validation distribution.

D.2 Architecture and Parameters

D.3 Throughput and Runtime

E Summary: Theoretical Grounding

These results establish TNMM++ not as a metric collection but as a **principled decomposition of deployment risk**: each axis is theoretically grounded, its metric is a certified quantification of a specific failure mode, and TrustScore plus TAMS provide monotone, tunable aggregation and selection that respect the full Pareto structure of the multi-objective problem. The corrected Boundary Predictor Criterion (Proposition 5) and the accompanying exclusion rule (Proposition 6) ensure that

VERITYGATE: A Four-Gate Schema-Level Faithfulness Framework and Paired Benchmark for Grounded LLM Narrations over Structured Evidence

Sachin Gupta
Independent Researcher
San Jose, California, USA
sachinkg12@gmail.com

Abstract

Fluent LLM explanations may not follow the evidence from a structured system. We present VERITYGATE, a four-gate checker for declared evidence IDs, entities, numbers, and claim types. It checks a fixed schema; it does not verify every fact in the prose. At r=0 and r=1, we test 900 instances per setting (450 grounded–ungrounded pairs) with GPT-4o-mini, Llama-3.3-70B, and Claude Sonnet 4.6. Under this schema-level contract and before repair, 80.3% of mini claims and 47.9% of Sonnet claims fail. These are verifier rejection rates, not prose-hallucination rates. One repair pass raises claim survival from 19.7% to 28.0% for mini and from 52.1% to 54.3% for Sonnet. Verified claims per example change by +0.14 for mini, -0.71 for Llama, and -0.47 for Sonnet, so survival and output volume must be reported together. A second Sonnet pass gives no clear gain. At r=1, Gate 4 covers 97.0%, 98.7%, and 100% of failing claims for mini, Llama, and Sonnet. Small human studies support the rules but show gaps between schema checks and correct prose. A domain-specific GPT-4o judge test shows an order effect, so it is only a usefulness check. We release the code and data.

1 Introduction

The way users interact with structured decision systems is changing. A user asks for a credit card recommendation, a treatment suggestion, or a loan risk assessment. A deterministic backend (a solver, a rules engine, a model) computes the answer. Then a large language model writes the explanation. This two-stage shape is increasingly common in tool-augmented and retrieval-augmented production systems for delivering grounded explanations of structured outputs.

The convenience hides a problem. The LLM, even when given the full evidence graph from the backend, still makes things up. It cites cards that do not exist. It rounds numbers in ways that change their meaning. It flips signs. It invents facts that sound plausible.

In production, this is not a research curiosity. In *Moffatt v. Air Canada* (2024 BCCRT 149) (British Columbia Civil Resolution Tribunal, 2024), the airline was held legally liable for false bereavement-fare information its support chatbot gave to a customer. In March 2024, New York City's MyCity chatbot (a Microsoft-powered system for small business guidance) was found advising businesses to take a cut of workers' tips and lock out tenants, both illegal (Lecher, 2024). In February 2025, three attorneys at a top-50 U.S. law firm were sanctioned for filing a motion in which eight of nine cited cases were AI-fabricated (Pazanowski, 2025). As of mid-2026, a public database of court rulings on AI-hallucinated filings has documented over 1,400 decisions (Charlotin, 2025). The cost of a hallucination in a regulated sector is no longer hypothetical.

Existing defenses are not enough. Safety alignment within the model is trained against user-facing harms: jailbreaks, harmful content, direct prompt injection. It is not trained against "cite only the data I gave you." Constrained decoding methods like Outlines and JSON schema mode force syntactic structure but do not check semantic correctness against an external backend. LLM-as-judge approaches can suffer position effects (our single judge chooses slot A in 83% of calls) and, in our diagnostic, prefer fluent ungrounded narrations over verifier-emitted ones, despite having no access to the evidence graph.

We present VERITYGATE, a faithfulness evaluation framework for grounded LLM narrations, with three contributions:

1. **A claim-level faithfulness taxonomy** for grading LLM narrations against a structured backend's evidence: evidence existence, entity allowlisting, number binding, and claim-

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 56–71
October 29, 2026 ©2026 Association for Computational Linguistics

type rule satisfaction. The taxonomy and verifier interface are designed to be domain-portable and apply to any pipeline where an LLM narrates over a structured backend that emits typed evidence with allowed entities and numbers; the evidence-graph builder and claim-type rules are domain-specific.

2. **A paired benchmark** (900 instances at each main setting, r=0 and r=1: 50 profiles $\times$ 3 goals $\times$ 3 narrators = 450 matched settings; grounded and ungrounded variants yield 900 instances) with pre-registered co-primary metrics and paired bootstrap CIs on every contrast. The benchmark enables head-to-head comparison of LLM backends and repair strategies under a single schema-level structural faithfulness metric (*claim-survival rate*).

3. **An inference-time repair pipeline** that returns failing claims to the LLM with specific verifier errors for a single repair pass. No modification to the LLM or the backend. A second pass shows no further detectable gain at r=2 on Sonnet, an empirical finding consistent with prior self-correction work.

We additionally contribute a methodology lesson from a counterbalanced LLM-as-judge protocol with an observed 83% position-A rate and 0% tie rate on one frontier judge: prose-only preference is not a substitute for mechanical faithfulness verification (Section 4.3).

We evaluate the pipeline on credit card portfolio optimization as a case study. The deterministic backend is a mixed-integer linear program (MILP) that computes the optimal 1–3 card portfolio for a user spending profile; the LLM narrator writes the explanation; VERITYGATE sits between them. We choose MILP as the concrete instantiation because it produces structured evidence with clean, audit-quality ground truth; the framework requires only that the backend emit typed evidence with allowed entities and numbers, a contract we revisit in Section 5.[1]

2 A Four-Gate Verification Taxonomy

We catalog the failure modes of LLM narrators when given full structured grounding. At each of r=0 and r=1, 900 narrations form 450 paired (grounded, ungrounded) comparisons across three LLM backends; four families account for essentially all observed failures. Each family corresponds to one verification gate.

Gate 1: Evidence Existence. Every cited evidence identifier must exist in the structured backend output. LLMs frequently fabricate identifiers that sound right but do not appear anywhere in the input. At r=0 (no repair) Sonnet 4.6 produces 1 evidence-existence error per 150 grounded instances and GPT-4O-MINI produces 6; after one repair pass these drop to 0 and 4 respectively (Table 2). The check is deterministic: a set membership against the backend's emitted identifier set.

Gate 2: Entity Allowlisting. Cited entity names (card identifiers, category names, currency codes) must come from the deployment's allowed entity set. LLMs paraphrase entity names from training prior, writing "Amex Blue Cash" when the backend used `amex-bcp`, or inventing "us-bank-altitude-go" when no such card was selected. The check is also deterministic: set membership against the backend's allowed-entity list.

Gate 3: Number Binding. Cited number strings (dollar amounts, percentages, counts) must exactly match a canonical string surfaced from the structured backend. LLMs round, sign-flip, fabricate, or change decimal formatting. At r=0 GPT-4O-MINI produces 388 number errors across 150 grounded instances and Llama-70B produces 182; Sonnet produces 0 at r=0 and 1 at r=1. These counts include exact-format mismatches such as `2400.0` versus `2400.00`. Small integers (0–3) are allowed by convention. The evaluated check is exact string membership.

Gate 4: Claim-Type Rules. Claims of a given type must cite evidence of the required type. A comparison claim must cite a winner-by-category evidence node; a fee-justification claim must cite a fee-break-even node; a cap-switch claim must cite cap-hit evidence and, when those node types are present in the graph, both cap-hit and allocation-segment evidence. LLMs frequently produce structurally well-formed claims that cite the wrong evidence category. This is the hardest gate in our evaluation: on Sonnet 4.6 the count drops only from 985 (r=0) to 841 (r=1) across 150 instances, and a second repair pass moves it no further (Section 4). Across these three models and repair set-

[1]The system's name reflects its function: four mechanical gates (one for each failure mode in the taxonomy) through which every generated claim must pass before it ships to the user.

`"citedEntity not allowed: amex-gold"`

→ *returned to LLM with this specific error for a repair pass.*

Figure 1: Illustrative traces reconstructed from claim text observed in our paper-grade evaluation; identifiers and structured declarations are simplified to isolate one gate at a time. *Top:* a `FEE_JUSTIFICATION` claim passes all four gates and ships. *Bottom:* a `COMPARISON` claim fails Gate 2 (the cited entity `amex-gold` is not in the allowed-entity list), is rejected with an explicit error message, and is returned to the LLM for a single repair pass. These are pedagogical traces rather than exact serialized log records. This is the verification contract that mechanically enforces structural faithfulness at the schema level.

tings, this persistence suggests a type-routing bottleneck; broader model and domain studies are needed.

Figure 1 shows two illustrative traces reconstructed from claim text observed in our paper-grade evaluation, making the four-gate contract concrete before we describe the framework architecture (Section 3).

Table 1 summarizes the four gates and their empirical profiles.

3 The VERITYGATE Framework

VERITYGATE operates as a transparent layer between the deterministic backend and the LLM narrator. It requires no modification to either side. The backend emits structured evidence in its native format; the LLM is called with a standard prompt. The framework performs three-stage validation.

3.1 Stage 1: Evidence Graph Construction

We build an evidence graph from the backend output. Each evidence block becomes a node; edges connect logically related nodes (for example, a cap-hit node depends on the winner-by-category node for the same category). The graph also carries two allowlists:

- **Allowed entities:** all entity strings that appear in the backend output (card identifiers, category names, currency codes).
- **Allowed numbers:** all numbers that appear in any evidence node's structured fields, plus a small-integer allowlist (0, 1, 2, 3).

The graph carries a SHA-256 digest of its canonical form. This makes the verification step deterministic and auditable: any two runs over the same backend output produce the same digest.

3.2 Stage 2: Four-Gate Verification

The narrator LLM is prompted (strict JSON) to emit prose plus a parallel list of structured claim objects with declared `citedEvidenceIds`, `citedEntities`, and `citedNumbers` (schema and Gate 4 type rules in Appendix C; prompt templates in Appendix D). The four gates check these declared structured fields against the evidence graph; the **guarantee** is *schema-level structural correctness*, not prose-level faithfulness: an under-citing LLM can mention unverified entities or numbers in prose that the verifier never inspects (Appendix A).

Each claim is checked against the four gates from Section 2. The check is purely structural: no LLM is involved. If any claim fails any gate, the claim is rejected. Crucially, rejection is independent of fluency. A grammatically beautiful, plausible-sounding claim that cites a non-existent number is rejected just like one containing an unallowed declared value.

The output of Stage 2 is two lists: *verified claims* (passed all four gates) and *failing claims* (with attached error messages indicating which gate(s) failed and which strings were unallowed).

Gate	What it checks	Detection	Empirical grounded error range (150 inst. per cell)
1. Evidence Existence	Cited evidence id is in the graph	Set membership	r=0: 1–6 r=1: 0–4 (Sonnet best, mini worst)
2. Entity Allowlisting	Cited entity is in allowed set	Set membership	r=0: 0–47 r=1: 0–43 (Sonnet best, mini worst)
3. Number Binding	Cited number string is in allowed set	Exact string membership	r=0: 0–388 r=1: 1–97 (Sonnet best, mini worst)
4. Claim-Type Rules	Claim type cites required evidence type	Type-rule check	r=0: 885–985 r=1: 652–841 (all tiers high)

Table 1: The four verification gates. Gates 1–3 are largely addressed by allowlist surfacing plus one repair pass on the frontier model. Gate 4 is the persistent residual mode in the evaluated cells: every tier produces hundreds of type-rule errors after repair, and a second Sonnet repair pass does not significantly reduce them (Section 4).

3.3 Stage 3: Repair Loop and Permissive Emission

If any claim failed verification, the framework can optionally re-prompt the LLM with the original context plus the specific verifier errors ("Your previous claims failed for these reasons. Use only the allowed strings."). The model produces a new claim list, which is verified again. We keep whichever of the initial and post-repair lists has fewer failing claims (intra-pass selection; distinct from the deployment-time best-of-(r=0, r=1) policy in Appendix E).

We use one repair pass as the headline operating point. On Sonnet, a second pass produces a paired Δ that is not statistically distinguishable from zero (Section 4). For Llama, one pass reduces shipped volume without a detectable survival gain, so deployments should select the operating point by model and report both co-primary metrics.

The final output is the *verified claim subset*: only claims that pass all four gates ship to the user, as their concatenated `text` fields. We call this *permissive emission*: emit whatever passes, drop what fails. The user never sees a failing claim. Permissive emission is a *filtering* policy, not a generation-time correction: the underlying LLM continues to fabricate; claim-survival measures what passes verification (what the user sees), not generator improvement.

Figure 2 shows the overall flow.

4 Evaluation

We evaluate VERITYGATE along three dimensions: claim-survival rate (the share of parsed-and-retained claims that pass verification), shipped verified claims per instance (the user-visible output), and judge-based usefulness preference (a secondary metric).

4.1 Setup

Case study and profiles. We test on credit card portfolio optimization. The deterministic backend is a MILP that emits six task-facing evidence types (cap-hit, winner-by-category, allocation-segment, fee-break-even, earn-rate, assumption); the schema also permits four support/container types. It is independently validated on 1,000 real households drawn from the U.S. BLS Public-Use Microdata (U.S. Bureau of Labor Statistics, 2024) (Spearman $\rho = 0.896$ vs ground-truth optimal portfolios across 25 survey waves). We rely on that validation for the credibility of the structured ground truth and do not re-derive it here. For this evaluation we use 50 parametric profiles $\times$ 3 goal types (cashback, flexible points, program points) = 150 (profile, goal) instances, fixed seed 42, stratified to include cap-boundary cases. Each of r=0 and r=1 has 150 $\times$ 3 narrators $\times$2 variants = **900 benchmark instances**, forming 450 matched grounded–ungrounded pairs. We add a Sonnet-only ablation at r=2 (300 more). The released result records contain 16,180 parsed-and-retained claim objects across these conditions. The verifier-passing subset is what we report as "shipped" in Table 2.

LLM backends. Three narrators spanning the capability range: GPT-4O-MINI-2024-07-18 (OpenAI, small closed), LLAMA-3.3-70B-INSTRUCT-TURBO (Meta, via Together AI, open-weights mid), and CLAUDE SONNET 4.6 (Anthropic, frontier closed). The judge model is GPT-4O-2024-08-06: a different model from the smallest narrator (GPT-4O-MINI) within the same vendor, and a different family entirely from the frontier narrator.[2]

[2]All API calls used temperature 0.0 with no provider-side caching; calls were made between 2026-03-01 and 2026-05-14. Cost estimates (Section 4.4) use vendor list pricing as of 2026-05-14, with per-call token counts measured from API

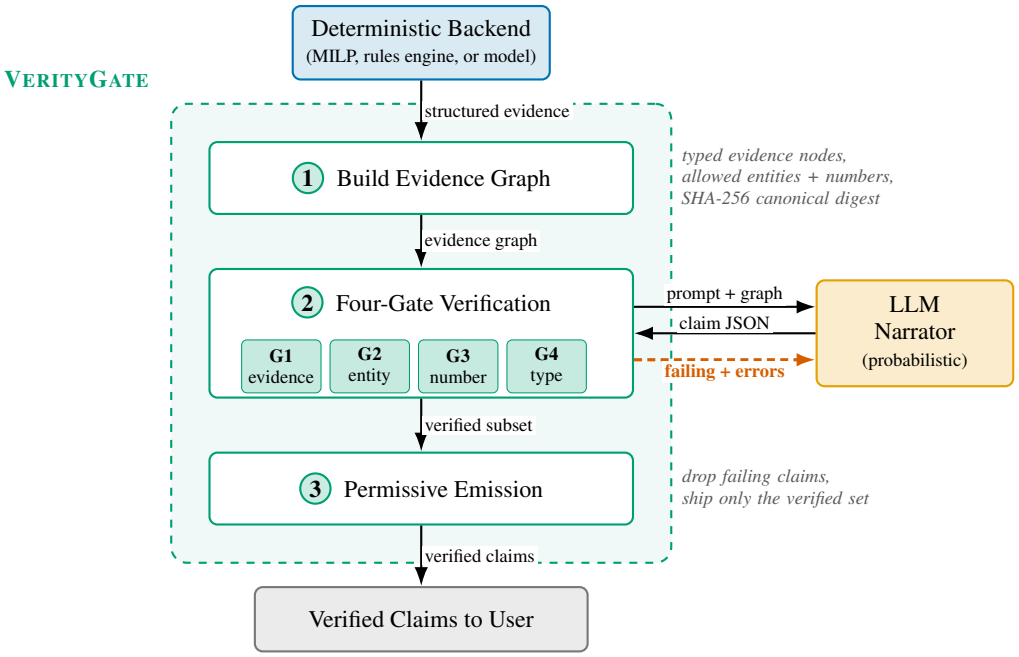

Figure 2: Three-stage interception architecture of VERITYGATE, operating as a transparent layer between the deterministic backend (here a MILP optimizer) and the LLM narrator. Stage 1 constructs the evidence graph with typed nodes, an allowed-entity set, and an allowed-number set. Stage 2 verifies each parsed claim against four gates (G1: evidence existence, G2: entity allowlist, G3: number binding, G4: claim-type rules); the optional repair loop (vermillion dashed arrow) re-prompts the LLM with the verifier errors for one pass. Stage 3 is a pure filter: only claims passing all four gates ship.

Variants. For each (profile, goal, model) we run two paired variants. *Grounded*: prompt includes the full structured evidence, the allowed entity list, and the allowed number list. *Ungrounded*: prompt includes only the goal name, the portfolio card list, and the top-line breakdown (matching the engine's production `UngroundedLlmNarrator`).

Two runs, plus an ablation. We perform two paired runs: $r{=}0$ (no repair, baseline) and $r{=}1$ (one repair pass, our headline configuration). We also run a Sonnet-only ablation at $r{=}2$ to confirm diminishing returns.

Pre-registration. Co-primary metrics, pairing units, statistics, and explicit non-claims were pre-registered; see Appendix E. The protocol called the survival denominator "generated claims." The evaluation used a lenient parser that skipped malformed individual records and marked an instance `schemaFailed` only if no record remained. Thus `totalClaims` counts parsed-and-retained claims; a fully failed instance ships zero but adds zero claims to this denominator. Pre-parse arrays were not archived, so the partial-record drop rate cannot be recovered.

responses.

Statistical procedure. All confidence intervals use cluster bootstrap on instances (the natural unit, since claims within an instance share a profile/goal/model), 10,000 iterations, seed 42. We primarily report paired differences. For repair-effect analysis, pairs are matched by (profile, goal, model). For cross-model contrasts, pairs are matched by (profile, goal).

Baselines. We compare three operating points: (i) *verify+filter only* ($r{=}0$ in Table 2); (ii) *full* VERITYGATE ($r{=}1$: verify+filter+repair); (iii) *ungrounded narration* (high-level summary only, every "Ungrounded" row). A *no-defense* (ship-all, no filter) baseline is not run; the complement of the $r{=}0$ survival fraction quantifies the user-visible failure rate (e.g., 80.3% at MINI grounded $r{=}0$). We *do not* evaluate LLM-as-judge as a *filter* baseline: our judge study (Section 4.3) finds that GPT-4o prefers ungrounded narrations over verified ones and chooses slot A in 83% of calls. Because it sees no evidence graph, we do not treat it as a claim-level filter. Instead, the judge is a diagnostic on *whether automatic preference signals track faithfulness*: they do not.

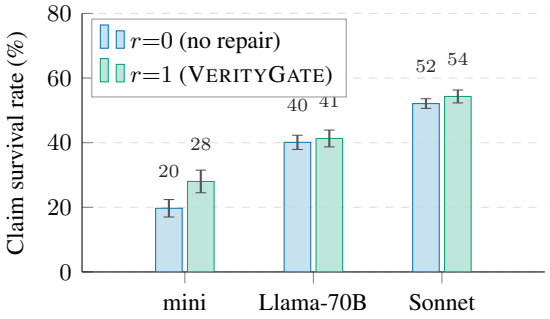

Figure 3: Claim-survival rate by model and repair setting, with 95% cluster-bootstrap CIs (n=150 per cell). Repair helps the smallest model most; Llama's change is inconclusive; Sonnet gains marginally.

4.2 Main results

Table 2 reports per-cell claim-survival rate, shipped verified claims per instance, and four-gate breakdown at both r=0 and r=1. Across all three model tiers, the grounded variant under repair ships more verified claims than the ungrounded variant; the gap widens with model capability. On the frontier model, the grounded variant under repair ships 6.67 verified claims per instance.

Figure 3 visualizes the per-model survival rates across both repair settings, with bootstrap CI bars.

Per-model repair effect (paired, r=1 − r=0). Table 3 shows the paired bootstrap differences. Repair helps small models a lot, frontier models a little, and the open-weights mid-tier not significantly.

Cross-model contrasts at r=1. The three-tier ordering is clean with non-overlapping CIs: Sonnet − mini = +26.4 pts [+22.6, +30.1], Llama − mini = +13.3 pts [+9.2, +17.4], and Sonnet − Llama = +13.0 pts [+10.3, +15.7].

Grounded vs ungrounded: rate is not volume. On mini at r=0, the ungrounded variant has a *higher* per-claim survival rate (26.1%) than the grounded variant (19.7%) even though it ships *fewer* verified claims per instance (1.29 vs 1.60). Without an evidence graph the model produces a shorter, safer narration that references fewer entities and numbers, so each individual claim is less likely to fail any gate, but the user receives less verifiable content overall. The deployment-relevant metric is therefore shipped verified claims per instance, not survival rate alone, which is why we pre-registered both as co-primary.

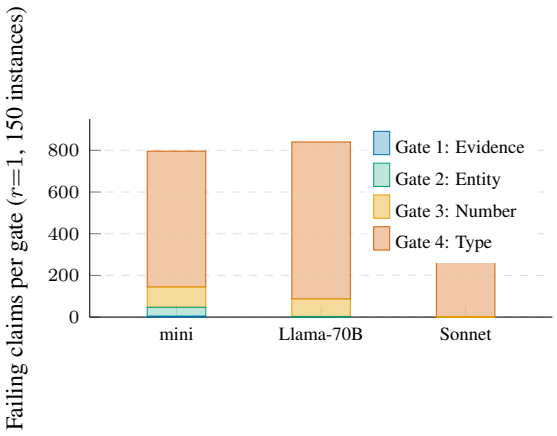

Figure 4: Failing claims per gate on the grounded variant at r=1 (150 instances per model; claims are counted once within each gate and may appear under multiple gates). Gate 4 (claim-type rules) dominates on every tier and is the residual problem after repair nearly eliminates Gates 1–3 on the frontier model. On Sonnet, all 841 distinct failing claims violate Gate 4; one also violates Gate 3. This is a persistent residual mode in the tested cells, not a universal scaling claim.

Diminishing returns and honesty under pressure. A second repair pass on Sonnet gives $\Delta(r{=}2 - r{=}1) = +0.77$ pts $[-1.22, +2.81]$ (CI crosses zero), so we deploy at r=1. Capable models become more conservative under repair: mean shipped count drops slightly on Llama ($\Delta = -0.71$) and Sonnet ($\Delta = -0.47$), abandoning claims they cannot substantiate rather than producing wrong ones. At r=1, Sonnet still ships 6.67 verified claims per instance, more than either other evaluated model; its own r=0 cell ships 7.15.

Where the failures live. Figure 4 visualizes the gate-error breakdown on the grounded variant under one repair pass. Gate 4 (claim-type rules) dominates across all three tiers: it affects 652/672 (97.0%), 753/763 (98.7%), and 841/841 (100%) distinct failing claims on mini, Llama, and Sonnet, respectively. The sole Sonnet Gate 3 failure overlaps a Gate 4 failure. Gates 1–3 are essentially eliminated on Sonnet under repair (0 evidence errors, 0 entity errors, 1 number error across 150 instances). Within the tested models, the residual bottleneck is type categorization rather than allowlisting or number-grounding.

Structural-only verification: prose-vs-citation gap. A small external rater study (Appendix A) surfaces two limitations distinct from Gate 4. On four items, all three raters accepted the prose val-

		Claim survival		Shipped / inst.		Failing claims per gate (r=1, total)			
Model	**Variant**	r=0	r=1	r=0	r=1	Evid.	Ent.	Num.	Type
GPT-4O-MINI	Grounded	19.7%	**28.0%**	1.60	1.74	4	43	97	652
	Ungrounded	26.1%	25.6%	1.29	1.31	4	27	263	486
LLAMA-3.3-70B	Grounded	40.1%	41.3%	4.29	3.58	0	3	84	753
	Ungrounded	21.6%	22.0%	0.99	1.02	0	344	334	227
CLAUDE SONNET 4.6	Grounded	52.1%	**54.3%**	7.15	6.67	0	0	1	841
	Ungrounded	43.2%	41.6%	2.36	2.21	0	46	196	294

Table 2: Main results for 900 benchmark instances at each repair setting (50 profiles × 3 goals × 3 narrators × 2 variants). Results are separate for r=0 and r=1. Conditions: *Grounded*/r=0 = verify+filter, no repair pass; *Grounded*/r=1 = full VERITYGATE (verify+filter+repair); *Ungrounded*/r = same pipeline, ungrounded prompt. The r=0 and r=1 columns are per-pass raw aggregates; the deployment policy (Appendix E) is per-instance best-of selection. Claim survival = passing claims / parsed-and-retained claims. "Shipped / inst." is mean verified claims per instance. The last four columns report **distinct failing claims per gate** at r=1 (once within each gate). A claim may appear in multiple gate columns, so their sum is not a distinct-claim total. Table 7 separately breaks Gate 4 into *verifier messages* by claim type.

Model	**Δ survival**	**Sig.**
GPT-4O-MINI	**+8.3 pts** [+4.3, +12.5]	yes
LLAMA-3.3-70B	+1.2 pts [-1.3, +3.6]	no
CLAUDE SONNET 4.6	+2.2 pts [+0.4, +4.1]	yes

Table 3: Paired Δ (r=1 − r=0) on grounded claim survival, 95% cluster bootstrap CI, paired by (profile, goal, model). Llama shows no detectable survival gain under one pass. Paired Δ on shipped verified claims per instance: mini $+0.14$ $[-0.17, +0.47]$ (NS); Llama -0.71 $[-1.05, -0.37]$ (down significantly, consistent with becoming more conservative under repair); Sonnet -0.47 $[-0.86, -0.08]$ (down significantly).

ues while the verifier rejected the declared number strings, mainly because numerically equivalent forms such as `2400.0` and `2400.00` did not match exactly; one item also failed a Gate 4 rule. In the opposite direction, one unanimous NO vs verifier YES case contained an undeclared prose phrase and empty cited fields, leaving the verifier nothing to inspect. Together, these cases motivate combined *structural* + *prose* verification and explicit numeric canonicalization as future work.

4.3 Counterbalanced Judge Analysis

We additionally evaluate user-facing usefulness via a counterbalanced LLM-as-judge protocol. The judge sees two explanations of the same optimization result: the *verifier-emitted prose subset* of the grounded narration (i.e., the user-visible output after permissive emission) and the raw ungrounded narration, without knowing which is which and without access to the evidence graph. To control for position bias, every pair is judged twice with the order swapped.

A pair score is computed by averaging the two ordering-wise grounded scores, producing one of {1.0, 0.75, 0.5, 0.25, 0.0} plus an *inconsistent* flag for pairs where the judge flipped its verdict across orderings.

Across a deterministic stratified slice of 150 matched pairs (50 per narrator × 3 narrators, the first 150 of 450 in lexicographic (profileId, goal, modelId) order) = 300 judge calls, we observe:

- **0% tie / parse-failure rate.** Every call returned a definitive A or B vote with mean confidence 0.91.
- **83% observed position-A rate.** Across the 300 counterbalanced calls, the judge picks the explanation in slot A 83% of the time.
- **Mean preference score < 0.5 on all three narrators.** Sonnet 0.30, mini 0.41, Llama 0.42: the judge prefers the *ungrounded* narration across the board (a usefulness preference, not a faithfulness measurement; the judge sees no evidence graph).

The 83% call-level position-A vote rate and 66% pair-level flip rate measure different quantities and are not algebraically interchangeable. Together they show a strong position effect while leaving room for content-sensitive decisions. Within the 34% of pairs where the judge agrees across orderings, ungrounded wins decisively.

Figure 5 visualizes the position-bias diagnostic and per-model preference distribution side by side.

This is the strongest argument for deterministic verification. A frontier LLM-as-judge, given full freedom to compare two explanations, picks the

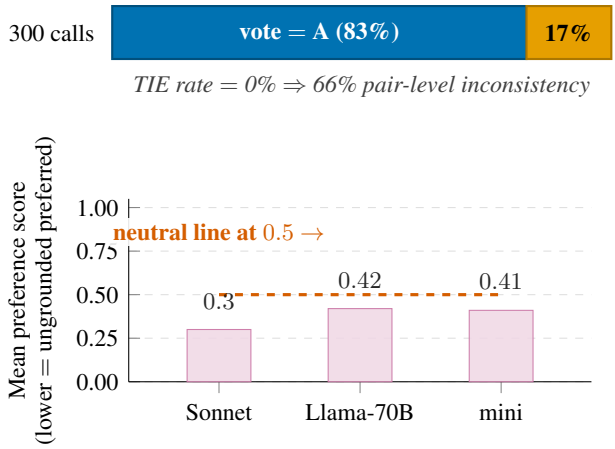

Figure 5: Counterbalanced judge diagnostic. *Top:* Position A is chosen in 83% of 300 calls and 66% of swapped pairs flip—a strong position effect, not proof of content independence. *Bottom:* All three mean scores are below 0.5, favoring raw ungrounded prose. Because the judge has no evidence graph, this is usefulness preference rather than faithfulness.

fluent ungrounded one (a preference signal, not faithfulness; no evidence access). Without counterbalancing, a one-shot judge would report "ungrounded wins 83 to 17": a fake headline driven by position bias. Counterbalancing exposes the position effect and isolates the order-consistent subset; we do not interpret the remaining preference as content-independent.

External rater validation. On a 25-item Gates 1–3 sample, three independent raters reach 74% mean pairwise agreement and expose structural–prose mismatches. A separate 25-item Gate 4 study (auxiliary seed 43) finds 88% majority-of-three agreement with the strict rule. Appendices A–B give both protocols.

4.4 Cost and deployment characteristics

Cost estimates. Author-recorded estimates based on run token counts and vendor list prices on 2026-05-14 give per-explanation cost at r=1 of: GPT-4O-MINI **$0.001**, LLAMA-3.3-70B **$0.0016**, CLAUDE SONNET 4.6 **$0.05**. Relative to Llama at r=1, Sonnet costs $\approx 31\times$ as much ($0.05/$0.0016) and ships $\approx 1.86\times$ as many verified claims per instance (6.67/3.58). The final estimates are archived, but the underlying provider token-count export was not preserved, so they are not independently re-estimable from the supplement.

Verifier microbench. On one CPU core using Java 21, a representative 14-claim instance takes p50/p95/p99 $\approx$ 9/16/29 μs (10k warmup, 100k measured iterations), sustaining ≈88,000 verifications/sec/core; observed post-run heap usage was 455.2 MB. LLM latency therefore dominates end-to-end walltime.

5 Discussion and Lessons Learned

Gate 4 isolated. On Sonnet at r=1, Gates 1–3 fall to 0/0/1 errors while Gate 4 has 841 distinct failing claims; a second pass has no clear effect. Across the tested tiers this suggests a type-routing bottleneck, not a universal ceiling.

Sparse-explanation edge case. At r=1 grounded, zero-verified-claim rates span **24.7%** (mini) to **1.3%** (Sonnet). Deployments need a minimum threshold, deterministic template fallback, or stronger narrator.

Generalization sketch. Graph builders and Gate 4 rules are domain-specific. Medical and loan-risk mappings are possible examples, not tested transfer.

6 Related Work

Structured-data and citation faithfulness. Slot-error methods check missing or spurious meaning-representation values (Wen et al., 2015; Dušek and Jurčíček, 2016; Juraska et al., 2018; Nie et al., 2019; Dušek et al., 2019); table-to-text metrics use extraction or reference alignment (Wiseman et al., 2017; Dhingra et al., 2019); and ALCE checks citations (Gao et al., 2023b). VERITYGATE adds a typed declaration/evidence contract and paired repair/filter evaluation, not a new set-membership operation (Appendix F).

Other defenses and metrics. NLI and atomic-fact metrics cover less structured evidence (Es et al., 2024; Rashkin et al., 2023; Min et al., 2023; Gao et al., 2023a; Yue et al., 2023; Chen et al., 2024). Complementary work studies constrained syntax (Willard and Louf, 2023), repair (Madaan et al., 2023; Yan et al., 2024; Huang et al., 2024), judge bias (Zheng et al., 2023; Wang et al., 2024), and tool safety (Radosevich and Halloran, 2025; Greshake et al., 2023).

Ethical Considerations

This work studies hallucination in LLM-generated explanations of structured decisions. All experiments were conducted in controlled local environments against a credit card portfolio benchmark.

No production systems or production end users were involved. Three external raters provided offline labels for a small sample of generated claims; the released rater files contain no names or directly identifying information. No directly identifying personal data was processed: the benchmark profiles used in this paper are generated parametrically; prior backend validation referenced in Section 4 used *public-use* BLS microdata, not personally identifiable records. We believe that documenting the failure modes of grounded LLM narration (and providing a deployable defense) serves the public interest, since organizations cannot protect against risks they do not understand. **Risk of false assurance from partial verification.** A "verified" label produced by VERITYGATE signals *schema-level* consistency between the declared claim fields and the evidence graph; it does *not* warrant that the prose shown to the user is faithful in full (see Appendix A). Deployments must surface this scope to end users (e.g., via product copy and/or audit logs) and must not present the label as a guarantee of complete factual accuracy. The versioned GitHub code release provides the framework implementation; the prompts, schemas, pre-registration, and reported per-cell logs are archived in the versioned Zenodo supplementary artifact under the repository's permissive license.

Limitations

VERITYGATE has several limitations.

First, we evaluate against three LLM backends. While these span a wide capability range (small / open-weights mid / frontier), the rapidly evolving landscape means results may not generalize to all future models. The observed pattern (repair helps the small model most while Gate 4 remains dominant in all three tested tiers) may not hold for other models; both the pattern and absolute numbers require replication.

Second, we use a single seed (42) for profile generation. We report tight paired bootstrap CIs as the primary uncertainty quantification rather than running multiple seeds. This is sufficient for the within-bench claims but does not assess seed robustness.

Third, our external rater studies (Appendix A) both use small stratified samples (3 raters $\times$ 25 items each, for Gates 1–3 and for Gate 4 separately). Larger studies with domain-expert raters and broader coverage are a clear follow-up. Note that the verifier's primary check is against the deterministic backend's allowlists, not against human judgment; the rater studies probe a different question (*do humans, given the same allowlists, agree with the verifier's accept/reject calls?*) rather than re-deriving the ground truth.

Fourth, the LLM-as-judge analysis was conducted using a single judge model (GPT-4O). Other judge models may exhibit different position-bias magnitudes and different absolute preferences. We report the judge result as a secondary metric and explicitly tag it as "blinded pairwise usefulness preference under counterbalancing," not as a faithfulness measure.

Fifth, adversarial robustness is not evaluated. The verifier is sound against non-adversarial LLM hallucination, but a model that knows the allowlist could craft outputs that pass verification while remaining semantically misleading. This is out of scope for this paper, since our threat model is unintentional fabrication, not adversarial attack.

Sixth, all empirical results are on a single application domain (credit-card portfolio optimization with the MILP backend described in §4). The verifier interface, claim schema, and Gate 4 type rules are designed to be portable, and we sketch mappings to medical decision support and loan-risk assessment in Section 5; neither mapping is empirically tested. Empirical cross-domain transfer is the most important follow-up.

Seventh, we do not compare narrative quality or coverage against a deterministic evidence-graph template, ablate strict versus relaxed Gate 4 rules, or run NLI/RAGAS/ALCE scorers on the generated outputs. The results therefore establish the behavior of the proposed structural audit-and-filter contract, not superiority over template generation or complementarity to neural faithfulness metrics.

Appendix A. Independent Rater Validation

Three independent raters with computer science backgrounds (no specific ML training) each rated the same stratified 25-item sample drawn from our paper-grade evaluation run: 10 items the verifier classified as VERIFIED and 15 items rejected by Gates 1–3. Items rejected by Gate 4 were excluded from the rater protocol because that gate requires domain-specific structural judgment beyond the rubric's scope; we discuss Gate 4 separately in Section 5.

Raters followed a fixed rubric (Appendix B) that asked a single binary question per item: *Does this claim reference only entities and numbers that appear in the evidence box?* The rubric was designed to require careful reading and table comprehension only, matching the mechanical nature of Gates 1–3. Raters had no visibility into the verifier's classification when rating. Items rated UNCLEAR by any rater were excluded from agreement calculations following standard practice.

Mean pairwise agreement across the three raters was 74% on the 25-item sample. Table 4 reports the full chance-corrected agreement statistics: pairwise Cohen's κ, Fleiss' κ across all three raters, and each rater's agreement with the verifier as the reference label. Fleiss' $\kappa = 0.48$ indicates moderate inter-rater agreement (Landis and Koch, 1977); pairwise Cohen's κ ranges from 0.35 (substantively fair) to 0.70 (substantial), with the wide span itself informative: rubric-following raters can disagree even on a deterministic structural check. Rater-vs-verifier κ is markedly lower (0.00–0.30), and the majority-of-3 vs. verifier κ is 0.02, consistent with the systematic structural-vs-prose disagreement pattern we discuss below. We interpret these numbers as supporting, not undermining, the case for mechanical verification: human raters disagree both with each other and (more sharply) with the verifier, while the verifier is reproducibly self-consistent across runs.

The qualitative disagreement pattern between raters and the verifier is systematic rather than noise:

- **All three raters disagreed with the verifier on four items** (a unanimous YES vs. verifier NO). The raters treated numerically equivalent trailing-zero forms as the same, while the verifier required exact membership of each declared number string. For example, `2400.0` did not match the allowed `2400.00`; one of

Comparison	Agreement	Cohen's κ	n
Rater 1 vs Rater 2	69.6%	0.39	23
Rater 1 vs Rater 3	66.7%	0.35	21
Rater 2 vs Rater 3	85.7%	0.70	21
Rater 1 vs Verifier	65.2%	0.30	23
Rater 2 vs Verifier	52.0%	0.03	25
Rater 3 vs Verifier	42.9%	0.00	21
Majority-of-3 vs Verifier	50.0%	0.02	24
Fleiss' κ (3 raters)	—	**0.48**	21

Table 4: Chance-corrected inter-rater and rater-vs-verifier agreement on the 25-item rater sample. UNCLEAR votes dropped from each comparison; sample sizes reflect per-pair retention. Fleiss' κ uses items where all three raters voted YES/NO (21 items).

the four items also failed Gate 4. This exposes an exact-string canonicalization limitation.

- **All three raters disagreed with the verifier in the opposite direction on one item** (unanimous NO vs. verifier YES). The claim's prose mentioned a phrase not in the allowed-entity list ("general purchases"), but the LLM emitted empty cited fields and the verifier had nothing to check.

These five items (4 + 1) account for the majority of the gap between rater majority vote and the verifier. They argue for numeric canonicalization and combined *structural + prose-level* verification as future work, while the structural check alone catches the failure classes (Gates 1–4) with reproducibility that subjective human judgment partially lacks (3 raters do not perfectly agree among themselves; mean pairwise agreement 74%).

Walkthrough 1: Verified claim, unanimous agreement (item 4). Claim: *"chase-freedom-flex earns $197.64, credits $0.00, fee $0.00, net $197.64"*. Allowed entities include `chase-freedom-flex`; allowed numbers include 0 and 197.64. Every entity and number in the prose appears in the evidence box. Verifier: YES. All three raters: YES. Clean case testing the rubric's *strict-literal* criterion.

Walkthrough 2: Gate 3 violation, all raters agree (item 13). Claim: *"The Capital One Savor card offers 4% cashback on dining, making it ideal for food-related expenses compared to standard cashback cards."* Allowed entities include `capl-savor` (matches "Capital One Savor" by paraphrase) and `DINING`; allowed numbers do not include 4. Verifier: NO (Gate 3). All three raters: NO (correctly identified the unallowed "4"). A clean Gate 3 violation case where rater majority and verifier converge on rejection.

Walkthrough 3: Verifier-vs-rater disagreement, structural-only limitation (item 17). Claim: *"Segment allocation for ONLINE shows amazon-prime-visa at $2400.00 and amex-bcp at $6000.00."* Allowed entities include `ONLINE`, `amazon-prime-visa`, `amex-bcp`; allowed numbers include 2400 and 6000. Every prose element appears in the displayed evidence box by inspection. All three raters: YES. Verifier: NO. The declared numbers were `2400.0` and `6000.0`, whereas the allowed strings were `2400.00` and `6000.00`. The prose values are numerically correct, but the evaluated exact-string check rejects the structured fields. This case motivates canonical numeric comparison in a future verifier version.

Gate 4 validation sub-study. The 25-item study above by design covers Gates 1–3 only. Because Gate 4 dominates residual failures, we ran a separate three-rater sub-study over 25 stratified Gate 4 failures sampled from a re-instrumented smoke run (7 `COMPARISON` + 6 `FEE_JUSTIFICATION` + 6 `CAP_SWITCH` + 6 `ASSUMPTION`, round-robin across the three narrators, seed 43). Raters saw the claim text and the human-readable types of the evidence records the LLM cited; the verifier's expected-type column and decision were withheld to avoid priming. Raters judged whether the cited evidence type(s) were a reasonable backing for the claim text (AGREE) or not (DISAGREE); UNCLEAR was a third option.

Table 5 reports the agreement statistics. **Majority-of-3 raters agreed with the verifier's rejection on 22 of 25 items (88%);** mean per-rater agreement with the verifier was 86% (92%, 71%, 96%). Pairwise Cohen's κ ranges 0.19–0.36 and Fleiss' κ across the three raters is 0.19, but these chance-corrected values are noise-dominated under the highly skewed prevalence (most items are clearly verifier-correct rejections): when $p_e \approx p_o$, κ collapses irrespective of the substantive level of agreement (Feinstein and Cicchetti, 1990; Gwet, 2008). κ against the verifier reference is undefined by construction (the verifier rejected every item, giving zero variance) and is reported here as 0.00 for completeness. Raw % agreement is the substantive metric under this prevalence regime.

The single rater with the lowest verifier agree-

Comparison	Agreement	Cohen's κ	n
Rater 1 vs Rater 2	79.2%	0.36	24
Rater 1 vs Rater 3	88.0%	−0.06	25
Rater 2 vs Rater 3	75.0%	0.19	24
Rater 1 vs Verifier	92.0%	0.00	25
Rater 2 vs Verifier	70.8%	0.00	24
Rater 3 vs Verifier	96.0%	0.00	25
Majority-of-3 vs Verifier	**88.0%**	0.00	25
Fleiss' κ (3 raters)	—	0.19	24

Table 5: Gate 4 validation sub-study: rater agreement on 25 stratified Gate 4 failures, blind rubric (verifier's expected type and decision hidden). κ values are deflated by the prevalence-skew paradox (verifier rejected every item, raters mostly agreed) and are reported alongside raw agreement, which is the substantive metric under skewed marginals. Majority-of-3 vs verifier 88% is the headline.

ment (Rater 2, 71%) showed a coherent pattern: they accepted `RESULT_BREAKDOWN` (final-money-totals records) as adequate backing for `COMPARISON` claims (e.g., *"compares result breakdown"*). This is a defensible *looser-grounding* interpretation in which related-but-not-exact evidence types are acceptable. We report it as a finding rather than noise: Gate 4 enforces a strict type-rule discipline, but a looser standard is intelligible and an alternative design choice. The fact that two raters land at $\geq 92\%$ verifier agreement and one rater at 71% with a coherent rationale gives a useful range, not a sharp validation ceiling.

Appendix B. Rater Rubric

Raters received the following one-page protocol prior to evaluation:

> For each paired (claim, evidence) item, answer: *Does this claim reference only entities and numbers that appear in the evidence box?* Choose one of: **YES** (every entity and number in the claim appears in the evidence box), **NO** (at least one entity or number is not in the evidence box), or **UNCLEAR** (the claim is too vague to extract entities/numbers, or an entity name is paraphrased and you cannot tell if it matches).

The rubric included five calibration examples covering YES, NO due to entity violation, NO due to number violation, UNCLEAR, and NO due to a derived (sum-of-allowed) number. Raters were instructed to be literal (do not use outside knowledge), to not perform arithmetic (derived numbers must appear directly in the evidence), and to trust their first read (mark UNCLEAR rather than debate for more than 60 seconds).

Appendix C. Claim Schema and Gate 4 Type Rules

This appendix gives the six-field prompt/schema contract. The evaluated parser requires `claimId`, `claimType`, and `text`; it defaults missing or non-array citation fields to empty arrays. Gates 1–3 inspect those declared arrays, and Gate 4 applies Table 6. The type rules are specific to the credit-card domain.

Claim object (per-claim). The prompt asks the LLM to emit a JSON object with six fields:

```
{
  claimId: string
  claimType: enum (one of the
six in Table 6)
  text: string             // the
user-visible prose
  citedEvidenceIds: array of
string            // Gate 1 input
  citedEntities:  array of
string            // Gate 2 input
  citedNumbers:  array of string
// Gate 3 input
}
```

Gates 1–3 check, respectively, that every element of `citedEvidenceIds` is a node in the evidence graph, that every element of `citedEntities` is in the per-instance allowed-entity set, and that every element of `citedNumbers` exactly matches a string in the per-instance allowed-number set. Gate 4 applies *type-specific structural rules*: it requires that at least one citation in `citedEvidenceIds` resolve to an evidence node of a required type. The six claim types and their Gate 4 rules in our credit-card domain are:

Gate 4 failure modes in practice. Table 7 breaks down the residual Gate 4 errors on the grounded variant at $r{=}1$ by the claim type that triggered the violation. On every model, `COMPARISON` (missing `WINNER_BY_CATEGORY` citation) and `FEE_JUSTIFICATION` (missing `FEE_BREAK_EVEN` citation) are the largest two sub-modes. `CAP_SWITCH` is a smaller fraction in absolute count but distinctive in its sub-structure. Sonnet produces 220 verifier messages from 106 distinct `CAP_SWITCH` claims. At claim level, 89 (84%) omit `CAP_HIT`, 72 (68%) omit `ALLOCATION_SEGMENT`, and 55 (52%) omit both. The last figure directly supports the interpretation that the model does not consistently recognize that `CAP_SWITCH` requires both

Claim type	Required evidence type(s) at Gate 4
COMPARISON	must cite WINNER_BY_CATEGORY
ALLOCATION	(no Gate 4 requirement)
THRESHOLD	(no Gate 4 requirement)
ASSUMPTION	must cite ASSUMPTION
FEE_JUSTIFICATION	must cite FEE_BREAK_EVEN
CAP_SWITCH	must cite CAP_HIT; when present in the graph, must cite both CAP_HIT and ALLOCATION_SEGMENT

Table 6: Gate 4 (claim-type rules) per claim type. The "required evidence type" column lists the evidence-graph node type(s) that at least one element of citedEvidenceIds must resolve to. CAP_SWITCH is the only claim type requiring two distinct evidence types (one of each) when those types are present in the graph; the separate unconditional CAP_HIT path explains the duplicate message unit described below. The others require at most one. ALLOCATION and THRESHOLD have no Gate 4 rule; their declared entities and numbers are checked only by Gates 2 and 3.

evidence types. At message level, the 220 total comprises 89 messages from the unconditional required-type check, 59 additional CAP_HIT messages from a guarded two-type check, and 72 ALLOCATION_SEGMENT messages. Thus any third message on a claim reflects the two verifier paths for CAP_HIT, not a data or aggregation error. Constrained decoding over the claim-type schema is the natural next intervention.

Gate 4 is predominantly type-routing. A re-instrumented smoke replay (3 profiles $\times$ 3 goals $\times$ 3 narrators at r=1, with per-claim cited-evidence type capture) yielded 139 grounded Gate 4 failures with full citation records. **Within this 27-instance replay, 138/139 (99.3%) had non-empty `citedEvidenceIds`**: nearly every rejected claim cited something, but not the required type; one was true under-citation. The dominant misrouting patterns were: FEE_JUSTIFICATION claims cited WINNER_BY_CATEGORY in 62.5% of their failures (25 / 40); COMPARISON cited FEE_BREAK_EVEN in 30.1% (22 / 73); ASSUMPTION cited WINNER_BY_CATEGORY in 55.6% (10 / 18). The required evidence type was available in the graph in the great majority of cases (verified by sibling claims of the same type passing Gate 4 within the same instance, e.g., a FEE_JUSTIFICATION that correctly cited FEE_BREAK_EVEN). The prompt provides the evidence graph with each node's type in JSON but does not enumerate the type→required-evidence mapping; even the repair pass, which includes the exact rule in the verifier-error feedback (e.g., "X must cite Y evidence"), does not reliably resolve the routing error. Mechanical Gate 4 enforcement catches this class of LLM limitation structurally.

Claim type	mini	Llama	Sonnet
COMPARISON	371 (55.9%)	394 (48.3%)	324 (33.9%)
FEE_JUSTIFICATION	185 (27.9%)	154 (18.9%)	268 (28.1%)
CAP_SWITCH	21 (3.2%)	136 (16.7%)	220 (23.0%)
ASSUMPTION	87 (13.1%)	131 (16.1%)	143 (15.0%)
Total error msgs	664	815	955

Table 7: **Gate 4 verifier error messages** by claim type (grounded variant, r=1, 150 instances per model). The cell counts report verifier error *messages*, not distinct failing claims – this is the key distinction from Table 2, whose Gate 4 column reports one count per distinct failing claim and is authoritative for the headline totals. CAP_SWITCH can generate up to three messages per claim because CAP_HIT is checked on two verifier paths and ALLOCATION_SEGMENT on one. This is why the totals exceed the Table 2 Gate 4 counts (e.g., Sonnet: 955 messages from 841 failing claims). COMPARISON (missing WINNER_BY_CATEGORY) is the largest sub-mode on every model.

Appendix D. Prompt Templates and Sample Evidence Graph

This appendix gives the verbatim system-prompt skeletons used in our runs and a redacted example evidence graph snippet for one instance. The versioned Zenodo supplementary artifact contains the full prompt source and reported per-instance logs; the excerpts here expose the high-signal portions of the prompt-engineering choices in the paper.

Grounded narrator prompt (skeleton).

```
You must output ONLY a valid
JSON array of
claim objects.  Cite only the
evidence IDs
listed below.
Each claim must have these
fields:
  - claimId (string)
  - claimType (one of:
COMPARISON, THRESHOLD,
    ALLOCATION, ASSUMPTION,
    FEE_JUSTIFICATION,
CAP_SWITCH)
```

```
  - text (string)
  - citedEvidenceIds (array of
strings)
  - citedEntities (array of card
ids or
    category names)
  - citedNumbers (array of
number strings)
Output ONLY a JSON array. No
commentary.
Evidence IDs you may cite (exact
strings):
  {evidenceIdsLine}
For citedEntities, use ONLY
these exact
strings (card ids, category
names, currencies):
  {allowedEntitiesLine}
For citedNumbers, use ONLY these
exact strings
(do not round, do not reformat;
small ints
0-3 are also allowed):
  {allowedNumbersLine}
Structured evidence (for
reference):
  {evidenceJson}
```

Ungrounded narrator prompt (skeleton). The ungrounded variant differs only in what evidence is supplied:

```
Explain why this credit card
portfolio is
a good choice.  Be specific.
Cite card names,
category earn rates, dollar
amounts, and
supporting reasons.
{same CLAIM_SCHEMA block as
grounded}
Portfolio summary:
  {goal, portfolio card ids,
   primaryCurrency, netValueUsd,
   totalEarnValueUsd,
totalCreditValueUsd,
   totalFeesUsd}
```

The grounded variant gives the LLM the full evidence graph plus verbatim allowed-entity and allowed-number lists; the ungrounded variant gives only top-line breakdown numbers (net, earn, credits, fees) and the portfolio card list. Neither prompt instructs the LLM to "hallucinate" or "be careful"; the difference is entirely the evidence provided.

Repair prompt (skeleton). On a repair pass, the original grounded prompt is reused with up to ten specific verifier errors appended:

```
{original grounded prompt}
Your previous output failed the
claim verifier
with these errors:
  - citedEntity not allowed:
amex-gold
  - citedNumber not in allowed
set:  4
  - claim type COMPARISON
requires citation
    of WINNER_BY_CATEGORY
evidence
  (up to 10 errors shown)
Produce a corrected JSON array.
Cite only
evidence ids, entities, and
numbers listed
in the prompt above.  Use
exactly the strings
provided.
```

Judge prompt (skeleton, used in §4.3).

```
You are an impartial judge
comparing two
explanations of a credit card
portfolio
recommendation.  Choose the
explanation that
is most useful to a user reading
it.
Consider:
  - Faithfulness to the context
  - Clarity
  - Helpfulness
Do not let length or position
influence you.
Output ONLY a single JSON object
on one line.
Schema:  {"winner":  "A" | "B" |
"TIE",
  "rationale":  "<one short
sentence>",
  "confidence":  <float 0.0 to
1.0>}
Context (the optimizer's actual
decision):
  {contextSummary:  goal +
portfolio
   ids only; no evidence graph}
Explanation A: {prose A}
Explanation B: {prose B}
```

Note that the judge sees *only the prose* of the two explanations plus the (goal, portfolio) header. It has no access to the evidence graph, the verifier output, or which explanation is grounded; this is why we report the result as a usefulness-preference diagnostic rather than a faithfulness measurement.

Sample evidence graph excerpt. A representative grounded instance emits an evidence graph with the following shape (entity ids replaced with public-domain placeholders for the excerpt):

```
{
  graphDigest:
"sha256:5af1...",
  nodes:  [
    {id:"ev_1",
type:"ALLOCATION_SEGMENT",
```

```
        card:
          "chase-freedom-flex",
        category:"DINING",
spend:"1200.00"},
    {id:"ev_2",
type:"WINNER_BY_CATEGORY",
        category:"DINING",
        winner:
          "chase-freedom-flex",
        runnerUp:"amex-gold"},
    {id:"ev_3",
type:"FEE_BREAK_EVEN",
        card:

"chase-sapphire-preferred",
        fee:"95.00",
breakEven:"1267.00"},
    ... (typical instance has
14-22 nodes)
  ],
  allowedEntities:
[chase-freedom-flex,
      chase-sapphire-preferred,
DINING,
      GROCERIES, TRAVEL, ... (30
strings)],
  allowedNumbers:  [0, 1, 2, 3,
95.00, 197.64,
      1031.00, 1200.00, 1267.00,
...
      (typically 80-110
strings)]
}
```

The graph digest is computed by canonicalizing the node list (sorted by id, fields in fixed order, all numbers as decimal strings) and hashing with SHA-256. The verifier's accept/reject decision is a deterministic function of (claim, graph) and is reproducible across runs with bit-identical input.

Appendix E. Pre-Registration Summary

The released `protocol/eval_preregistration.md` separates these pre-run decisions from later analysis and deployment choices:

- **Co-primary metrics:** (a) *claim survival* = passing / totalClaims per cell, where the implemented totalClaims counts parsed-and-retained claims; (b) mean shipped verified claims per instance under permissive emission.
- **Pairing units.** Repair-effect contrasts: paired by (profileId, goal, modelId). Cross-model contrasts at $r{=}1$: paired by (profileId, goal). Sonnet $r{=}2$ ablation: paired by (profileId, goal).
- **Statistical procedure.** Instance-cluster bootstrap (10,000 iterations, seed 42); report paired differences with 95% CIs (significant iff excluding zero).
- **Run and decision rules.** Compare $r{=}0$ with $r{=}1$; claim a repair benefit only if a paired survival CI excludes zero. The pre-registered diminishing-returns rule used the Sonnet smoke $r{=}2 - r{=}1$ CI, which crossed zero at $N{=}9$.
- **Stop conditions.** Abort a run above 5% provider-call failures or 50% above its cost budget; diagnose before rerunning the affected cell.
- **Explicit non-claims** committed up-front:
  - No claim of state-of-the-art on any open-domain factuality / RAG benchmark.
  - No claim of empirical cross-domain transfer or seed robustness.
  - No unqualified claim that grounding beats the ungrounded variant.

Post-registration analysis and deployment choices. The per-instance best-of-($r{=}0, r{=}1$) deployment policy, the first-150 lexicographic judge sample, and the large-run Sonnet $r{=}2$ ablation were specified later. Table 2 and the main figures instead report $r{=}0$ and $r{=}1$ separately. The observed 1.78% schema-failed instance rate at $r{=}1$ is descriptive; the 5% stop rule concerned provider calls. The judge is a usefulness diagnostic, and permissive emission is a filtering policy, not evidence that the generator improves.

Appendix F. Structured-Data and Citation-Metric Lineage

Slot-error and semantic-control work checks missing or spurious meaning-representation values (Wen et al., 2015; Dušek and Jurčíček, 2016; Juraska et al., 2018; Nie et al., 2019; Dušek et al., 2019); IE and PARENT evaluate table-to-text content (Wiseman et al., 2017; Dhingra et al., 2019), while ALCE separates citation correctness and completeness (Gao et al., 2023b). VERITYGATE adds a typed declaration/evidence contract plus repair-and-filter evaluation, not a new set-membership operation. Neural-metric and relaxed-rule comparisons remain future work.

EVO-RAG: Evolving Retrieval-Augmented Agents for Efficient Multi-Hop Query Optimization

Yuelyu Ji[1], Rui Meng[2], Zhuochun Li[1], Daqing He[1]
[1]School of Computing and Information, University of Pittsburgh
[2]Google Cloud AI Research, Sunnyvale, CA, USA

Abstract

Retrieval-augmented generation (RAG) grounds large language models (LLMs) in external evidence, yet *multi-hop* pipelines still suffer from redundant sub-queries, shallow exploration, and premature or delayed stopping. We present EVO-RAG, a phase-aware framework that couples a lightweight two-stage curriculum (**Discovery→Refinement**) with **seven step-level rewards** and an **in-episode time scheduler**. The scheduler decays exploration incentives as evidence accumulates while increasing efficiency and correctness pressure as uncertainty shrinks. Beyond scalar rewards, we train a **multi-head preference model** and benchmark **DPO**, **PPO**, and **GRPO** under *identical* rollouts and curricula for a controlled comparison. Evaluated on HotpotQA, 2WikiMultiHopQA, MuSiQue, and Bamboogle with 8B-class backbones, EVO-RAG improves EM/F1 while reducing redundant hops. Ablations show that (i) suppressing query overlap, (ii) rewarding *controlled backtracking* and *justified refusal*, and (iii) time-dynamic weighting are key to the accuracy–efficiency trade-off.

1 Introduction

Large language models (LLMs) deliver strong results in QA, dialogue, and text generation (Brown et al., 2020; Ouyang et al., 2022; Raffel et al., 2020), yet they still hallucinate when relying on static pretraining. Retrieval-Augmented Generation (RAG) grounds responses in external documents (Lewis et al., 2020), but *multi-hop* QA remains difficult: an agent must issue a *sequence* of sub-queries, integrate partial evidence, and decide when to backtrack, answer, or refuse.

Modern RAG pipelines span query rewriting, retrieval, filtering/reranking, and answer generation (Chen et al., 2024b; Gao et al., 2024). End-to-end objectives that couple retriever and generator reduce handoff errors (Chen et al., 2024b; Gao et al., 2024; Xiong et al., 2025), but most supervision is *static* and phase-agnostic. As a result, systems often over-search early or fail to consolidate late. RL-based approaches attempt to align modules to task rewards, yet many depend on episode-level signals and fixed weight schedules, offering weak credit assignment for intermediate actions and poor guidance on the transition from *exploration* to *refinement* (Huang et al., 2025; Song et al., 2025; Liu et al., 2025; Sun et al., 2025).

We introduce EVO-RAG, a phase-aware framework for multi-hop retrieval (Fig. 1). The agent operates in two stages—*Discovery* then *Refinement*—and receives seven interpretable *step-level* signals: retrieval hit/miss, retrieval-action penalty, sub-query overlap, backtrack, refusal validity, step cost, and answer correctness. A time-based scheduler adjusts signal weights *within each episode*, decaying exploration incentives as evidence accumulates while increasing efficiency and correctness pressure as uncertainty shrinks. Beyond scalar rewards, we build a multi-head preference model that scores trajectory prefixes along these aspects, enabling both preference alignment (DPO) and scalarized policy gradients (PPO/GRPO) under identical rollouts.

Our design couples two time scales. Across training, a lightweight two-stage curriculum sets *endpoints* for each reward weight (discovery, then refinement) without freezing behavior; within episodes, linear interpolation by progress ratio $p(t)$ produces smooth, phase-aware guidance. This separation keeps implementation simple—no additional modules at inference time—while providing dense, interpretable feedback for control-flow decisions such as BACKTRACK and REFUSE.

We evaluate on HotpotQA, 2WikiMultiHopQA, MuSiQue, and Bamboogle (Yang et al., 2018; Ho et al., 2020; Trivedi et al., 2022b; Press et al., 2022) using 8B-class backbones. To probe generalization, we train on a small HotpotQA subset and test across datasets. EVO-RAG improves EM/F1 while curb-

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 72–83
October 29, 2026 ©2026 Association for Computational Linguistics

ing redundant hops; ablations show that (i) suppressing query overlap, (ii) rewarding controlled backtracking and justified refusal, and (iii) time-based weighting are key to the accuracy–efficiency trade-off. We also report a controlled comparison of DPO, PPO, and GRPO on the *same* rollouts and curricula, surfacing objective-dependent differences without confounds. Our experimental emphasis is a controlled analysis of phase-aware step-level supervision and policy objectives under matched rollouts, rather than an exhaustive comparison against every recent search-augmented RAG variant.

2 Related Work

RAG paradigms. RAG combines retrieval with generation to improve factuality and reduce hallucinations (Lewis et al., 2020). Comparative studies map retriever–generator trade-offs and explore end-to-end/process supervision that tightens interaction between the two (Chen et al., 2024b; Gao et al., 2024; Xiong et al., 2025). These objectives are typically *static* and phase-agnostic; our approach provides step-level, time-scheduled guidance within an episode to reflect evolving information needs in multi-hop reasoning.

Query rewriting and multi-hop retrieval. Multi-hop QA requires issuing well-formed sub-queries conditioned on partial evidence; errors propagate if later hops inherit poor queries. Methods mitigate this with missing-entity completion, interleaved reasoning–retrieval (e.g., IRCoT), speculative querying, and coherence-aware reranking (Trivedi et al., 2022a; Wang et al., 2024; Zhang et al., 2024; Wei et al., 2024; Zhu et al., 2025). These approaches seldom supervise *when* to diversify versus consolidate. Our overlap and step-cost signals explicitly regulate duplication and chain length, while backtrack/refusal signals shape control flow.

RL and preference optimization for RAG. RL has been used to align retrieval, reranking, and generation (e.g., multi-agent or curriculum-based training) and to leverage preference objectives such as DPO/GRPO (Chen et al., 2025; Huang et al., 2025; Ramesh et al., 2024; Kaiser and Weikum, 2025; Liu et al., 2025). Most rely on episode-level rewards with fixed schedules, which weakens credit assignment for intermediate actions. EVO-RAG instead supplies seven *step-level* signals with an in-episode scheduler and reports DPO/PPO/GRPO under identical rollouts for a controlled comparison.

3 Method

3.1 Preliminaries: Agentic RAG on RAG-Gym

We build on the high-level MDP abstraction of agentic RAG popularized by prior toolkits ("RAG-Gym" (Xiong et al., 2025)). Each episode corresponds to one question x and unfolds as a sequence $(s_t, a_t, o_t)_{t=1}^{T}$: **State** s_t: the question, the history of sub-queries and retrieved snippets, and the current scratchpad. **Observation** o_t: the top-k passages returned by the IR system when $a_t = \textsc{Search}$, or $\varnothing$ for other actions. **Action space**:

$$\mathcal{A} = \{\textsc{Search}, \textsc{Backtrack}, \textsc{Answer}, \textsc{Refuse}\}.$$

Termination: when the agent emits ANSWER or REFUSE, or $t = T_{\max}$. This paper keeps the outcome reward on the final ANSWER (EM/F1) but *decomposes* process feedback at intermediate steps into seven interpretable signals (Sec. 3.4). A two-stage curriculum (Discovery→Refinement) and an in-episode time scheduler (Sec. 3.7) shape the relative weights of these signals.

3.2 Why these actions and signals?

Multi-hop RAG agents fail in a few recurring ways: (i) issuing paraphrased sub-queries that retrieve near-duplicate evidence, (ii) over-searching late and polluting the context window, (iii) getting stuck after a retrieval miss and failing to recover, and (iv) hallucinating answers when evidence is insufficient. EVO-RAG exposes four control actions to directly address these failure modes: SEARCH expands evidence, BACKTRACK recovers from dead-ends, ANSWER commits when evidence is sufficient, and REFUSE abstains when the question is not answerable given retrieved evidence. We design seven step-level signals to provide observable, low-overhead feedback aligned with these behaviors: retrieval hit/miss encourages early grounding; overlap and step cost discourage redundancy and long chains; action penalty discourages late, redundant searching; backtrack penalty regularizes reversibility; refusal validity prevents unsafe abstention; and answer correctness provides the final task objective.

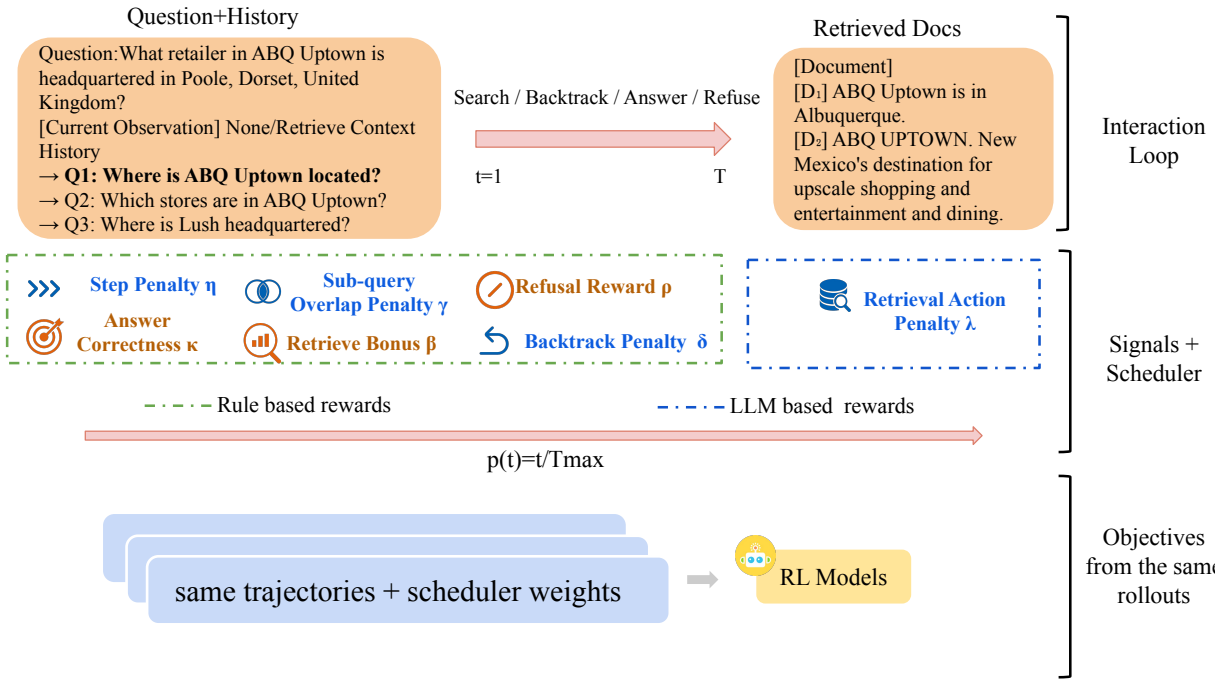

Figure 1: **EVO-RAG overview.** Left: at hop t the agent rewrites a sub-query and retrieves evidence; four actions are available (continue, backtrack, answer, refuse). Right: seven step-level signals—*Retrieval Bonus*, *Retrieval Action Penalty*, *Sub-query Overlap Penalty*, *Backtrack Penalty*, *Refusal Reward*, *Step Penalty*, *Answer Correctness*—with a time-based scheduler that shifts emphasis from exploration to refinement. Lower: we train the same rollouts with three policy objectives (DPO/PPO/GRPO) for transparent per-dataset/per-backbone comparison. Only refusal validity uses an external LLM judge; all other signals are computed from the environment / trajectory statistics.

3.3 Reward Sources and Action Triggers

We use two feedback sources: (i) *rule-based* signals computable from the environment (hit gold doc, query redundancy, step cost), and (ii) *LLM-based* judgments for semantics-heavy cases (whether the current evidence suffices, thus REFUSE is justified). Table 1 summarizes *when* each signal fires and *who* provides it; formal definitions follow in Sec. 3.4.

Refusal validity judge. When the policy selects REFUSE, we validate whether the question is answerable *using only the currently retrieved evidence* with an external LLM judge. We use **GPT-4.1** (temperature 0) and a short rubric prompt (Appendix E). The judge is called *only* on the REFUSE action (one call per refusal) and outputs a single label in {`answerable`, `unanswerable`}. This design keeps judge usage minimal and prevents it from affecting non-refusal trajectories.

3.4 Step-level Reward

Overlap statistic.

$$\Delta_t = \max_{j<t} \cos(q_t, q_j).$$

Table 1: Process signals, trigger, and source. All symbols are defined in Sec. 3.4.

Signal	Action / Timing	Source	Intuition
r_{ret}	SEARCH	Rule	Reward early hits on D^*.
r_{dup}	SEARCH	Rule	Penalize redundant sub-queries.
r_{bt}	BACKTRACK	Rule	Discourage blind backtracking.
r_{ref}	REFUSE	LLM judge	Refuse when evidence is insufficient.
r_{step}	every step	Rule	Keep chains short.
r_{act}	late SEARCH	Rule	Curb late redundant searches.
r_{ans}	terminal ANSWER	Rule	EM/F1 w.r.t. A^*.

Retrieval Bonus (r_{ret}). Let D_t be retrieved documents at step t and D^* the gold-supporting set.

$$r_{\text{ret}}(s_t, a_t) = \mathbb{I}[a_t = \text{SEARCH}] \cdot \big(2\,\mathbb{I}[D_t \cap D^* \neq \varnothing] - 1\big).$$

Training-time oracle signals vs. inference-time behavior. The gold supporting set D^* is provided by datasets with annotated supporting documents (e.g., HotpotQA/2Wiki/MuSiQue) and is used *only during training* to compute r_{ret} (and for analysis).

At inference time, D^* is unavailable; the deployed policy conditions solely on the question and retrieved passages, and no oracle-based reward is used. Thus, our method does not require supervision signals at test time and introduces no information leakage into inference.

Sub-query Overlap Penalty (r_{dup}).

$$r_{\text{dup}}(s_t, a_t) = -\,\mathbb{I}[a_t = \textsc{Search}] \cdot \Delta_t.$$

Backtrack Penalty (r_{bt}).

$$r_{\text{bt}}(s_t, a_t) = -\,\mathbb{I}[a_t = \textsc{Backtrack}].$$

Refusal Reward (r_{ref}). Let $J_{\text{ref}}(s_t) \in \{0, 1\}$ be the external judge output given current evidence, where 1 marks an `unanswerable` question and 0 an `answerable` one.

$$r_{\text{ref}}(s_t, a_t) = \mathbb{I}[a_t = \textsc{Refuse}] \cdot \big(2J_{\text{ref}}(s_t) - 1\big).$$

Step Cost (r_{step}).

$$r_{\text{step}}(s_t, a_t) = -1.$$

Answer Correctness (r_{ans}).

$$r_{\text{ans}}(s_T, a_T) = \mathbb{I}[a_T = \textsc{Answer}] \cdot \tfrac{1}{2}\big(\text{EM}(A_T, A^*) + \text{F1}(A_T, A^*)\big).$$

Retrieval Action Penalty (r_{act}). We penalize redundant late searches only after progress $p(t) \geq 0.3$:

$$r_{\text{act}}(s_t, a_t) = -\,\mathbb{I}[a_t = \textsc{Search}]\,\mathbb{I}[p(t) \geq 0.3]\,\mathbb{I}[\Delta_t \geq \tau].$$

Total scalarized reward. Let $K = 7$ be the number of step signals above. The per-step scalar reward is

$$R_t \;=\; \sum_{k=1}^{K} w_k(t)\, r_t^{(k)},$$

where the weights $w_k(t)$ are scheduled as described in Sec. 3.7.

3.5 Preference Modeling & Policy Objectives

Multi-head preference model. Given rollouts with step-level labels $\{r_t^{(k)}\}_{k=1}^{7}$ and time weights $\{w_k(t)\}$, we construct preference pairs (x^+, x^-) at the *trajectory-prefix* level using the weighted return $\sum_t \sum_k w_k(t) r_t^{(k)}$. A shared encoder with seven linear heads $\{f_\phi^{(k)}\}_{k=1}^{7}$ scores each aspect; the head-wise pairwise loss is

$$\mathcal{L}_{\text{RM}} = -\tfrac{1}{7} \sum_{k=1}^{7} \log \sigma\big(f_\phi^{(k)}(x^+) - f_\phi^{(k)}(x^-)\big),$$

where $\sigma(\cdot)$ is the logistic function. This factorization preserves interpretability and allows either preference- or reward-based policy learning.

Path A: preference alignment (DPO). We feed (x^+, x^-) directly to the policy and optimize

$$\mathcal{L}_{\text{DPO}} = -\log \sigma\big(\beta_{\text{dpo}}[\log \pi_\theta(x^+) - \log \pi_\theta(x^-)]\big).$$

No scalarization is required.

Path B: scalarized policy gradients (PPO / GRPO). When desired, aspect scores (or environment labels) are linearly combined into a scalar per-step reward:

$$\tilde{r}_t = \sum_k w_k(t)\, r_t^{(k)}.$$

We compute advantages with GAE and apply the PPO objective

$$\mathcal{L}_{\text{PPO}} = -\mathbb{E}_t\Big[\min\Big(r_t(\theta)\, A_t, \; \text{clip}\big(r_t(\theta), 1-\epsilon, 1+\epsilon\big)\, A_t\Big)\Big],$$

and its group-normalized variant (GRPO) by replacing A_t with

$$\hat{A}_t^{(i)} = \frac{\tilde{r}_t^{(i)} - \mu_t}{\sigma_t + \varepsilon} \quad \text{over candidates } i.$$

Objective summary. We report all three objectives under identical rollouts and curricula. DPO consumes preferences; PPO/GRPO use the same per-step weights for scalarization. We refrain from universal claims; effects depend on dataset/backbone and are analyzed in Sec. 4.5.

Retrieval-focused weights (β, λ) monotonically decrease, whereas efficiency-focused weights (γ, η, κ) increase; the refusal weight ρ stays constant. This "gearbox" provides step-level guidance that is missing from a static two-stage switch.

3.6 Two-Stage Curriculum (across training)

We use two time scales for guidance: a *training-time* two-stage curriculum (Discovery → Refinement) and an *in-episode* time-based scheduler (Sec. 3.7). A "stage" does *not* fix weights; it only specifies the *interpolation endpoints*—Start→Mid in Discovery and Mid→End in Refinement—while the actual step-wise weights still evolve within each episode via $p(t)$.

Table 2: Reward weights for EVO-RAG training. Start→Mid are the interpolation endpoints used in Stage 1 (Discovery); Mid→End are those used in Stage 2 (Refinement).

Reward Component	Stage 1: Discovery			Stage 2: Refinement		
	Start	Mid	Trend	Mid	End	Trend
Retrieval Bonus (β)	2.0	1.0	↘	1.0	0.5	↘
Retrieval Act. Pen. (λ)	1.5	0.8	↘	0.8	0.4	↘
Overlap Pen. (γ)	0.1	0.5	↗	0.5	1.2	↗
Backtrack Pen. (δ)	0.3	0.5	↗	0.5	1.0	↗
Refusal Reward (ρ)	0.5	0.5	–	0.5	0.5	–
Step Penalty (η)	0.02	0.05	↗	0.05	0.10	↗
Answer Corr. (κ)	0.05	0.10	↗	0.10	1.00	↗

What each stage emphasizes. **Discovery** exposes the policy to a high-entropy evidence space. We therefore set larger Start–Mid endpoints for retrieval-oriented terms (w_β, w_λ) and smaller ones for efficiency/precision $(w_\gamma, w_\eta, w_\kappa)$ to encourage breadth and early hits. **Refinement** shifts these endpoints in the opposite direction (larger $w_\gamma, w_\eta, w_\kappa$, smaller w_β, w_λ), promoting consolidation, controlled stopping, and precise answering. The refusal weight w_ρ stays constant across stages so that safe refusal is always available.

When to switch stages. We switch from Discovery to Refinement once exploration no longer increases the *composite return*. Concretely, let

$$R(\tau) = \sum_{t=1}^{T} \sum_{k} w_k(t)\, r_t^{(k)}$$

be the scalarized return of a trajectory τ on a held-out dev split (with $w_k(t)$ produced by the in-episode scheduler in Sec. 3.7). We keep an exponential moving average $\widehat{J}$ of episode-average returns and trigger the stage change when the improvement over the best running $\widehat{J}$ falls below a tolerance ε for P consecutive checkpoints (patience). Intuitively, once exploration plateaus, endpoints are shifted toward efficiency/accuracy for refinement.

Why two stages rather than a fixed two-block schedule. If one sets $w_k^{\text{early}} = w_k^{\text{late}}$ inside each stage, the scheme degenerates to a fixed two-block schedule. Our curriculum controls only the *endpoints*; the actual behavior in each episode is governed by the time-based scheduler below.

3.7 Time-Based Scheduler (within episode)

Progress ratio and interpolation. We schedule step-level weights within each episode using a progress ratio

$$p(t) = \frac{t-1}{T_{\max}-1} \in [0,1],$$

where t is the current step and $T_{\max}$ is the episode cap defined in Sec. 3.1. We then linearly interpolate between stage-specific endpoints $(w_k^{\text{early}}, w_k^{\text{late}})$:

$$w_k(t) = (1-p(t))\, w_k^{\text{early}} + p(t)\, w_k^{\text{late}}.$$

This guarantees $w_k(1) = w_k^{\text{early}}$ and $w_k(T_{\max}) = w_k^{\text{late}}$. If an episode terminates early (ANSWER/REFUSE), the schedule stops at the current t.

By choosing endpoints such that

$$\begin{aligned} w_\beta^{\text{early}} &\geq w_\beta^{\text{late}}, \quad w_\lambda^{\text{early}} \geq w_\lambda^{\text{late}}, \\ w_\gamma^{\text{early}} &\leq w_\gamma^{\text{late}}, \quad w_\eta^{\text{early}} \leq w_\eta^{\text{late}}, \\ w_\kappa^{\text{early}} &\leq w_\kappa^{\text{late}}, \quad w_\rho^{\text{early}} = w_\rho^{\text{late}}, \end{aligned}$$

we ensure exploration incentives (w_β, w_λ) *decay* as evidence accumulates, while efficiency/accuracy $(w_\gamma, w_\eta, w_\kappa)$ *increase*; w_ρ stays flat.

Rationale. (i) *Uncertainty reduction:* early steps face high-entropy evidence; rewarding early hits (large w_β) is valuable, but the marginal utility of additional searches diminishes with $p(t)$, so w_β decays. (ii) *Cost–benefit dynamics:* late searches incur growing costs (latency, duplication, context pollution), hence we gradually strengthen overlap/step penalties (w_γ, w_η) and answer accuracy (w_κ). (iii) *Credit assignment:* terminal-only rewards poorly supervise BACKTRACK/REFUSE/STOP; reweighted step signals provide phase-appropriate gradients within the same episode.

Implementation notes. We use linear interpolation for reproducibility; other smooth monotone maps (e.g., sigmoid) are drop-in replacements. Boundary conditions are $w_k(1) = w_k^{\text{early}}$ and $w_k(T_{\max}) = w_k^{\text{late}}$.

4 Experiments

We systematically evaluate EVO-RAG on four prominent multi-hop QA benchmarks: HotpotQA, 2WikiMultiHopQA, MuSiQue, and Bamboogle. Our evaluation specifically targets the following three research questions.

Table 3: Comparison of RAG methods on multi-hop QA datasets. Metrics are EM/F1 (%). For EVO-RAG we report, per backbone, the better of the two reward schedules in Table 4 (Time-dynamic for DeepSeek-8B and Qwen-2.5-7B, Two-stage for LLaMA-3.1-8B). Best value per column in bold.

Method	Backbone	HotpotQA		2Wiki		MuSiQue		Bamboogle	
		EM	F1	EM	F1	EM	F1	EM	F1
RAG-Gym (ReSearch + PRM)	LLaMA-3.1-8B	44.1	56.8	50.2	57.9	48.0	60.0	**51.2**	**63.1**
IRCoT	Flan-T5-XXL	45.0	56.2	45.4	56.8	19.9	24.9	44.0	55.0
EVO-RAG	DeepSeek-8B	56.8	70.5	52.6	66.4	51.8	63.7	45.3	58.2
EVO-RAG	LLaMA-3.1-8B	57.4	71.2	53.0	66.9	**52.5**	**64.4**	45.7	58.6
EVO-RAG	Qwen-2.5-7B	**57.6**	**71.5**	**53.2**	**67.1**	52.2	64.0	46.0	59.0

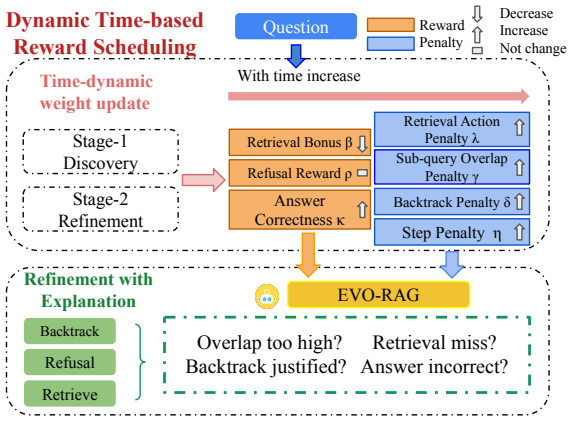

Figure 2: Time-based reward scheduling within an episode. Exploration-oriented weights (β, λ) decrease with progress $p(t)$, efficiency/accuracy weights (γ, η, κ) increase, and the refusal weight (ρ) remains constant.

Table 4: HotpotQA results under different reward schedules. The best schedule per backbone (bold) is the configuration reported in Table 3.

Backbone	Strategy	EM	F1
DeepSeek-8B	No Reward	52.6	66.2
	Two-stage	55.0	68.7
	Time-dynamic	**56.8**	**70.5**
LLaMA-3.1-8B	No Reward	52.9	66.6
	Two-stage	**57.4**	**71.2**
	Time-dynamic	55.6	69.4
Qwen2.5-7B-Instruct	No Reward	53.1	66.7
	Two-stage	55.9	69.5
	Time-dynamic	**57.6**	**71.5**

Table 5: Single-reward ablation. Acc. is the accuracy of the multi-head preference model (Sec. 3.5) at ranking the preferred trajectory prefix on a held-out split when trained with that signal alone; Loss is the corresponding pairwise loss.

Single Reward	Acc. (%)	Loss
Backtrack	**70.31**	0.913
Refusal	60.58	1.018
Retrieve	55.24	1.089
Step	54.17	1.184
Sub-query Overlap	54.35	1.015

4.1 Research Questions

Across these benchmarks we focus on three aspects: (i) overall accuracy/efficiency vs. RAG baselines across backbones; (ii) contribution of curriculum/scheduler and the interaction among reward components; (iii) effects of policy objectives (DPO/PPO/GRPO) under identical rollouts/curricula. Results are summarized in Tables 3, 4, 5, 6, and 7.

4.2 Datasets and Setup

We evaluate EVO-RAG on four multi-hop QA benchmarks (Table 8). All models are trained using 1,000 queries sampled from HotpotQA. Evaluation is conducted on official validation sets. Answer generation is evaluated using Exact Match (EM) and F1 scores. We intentionally keep training confined to HotpotQA to test cross-dataset generalisation.

LLM Backbone and Retriever. We use Llama-3.1-8B-Instruct (Touvron et al., 2023), Qwen2.5-7B-Instruct (Yang et al., 2025), and DeepSeek-R1-Distill-Llama-8B (Guo et al., 2025) as the agent backbones, paired with an RRF-BGE retriever (Chen et al., 2024a) that combines BM25 (Robertson et al., 2009) and BGE dense retrieval. We select these backbones to control for model scale while covering different instruction- and reasoning-oriented model families. LLaMA-3.1-8B-Instruct serves as a strong general-purpose instruction baseline, Qwen2.5-7B-Instruct provides a competitive alternative with strong instruction-following behavior, and DeepSeek-R1-Distill-Llama-8B represents

Table 6: Impact of reward combinations on HotpotQA (Qwen2.5-7B-Instruct). Metrics: EM/F1; Steps is the average retrieval chain length.

Reward Combination	EM	F1	Steps
Baseline (No Reward)	53.1	66.7	8.2
Best-2 (Backtrack + AnsCorr)	56.2	70.0	11.3
Best-3 (+Overlap)	56.9	70.6	10.1
Exploration-Heavy	55.0	69.1	13.4
Efficiency-Heavy	55.4	68.8	9.0
Full (All Rewards)	**57.6**	**71.5**	10.4

Table 7: HotpotQA (LLaMA-3.1-8B-Instruct) under different policy objectives, using identical rollouts and curricula. Mean over 3 seeds.

Objective	**EM (%)**	**F1 (%)**	**Steps**
PPO (scalarized)	55.1	69.0	11.7
DPO (multi-pref.)	55.9	69.4	11.1
GRPO (group-norm.)	**57.4**	**71.2**	**10.2**

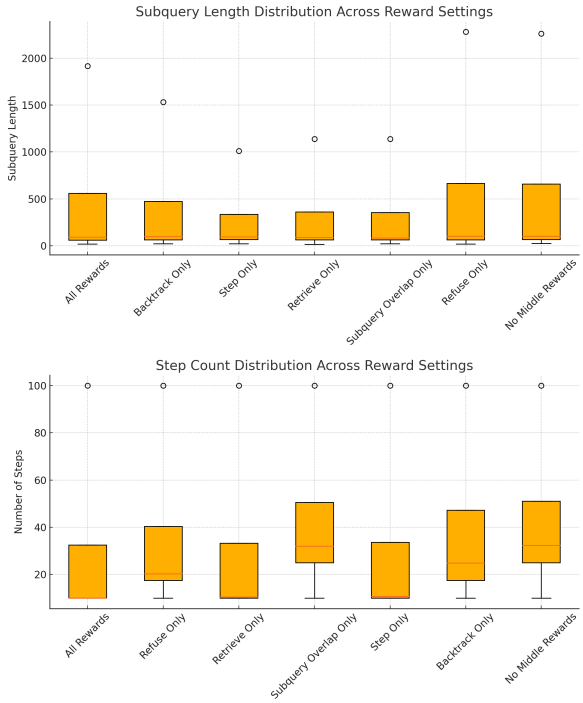

Figure 3: Distribution of sub-query length (left) and step count (right) under different reward settings. Time-dynamic scheduling reduces long-tail behavior compared with exploration-heavy variants.

a reasoning-distilled model. Keeping all three models in the 7B–8B range reduces confounding from model size and makes the effect of reward shaping and policy objectives easier to interpret.

We report refusal frequency and judge outcomes in Table 9 for the full EVO-RAG configuration with time-dynamic scheduling using Qwen2.5-7B-Instruct. Across these mostly answerable benchmarks, refusals are rare, and the false-refusal rate remains low, indicating that REFUSE primarily acts as a safety valve against low-evidence answering rather than a shortcut strategy.

Table 8: Evaluation data statistics. All models are trained on the same 1,000-query HotpotQA subset and evaluated on the official validation sets.

Dataset	Eval Size	Style
HotpotQA	7,404	Factoid
2WikiMultiHopQA	12,575	Structured
MuSiQue	2,417	Compositional
Bamboogle	125	Adversarial

Table 9: Refusal behavior statistics. Refuse (%) is the share of *all* evaluation questions on which the agent abstains; Valid (%) is the share of *those refusals* judged `unanswerable`; False (%) is the share of *all* questions on which the agent refuses although the judge deems them `answerable`.

Dataset	**Refuse (%)**	**Valid (%)**	**False (%)**
HotpotQA	1.9	88	0.2
2Wiki	1.3	85	0.2
MuSiQue	2.4	83	0.4
Bamboogle	0.8	80	0.2

4.3 RQ1: Do we improve over multi-hop RAG baselines?

Main results. Table 3 compares EVO-RAG against RAG-Gym and IRCoT across three backbones. On **HotpotQA**, EVO-RAG (Qwen2.5-7B-Instruct) reaches **57.6/71.5**, outperforming RAG-Gym (44.1/56.8) by +13.5 EM / +14.7 F1 and IRCoT (45.0/56.2) by +12.6 / +15.3. On **2Wiki**, the best EVO-RAG score (53.2/67.1) exceeds RAG-Gym (50.2/57.9) by +3.0 / +9.2 and IRCoT (45.4/56.8) by +7.8 / +10.3. As an exception, **Bamboogle** favors RAG-Gym (51.2/63.1), while EVO-RAG trained only on HotpotQA scores 45–46 / 58–59 (Table 3), indicating that while EVO-RAG generalizes across standard multi-hop QA, it can underperform on adversarially constructed queries without target-domain tuning. Bamboogle contains only 125 items, so a single question shifts EM by 0.8 points; we therefore read this cross-domain gap as indicative rather than conclusive.

Takeaway (RQ1). Across three datasets and multiple backbones, EVO-RAG materially improves EM/F1 over the RAG baselines considered here; the remaining gap on Bamboogle highlights

domain-shift sensitivity for adversarial queries.

4.4 RQ2: What design choices matter—components and scheduling?

(a) Single-reward ablation (component strength). Table 5 isolates each signal and reports internal decision quality (evaluation accuracy/loss of the preference model; see Sec. 3.4 and Sec. 3.5). **Backtrack** alone yields the highest internal accuracy (70.31%), indicating that controlled reversibility is a strong driver for robust exploration. **Refusal** ranks second (60.58%), supporting our design to explicitly reward safe abstention when evidence is insufficient. Pure **Retrieve/Step/Overlap** signals are weaker in isolation, suggesting they are most effective in combination rather than alone.

Takeaway. Signals that regulate *control flow* (when to backtrack or refuse) carry disproportionate value; more local efficiency signals need to be paired with them.

(b) Reward combinations and scheduling (Two-stage vs. Time-dynamic). *Combinations.* We use Qwen2.5-7B-Instruct for the reward-combination study because it gives the strongest overall HotpotQA performance under the full EVO-RAG setting in Table 4, making it the most informative setting for isolating which reward subsets matter. On HotpotQA (Qwen2.5-7B-Instruct), Table 6 shows that moving from Baseline (No Reward) (53.1/66.7, 8.2 steps) to **Best-2** (Backtrack+AnswerCorrectness) already gives +3.1 EM; adding **Overlap** (**Best-3**) both increases EM/F1 (56.9/70.6) and shortens chains (10.1 vs. 11.3). The **Full** configuration (all rewards, time-dynamic) yields the best accuracy **57.6/71.5** at 10.4 steps—longer than Baseline but substantially more accurate, indicating a better accuracy–efficiency trade-off. *Exploration-Heavy* extends chains (13.4 steps) with lower EM (55.0); *Efficiency-Heavy* shortens chains (9.0) but loses EM (55.4).

Schedules. Table 4 compares No Reward, Two-stage, and Time-dynamic: **DeepSeek-R1-Distill-Llama-8B**: Time-dynamic > Two-stage > No-Reward (56.8/70.5 vs. 55.0/68.7 vs. 52.6/66.2), i.e., +1.8/+1.8 over Two-stage and +4.2/+4.3 over No-Reward. **Qwen2.5-7B-Instruct**: Time-dynamic likewise wins (57.6/71.5 vs. 55.9/69.5 vs. 53.1/66.7), i.e., +1.7/+2.0 and +4.5/+4.8. **LLaMA-3.1-8B**: Two-stage slightly outperforms Time-dynamic (57.4/71.2 vs. 55.6/69.4), while both clearly beat No-Reward (52.9/66.6).

Interpretation. The in-episode scheduler consistently helps (DeepSeek/Qwen), while LLaMA-3.1-8B-Instruct appears to benefit more from fixed stage endpoints. This suggests a backbone–schedule interaction: when the model's search policy is already stable, a smoother decay (Time-dynamic) prevents over-search; otherwise, a stiffer stage separation (Two-stage) may be easier to learn. Figure 3 corroborates the efficiency story: dynamic scheduling suppresses long tails in step counts and sub-query lengths.

Takeaway (RQ2). Component-wise, **Backtrack + AnswerCorrectness (+Overlap)** form a strong core; curriculum-wise, the Time-dynamic scheduler is generally superior, with a small exception on LLaMA-3.1-8B-Instruct, where Two-stage wins by a narrow margin.

4.5 RQ3: How do policy objectives compare (DPO vs. PPO vs. GRPO)?

For the objective comparison, we use LLaMA-3.1-8B-Instruct as a stable reference backbone because it exhibits competitive performance under both schedules (Table 4) and provides a clean setting for comparing DPO, PPO, and GRPO under identical rollouts.

Observed trends. Table 7 reports the three objectives under identical rollouts and curricula, averaged over three seeds. GRPO attains both the highest accuracy and the shortest chains, DPO is intermediate, and PPO trails on both axes. We read this as a variance-structure effect rather than a general ranking: group normalization helps most when sibling actions at a given state receive similar scalarized rewards, DPO sidesteps scalarization altogether and is therefore robust when reward weights are hard to tune, and PPO can match either when the weights are well calibrated. Because we measure a single dataset/backbone pair, we do not claim a universal ordering.

Takeaway (RQ3). On HotpotQA with LLaMA-3.1-8B-Instruct we observe **GRPO > DPO > PPO** in both accuracy and efficiency (Table 7); the preferred objective may vary with dataset/backbone and with the variance structure of sibling actions.

5 Conclusion

We presented EVO-RAG, a phase-aware framework for multi-hop agentic RAG that combines (i) a lightweight Discovery→Refinement curriculum, (ii) seven interpretable step-level signals, and

(iii) an in-episode time scheduler that shifts emphasis from exploration to efficiency and correctness as evidence accumulates. Beyond scalar rewards, we introduced a multi-head preference model that preserves interpretability while enabling preference alignment (DPO) and scalarized policy gradients (PPO/GRPO) under identical rollouts for controlled comparisons. Across HotpotQA, 2WikiMultiHopQA, and MuSiQue, EVO-RAG consistently improves EM/F1 over the representative baselines and internal variants considered in this study, while reducing redundant behavior. Ablations further highlight the importance of control-flow signals and time-dynamic weighting. Future work includes broader baseline coverage, deeper and more diverse benchmarks, and learning adaptive schedulers and refusal validation with stronger human-grounded evaluation.

Limitations

Our empirical comparison focuses on RAG-Gym and IRCoT as representative multi-hop RAG baselines. Recent search-augmented or RL-trained RAG agents (e.g., R1-Searcher, O^2-Searcher, FrugalRAG, SimpleDeepSearcher, Chain-of-Retrieval Augmented Generation) are not included in our experimental tables. This limits how strongly we can claim competitiveness against the latest systems; our primary goal is instead a controlled study of phase-aware step signals and objective choices under identical rollouts.

We evaluate on four Wikipedia-style multi-hop QA datasets (HotpotQA, 2WikiMultiHopQA, MuSiQue, Bamboogle), which are mostly 2–4-hop in nature. Performance on deeper reasoning tasks, longer-horizon search, or non-Wikipedia domains remains uncertain. The drop on adversarial Bamboogle further suggests sensitivity to domain shift and dataset construction artifacts; with only 125 evaluation items, differences on this benchmark should be interpreted cautiously.

Reward weights and interpolation endpoints are manually specified (Table 2). While we provide a pilot study on adaptive tuning, our main method does not learn the scheduler itself. In addition, the Discovery→Refinement curriculum assumes a roughly monotone transition from exploration to consolidation; tasks that require intermittent re-exploration may not perfectly match this linear trajectory.

The refusal reward relies on an external LLM judge to label `answerable` vs. `unanswerable`. This introduces potential bias, judge-model dependency, and misalignment with human judgments. We do not report a dedicated human study for refusal validity, which is important for understanding the reliability of abstention behaviors.

A Adaptive Reward Weight Tuning (Pilot Study)

As a feasibility check for learning the schedule rather than specifying it by hand, we compare our manual endpoints against Bayesian optimization (BO) and a bandit-based (UCB1) controller over the same weight space (Table 10). Adaptive methods yield comparable or slightly better accuracy than the manual schedule. BO converged to weights close to our hand-tuned configuration with marginal EM/F1 gains; UCB1 adapted weights online without manual intervention. These results support the feasibility of adaptive tuning for robustness and cross-domain transfer (e.g., MuSiQue, Bamboogle).

Table 10: Pilot study of adaptive reward weight tuning on HotpotQA (LLaMA-3.1-8B-Instruct).

Method	EM (%)	F1 (%)	Steps
Manual (main paper)	57.4	71.2	10.2
Bayesian opt. (BO)	57.8	71.5	10.1
Bandit (UCB1)	57.6	71.3	10.4

B Parameters used in VERL

Table 11 lists the training hyperparameters for each policy objective.

C Compute and Cost

Table 12 reports the training overhead of EVO-RAG. Reward computation is lightweight at inference time; the extra cost is incurred during training due to rollout generation, preference modeling, and optional LLM-based refusal validation.

D Case Studies

Case study interpretation. Across Q1–Q2, the baseline repeatedly issues paraphrased queries, which inflates steps and often misses the key entity. Two-stage reduces duplication but can still oversearch late. Time-dynamic scheduling increases overlap/step pressure as $p(t)$ grows, leading to earlier consolidation and fewer redundant hops. For Q3 (unanswerable), the refusal signal prevents the agent from hallucinating a plausible location and terminates with REFUSE.

Case Q1 (answerable, entity linking). Question trait: 2-hop bridging question; the second hop depends on resolving an ambiguous entity mention (alias/name collision). **Baseline failure:** the baseline keeps issuing paraphrased sub-queries that preserve the same ambiguous surface form, leading to near-duplicate retrievals and repeated evidence; after a miss, it continues searching late instead of revising the entity. **EVO-RAG turning point:** the overlap penalty increases as $p(t)$ grows, forcing a lexical/semantic pivot in the query (entity disambiguation cue added); after the first miss, the agent executes a BACKTRACK and rewrites the query conditioned on the most informative snippet, which yields the missing bridge passage. **Outcome:** fewer redundant hops (steps ↓), earlier hit on the supporting document, and the final answer is correct (EM/F1 ↑).

Case Q2 (answerable, multi-evidence consolidation). Question trait: 3–4 hop compositional QA requiring synthesizing two complementary facts from different pages (e.g., entity attribute + event relation); intermediate evidence is partially relevant but not sufficient alone. **Baseline failure:** the baseline over-explores late: after already retrieving the key supporting passages, it continues to issue additional searches with high overlap, which adds distractor snippets and degrades the final generation (context pollution / delayed stopping). **EVO-RAG turning point:** as $p(t)$ increases, the step penalty and retrieval-action penalty dominate, making late SEARCH costly; the agent stops searching once redundancy rises and instead commits to ANSWER using the already retrieved evidence (controlled stopping). **Outcome:** average steps decrease while maintaining or improving correctness; the answer is supported by the consolidated evidence (EM/F1 ↑; steps ↓).

Case Q3 (unanswerable, safe refusal). Question trait: unanswerable under the available corpus / retrieved context (missing required entity or the question presupposes a false premise); retrieval returns plausible but non-supporting snippets. **Baseline failure:** the baseline attempts to answer anyway by extrapolating from loosely related passages, producing a fluent but unsupported response (hallucination). **EVO-RAG turning point:** the policy selects REFUSE after repeated retrieval misses / low-support evidence; the refusal validity reward (LLM judge) verifies insufficient evidence and reinforces abstention rather than speculative answering. **Outcome:** the agent correctly abstains (REFUSE is judged valid), avoiding hallucination; refusal correctness ↑ and unsafe answers ↓.

Table 12: Compute cost breakdown (3 seeds; $\approx$ marks approximate values). Policy-optimization hours are reported as PPO / DPO / GRPO.

Component	**Quantity**	**Value**
Rollout generation	GPU	A100-80G
	Episodes	1000×3 seeds
	GPU-hours	13.0
Preference model	Updates	$\approx$ 6k
	GPU-hours	$\approx$ 1.6
Policy optimization	GPU-hours	$\approx$ 3.8 / 1.2 / 2.4
Refusal judge	Calls	$\approx$ 60
	Latency	$\approx$ 1.2 s / call
	Tokens	$\approx$ 350 / call

E Refusal Judge Prompt

Input: question x, retrieved snippets $\{d_1, \ldots, d_k\}$, and the agent's proposed refusal.
Task: decide whether the question is answerable using only the provided evidence. Output one token: `answerable` or `unanswerable`.

```
You are a strict evaluator for evidence-based answerability.

[Question] {QUESTION}

[Retrieved Evidence] {SNIPPETS}

Task: Decide whether the question is answerable using ONLY the retrieved evidence above. Do NOT use outside knowledge. Do NOT guess. The evidence may be partially relevant or misleading.

Decision Rule: Return answerable iff the evidence contains enough information to answer the question correctly and specifically. Return unanswerable if key facts are missing, contradictory, or the evidence only supports a vague guess.

Output: Output exactly one token: answerable or unanswerable.
```

Retrieval–Reasoning Processes for Multi-hop Question Answering: A Four-Axis Design Framework and Empirical Trends

Yuelyu Ji[1], Zhuochun Li[1], Rui Meng[2], Daqing He[1]
[1]School of Computing and Information, University of Pittsburgh
[2]Google Cloud AI Research, Sunnyvale, CA, USA

Abstract

Multi-hop question answering (QA) requires a system to *retrieve* and *reason* over multiple pieces of evidence. Recent advances in retrieval-augmented generation (RAG) and agent-style systems have achieved strong performance on benchmarks such as HotpotQA, 2WikiMultiHopQA, and MuSiQue. However, the *retrieval–reasoning process*, which explicitly interleaves evidence acquisition and inference decisions, is often left implicit and treated as an implementation detail. We propose a design framework that treats this process as the unit of analysis and describes it along four axes: the overall execution plan, the index structure, the next-step execution plan, and the stop/continue criteria. Using this framework, we synthesize reported empirical results from representative multi-hop QA systems on standard datasets and analyze how different procedural design choices are discussed in relation to effectiveness, efficiency, and explanation faithfulness across the literature. We then distill a set of open problems for future retrieval–reasoning agents, including coupling retrieval with index structures, learning generalizable control policies, and designing robust stopping signals.

1 Introduction

Multi-hop question answering (QA) has become a core testbed for machine reasoning. Compared to single-hop QA, where a single passage often suffices, multi-hop benchmarks such as HotpotQA (Yang et al., 2018), 2WikiMultiHopQA (Ho et al., 2020), and MuSiQue (Trivedi et al., 2022) require systems to combine several pieces of evidence, compare attributes across entities, or follow chains of relations that span multiple documents (Shi et al., 2024). Many of these datasets annotate supporting sentences and sometimes explicit reasoning paths, making them natural grounds for analyzing how systems actually reason.

Large language models (LLMs) equipped with retrieval have become the dominant approach for such tasks. Retrieval-augmented generation (RAG) couples a retriever with an LLM and has achieved strong performance on knowledge-intensive QA (Lewis et al., 2020; Gao et al., 2023b), while more recent agent-style systems model question answering as a sequence of actions over tools and documents (He et al., 2024; Kim et al., 2024). However, most of this literature focuses on architectural or training innovations and treats *how retrieval and reasoning interact* as an implementation detail. Concretely, the sequence of retrieval calls, intermediate hypotheses, and stopping decisions is rarely made explicit or analyzed systematically. This omission matters because many multi-hop benchmarks are brittle to single-pass retrieval under distractors or long contexts, motivating explicit retrieval–reasoning loops that adapt queries, evidence selection, and stopping over time.

At the algorithmic level, what distinguishes multi-hop QA from single-hop QA is not only the presence of retrieval, but how retrieval and reasoning are coupled over time. These procedural decisions directly shape reported trade-offs in accuracy, efficiency, and robustness, and motivate treating the retrieval–reasoning process as an explicit object of analysis.

Unlike existing surveys that primarily organize methods by modules, stages, or training loops, our framework treats the execution procedure as the unit of analysis. This emphasizes how retrieval, reasoning, control, and stopping decisions are interleaved over time, rather than discussed as separable components. As a result, design choices that are often presented as method-specific heuristics—e.g., controller triggers and stop/continue signals—become alignable across model families under a shared axis-based schema.

Our goal is to make these procedural choices explicit and comparable across systems rather than

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 84–103

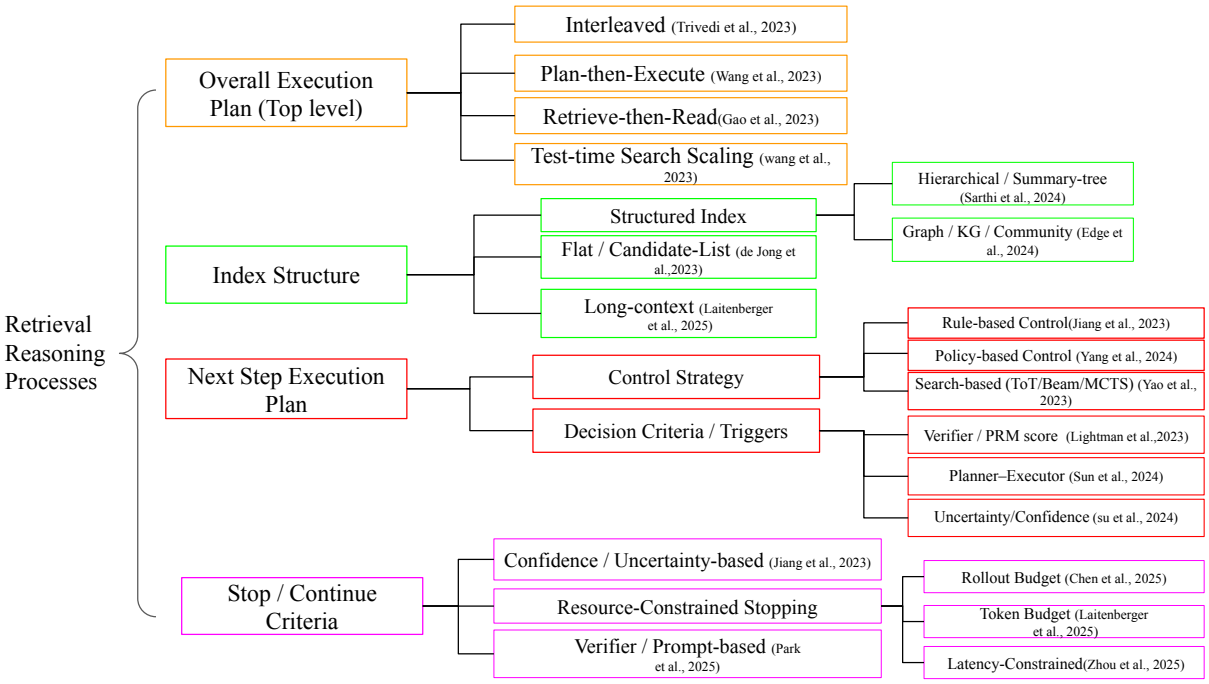

Figure 1: Overview of the four design axes we use to describe retrieval–reasoning processes in multi-hop QA: (A) overall execution plan, (B) index structure, (C) next-step execution plan, and (D) stop/continue criteria. The framework abstracts over concrete model architectures and datasets.

to claim causal superiority. We organize the survey around four questions: (RQ1) why make the procedure explicit, (RQ2) what are the key procedural design axes, (RQ3) what trade-offs are reported, and (RQ4) what open challenges remain.

2 Background

2.1 Multi-hop QA Datasets

Multi-hop question answering (QA) requires a system to combine information from multiple pieces of evidence to answer a single question. Datasets such as HotpotQA, 2WikiMultiHopQA, and MuSiQue are explicitly designed to test this ability (Yang et al., 2018; Ho et al., 2020; Trivedi et al., 2022). HotpotQA provides Wikipedia-based questions with sentence-level supporting facts and adversarial distractor paragraphs (Yang et al., 2018). 2WikiMultiHopQA mixes structured and unstructured evidence and includes annotated reasoning paths (Ho et al., 2020), while MuSiQue composes single-hop questions into 2–4 hop questions and controls for artifacts and disconnected reasoning (Trivedi et al., 2022). More recent datasets, such as MEQA and FanOutQA, further emphasize multi-document aggregation and the completeness and consistency of supporting evidence (Li et al., 2024a; Zhu et al., 2024).

2.2 Existing Surveys and Remaining Gaps

Several surveys and tutorials organize the rapidly growing literature on multi-hop QA and reasoning-capable LLMs. Mavi et al. (2024) review multi-hop QA datasets and model architectures, focusing on how graphs, question decomposition, and memory mechanisms support complex reasoning. Other surveys discuss reasoning LLMs more broadly, covering prompting strategies, training recipes, and cognitive perspectives (Li et al., 2025b; Sui et al., 2025), or analyze when parametric knowledge needs to be complemented by external tools and retrieval (Li et al., 2025a). These overviews cover many *ingredients* relevant to our focus (decomposition, retrieval modules, memory, verification), but they typically organize the space around *components*, stages, or model families (e.g., graph-based vs. decomposition-based; RAG vs. non-RAG) rather than treating the *execution procedure*—the step-by-step coupling between retrieval and reasoning—as the primary unit of analysis (Gao et al., 2023c).

Consequently, procedural questions such as *when retrieval is invoked relative to reasoning*, *how evidence is organized and retained under context budgets*, *how the next action is chosen*, and *how stop/continue decisions are made* often appear

only implicitly as method-specific design details or scattered heuristics. In particular, stop/continue is rarely separated as a first-class design choice, and the literature is not mapped into an execution-oriented coding schema enabling aligned comparisons across model families. In contrast, our framework takes the execution procedure itself as the unit of analysis and makes retrieval, reasoning, control, and stopping decisions explicitly comparable along shared axes.

3 Why an Explicit Retrieval–Reasoning Process?

Our first research question (**RQ1**) asks why it is useful to treat multi-hop QA as an explicit retrieval–reasoning *procedure* rather than as a one-time retrieve-and-read. The core reason is that, for knowledge-intensive multi-step questions, the *procedure*—when to retrieve, how to form the next query, what evidence to keep under budgets, and when to stop—is often the main lever that changes both accuracy and failure modes. For example, IRCoT improves multi-step QA by *interleaving* retrieval with chain-of-thought, i.e., by changing the retrieval–reasoning interaction rather than only scaling the reader (Trivedi et al., 2023). Moreover, agentic QA methods such as ReAct make tool calls and evidence usage explicit, turning the trajectory itself into a process-level account of how an answer is obtained (Yao et al., 2022). Finally, recent work treats stopping as a first-class decision (instead of a fixed hop budget), highlighting that *continue vs. stop* is part of the procedure and directly controls cost and robustness (Park et al., 2025). Our coding of 252 recent multi-hop QA/RAG papers (Appendix B) further suggests that many recent advances can be reinterpreted as innovations in retrieval–reasoning coupling: 104 of the 252 papers (41%) are rated high-fit on this dimension, motivating a survey organized around procedural design choices and their trade-offs.

4 Design Axes of Retrieval–Reasoning Procedures

To answer **RQ2**, we describe multi-hop QA systems in terms of the four design axes shown in Figure 1. Each axis abstracts over many concrete modules and implementations; our goal is to provide a shared vocabulary for characterizing execution procedures.

4.1 Overall Execution Plan

The overall execution plan specifies *when* retrieval is invoked relative to reasoning. We highlight four recurring patterns that correspond to the sub-panels in Figure 2: retrieve-then-read, interleaved retrieval, plan–then–execute, and test-time search scaling.

Retrieve-then-Read. Classical retrieval-augmented QA pipelines retrieve a fixed set of passages given the original question, then feed them once into a reader or generator. Examples include DrQA-style open-domain QA (Chen et al., 2017), DPR + BERT readers (Karpukhin et al., 2020), FiD-style fusion-in-decoder models (Izacard and Grave, 2021), and the original RAG model (Lewis et al., 2020). Multi-hop extensions such as MDR (Qi et al., 2019) follow the same pattern: the retriever is called a small fixed number of times, and the reader operates in a single, long-context pass.

Interleaved Retrieval and Reasoning. Interleaved plans alternate between reasoning steps and retrieval calls. Self-Ask (Press et al., 2023) and ReAct (Yao et al., 2022) are early examples that prompt the LLM to produce intermediate thoughts and explicit SEARCH/LOOKUP actions. IRCoT (Trivedi et al., 2023) couples chain-of-thought with retrieval on HotpotQA and MuSiQue. FLARE (Jiang et al., 2023) and DRAGIN (Su et al., 2024) further refine when and how new queries are issued during generation. Recent analyses of retrieval failure modes in such loops propose targeted query reformulation and filtering for multi-hop RAG.

Plan–then–Execute. Plan–then–execute methods first produce an explicit reasoning or decomposition plan, and only then execute retrieval and answering steps according to that plan. Decomposed Prompting (Khot et al., 2022), Plan-and-Solve (Wang et al., 2023), and Least-to-Most Prompting (Zhou et al., 2022) decompose questions into sub-questions that can be answered sequentially. QDMR (Wolfson et al., 2020) and recent QDMR-based multi-hop QA systems use structured decomposition graphs as plans. In retrieval settings, PAR-RAG (Zhang et al., 2025) and BEAM Retrieval (Zhang et al., 2024) first plan candidate evidence chains and then execute retrieval over them, sometimes with verifier feedback.

Test-Time Search Scaling. A more aggressive family of overall execution plans treats the whole retrieval–reasoning process as a search problem and scales performance by exploring many can-

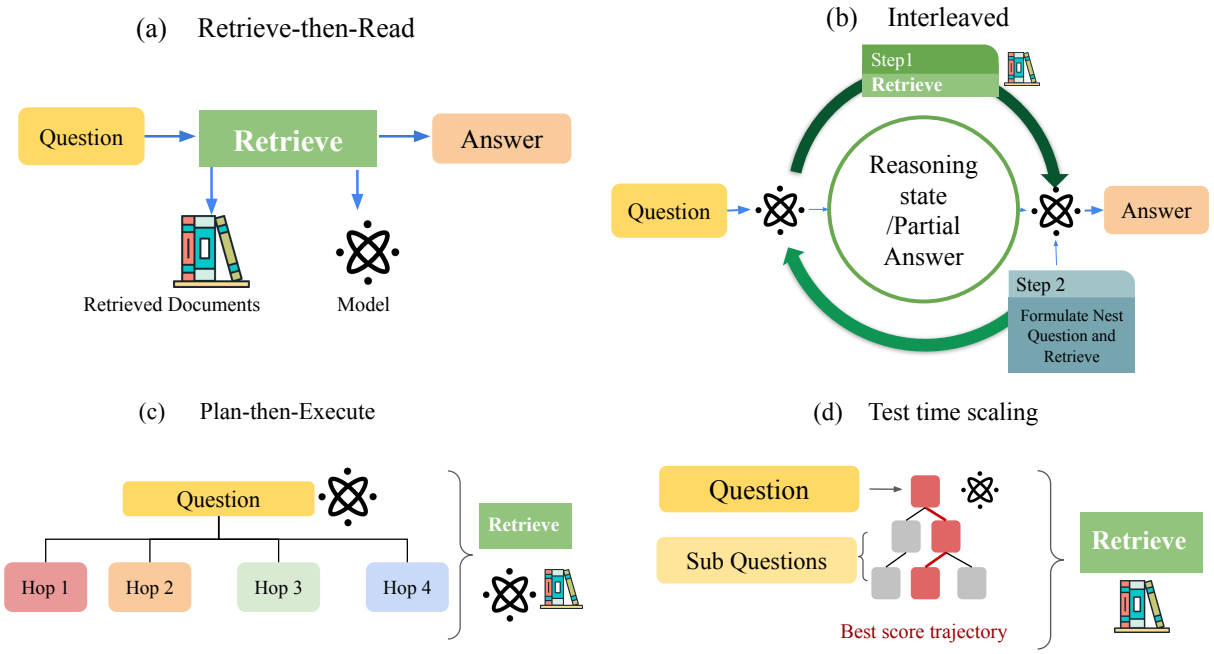

Figure 2: Overall execution plans for retrieval–reasoning in multi-hop QA (Axis A of our framework). (a) *Retrieve-then-Read*: a single retrieval pass feeds the reader model. (b) *Interleaved*: the model alternates reasoning with additional retrieval calls, updating a partial answer/state. (c) *Plan–then–Execute*: the model first decomposes the question into sub-hops, then retrieves and answers for each hop following the plan. (d) *Test-time search scaling*: the model explores multiple candidate reasoning trajectories over the question/sub-questions and selects the best-scoring path for retrieval and answering.

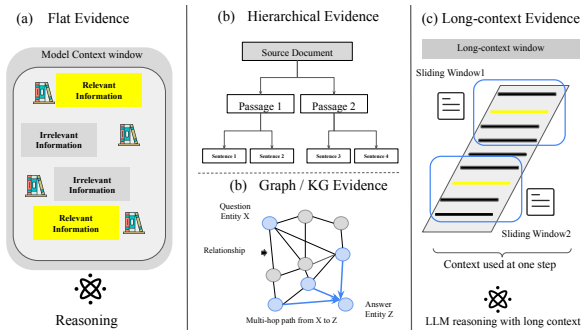

Figure 3: Index structures for retrieval–reasoning (Axis B): flat passage lists, hierarchical / tree-structured indices, graph-based indices, and long-context storage.

didate trajectories at test time. Tree-of-Thoughts (Yao et al., 2023) and Graph-of-Thoughts (Besta et al., 2024) use explicit search over thought trees and graphs. MindStar (Kang et al., 2024), MCTS-DPO (Xie et al., 2024), and Monte-Carlo-tree self-refinement methods apply MCTS-style search guided by value functions or process reward models such as ReARTeR (Sun et al., 2025). In knowledge-intensive settings, RAP (Hao et al., 2023) plans over world models, and several GraphRAG (Han et al., 2024) variants explore multiple graph traversal paths before committing to an answer.

4.2 Index Structure

Index structure specifies *how* external knowledge is organized and accessed. Figure 3 distinguishes four common forms: flat candidate lists, hierarchical or summary trees, graph- or KG-based structures, and long-context evidence units.

Flat / Candidate-List Indices. The default in most multi-hop QA systems is a flat collection of passages or documents indexed by BM25 or dense embeddings. DrQA (Chen et al., 2017), DPR (Karpukhin et al., 2020), FiD (Izacard and Grave, 2021), and RAG adopt this structure in open-domain QA. Multi-hop retrievers such as MDR (Xiong et al., 2020), HopRetriever (Li et al., 2021), and step-wise dense retrievers for HotpotQA and 2WikiMultiHopQA operate over flat indices, even when they train separate retrievers per hop.

Hierarchical / Summary-Tree Indices. Hierarchical indices organize documents into multi-level clusters or summary trees, allowing systems to retrieve coarse summaries first and zoom in on relevant subtrees. RAPTOR (Sarthi et al., 2024) builds recursive summary trees and shows that retrieving via tree nodes can substantially reduce tokens while preserving answer accuracy. Other long-document QA systems build section- or chapter-based hierar-

System	A	B	C	D	Benchmarks (typical)
DrQA / DPR+FiD	R	F	H	B	NQ, TriviaQA (Chen et al., 2017; Karpukhin et al., 2020; Izacard and Grave, 2021)
IRCoT	I	F	H	B	HotpotQA, MuSiQue, IIRC (Trivedi et al., 2023, 2022)
DEC	I	F	P	B/V	HotpotQA (Ji et al., 2025)
Beam Retrieval	P	F	P	B	HotpotQA, 2Wiki, MuSiQue (Zhang et al., 2024)
PAR-RAG	P	F/G	V	B	HotpotQA, 2Wiki (Zhang et al., 2025)
RAPTOR	R/I	H	H	B	Long-doc QA, Hotpot variants (Sarthi et al., 2024)
LongRAG	R/I	L	H	B	HotpotQA, ODQA (Jiang et al., 2024; Zhao et al., 2024)
GraphRAG	I	G	H/P	B	Sensemaking, MHQA (Edge et al., 2024)
KG-o1	P/I	G	P/V	B	2Wiki, KGQA (Wang et al., 2025a)
SIM-RAG	I	F	P/V	C/L	Multi-round RAG (Xu et al., 2025)
Stop-RAG	I/P	F	P	L	Iterative RAG / MHQA (Park et al., 2025)

Table 1: Representative systems mapped into our four-axis framework. A: overall execution plan (R=retrieve-then-read, I=interleaved, P=plan–then–execute, S=test-time search scaling). B: index structure (F=flat, H=hierarchical, G=graph/KG, L=long-context). C: control (H=hand-written rules, P=learned policy, V=verifier-gated, S=search-based). D: stopping (B=budget, C=confidence-based, V=verifier-gated, L=learned/value-based).

chies and retrieve using both coarse and fine nodes (Xia et al., 2025). LongRAG (Zhao et al., 2024) uses long retrieval units (e.g., 4K tokens) as coarse segments and lets the LLM decide which parts to attend to, effectively creating a two-level index structure. Hierarchical community-based indices in GraphRAG also fall into this category when communities are organized in a tree (Edge et al., 2024).

Graph / KG / Community Structures. Graph-based structures connect entities, documents, or passages via explicit edges, enabling path-based reasoning and community-level summarization. Early multi-hop QA work over KGs includes GraftNet (Sun et al., 2018) and PullNet (Sun et al., 2019). More recent GraphRAG systems construct entity and document graphs from text and perform retrieval along graph edges or communities (Edge et al., 2024). KG-augmented RAG approaches such as KG-FiD (Yu et al., 2022), UniKGQA (Jiang et al., 2022), and KG-o1 (Wang et al., 2025a) extend this idea by combining KG traversal with text retrieval for multi-hop QA.

Long-Context Evidence. Instead of relying on a structured index, some methods rely on long-context LLMs and store very long segments or entire documents as retrieval units. LongRAG explicitly proposes long units to reduce the number of hops needed to cover the required evidence (Zhao et al., 2024; Lee et al., 2025; Das et al., 2025). LongT5 and other long-context models similarly retrieve and process long sequences in a retrieve-and-read style (Guo et al., 2022; Li et al., 2024b).

4.3 Next-Step Execution Plan

The *next-step execution plan* specifies how a system chooses its next action—retrieve again, expand candidates, verify, backtrack, or answer—given the current state. We separate this component into (1) a control strategy, which proposes candidate actions, and (2) decision criteria / triggers, which determine whether to continue expanding or to revise/hand off control (termination is covered in Axis D).

Rule-based control. Many systems hard-code a reasoning control pattern: a fixed alternation of REASON and SEARCH steps, simple heuristics for query reformulation, and manually tuned filters over retrieved passages. Self-Ask, ReAct, IRCoT, and DEC all fall in this family, using prompts and hand-designed rules to decide when to ask a follow-up question, when to call the retriever, and when to output an answer (Press et al., 2023; Yao et al., 2022; Trivedi et al., 2023; Ji et al., 2025). Rule-based controllers are easy to implement and robust in small-data regimes, but they do not learn from failures and often need re-tuning when the domain or retriever changes.

Policy-based control. Here the next action is chosen by a learned policy that observes the question, retrieved evidence, and partial reasoning trace. Examples include beam-style multi-hop retrievers with learned expansion policies (Zhang et al., 2024), RAG agents trained to select between tools or retrieval templates via supervision or reinforcement learning (Yang et al., 2024; Park et al., 2025), and multi-round RAG systems whose controllers are fine-tuned on inner-monologue trajectories (Xu et al., 2025).

Search-based control. A third pattern treats next-step selection as search over partial trajectories. Tree-of-Thoughts explores a tree of reasoning states and uses value- or vote-based scores to decide which branches to expand (Yao et al., 2023). MindStar and related MCTS-style methods perform Monte-Carlo search over tool-use and reasoning sequences, guided by process reward models or learned value functions (Kang et al., 2024; Xie et al., 2024). Beam-style search over plans or KG paths similarly expands multiple candidate chains in parallel before committing to an answer (Zhang

et al., 2024; Jiang et al., 2022). These approaches can substantially improve long-horizon success, but incur higher inference cost and rely on strong scoring signals.

Verifier / PRM-score triggers. Verifier-gated loops insert an explicit judge—an NLI-style checker, a process reward model, or a self-evaluation module—and use its score as a trigger. Process reward models that score intermediate reasoning steps (Lightman et al., 2023) and hallucination detectors such as SelfCheckGPT (Manakul et al., 2023) exemplify this pattern: low-scoring answers or chains trigger extra retrieval or revision instead of termination. Tool-centric systems such as TaskMatrix-style agents also rely on verifier-like scoring over tool outputs to decide whether a subgoal is solved or whether another tool call is needed (Liang et al., 2024). In RAG settings, verifier / PRM triggers are often combined with sufficiency critics, as in SIM-RAG and related multi-round controllers (Xu et al., 2025; Zhang et al., 2025).

Planner–executor triggers. Some agents separate planning and execution and use the plan's status as an explicit trigger. Planner–executor architectures first generate a structured plan (sub-questions, tool calls, or graph operations) and then execute it step-wise, revising or extending the plan when execution fails or when critical preconditions are not met (Khot et al., 2022; Wang et al., 2025b; Sun et al., 2025). In this view, the decision criterion is whether the current plan still appears feasible and sufficiently specified; negative feedback triggers re-planning or refinement, while successful plan completion triggers termination. This pattern is especially common in web and tool agents that must coordinate several API calls (He et al., 2024).

Uncertainty / confidence triggers. Finally, uncertainty-aware triggers estimate how likely the current answer (or intermediate state) is to be correct or sufficiently supported, and continue retrieving or reasoning only while confidence is below a threshold. Signals include calibrated answer probabilities, disagreement across sampled chains, and explicit "uncertainty of thoughts" scores (Hu et al., 2024; Sui et al., 2025). Dynamic context-cutoff policies similarly stop reading long inputs once new tokens are unlikely to change the prediction (Xie et al., 2025). In multi-round RAG, such confidence signals are often combined with learned sufficiency critics or value-based controllers (Xu et al., 2025; Park et al., 2025), yielding adaptive-depth retrieval loops that trade a small amount of computation for more stable behavior under distribution shift.

4.4 Stop / Continue Criteria

Stop / continue criteria specify *when* the retrieval–reasoning procedure terminates. In multi-hop QA, stopping too early misses necessary evidence, while stopping too late inflates prompt length and latency and increases exposure to distractors.

Resource-constrained stopping. Many systems ignore the detailed state and instead impose hard budgets on search. A first subtype is a *rollout budget*: interleaved agents such as Self-Ask, ReAct, IRCoT, and DRAGIN restrict the number of reasoning or tool-use steps (e.g., at most K SEARCH calls or H decomposition steps) and must answer once the budget is exhausted (Press et al., 2023; Yao et al., 2022; Trivedi et al., 2023; Su et al., 2024). A second subtype is a *token budget*, where multi-hop RAG pipelines (e.g., LongRAG, DEC, and budget-aware chain-of-thought methods) fix the maximum retrieved or prompt tokens per question and truncate extra evidence or thoughts when this limit is reached (Jiang et al., 2024; Ji et al., 2025; Han et al., 2025). A third subtype is *latency-constrained* stopping, where web or tool agents terminate once a wall-clock or API-call budget is consumed (Shen et al., 2024).

Confidence- / uncertainty-based stopping. A second family asks how *confident* the model (or a small auxiliary head) is in the current answer or intermediate state, and stops once uncertainty falls below a threshold. Representative signals include logit margins, entropy, and disagreement across self-consistent samples, as surveyed in work on "stop overthinking" and early-exit reasoning (Sui et al., 2025; Li et al., 2025b). Uncertainty-of-thought approaches explicitly estimate the uncertainty of candidate thoughts and decide whether to produce more intermediate steps or to answer directly (Hu et al., 2024), while dynamic context-cutoff methods learn when an LLM has read enough of a long input and can safely stop consuming further tokens (Xie et al., 2025).

Verifier- / prompt-based stopping. The third family inserts an explicit *checking* stage and delegates the stop / continue decision to a verifier. Rationale-refinement and fact-checking pipelines such as RARR, SelfCheckGPT, and Chain-of-Verification first generate a draft answer and then ask a verifier (often another LLM or an NLI-style model) whether each claim is sufficiently supported

by the retrieved evidence; a positive verdict triggers termination, while unsupported claims trigger additional retrieval, clarification questions, or answer revision (Gao et al., 2023a; Manakul et al., 2023; Dhuliawala et al., 2024). In multi-round RAG, sufficiency critics and value-based controllers such as SIM-RAG, Stop-RAG, DEC, and ReARTeR can be viewed as *learned verifiers*: they inspect the question, retrieved evidence, and inner-monologue trace and decide whether another retrieval round is expected to help, using QA accuracy or process rewards as supervision (Xu et al., 2025; Park et al., 2025; Ji et al., 2025; Sun et al., 2025).

Table 1 maps representative systems onto these four axes.

5 RQ3: Reported Empirical Tendencies in Retrieval–Reasoning Design

This section performs a pattern-mining synthesis of empirical findings as reported in the original papers. Because results are obtained under heterogeneous retrievers, LLMs, prompts, and budgets, we do not claim causal superiority of any axis choice. Instead, we summarize directional tendencies that (1) recur across multiple studies, or (2) are supported by within-paper ablations under matched budgets, and we treat cross-paper comparisons as suggestive rather than definitive.

Overall execution plan. Compared to retrieve-then-read (single-pass retrieval) baselines, several studies report an association between explicitly multi-step execution plans and higher answer F1 and joint answer–evidence scores, particularly in full-wiki and distractor-heavy settings (Trivedi et al., 2023). Interleaved plans that alternate chain-of-thought and retrieval, such as IRCoT-style interleaving, are reported to increase recall and joint F1 on HotpotQA, 2WikiMultiHopQA, and MuSiQue (Trivedi et al., 2023). Within the reported settings (often under matched budgets within the same study), plan–then–execute methods are reported to reach comparable gains while batching sub-queries (Zhang et al., 2024, 2025). Test-time search-scaling methods (e.g., Tree-of-Thoughts, MindStar, MCTS-style search) further boost long-horizon accuracy by exploring many candidate trajectories, but incur the highest latency and compute costs (Yao et al., 2023; Kang et al., 2024; Xie et al., 2024).

Index structure. Most multi-hop QA systems still operate over flat BM25 or dense passage collections, and attribute gains mainly to changes in overall execution plan or control policy rather than radically different indices (Chen et al., 2017; Karpukhin et al., 2020; Trivedi et al., 2023; Zhang et al., 2024; Ji et al., 2025). Index structures are primarily discussed in relation to efficiency and path faithfulness. Hierarchical or summary-tree structures such as RAPTOR reduce context length on long-document QA by retrieving summaries and then drilling down to raw passages, typically preserving or slightly improving EM (Sarthi et al., 2024). Graph- and KG-based index structures (e.g., GraphRAG, KG-o1) organize entities and documents into graphs or communities and retrieve along paths, improving joint answer+path metrics and producing more coherent evidence chains, at the cost of graph construction and maintenance (Edge et al., 2024; Wang et al., 2025a).

From control and triggers (Axes C/D) to outcomes. For the next-step execution plan, our coded systems are consistent with three recurring patterns. First, moving from purely rule-based control with static budgets to learned or planner-style control tends to improve answer accuracy at similar average cost. Beam Retrieval and PAR-RAG replace hand-written rhythms with plan-driven controllers and beam-style expansion: Beam Retrieval reports 69.2 answer F1 / 91.4 support F1 on MuSiQue, and PAR-RAG reports 2Wiki and HotpotQA EM gains of roughly 15–30 points over their strongest non-planning baselines under matched or smaller budgets (Zhang et al., 2024, 2025). These results suggest that global, plan-aware controllers are especially beneficial when the evidence graph is rich and hop depth varies widely.

Second, combining policy-based control with verifier or PRM-style triggers is repeatedly reported to coincide with improved faithfulness and joint answer+evidence scores. Verifier-gated refinement in RARR and Chain-of-Verification reduces unsupported claims compared to single-pass RAG and vanilla CoT (Gao et al., 2023a; Dhuliawala et al., 2024). Similar trends appear in search-based controllers such as MindStar and MCTS-DPO, where PRM-guided tree search prunes low-scoring trajectories and improves math or strategy benchmarks at the cost of a small constant factor in inference time (Kang et al., 2024; Xie et al., 2024). In our framework, "policy/search + verifier/PRM" appears effective on noisy-retrieval or long-horizon tasks where hallucinated chains are common.

Third, uncertainty- or value-based stopping

(Axis D) helps controllers avoid both over- and under-search and stabilizes latency under shift (Xu et al., 2025; Park et al., 2025). Overall, the most robust designs in our corpus pair an adaptive controller (policy- or search-aware, Axis C) with verifier/PRM- or sufficiency-based triggers (Axis D), especially under noisy retrieval and long horizons. Static hop/token budgets can be competitive when tuned in-domain, but they transfer poorly across datasets with different hop and distractor profiles.

6 RQ4: Open Problems and Future Directions

Challenge 1: Aligning overall execution plans with index structures. Most systems fix an *index structure* (flat passages, hierarchical summaries, graphs, or long-context units) and then adopt an *overall execution plan* (retrieve-then-read, interleaved, plan–then–execute, or test-time search scaling) in an ad hoc manner. For example, IRCoT, Beam Retrieval, and DEC operate over flat indices and primarily innovate in scheduling and control (Trivedi et al., 2023; Zhang et al., 2024; Ji et al., 2025), whereas RAPTOR, LongRAG, and GraphRAG redesign the structure but often retain standard multi-hop schedules (Sarthi et al., 2024; Jiang et al., 2024; Edge et al., 2024). A principled mapping between structure and plan is still missing. Promising directions include factorial sweeps over execution plans and index structures under matched budgets, and controllers that choose among multiple (plan, structure) configurations based on query difficulty and resource constraints.

Challenge 2: Scalable and adaptive structured indices. Structured indices—such as summary trees (RAPTOR), long units (LongRAG), and graphs (GraphRAG, KG-o1)—can improve efficiency and faithfulness, but they are costly to build and maintain (Sarthi et al., 2024; Jiang et al., 2024; Edge et al., 2024; Wang et al., 2025a). Most work assumes static corpora and relies on hand-tuned hyperparameters for granularity (e.g., cluster size, unit length, and graph pruning). Future research is needed on self-supervised or task-aware structure induction that optimizes these choices for downstream multi-hop objectives, as well as incremental maintenance algorithms that keep trees and graphs up to date as documents evolve.

Challenge 3: Generalizable control policies and decision criteria. Current learned or search-based control policies and verifier/PRM-gated decision rules are often trained on specific datasets and retrievers, and may not generalize across hop distributions, index structures, or domains (Zhang et al., 2024; Ji et al., 2025; Yao et al., 2023). This brittleness limits the practical promise of adaptive retrieval–reasoning beyond benchmark-specific tuning. A promising direction is to cast retrieval–reasoning as a process-level decision problem and train controllers with objectives that jointly reward evidence quality, trajectory coherence, and cost, e.g., via preference learning over trajectories or hybrid RL.

Challenge 4: Robust stop/continue criteria under budgets and shift. Most systems still rely on static hop, token, or latency budgets, while adaptive stopping based on confidence, sufficiency, or value estimates is evaluated on limited benchmarks and remains poorly calibrated under distribution shift (Xu et al., 2025; Park et al., 2025). This matters because over- and under-search simultaneously degrade reliability and efficiency in deployment. An important open problem is to develop stop/continue criteria that remain calibrated across retrievers, corpora, and LLM backbones, and to evaluate them under controlled variations of hop depth and retrieval noise.

7 Conclusion

We have surveyed retrieval–reasoning in multi-hop question answering through the lens of four research questions. We argued that multi-hop QA requires an explicit retrieval–reasoning process (RQ1), introduced a four-axis design space for describing this process (RQ2), and analyzed how axis-level design choices are reported to affect effectiveness, efficiency, and faithfulness on standard benchmarks (RQ3). Finally, we highlighted several open problems in designing and evaluating retrieval–reasoning systems (RQ4). We hope that our framework helps researchers organize existing methods and design new retrieval–reasoning agents in a more principled way.

Limitations

First, while we strive to cover a broad range of multi-hop QA systems, the field is evolving rapidly and our selection is necessarily incomplete. Second, we focus primarily on English, text-based benchmarks and do not systematically cover multilingual or multi-modal settings. Third, our empiri-

cal synthesis relies on numbers reported in original papers, which may be influenced by differences in hyperparameters, compute budgets, or evaluation scripts. Fourth, our axis assignments are the product of manual coding; although a subset of papers was double-coded, residual subjectivity remains, particularly for papers that under-specify their control and stopping logic. Despite these limitations, we believe the four-axis framework provides a useful starting point for analyzing retrieval–reasoning systems.

A PRISMA-style Literature Collection

To identify existing surveys and overviews related to multi-hop question answering (QA), we followed a PRISMA-style (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) procedure adapted to the NLP setting (Page et al., 2021).

Scope and time window. Our goal was to collect survey- or review-type papers that discuss multi-hop QA, multi-step or compositional QA, or widely used multi-hop benchmarks (e.g., HotpotQA, 2WikiMultiHopQA, MuSiQue). We restricted our search to publications from 2022 on-

wards, so as to focus on work in the LLM era and recent retrieval-augmented systems.

Data sources. We queried multiple scholarly search engines and digital libraries, including Google Scholar (using `allintitle` and keyword queries), the ACL Anthology, arXiv, and conference proceedings accessible through ACM and IEEE portals. When a candidate paper appeared in multiple sources, we treated it as a single record.

Search queries. For each source, we issued the following keyword combinations (illustrated here in a Google Scholar–style syntax), always with the time filter set to *since 2022*:

- `allintitle: (survey OR review OR taxonomy OR "systematic review" OR tutorial) ("multi-hop question answering" OR multihop OR "multi hop")`
- `("multi-hop question answering" OR multihop OR "multi hop" OR "multi-step reasoning" OR "complex question answering" OR "compositional question answering") (survey OR review OR taxonomy OR "systematic review" OR tutorial) (NLP OR "natural language processing")`
- `("HotpotQA" OR "2WikiMultiHopQA" OR "MuSiQue" OR "IIRC" OR "ComplexWebQuestions" OR "QAngaroo" OR "MedHopQA") (survey OR review OR taxonomy OR tutorial OR overview)`

These queries were chosen to (1) capture surveys explicitly labelled as such in the title, (2) retrieve broader surveys and tutorials that cover multi-hop or complex QA within NLP, and (3) find overview papers centered around standard multi-hop benchmarks.

Screening and eligibility. We first merged results from all queries and removed exact duplicates based on title and venue. We then screened titles and abstracts to exclude papers that were not surveys, reviews, taxonomies, tutorials, or overviews (e.g., individual method papers, purely theoretical work, or non-NLP applications). In a second pass, we read introductions and methodology sections of the remaining papers to check that multi-hop or complex QA was a primary focus rather than a minor side topic. We retained only English-language papers that discussed multi-hop QA, multi-step/compositional QA, or the above benchmarks in sufficient detail to be useful for positioning our work.

Data extraction and use in this survey. For each included paper we recorded meta-data such as publication year, venue, target tasks (multi-hop QA, reasoning LLMs, RAG, benchmarks), and the main organisational axes used by the authors (e.g., model architecture, prompting strategy, training regime). These annotations were used in Section 2 to (1) situate our four-component design framework relative to existing taxonomies and (2) ensure that our discussion of multi-hop QA and reasoning surveys is comprehensive with respect to the 2022–2025 literature. Beyond this PRISMA-style survey collection, individual method papers (e.g., specific retrieval–reasoning systems or search algorithms) were added through targeted searches, forward and backward citation tracing, and domain expertise.

B Paper Coding and Topical Distribution

For the analysis in Section 3 we coded each retrieved multi-hop QA / RAG paper along five topical dimensions:

- **T1: Definitions and boundaries of "multi-hop".** Papers that explicitly discuss what counts as multi-hop reasoning, how many supporting facts or hops are required, or how to distinguish genuine multi-hop questions from artifacts.
- **T2: Decomposition strategies.** Papers that introduce explicit intermediate representations such as chain-of-thought, question decomposition, sub-goal planning, programs/graphs/templates, or MCTS-style search.
- **T3: Evidence sufficiency and faithfulness.** Papers that focus on guaranteeing sufficient support for answers and on aligning reasoning chains with retrieved evidence, often via supporting-fact metrics, verification modules, or LLM-as-judge diagnostics.
- **T4: Retrieval–reasoning coupling.** Papers whose main contribution lies in how retrieval and reasoning are interleaved or controlled, including interleaved CoT–retrieval

loops (Trivedi et al., 2023), beam-based multi-hop retrievers (Zhang et al., 2024), hierarchical or graph-aware retrieval controllers (Sarthi et al., 2024; Edge et al., 2024), and sufficiency-aware multi-round RAG (Xu et al., 2025; Ji et al., 2025).

- **T5: Evaluation and diagnostics.** Papers that propose new diagnostics, process-level metrics, or robustness tests for multi-hop reasoning.

Among all coded papers, topic T4 (retrieval–reasoning coupling) constitutes the largest high-fit group (104 of 252 papers, 41%), followed by T2 (decomposition strategies) and T5 (evaluation and diagnostics); see Table 2. This distribution motivates our decision to take the retrieval–reasoning procedure as the primary object of analysis in the main text.

B.1 Coding Methodology

We constructed a paper corpus through keyword-based search (Google Scholar, ACL Anthology, arXiv, AAAI, ICLR, NeurIPS, ICML, SIGIR, KDD, CVPR, and ICCV) followed by forward/backward citation tracing. After deduplication, we screened titles and abstracts to retain work on multi-hop QA, retrieval-augmented QA, and agentic retrieval–reasoning. For each included paper, we extracted metadata (year, task/benchmarks, supervision, and reported metrics) and coded the method using our four-component schema: overall execution plan, index structure, control policy, and stop/continue criteria. We also assigned each paper to one or more topical dimensions (T1–T5). To improve consistency, a subset of papers was double-coded and disagreements were resolved via discussion; the final codes were then applied to the full set.

From 252 papers to a 104-paper subset. The full corpus contains 252 multi-hop QA/RAG papers used for the broad topical analysis in Section 3. For axis-level distributions and method maps, we focus on a 104-paper subset that provides sufficient methodological detail to instantiate our four components (overall execution plan, index structure, control policy, and stop/continue criteria). This subset is therefore a detail-available, framework-compatible slice of the larger corpus rather than a separate collection.

Topic	High	Med	Low	Total
T1: Definitions / boundaries	6	37	209	252
T2: Decomposition strategies	32	33	187	252
T3: Sufficiency / faithfulness	17	51	184	252
T4: Retrieval–reasoning coupling	104	14	134	252
T5: Evaluation / diagnostics	29	38	185	252

Table 2: Number of papers coded as High / Medium / Low fit for each topical dimension. Retrieval–reasoning coupling (T4) is the largest group in terms of high-fit papers, with 104 of 252 (about 41%) methods focusing primarily on how retrieval and reasoning are coupled.

C Distributions of Design Axes

We summarize corpus-level statistics for the 104-paper subset. Tables 5–8 report single-label distributions (each paper is assigned to exactly one combination), while Table 9 reports the corresponding multi-label marginals.

C.1 Overall Execution Plan

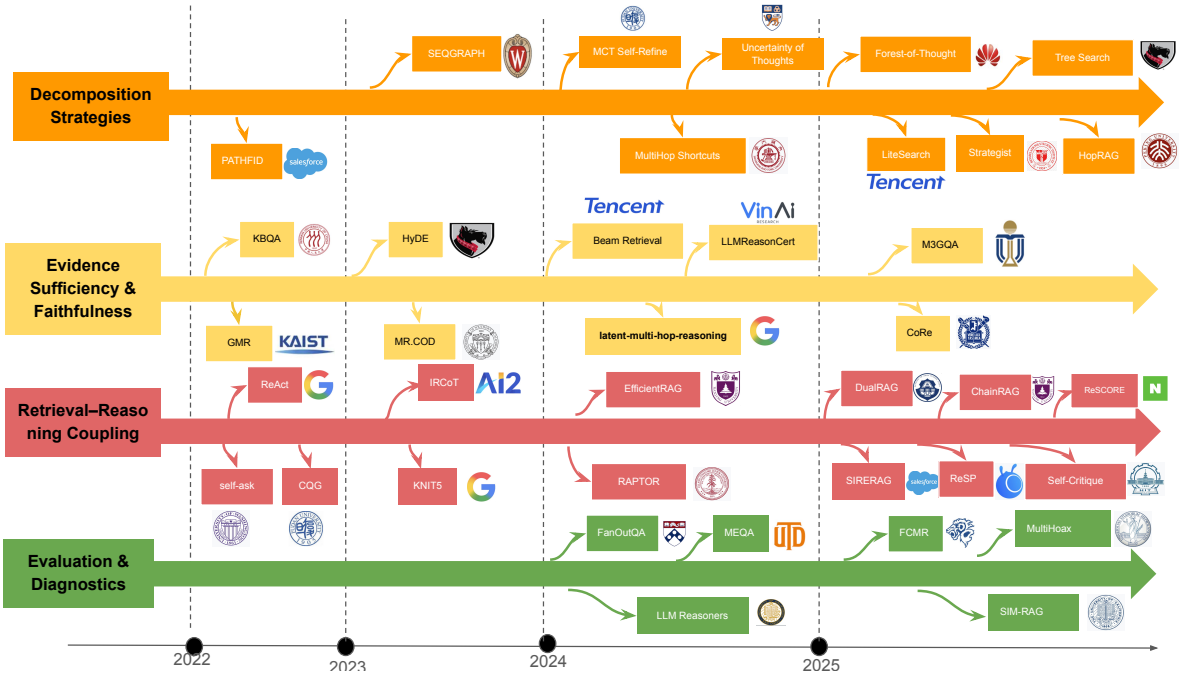

Figure 4: A taxonomy of major research topics in multi-hop question answering and retrieval–reasoning systems from 2022 to 2025. Methods are grouped by decomposition strategies, evidence sufficiency and faithfulness, retrieval–reasoning coupling, and evaluation and diagnostics, illustrating how different lines of work populate these dimensions over time.

Dataset	Type	#papers	Typical role in Topic 4 papers
HotpotQA	Wiki 2-hop RC (supporting facts)	29	Core multi-hop benchmark for retrieval–reasoning loops and supporting-fact faithfulness.
2WikiMultiHopQA	Hybrid KG+Wiki multi-hop QA	15	Tests cross-document and KG–text reasoning; usually paired with HotpotQA and MuSiQue.
WebQuestionsSP	KB QA over Freebase (1–2 hops)	14	Standard KG-QA baseline; many Topic 4 systems evaluate graph or KG controllers on it.
MuSiQue	Compositional multi-hop QA (Wiki)	11	Harder multi-hop benchmark built by composing single-hop questions; stresses connected reasoning.
ComplexWebQuestions (CWQ)	Web+KB complex QA (search+SPARQL)	11	Open-web setting with complex questions; used to test decomposition and web-search control.
MRAMG	Multimodal retrieval (image+text)	6	Extends retrieval–reasoning from text-only QA to multimodal RAG and agent-style systems.
StrategyQA	Boolean QA with implicit multi-hop	5	Benchmarks control policies for implicit, commonsense multi-hop reasoning and decomposition.
MetaQA	Movie-domain multi-hop KGQA (1–3 hops)	4	Tests KG traversal policies and beam / search-based controllers over large KGs.
CronQuestions	Temporal KGQA (time-aware)	4	Evaluates controllers that must handle temporal constraints on KG reasoning paths.
HybridQA	Table+text hybrid multi-hop QA	4	Benchmarks retrieval–reasoning over structured tables plus linked Wikipedia passages.

Table 3: Most commonly used datasets in our Topic 4 (retrieval–reasoning coupling) sample. "#papers" counts how many of the 104 coded papers report results on each dataset. Counts are multi-label: a system may be evaluated on several benchmarks, so the column does not sum to 104.

Dataset	Type	#papers
TriviaQA	Open-domain QA (Wiki + web)	3
Qasper	Long-document QA on NLP papers	3
NarrativeQA	Generative narrative QA (stories)	2
GSM8K	Grade-school math reasoning	2
Natural Questions	Open-domain QA from search logs	2
FB15k-237	Knowledge-graph QA / link prediction	2
ALFWorld	Text-based interactive environment	2
EntailmentBank	Multi-step textual entailment proofs	2
MQuAKE-CF-3k / MQuAKE-T	Counterfactual / transfer multi-hop QA	2
FEVER	Wikipedia fact verification	2
CommonsenseQA	Commonsense multiple-choice QA	2
OpenBookQA	Open-book science QA	2

Table 4: Datasets that appear 2–3 times in the Topic 4 sample.

Scheduling pattern (Axis A)	#papers	Share
Retrieve-then-Read only	49	47.1%
Interleaved only	24	23.1%
Interleaved + Plan-then-Execute	8	7.7%
Retrieve-then-Read + Plan-then-Execute	7	6.7%
Interleaved + Test-time Search Scaling	7	6.7%
Test-time Search Scaling only	5	4.8%
Plan-then-Execute + Test-time Search Scaling	1	1.0%
Plan-then-Execute only	1	1.0%
Other / unspecified	2	1.9%
Total	104	100%

Table 5: Distribution of scheduling patterns (Axis A) across all 104 coded methods in our corpus (topic T4: retrieval–reasoning coupling).

C.2 Index Structure

Index structure (Axis B)	#papers	Share
Graph / KG / community	46	44.2%
Flat / candidate list	29	27.9%
Hierarchical / summary tree	3	2.9%
Long-context	3	2.9%
Web / live retrieval	6	5.8%
Multi-modal / other	5	4.8%
Other / unspecified	12	11.5%
Total	104	100%

Table 6: Distribution of index structures (Axis B) across all 104 methods. Graph- and KG-style indices are the most common among retrieval–reasoning coupling papers, followed by flat passage lists.

C.3 Next-Step Execution Plan

Control pattern (Axis C)	#papers	Share
Policy-based	32	30.8%
Rule-based	31	29.8%
Policy-based + Rule-based	14	13.5%
Rule-based + Verifier/PRM-based	7	6.7%
Policy-based + Search-based	5	4.8%
Search-based + Verifier/PRM-based	4	3.8%
Search-based	2	1.9%
Verifier/PRM-based	2	1.9%
Unspecified	2	1.9%
Policy-based + Verifier/PRM-based	1	1.0%
Policy-based + Uncertainty-gated	1	1.0%
Rule-based + Search-based	1	1.0%
Rule-based + Uncertainty-gated	1	1.0%
Policy-based + Rule-based + Verifier/PRM-based	1	1.0%
Total	104	100%

Table 7: Distribution of next-step execution / control patterns across all 104 methods (Axis C).

C.4 Stop / Continue Criteria

Stop / continue pattern (Axis D)	#papers	Share
Budget-based + Heuristic-done	42	40.4%
Budget-based	40	38.5%
Budget-based + Verifier-threshold	10	9.6%
Budget-based + Memory/Progress	5	4.8%
Heuristic-done	5	4.8%
Unspecified	2	1.9%
Total	104	100%

Table 8: Distribution of stop / continue criteria across all 104 methods (Axis D).

D Marginal Distribution of the Four Components

Table 9 summarizes how the four components in our framework are instantiated across the 104 multi-hop QA / RAG papers in our Topic 4 sample. Along Axis A (overall execution plan), more than half of the systems (56/104, 53.8%) still follow a frozen-pool "retrieve-then-read" pattern, while 39/104 (37.5%) explicitly interleave retrieval and reasoning, 17/104 (16.3%) implement plan–then–execute strategies, and 13/104 (12.5%) scale test-time search (e.g., Tree-of-Thoughts or MCTS) on top of these patterns.

Axis B (index structure) shows that graph- or KG-style indices are the most common single family, followed by flat text indices, whereas hierarchical summary trees and long-context retrieval units remain rare. A further group of papers operates without a fixed static index, instead relying on web search, multimodal retrieval, or purely parametric knowledge.

For Axis C (next-step execution plan), roughly half of the systems employ a learned control policy, and a similar number still use rule-based action selection such as fixed reasoning rhythms or hand-crafted heuristics; only a small minority rely on fully search-based controllers (beam search, MCTS, or Tree-of-Thoughts).

Finally, Axis D (stop / continue criteria) is dominated by resource-constrained stopping: 97/104 systems (93.3%) impose explicit hop, token, or latency budgets, and 47/104 (45.2%) combine these with simple "done when the path is complete" heuristics or beam-exhaustion rules. Verifier- or PRM-based stopping remains less common but growing, and only a handful of systems explicitly use uncertainty- or confidence-based stopping. These distributions support our claim that most recent progress focuses on richer control and planning on top of relatively conservative index struc-

Axis / choice	#papers	Share of 104
(A) Overall execution plan		
Retrieve-then-read	56	53.8%
Interleaved retrieval + reasoning	39	37.5%
Plan–then–execute	17	16.3%
Test-time search scaling (ToT/MCTS/beam)	13	12.5%
(B) Index structure		
Flat text / candidate list	29	27.9%
Graph / KG / community index	46	44.2%
Hierarchical / summary tree	3	2.9%
Long-context units	3	2.9%
Other (web / multimodal / param.)	23	22.1%
(C) Next-step execution plan: control strategy		
Policy-based control	54	51.9%
Rule-based control	55	52.9%
Search-based control (beam / MCTS / ToT)	12	11.5%
Verifier / PRM-gated control	15	14.4%
Uncertainty-gated control	2	1.9%
(D) Stop / continue criteria		
Budget-based stopping (hop / token / latency)	97	93.3%
Heuristic / done-when-path-complete rules	47	45.2%
Progress-based rules (memory / frontier)	5	4.8%
Verifier- / PRM-based stopping	10	9.6%

Table 9: Distribution of retrieval–reasoning design choices across the 104 multi-hop QA / RAG papers in our Topic 4 sample, aligned with the four components in Figure 1. Counts are multi-label within each block: a single system may instantiate multiple choices along an axis, so percentages do not sum to 100%. Values are the marginals of Tables 5–8.

tures and budgeted stopping schemes.

E Reported Performance of Representative Systems

Dataset	System	Year	Reported performance on this dataset
2WikiMultiHopQA	Credible Plan-Driven RAG Method for Multi-hop Question Answering (PAR-RAG)	2025	EM 71.23, Acc 78.25
2WikiMultiHopQA	KG-o1: Enhancing Multi-hop Question Answering in LLMs with Knowledge Graphs	2025	EM 62.40 / F1 74.45 / Prec. 72.56 / Rec. 79.45
HotpotQA	Resource-Friendly Dynamic Enhancement Chain for Multi-hop QA (DEC)	2025	CoverEM 47.19 / F1 50.96 / Acc 49.60; CoverEM 58.52 / F1 62.11 / Acc 60.32

Abstract

LLM-based zero-shot object-goal navigation requires agents to retain visual, spatial, and motion evidence over long horizons. When this evidence is serialized into a growing trajectory prompt, earlier observations can become difficult to use amid redundant or conflicting context. We present SkillNav, a role-specialized multi-agent architecture that moves the navigation history needed for later decisions out of the prompt and into a shared spatial blackboard. Built on a sparse Voronoi–Frontier graph, the blackboard stores node-level evidence in role-specific fields maintained by Safe, Memory, and Exploration agents. Independent safety and memory gates reduce the influence of repeated motion failures and rejected target hypotheses, while the Exploration agent reads only a compact top-K snapshot. Their updates are combined through a unified node-value function, preserving relevant evidence without replaying the full trajectory. On the HM3D validation split, SkillNav achieves **71.9 SR / 34.0 SPL** with **22.5** calls and $\sim$11.9K tokens per episode for its high-level LLM, outperforming RATE-Nav, the strongest zero-shot baseline in our comparison, by 4.1 SR and 2.7 SPL. Ablations on a matched 200-episode subset show that removing either Safe or Memory reduces both metrics.

1 Introduction

Embodied object-goal navigation (ObjectNav) asks an agent to locate an instance of a target category in an unseen environment using egocentric observations and odometry (Chaplot et al., 2020; Savva et al., 2019). In the *zero-shot* setting (Majumdar et al., 2022), recent systems combine frozen vision-language models (VLMs) with metric maps, frontier representations, or topological graphs, sometimes using a language model for high-level decisions (Yokoyama et al., 2024; Yu et al., 2023; Wu et al., 2024a; Zhang et al., 2024). Over an episode, the agent accumulates observations, candidate targets, visited regions, and action outcomes. For LLM-based controllers that repeatedly append this history to the prompt, the input may contain redundant or conflicting evidence. Long-context models also use information unevenly across prompt positions, a behavior known as *lost-in-the-middle* (Liu et al., 2024a). A separate problem is that a false-positive target hypothesis may persist in the decision state and bias later navigation.

A spatial map organizes where evidence is observed, but does not by itself define how different modules should update and combine that evidence. We present SkillNav (fig. 1), which uses a sparse Voronoi–Frontier graph as a shared spatial blackboard. Each node stores visual-semantic evidence and two multiplicative gates. The geometry-based Safe agent updates $\mu_{\text{safe}}(v)$ from viability and motion failures. The VLM-based Memory agent updates $\mu_{\text{mem}}(v)$ through multi-frame verification of target hypotheses. The LLM-based Exploration agent reads a compact blackboard snapshot and returns a navigation phase and $(w_{\text{SR}}, w_{\text{IG}})$ fusion weights. The agents write to separate channels, which are combined only by the node-value function. Rejected target hypotheses and motion failures can then inform later decisions without replaying their supporting observations or action history.

On the HM3D validation split, SkillNav achieves **71.9 SR / 34.0 SPL**, using an average of **22.5** calls and $\sim$11.9K tokens per episode for the high-level LLM. It exceeds RATE-Nav, the strongest zero-shot baseline in our comparison, by 4.1 SR and 2.7 SPL. Removing either Safe or Memory reduces both metrics on a matched 200-episode subset.

unified node-value function (§3.3). (3) An HM3D evaluation showing gains in SR and SPL over the strongest zero-shot baseline in our comparison, together with measured high-level LLM usage (§4).

2 Related Work

Zero-shot Object Navigation. Frontier-based ZSON systems score each frontier cell with a single VLM signal and pick the best at every step (VLFM, L3MVN, ESC (Yokoyama et al., 2024; Yu et al., 2023; Zhou et al., 2023)). TriHelper (Zhang et al., 2024) adds three helper modules sharing one planner; ImagineNav (Zhao et al., 2025) prompts a VLM to imagine future views; RATE-Nav (Li et al., 2025) adds region-aware termination. Topology methods reason at the node level instead: VoroNav (Wu et al., 2024a) runs an LLM at every Voronoi waypoint, SG-Nav (Yin et al., 2024) prompts over a 3D scene graph, CogNav (Cao et al., 2025) casts the episode as a 5-state LLM-driven process. All of them route every decision through one LM with a shared, monotonically-growing context.

Grounding and hallucination. Grounding has been studied extensively for text and knowledge bases (Lewis et al., 2020), but these works ground the LM in *retrieved text*, not in a dynamically-built spatial state. Long-context LMs lose middle-context information (Liu et al., 2024a); LLM-based embodied agents compound this into trajectory-level hallucination (Chakraborty et al., 2025; Lin et al., 2025). Common mitigations (self-revision, RAG over prior outputs) still ask the LM to correct its own past assertions; SkillNav suppresses false-positive evidence *below* the LM, in the blackboard's algebra.

Multi-agent LLM architectures. Recent agentic systems (Wu et al., 2024b; Park et al., 2023) coordinate via free-form dialogue, recreating the long-context problem at the inter-agent level. SkillNav inherits the *blackboard* pattern from classical problem solving (Erman et al., 1980): agents write to disjoint channels, never to each other's prompts. Combined with the options framework (Sutton et al., 1999) this yields strict context isolation.

3 Method

3.1 Overview

At time t, SkillNav receives an RGB-D observation I_t, the agent pose p_t, and a target category c. The mapping module updates the occupancy map, frontier set, and sparse Voronoi graph, which together form the spatial blackboard $\mathcal{B}_t$. Safe and Memory update node-level gates in response to motion and verification events. At scheduled high-level updates, Exploration reads a compact summary of $\mathcal{B}_t$ and returns a navigation phase and the SR/IG fusion weights. At each node-selection tick, SkillNav combines geometric information gain, connectivity, visual-semantic scores, and the two gates into a node value $V(v)$. The highest-scoring reachable node is passed to the low-level planner. Because the blackboard persists across ticks, rejected target hypotheses and motion failures remain available to later decisions without adding the corresponding observations and actions to the Exploration prompt.

3.2 The Voronoi–Frontier Blackboard

As illustrated in fig. 1, the blackboard compresses a dense map into a small set of navigation choices. A *frontier* is a boundary between explored free space and unknown space. From the current occupancy map, we extract a sparse Voronoi graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ over explored free space (Lau et al., 2010). Nodes are degree-≥ 3 junctions and edges are traversable connections between them. Each frontier $f \in \mathcal{F}$ is assigned to its nearest reachable node by an A*-aware map $\pi : \mathcal{F} \to \mathcal{V} \cup \{\perp\}$. We write $\mathcal{F}_v = \pi^{-1}(v)$ for the frontiers anchored to node v. Frontiers that cannot be assigned reliably ($\pi(f) = \perp$) are kept for a fallback policy. Thus, a node represents both a navigable waypoint and the unexplored regions reachable through it. Exact extraction and anchoring rules are given in App. E.

For a node v at grid location x_v, the blackboard stores

$$\mathcal{B}_t(v) = \big(x_v, \mathcal{F}_v, S(v), E(v), m(v), \mu_{\text{safe}}(v), \mu_{\text{mem}}(v)\big). \tag{1}$$

Here $S(v) = V_{\text{SR}}^{\text{cell}}(x_v)$ is a goal-conditioned BLIP-2 ITM score, whereas $E(v) = V_{\text{IG}}^{\text{cell}}(x_v)$ is an object-agnostic visual-explorability score. Their prompt templates are provided in App. D. The memory field $m(v)$ records a room hypothesis, observed objects, and freshness; it is included in the compact summary read by Exploration. The remaining fields are the safety and memory gates written by Safe and Memory. Exploration supplies a navigation phase and the global fusion weights $(w_{\text{SR}}, w_{\text{IG}})$.

We first compute an ungated utility $U(v)$. Its three terms measure the geometric gain of the anchored frontiers, the connectivity of the node, and its weighted visual evidence:

$$A_{\text{IG}}(v) = \sigma^{-1} \sum_{f \in \mathcal{F}_v} \text{IG}_{\text{geom}}(f), \tag{2}$$

$$B(v) = \beta \log\big(1 + \deg(v)\big), \tag{3}$$

$$A_{\text{comb}}(v) = w_{\text{SR}} S(v) + w_{\text{IG}} E(v), \tag{4}$$

$$U(v) = A_{\text{IG}}(v) + B(v) + \gamma A_{\text{comb}}(v). \tag{5}$$

The normaliser σ keeps aggregated frontier gain on a comparable scale, β controls the connectivity bonus (Wu et al., 2024a), and γ controls the contribution of visual evidence. Note that A_{IG} is *geometric* frontier gain, whereas $E(v)$ is the VLM-derived visual-explorability score.

Safe and Memory then act as independent soft gates on the whole utility:

$$V(v) = \text{clip}(\mu_{\text{safe}}(v)\mu_{\text{mem}}(v)U(v), V_{\min}, V_{\max}), \tag{6}$$

where $[V_{\min}, V_{\max}] = [0.01, 1.0]$. A node remains attractive only when it is both useful under $U(v)$ and credible under the two gates. The selected target is the highest-valued reachable node, $v^\star = \arg\max_{v \in \mathcal{V}} V(v)$; orphan frontiers are handled by the fallback policy. Algorithm 1 in App. C gives the complete update and selection cycle.

3.3 Three Agents on Disjoint Channels

Table 1 summarises which channel each agent owns and how it reasons. All three agents read the same blackboard state; they never see one another's prompts.

Memory. On each VLM verdict at v, the memory gate is updated as

$$\mu_{\text{mem}} \leftarrow \text{clip}(\gamma_e \, \mu_{\text{mem}}, \mu_{\min}, \mu_{\max}), \tag{7}$$

with $\gamma_e \in \{0.5, 0.7, 1.1\}$ for a multi-frame FP, a single-shot FP, and a TP respectively, and floor $\mu_{\min} = 0.1$. Three repeated REJECTs take μ_{mem} to 0.125, dropping $V(v)$ by an order of magnitude regardless of SR/IG. Repeated rejections therefore lower the node value without requiring the high-level LLM to revise an earlier decision.

Safe. Tryout escape writes

$$\mu_{\text{safe}} \leftarrow \max(\mu_{\min}, \gamma_{\text{stuck}} \, \mu_{\text{safe}}) \tag{8}$$

on each consecutive escape failure ($\gamma_{\text{stuck}} = 0.3$, floor 0.05); three failures would yield ≈ 0.027 before clipping and therefore reach the 0.05 floor, encoding a geometric blocker as a language-agnostic gate. The Safe agent never calls a language model.

Exploration. The Exploration agent uses DeepSeek-Chat as its high-level LLM. Every 3 s, the model receives a compact state vector (coverage, candidate count, FP count, stuck count, previous phase) and returns JSON with the next phase and a normalised $(w_{\text{SR}}, w_{\text{IG}})$. A rule-based fallback uses the same weight tiers so navigation can continue when the LLM API is unavailable (App. D).

Agent	Reads	Writes	Vocabulary	Backbone
Safe	pose, occupancy, recent trajectory	$\mu_{\text{safe}}(v)$	{wedged, stuck, tryout, ok}	pure geometry (no LM)
Memory	multi-frame RGB + per-cand. FP count	$\mu_{\text{mem}}(v)$	{CONFIRM, UNCERTAIN, REJECT}	Qwen-VL-Plus, event-trig.
Exploration	compact blackboard summary	$(w_{\text{SR}}, w_{\text{IG}})$, phase	{BROAD, DIRECTED, APPROACH, VERIFY}	DeepSeek, 3 s cadence

Table 1: The three agents of SkillNav. Each reads the shared blackboard but writes a single, named channel; vocabularies are disjoint so writes commute. Full prompts in App. D.

4 Experiments

4.1 Setup

We evaluate on the HM3D ObjectNav val split (Ramakrishnan et al., 2021) in the standard $25\times25\,\text{m}^2$ configuration with a 500-step horizon and 1 m success radius. SR and SPL are computed as in Savva et al. (2019). SkillNav is implemented on a Habitat–ROS bridge; its high-level LLM is DeepSeek-Chat, consulted at a fixed 3 s cadence, the Memory verifier is Qwen-VL-Plus, and both SR and IG channels score BLIP-2 ITM (Li et al., 2023) under the templates in App. D.

4.2 Main Results

Table 2 reports HM3D val SR and SPL. SkillNav reaches **71.9 SR / 34.0 SPL**, +4.1 SR / +2.7 SPL over the strongest zero-shot baseline in our comparison (RATE-Nav, ACL'25 (Li et al., 2025)). It also surpasses the privileged *ImagineNav-Oracle* variant (Zhao et al., 2025) by +9.9 SR / +2.9 SPL.

4.3 Ablation Study

Table 3 evaluates the contributions of the Safe and Memory agents and adaptive SR/IG control on the same **200** HM3D-v2 val episodes. The full model achieves 72.5 SR / 36.3 SPL on this subset.

Safe agent. Removing Safe causes the largest drop: 10.5 SR and 3.2 SPL. Stuck-related terminal outcomes also rise from 1 to 24. μ_{safe} retains these failures at the node level, discounting a semantically attractive waypoint after repeated failed escapes.

Memory agent. Removing the Memory agent lowers SR by 3.5 points and SPL by 3.1 points. A rejection is stored in μ_{mem} rather than left in an earlier prompt, so its penalty remains when the candidate is seen again from another view.

Exploration agent: adaptive SR/IG control. Adaptive weighting helps the agent reach likely target candidates sooner, raising SPL from 35.5 to 36.3. The same focus leaves fewer alternatives for Memory to verify and can increase commitment to an incorrect target: false-positive terminal outcomes rise from 16 to 22, while SR falls from 73.5 to 72.5.

4.4 High-Level LLM Inference Cost

Table 4 reports the measured per-episode cost of the high-level LLM in SkillNav on the HM3D val sweep. Each prompt contains a static prefix and a compact blackboard snapshot, so its size is set by topology rather than trajectory length. Per-step LLM designs such as VoroNav (Wu et al., 2024a) or L3MVN (Yu et al., 2023) consult the LM once per low-level decision; on a 500-step episode this al-

Metric (HM3D val)	Value
Calls / episode (mean)	22.5
Prompt tokens / call (mean)	527
Tokens / episode (mean)	11,885
LM call latency (mean / p_{95})	1.95 s / 2.50 s
VLM verifier calls / episode	4.54

Table 4: Measured high-level LLM cost on HM3D val. Token counts exclude the Memory VLM (4.54 calls/episode) and dual BLIP-2 ITM scoring.

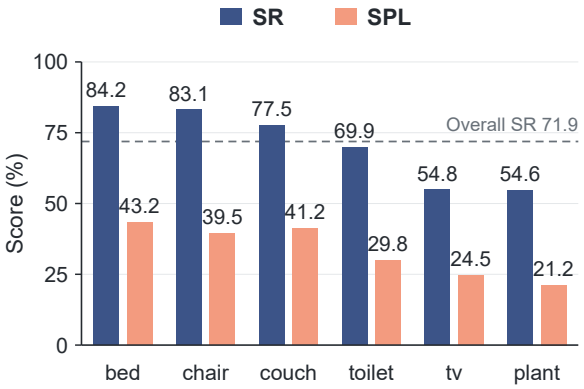

Figure 2: Per-category SR and SPL on HM3D val. The dashed line marks the overall SR (71.9).

lows up to ∼500 calls. SkillNav's option-boundary cadence cuts this to 22.5 calls per episode while *improving* SR (71.9 vs. VoroNav's 42.0 in table 2).

Figure 2 shows over 75% SR for large furniture but about 55% for small or partially occluded targets, consistent with prior ObjectNav results (Yokoyama et al., 2024; Zhang et al., 2024). Detection remains the dominant failure mode (App. A).

4.5 Context Isolation and Hallucination Resistance

A monolithic agent serialises observations, decisions, and recovery attempts into a growing trajectory prompt. SkillNav instead stores typed fields: Memory writes its verification state and μ_{mem}, Safe writes μ_{safe}, and Exploration reads only the top-K nodes and candidates. Earlier visual and motion evidence can then affect later decisions without being replayed.

An early rejection or stuck event is thus carried forward as a value attached to a node, not as prose appended to every later prompt. At 527 tokens per call and 22.5 calls per episode (table 4), the prompt is bounded by the topology rather than trajectory length. The high-level LLM chooses from the current state instead of replaying the trajectory. Earlier corrections therefore do not have to be recovered from the middle of a long prompt.

Channel ownership also prevents one agent from overwriting another's evidence. A decision can be traced to a named field without reconstructing the action history. The compression is not lossless, however: restricting the snapshot to top-K entries may omit a useful distant frontier.

The full run still has 83 false-positive lock-ins (8.3%; App. A). The Memory ablation tests whether a rejection persists, not whether the VLM produces fewer false positives. Direct frame-level tests and a matched monolithic baseline are still needed.

5 Conclusion

SkillNav uses a Voronoi–Frontier blackboard to separate persistent navigation evidence from high-level choice. Safe records motion failures, Memory stores the status of target hypotheses, and Exploration sets the fusion weights and phase from a topology-bounded view. SkillNav reaches 71.9 SR / 34.0 SPL with 22.5 LM calls per HM3D val episode. On the ablation subset, removing Safe causes the largest drop, while removing Memory also lowers both metrics. Adaptive SR/IG weighting gives higher SPL but slightly lower SR than fixed weights.

Limitations

Our evaluation is limited to HM3D validation in Habitat and one VLM/LM stack; cross-simulator and cross-model generalisation remain untested. Memory updates can lag the current pose, and the fixed-size LLM summary omits graph-global structure that a graph-attention head could exploit.

Ethics Statement

SkillNav is evaluated only in HM3D simulation, with no human subjects or private data. DeepSeek and DashScope APIs are used under their standard terms. We see no direct dual-use risk beyond embodied navigation research.

A Full Failure-Mode Taxonomy

Automatic outcome breakdown over all **281** HM3D val failures (of 71.9% success):

- **Timed-out on correct path** (**61.2%** of failures, 17.2% of all episodes): the agent ran out of the 500-step budget along a feasible path to the goal; combines the `stepout_feasible` (10.0%) and `stepout_fn` (7.2%) outcome tags.
- **VLM false-positive locked** (**29.5%** of failures, 8.3% of episodes): the agent committed to a candidate that the Memory agent's verification eventually rejected, but not in time to recover within the step budget.
- **Genuine unreachable / no-frontier** (**6.0%** of failures, 1.7% of episodes): the target is behind a closed door, on another floor, or the explored region was exhausted with no remaining frontier; no purely navigational policy could succeed (`infeasible` + `no_frontier(_fn)`).
- **Un-escaped dead-zone** (**3.2%** of failures, 0.9% of episodes): the Safe agent's μ_{safe} decay isolated a region whose re-entry was later needed (`stucking` + `stucking_fn`).
- **Map error / SLAM drift** (**<1%**): rare in Habitat with provided GT pose; included for taxonomy completeness.
- **Other / unclassified** (**0%**).

B Hyperparameters

D Prompt Templates

Semantic-relevance prompt. The SR channel uses a goal-conditioned BLIP-2 template:

"a {goal} in the room"

where `{goal}` is the episode's object category (e.g. `toilet`, `potted plant`). The cosine similarity between this text and the current view is rendered into $V_{\text{SR}}^{\text{cell}}(x)$ across the agent's projected field of view.

Symbol	Meaning	Value
Frontier-anchored topology (§3.2)		
λ	geom-IG weight in A_{IG}	0.5
β	degree-bonus weight	0.5
$r_{\max}$	anchor radius (A*)	5.0 m
τ	orphan threshold (%-ile)	30
d_{deg}	min node degree	3
Memory agent (§3.3)

Table 5: Hyperparameters used in SkillNav.

Information-gain prompt. The IG channel uses a single, object-agnostic explorability template:

> *"An image of a doorway, corridor, or open passage leading to an unexplored region of the building."*

The template captures the classical explorability prior that doorways, corridors, and partial openings tend to reveal large unmapped areas. We experimented with multi-template averaging (three variants emphasising *doorway*, *corridor*, *opening* respectively); the gain over single-template was within ± 0.3 SR on HM3D val, and the single-template version is what we report in the main text.

Option-boundary LLM consultation. At each option-boundary tick or stagnation event, the Exploration agent sends a structured prompt to the language-model backend (DeepSeek-Chat) following the template in table 6. Each component is bounded in size: the topology summary lists at most $K = 8$ nodes, each formatted as $\langle$id, visited, nearby_objects, $V(v)\rangle$ in $\sim$30 tokens; the candidate summary is similar; the total prompt stays under $\sim$1.3 K tokens regardless of episode length.

Algorithm 1 SkillNav decision cycle

Input: RGB-D observation I_t, pose p_t, target category c; persistent blackboard $\mathcal{B}_{t-1}$.

Phase 1: Map and score update

1: Update the occupancy map and dense SR/IG score maps from (I_t, p_t, c).
2: Extract $\mathcal{G}_t$ and $\mathcal{F}_t$; anchor each frontier with π_t and retain unassigned frontiers.

Phase 2: Blackboard update

3: Refresh $m(v)$ and the Safe/Memory gates when their respective motion or verification triggers fire.
4: If a high-level update is due, obtain the phase and $(w_{\text{SR}}, w_{\text{IG}})$ from Exploration using a compact summary of $\mathcal{B}_t$.

Phase 3: Node selection

5: For each v, compute $U(v)$ by eq. (5) and gated value $V(v)$ by eq. (6).
6: Set $v^\star \leftarrow \arg\max_{v \in \mathcal{V}} V(v)$; invoke the orphan-frontier fallback if no valid anchored node remains.
7: Send $v^\star$ to the low-level planner and retain $\mathcal{B}_t$ for the next tick.

Figure 3: End-to-end decision cycle. Agent-specific update rules are given in §3.3; map and frontier implementation details are given in App. E.

E Implementation Details

Source code. Source code is available at `https://github.com/Pandakingxbc/SkillNav`.

Habitat / ROS stack. SkillNav is implemented as a Python evaluator (`habitat_evaluation.py`) communicating with a C++ ROS planner (`exploration_node`) via standard ROS topics. The evaluator publishes RGB-D + odometry at $\sim$3 Hz and the dual ITM scores at $\sim$5 Hz; the planner publishes the current goal node, trajectory, and option state at $\sim$1 Hz. Each episode is preceded by a hard reset of the planner process to ensure no cross-episode state leakage between scenes.

VLM serving. We host BLIP-2 ITM, Grounding-DINO (Liu et al., 2024b), and SAM (Kirillov et al., 2023) as independent GPU-backed Flask services listening on ports 12181–12184. The dual ITM is a single BLIP-2 endpoint queried twice per frame (once with the SR prompt, once with the IG prompt); we cache the visual encoder forward pass on the server side to amortise the cost.

Voronoi topology. The generalised Voronoi diagram is computed from the obstacle distance field at each map update (Lau et al., 2010). Decision nodes are extracted as Voronoi vertices with degree ≥ 3 (junctions), filtered by a minimum inter-node distance of 1.5 m and a minimum obstacle clear-

System. You are the Exploration agent for a zero-shot object-goal navigation robot. Output the next navigation phase, and optionally an override of the SR / IG fusion weights. Respond in JSON with keys: `phase`, `w_sr`, `w_ig`.

User. Target object: `{goal}`.
Current phase: `{current_option}`.
Phase history (last 5): `[{o_{t-4}}, ..., {o_t}]`.
Top-K topology nodes (sorted by $V(v)$), each formatted as
`{id, visited, nearby=[obj_1, ...], V}`.
Top-K target candidates (sorted by reliability), each as
`{obj, rel, fp, dist}`.
Choose the next phase from `{broad-explore, directed-search, target-approach, verification}`.

Table 6: Template for the Exploration agent's LLM consultation (§3.3). Slot values are populated from the current blackboard state by the Exploration agent.

ance of 0.3 m. The graph typically contains 30–100 nodes mid-episode in HM3D scenes.

Frontier extraction and anchoring. Frontiers are extracted as 8-connected boundaries between free and unknown cells, clustered into groups of ≥ 5 cells. The anchor map π (§3.2) is computed by running a multi-source A* from all Voronoi nodes simultaneously; cells inherit the closest node's id when their reachable distance is $\leq r_{\max} = 5.0$ m, else they enter the orphan queue.

Token instrumentation. LLM call statistics are collected by a lightweight wrapper around each backend client; for DeepSeek we use the exact `prompt_tokens` and `completion_tokens` fields from `response.usage`, and for Ollama the exact `prompt_eval_count` / `eval_count` fields. VLM call latency is measured at the client side as wall-clock around the Flask request. Where exact token counts are unavailable we fall back to a character-based approximation ($\sim$4 chars / token for ASCII, $\sim$2 for CJK), and this approximation is used for $<1\%$ of the calls in our final runs.

Compute. All evaluation was performed on a single workstation with one NVIDIA GeForce RTX 4070 Ti GPU for the local VLM servers (BLIP-2 ITM, Grounding-DINO, SAM), one CPU thread per Habitat simulator instance, and the DeepSeek-Chat and DashScope (Qwen-VL-Plus) API endpoints for the high-level LLM and Memory verifier respectively. Wall-clock per HM3D episode averaged 85.6 s (median 60.6 s) for SkillNav; the full 1000-episode HM3D val sweep completed in 23.8 h.

Riemannian Geometry for Pre-trained Language Model Embeddings

Abstract

Understanding the geometric structure of pre-trained language model embeddings matters for interpretability and safety. We ask whether sentence-level classification signal lives in the Riemannian geometry of contextual token embeddings, and probe it by extracting per-token pullback metrics from a learned encoder's analytical Jacobian and aggregating them with the Fréchet mean on the symmetric positive definite (SPD) manifold, we call this procedure Riemannian Mean Pooling (RMP). Across three datasets with non-trivial linguistic structure (CoLA, CREAK, RTE), RMP outperforms Euclidean mean pooling, while on FEVER-Symmetric, a benchmark constructed to remove annotation-driven lexical artifacts, the method correctly stays at chance. Ablations show that a randomly initialised encoder combined with Fréchet aggregation already beats Euclidean pooling before any training, localising the source of the gain to the geometric aggregation rather than to learned manifold structure. The trained encoder adds a further 1.7 to 2.2 AUC points, consistently across the signal-bearing datasets rather than on any one of them.

1 Introduction

Pre-trained language models achieve remarkable success in natural language understanding, yet the geometric structure of their internal representations remains an open challenge. Most analyses treat token embeddings as points in flat Euclidean space, but three lines of evidence motivate departing from that assumption. First, hierarchical structure in language admits lower-distortion embeddings in negatively curved spaces (Nickel and Kiela, 2017, 2018; Sala et al., 2018; Park et al., 2025) and is reflected in non-standard inner products on the embedding space (Park et al., 2024; Marks and Tegmark, 2024). Second, contextualized representations in BERT, ELMo, and GPT-2 are strongly anisotropic, occupying narrow cones not invariant under Euclidean transformation (Ethayarajh, 2019; Kataiwa et al., 2025). Third, token embedding spaces may also fail to form smooth manifolds globally, even if local-manifold-like structure still supports geometric analysis at the neighbourhood level (Robinson et al., 2025).

This work investigates whether sentence-level classification signal lives in the Riemannian geometry of token embeddings. We address three questions: (1) Do embeddings exhibit local geometric structure accessible via pullback metrics? (2) Does this geometric structure carry signal beyond what flat Euclidean aggregation extracts? (3) Which component of a geometric aggregation pipeline is responsible for any observed gain: the encoder, the metric, or the aggregation?

We evaluate our approach, *Riemannian Mean Pooling* (RMP), on four diverse NLP tasks: fact verification (FEVER-Symmetric), textual entailment (RTE), grammatical acceptability (CoLA), and commonsense reasoning (CREAK). FEVER-Symmetric is included specifically as a negative control, since it was constructed to remove lexical and annotation artifacts (Schuster et al., 2019), and we expect any method relying solely on claim-surface geometry to perform at chance.

Any differentiable encoder yields a pullback metric through its Jacobian, but the metric's geometric interpretability depends on the training objective. We use Intrinsic Green's Learning (IGL) (Quemy, 2026)[1], where a closed-form kernel readout replaces the learned decoder, constraining the encoder to coordinates aligned with the smooth structure of the data manifold rather than with arbitrary nonlinear features. Our ablations (Section 5) test this choice by comparing

IGL against random and untrained encoders.

Contributions

- We instantiate a pipeline that extracts per-token pullback metrics from a learned encoder's Jacobian, aggregates them on the SPD manifold via the Fréchet mean, and classifies in the tangent space at the population Riemannian mean.
- Across three signal-bearing datasets (RTE, CoLA, CREAK), Riemannian aggregation consistently outperforms Euclidean mean pooling under a controlled comparison on identical embeddings. On FEVER-Symmetric, included as a negative control, the method correctly stays at chance.
- A randomly initialised encoder combined with Fréchet aggregation already beats Euclidean pooling, localising the source of the geometric signal to the aggregation rather than to learned manifold structure. The trained encoder contributes a further 1.7 to 2.2 AUC points on every signal-bearing dataset.

2 Related work

Riemannian Methods in Neuroscience Riemannian geometry is a ubiquitous machine learning technique in brain-computer interfaces (BCIs) and signal processing (Congedo et al., 2017). Barachant et al. (2012) introduced the use of symmetric positive definite (SPD) matrices as a descriptor for electroencephalography time series, demonstrating that geometric methods can capture the intrinsic structure of signals better than Euclidean approaches. The riemannian minimum-distance-to-means (MDM) and tangent space (TS) classifiers have become ubiquitous tools for neurosciences application, still unbeaten even by the most recent deep learning algorithms (Chevallier et al., 2024), while remaining simple, deterministic, robust to noise, computationally efficient, and prone to transfer learning (Andreev et al., 2025). Beyond the BCI setting, SPD-manifold deep learning has matured: differentiable Fréchet-mean layers (Lou et al., 2020), Riemannian batch normalisation for SPD networks (Brooks et al., 2019), and Riemannian extensions of logistic regression (Chen et al., 2024) now provide standard components for end-to-end SPD pipelines, with recent surveys covering the area (Ju et al., 2024).

Geometric Approaches in NLP In modern NLP architectures, tokens are represented as vectors in a high-dimensional latent space. As tokens propagate through the network layers, their representations evolve inside the Residual Stream, the model's dynamic internal state. This evolution is not purely linear or syntactic, but can be described as a structured trajectory whose geometry changes depending on the semantic context (Manson, 2025). Concrete instances of this structure have been demonstrated empirically: linear directions in LLM representations encode space, time, and other conceptual attributes (Gurnee and Tegmark, 2024), and architectural variants explicitly equip attention with non-Euclidean geometry, either via mixed-curvature transformers (Cho et al., 2023) or via parallel-transport-based attention on manifolds (Ji, 2025). Recent work has also proposed that the latent space itself can be modelled as a curved spacetime whose curvature reflects linguistic structure (Di Sipio et al., 2025).

Current approaches estimate local tangent spaces from k-nearest-neighbor (kNN) patches and derive curvature information from variations between neighboring tangent directions (e.g., Gao and Liang, 2011; Li, 2017). However, these methods often suffer from numerical instability and sensitivity to sampling density, with metric estimates degrading as the local sample size shrinks (Brand, 2003; Singer, 2006). A different style of approach first projects the data to a lower-dimensional space (for example via UMAP (McInnes et al., 2018)) and computes metrics in the projection, but UMAP preserves local topology rather than metric structure: distances after UMAP are unsuitable as approximations of distances on the original manifold, so subsequent geometric computations operate on a non-isometric image of the data. Recent work has also questioned whether token embeddings form a single connected manifold at all (Robinson et al., 2025). The question we ask here is whether aggregated token geometry nevertheless carries class signal at the sentence level, regardless of whether global manifold structure holds.

Intrinsic Dimension and Manifold Learning Sobieski et al. (2026) showed that local intrinsic dimension (LID) reveals hallucinations in diffusion models by identifying instabilities on model-induced manifolds. Their work treats hallucinations as geometric instabilities, proposing Intrinsic

Quenching to correct these anomalies. Similarly, Damirchi et al. (2026) introduced "Truth as a Trajectory," analysing LLM reasoning through layer-wise geometric metrics rather than static activations. By examining how representations evolve across layers, they uncover geometric invariants distinguishing valid reasoning from spurious behaviour. Beyond these layer-wise trajectory analyses, a body of recent work uses intrinsic dimension as a probe of how LLMs process information across layers: representations expand in early layers and compress in later layers (Valeriani et al., 2023), with characteristic per-layer profiles that include a high-dimensional abstraction phase in the middle layers (Cheng et al., 2025). ID has also been used to compare learning paradigms such as supervised fine-tuning and in-context learning (Janapati and Ji, 2025). Our work complements these perspectives.

Sentence Representation Learning Standard sentence-representation approaches such as mean pooling of token embeddings and the BERT `[CLS]` token implicitly assume flat Euclidean geometry. We replace arithmetic averaging with an SPD-manifold Fréchet aggregation. Recent work has also highlighted the entanglement of pooled sentence representations (Tehenan et al., 2025), motivating geometric alternatives.

3 Material & Method

3.1 Datasets

We evaluate on four binary-classification benchmarks. **FEVER-Symmetric** (Schuster et al., 2019) contains 316 fact-verification claims, debiased by Schuster et al. against the annotation artifacts of the original FEVER (Thorne et al., 2018) by pairing each claim with its negation against shared evidence. We include it as a *negative control*, since methods relying solely on claim-surface features cannot exceed chance by construction. **RTE** (Wang et al., 2018): 2,490 premise–hypothesis pairs for textual entailment. **CoLA** (Warstadt et al., 2018): 3,000 sentences labelled for grammatical acceptability. **CREAK** (Onoe et al., 2021): 3,000 commonsense statements requiring world knowledge to verify.

3.2 Baseline Method: Linear Probe

We use **Linear Probe** (Alain and Bengio, 2017) as the headline baseline, referring to this baseline as the Linear Probe throughout and reserving the term *Euclidean mean pooling* for the underlying aggregation operation when contrasting it with the Riemannian alternative. The baseline operates entirely on internal states of the pre-trained model, isolating the contribution of geometric aggregation from any additional trainable parameters or external information sources.

Token embeddings and pooling. We extract token-level embeddings from the ninth hidden layer of `BERT-base-uncased` (Devlin et al., 2019), yielding 768-dimensional representations per token. The layer choice is motivated by prior work showing that upper layers encode more abstract semantic features while lower layers capture syntactic information (Rogers et al., 2020). For single-sentence datasets (FEVER, CoLA, CREAK) we encode the input directly. For the textual-entailment task (RTE) we concatenate premise and hypothesis with separator tokens (`[CLS] [premise] [SEP] [hypothesis] [SEP]`). Token embeddings are aggregated via arithmetic mean pooling:

$$\mathbf{v}_{\text{sentence}} = \frac{1}{n}\sum_{i=1}^{n}\mathbf{v}_i \in \mathbb{R}^{768}, \tag{1}$$

with $\{\mathbf{v}_1, \ldots, \mathbf{v}_n\}$ the token embeddings for a sentence with n tokens.

Classification. Pooled sentence representations are normalised and classified with a logistic regression using scikit-learn's (Pedregosa et al., 2011) default hyperparameters (no regularisation, LBFGS solver, max-iter 1000). The same classification head is used for the Riemannian pipeline downstream of the Fréchet aggregation (Section 3.5), so performance differences attribute cleanly to the aggregation step.

3.3 Intrinsic Green's Learning

Inverse-PDE objective. IGL (Quemy, 2026) is a framework for learning low-dimensional manifold representations through an inverse-PDE formulation. A small MLP encoder $\Psi_\theta : \mathbb{R}^D \to \mathbb{R}^{d_{\max}}$ maps each input $\mathbf{v} \in \mathbb{R}^D$ to a latent code $\boldsymbol{\xi} = \Psi_\theta(\mathbf{v})$. In the encoder's coordinates, the target function (here, the input itself) is expressed as the solution of a linear PDE

$$Lu = s, \tag{2}$$

where L is a fixed operator (a Laplacian in our setup whose Green's function is approximated by

a Gaussian kernel) and s is a learned source term.

Closed-form kernel readout. The PDE is solved in closed form via a Green's-function kernel. In practice, at any latent point $\boldsymbol{\xi}$, the reconstruction is a linear combination of kernel evaluations at K learned anchor points $\{\boldsymbol{\zeta}_k\}_{k=1}^{K}$,

$$\hat{u}(\boldsymbol{\xi}) = \sum_{k=1}^{K} w_k \, G(\boldsymbol{\xi}, \boldsymbol{\zeta}_k), \tag{3}$$

where G is the Gaussian kernel. The weights $\mathbf{w}$ are not learnable parameters. At every minibatch they are recomputed by ridge regression on the reconstruction targets (variable projection).

Encoder-only optimisation. IGL has no symmetric decoder. Because $\mathbf{w}$ is closed-form, gradient descent operates only on the encoder parameters θ, and the encoder must find coordinates in which the input admits a low-rank kernel decomposition. Those coordinates align with the smooth structure of the data manifold rather than with arbitrary nonlinear features a learned decoder could compensate for. As a byproduct, because Ψ_θ is a differentiable MLP, its Jacobian $J(\mathbf{v}) = \partial\Psi_\theta/\partial\mathbf{v}$ is analytically computable, giving direct access to the pullback metric at every input point.

Under the configuration used in this work (MLP encoder, $d_{\max}$=64, K=128 anchors, 4 Gaussian scales per factor), training converges to stable reconstruction. Full architectural details are deferred to Appendix A. The full pipeline (training top, inference bottom) is shown schematically in Figure 1. Representative validation-loss curves are shown in Appendix F.

3.4 Pullback metric extraction

After training the IGL encoder $\Psi_\theta : \mathbb{R}^{768} \to \mathbb{R}^{d_{\max}}$ on token-level BERT embeddings $\mathbf{v} \in \mathbb{R}^{768}$ (Section 3.3), we extract a local Riemannian metric at each token via the *pullback metric*. The intuition is that Ψ_θ maps the ambient embedding space to a lower-dimensional latent space. The pullback metric measures distances in the input space as they appear after this mapping, capturing how the encoder locally stretches or compresses different directions of the embedding space.

From Jacobian to metric. For an input $\mathbf{v} \in \mathbb{R}^{768}$, the Jacobian of the encoder is

$$J(\mathbf{v}) = \partial\Psi_\theta/\partial\mathbf{v} \in \mathbb{R}^{d_{\max}\times 768}, \tag{4}$$

computed in closed form by automatic differentiation through Ψ_θ. Pulling back the ambient Euclidean metric I_{768} through the encoder yields the co-metric on the latent manifold:

$$g^{-1}(\mathbf{v}) = J(\mathbf{v})\, J(\mathbf{v})^\top \in \mathbb{R}^{d_{\max}\times d_{\max}}. \tag{5}$$

By construction $g^{-1}(\mathbf{v})$ is symmetric and positive semi-definite. To obtain a metric tensor that is strictly positive-definite (required for the Riemannian operations in Section 3.5), we add a small regulariser before inversion:

$$g(\mathbf{v}) = \left(g^{-1}(\mathbf{v}) + \epsilon I_{d_{\max}}\right)^{-1}, \quad \epsilon = 10^{-6}, \tag{6}$$

and a further additive regularisation $\lambda I_{d_{\max}}$ with $\lambda = 10^{-2}$ to guarantee numerical stability across the full range of input tokens. The resulting $g(\mathbf{v}) \in \mathcal{S}_{++}^{d_{\max}}$ is the per-token SPD matrix used as input to the sentence-level aggregation.

Remark. *The expression* pullback metric *is an abuse of language, since $d_{\max} < 768$, Ψ_θ is a submersion, and (5) is not a metric but a co-metric, obtained by pushing the ambient I_{768} forward along Ψ_θ. The strict pullback would be the degenerate $J^\top J$ on $\mathbb{R}^{768}$. Restricting Ψ_θ to an estimated data manifold M of dimension $m < d_{\max}$ makes it an immersion and replaces (5) with $JP_MJ^\top$. Our runs show that it does not improve RMP on any dataset, achieving the same or worse performance than the unrestricted metric. We report that in Appendix G.*

Why pullback rather than direct estimation? The two most direct alternatives, that is, neighbour-based metric estimation and projection-then-metric approaches (e.g. UMAP), suffer from sensitivity to local sampling density and non-isometric distortion, respectively (Section 2). The pullback through a trained encoder avoids both issues: the metric is computed analytically from J rather than estimated from neighbours, and its position dependence is a smooth function of the original 768-dimensional input rather than of a non-isometric projection of it. The sensitivity of neighbour-based estimation is measurable on these embeddings and has been reported in Appendix G. Pulling back an ambient metric through an encoder's Jacobian follows Hauser and Ray (2017) and Arvanitidis et al. (2018). Recent extensions analyse discretisation of continuous inputs (Brandon et al., 2025) and score-based extraction of data-manifold geometry (Diepeveen et al., 2024).

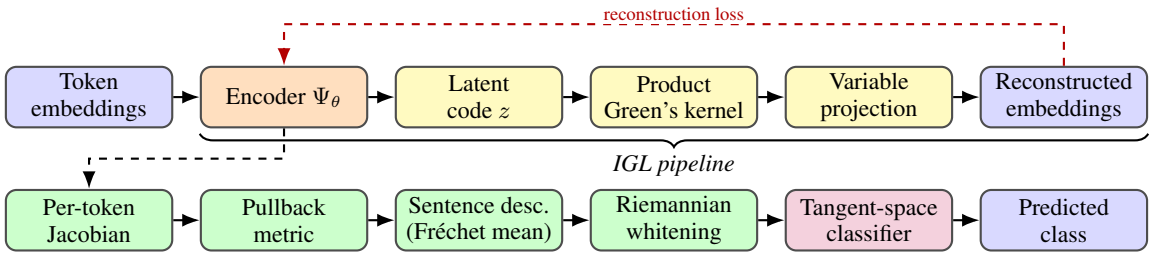

Figure 1: Overview of the pipeline. **Top row (training):** the encoder Ψ_θ is trained to reconstruct token embeddings (early stopping with patience=50, $\delta = 2 \times 10^{-5}$), mapping them to a low-dimensional latent code from which a product Green's kernel with variable projection recovers the input. The reconstruction loss flows back to the encoder (dashed arrow). **Bottom row (inference):** once trained, the encoder's Jacobian induces a pullback metric at each token. The per-token metrics are aggregated on the SPD manifold via the Fréchet mean to a sentence-level descriptor, preprocessed with Riemannian whitening, projected to the tangent space, and classified. The classification (inference) path carries no gradients and uses the encoder frozen post-training, and only the reconstruction (training) path is differentiable. The full architecture with formulas is given in Figure 3 of Appendix A.

Independence from the training loss. Because the pullback metric depends only on the encoder's Jacobian rather than on its training loss, the geometric pipeline downstream of $g(\mathbf{v})$ is well-defined for any differentiable encoder. We exploit this in Section 5 to isolate the contribution of the encoder from the contribution of the geometric aggregation.

3.5 Sentence aggregation and classification

Token-to-Sentence Aggregation Given a sentence with n tokens producing per-token SPD matrices $\{g(\mathbf{v}_1), \ldots, g(\mathbf{v}_n)\} \in \mathcal{S}_{++}^{d_{\max}}$ (Section 3.4), we aggregate them into a single sentence-level SPD descriptor using the Fréchet mean (Fletcher et al., 2004) on the SPD manifold:

$$G_{\text{sentence}} = \arg\min_{G \in \mathcal{S}_{++}^{d_{\max}}} \sum_{i=1}^{n} d^2_{\text{Riem}}(G, g(\mathbf{v}_i)), \quad (7)$$

with d_{Riem} the affine-invariant Riemannian distance (Förstner et al., 2000):

$$d_{\text{Riem}}(G_1, G_2) = \left\| \log(G_1^{-1/2} G_2 G_1^{-1/2}) \right\|_F. \quad (8)$$

G_{sentence} is the geometric counterpart of Euclidean mean pooling, a Fréchet-mean point on the SPD manifold rather than an arithmetic mean.

Classification The sentence-level SPD matrices are classified in three steps. First, we apply Riemannian whitening, which rescales each matrix to unit determinant while preserving its affine-invariant geometric properties, removing scale differences across samples. Second, we project each whitened matrix to the tangent space at the population Riemannian mean of the training set. The tangent space at a point on the SPD manifold is a flat Euclidean space, so standard linear classifiers apply. Third, we fit a logistic regression on the vectorised tangent-space representations. We use pyRiemann's (Barachant et al., 2026) `TSClassifier` with default hyperparameters, which implements the projection-plus-linear-classifier pipeline.

3.6 Experimental configuration

All experiments employed 5-fold stratified cross-validation to ensure balanced class distributions across folds, using two seeds. We report the mean and standard deviation across folds to capture performance variability.

Because the classification pipeline reuses established BCI components (e.g., Fréchet mean of SPD matrices, Riemannian whitening, and tangent-space classifier) we adopt the evaluation and statistical protocol of the Mother of all BCI Benchmarks (MOABB) (Aristimunha et al., 2023). Statistical significance was computed independently for each dataset using significance thresholds of $\alpha < 0.05$ and $\alpha < 0.01$. Effect sizes are reported using the standardised mean difference (SMD), and the aggregated meta-effect across datasets is also provided.

4 Experimental results

Table 1 reports two baselines, Linear Probe (Euclidean mean pooling) and CLS Token Aggregation, alongside RMP on the three signal-bearing datasets (CoLA, CREAK, RTE) and the FEVER-Symmetric negative control, with means and standard deviations across the multi-seed cross-

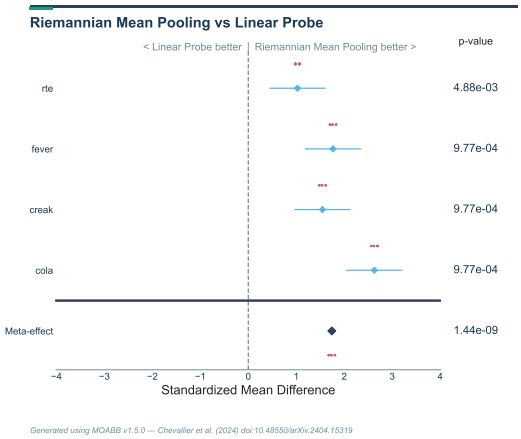

Figure 2: Statistical comparison between Linear Probe and Riemannian Mean Pooling across random seeds. Box plots show the distribution of AUC scores obtained from 10 evaluations (2 seeds $\times$ 5 folds). Corresponding p-values are displayed on the right side of each plot. One (respectively, two and three) red star(s) indicate that the p-value is below the significance threshold of $\alpha < 0.05$ (respectively, $\alpha < 0.01$, $\alpha < 0.001$). FEVER-Symmetric is a negative control (Section 3), so a chance-level result there is the expected behaviour.

validation protocol.

Figure 2 presents forest plot comparing the distribution of AUC scores across all 10 evaluations for each dataset.

Per-dataset AUC, Accuracy, and F1 bar plots together with the CLS-vs-RMP forest plot (Figures 10, 11, 12, 13) are deferred to Appendix C. Figure 2 and Table 1 carry the headline comparison in the body.

The multi-seed meta-analysis shows RMP outperforming both baselines (Linear Probe and CLS Token Aggregation) on CoLA, CREAK, and RTE, the three datasets with classification signal accessible from claim surface. CLS Token Aggregation underperforms Linear Probe on three of four datasets (FEVER, CoLA, CREAK), with RTE the exception (0.611 vs 0.591 AUC). This replicates the observation of Reimers and Gurevych (2019) that vanilla CLS embeddings underperform mean pooling on transfer tasks without task-specific fine-tuning, and provides a second controlled Euclidean baseline against which to measure the Riemannian gain. On FEVER-Symmetric, RMP stays at chance, which is the behaviour expected from a negative control. Its point estimate of 0.507 AUC nominally exceeds 0.5, but it falls well inside the 95 % interval $[0.419, 0.579]$ of a label-permutation null over 10,000 draws (Müller-Putz et al., 2008; Maris and Oostenveld, 2007), at $p = 0.83$ and a standardised mean difference of 0.16, below the conventional threshold for a small effect. The two Euclidean baselines do not stay at chance but fall significantly below it. This is further discussed in Section 6.

5 Decomposing the geometric gain

5.1 Ablation Components

To localise the source of the geometric gain, we ablate the pipeline along two axes: (i) whether the encoder is trained or randomly initialised, and (ii) whether the encoder is the IGL MLP architecture or a simpler random linear projection. **Encoder-Only** projects tokens through the trained IGL encoder and applies Euclidean mean pooling in latent space (no metric extraction), testing whether the encoder alone matters. **Frozen Random IGL** replaces the trained encoder with a randomly initialised MLP of identical architecture (256-d hidden, SiLU) and runs the full geometric pipeline, testing whether encoder training matters. **Random Projection + SiLU** uses a frozen random linear projection $\mathbb{R}^{768} \to \mathbb{R}^{64}$ followed by SiLU, then the full geometric pipeline, testing whether the depth and nonlinearity of the IGL MLP matter even without training.

5.2 Experimental Results

The full ablation table (Table 2) and per-comparison forest/bar plots are deferred to Appendix B, and the qualitative findings are summarised below. In addition, Appendix E reports a further control in which the tangent-space and mean-pooled BERT features are evaluated separately and concatenated under one classifier, and finds that the size of the feature set does not account for the geometric gain.

5.3 Findings

Three patterns emerge from Table 2. First, a randomly initialised encoder recovers most of the geometric gain on every signal-bearing dataset (CoLA 0.760 against 0.782, CREAK 0.667 against 0.685, RTE 0.615 against 0.632), indicating that the geometric aggregation, rather than encoder training, carries most of the gain. Second, the trained encoder adds 1.7 to 2.2 AUC points on all three datasets (paired over folds, CoLA gains $+0.022$ at $p = 0.0002$, CREAK $+0.018$ at $p = 0.004$, and RTE $+0.017$ at $p = 0.024$). Third,

Dataset	Method	Accuracy	F1-Score	AUC
FEVER†	Linear Probe	0.405 ± 0.046	0.426 ± 0.036	0.425 ± 0.029
	CLS Token Aggregation	0.375 ± 0.051	0.398 ± 0.053	0.402 ± 0.052
	Riemannian Mean Pooling	0.494 ± 0.043	0.513 ± 0.044	0.507 ± 0.039
CoLA	Linear Probe	0.675 ± 0.018	0.678 ± 0.017	0.731 ± 0.021
	CLS Token Aggregation	0.661 ± 0.014	0.662 ± 0.016	0.711 ± 0.012
	Riemannian Mean Pooling	$\mathbf{0.711 \pm 0.014}$	$\mathbf{0.723 \pm 0.014}$	$\mathbf{0.782 \pm 0.021}$

	Riemannian Mean Pooling	$\mathbf{0.594 \pm 0.021}$	$\mathbf{0.597 \pm 0.018}$	$\mathbf{0.632 \pm 0.025}$

Table 1: Multi-seed meta-analysis results (mean $\pm$ std across 10 evaluations). †FEVER is included as a negative control (Section 3). Chance-level performance is the expected and correct behaviour, so no method is bolded for this dataset.

the simpler Random Projection + SiLU underperforms the random IGL encoder on every signal-bearing dataset, indicating that the depth and non-linearity of the MLP matter even without training. The FEVER-Symmetric rows are reported for completeness but, by the negative-control framing of Section 3, are not informative about the source of geometric signal.

6 Discussion

6.1 Hypothesis validation

Geometric advantage and what it tests. Riemannian aggregation of token-level pullback metrics outperforms Euclidean mean pooling on the three signal-bearing datasets and stays at chance on the FEVER-Symmetric negative control (Table 1 and Figure 2). The gain is largest on CoLA (ΔAUC $= 0.051$) and similar on RTE and CREAK (0.041 and 0.040). The ablations localise most of this gain to the geometric aggregation rather than to learned manifold structure. RMP with a random encoder already significantly beats Euclidean pooling on CoLA and CREAK, while the trained encoder adds 1.7 to 2.2 AUC points across all three datasets (Table 2, with per-comparison forest plots in Appendix B). Rather than concluding that BERT embeddings lie on a globally coherent manifold, the evidence supports *locally manifold-like structure* (Robinson et al., 2025), under which aggregated geometric features yield classification gains even where global manifold structure fails.

Role of the negative control The inclusion of FEVER-Symmetric (Schuster et al., 2019) serves a methodological purpose distinct from the other three datasets. Where CoLA, CREAK, and RTE probe whether geometric structure encodes specific linguistic properties, FEVER-Symmetric probes whether the method exploits residual signal in the underlying representations.

RMP stays at chance on it, reaching 0.507 against a label-permutation null of 0.500 (10,000 permutations, 95 % interval $[0.419, 0.579]$, $p = 0.83$, SMD 0.16). The two Euclidean baselines perform significantly below chance (Linear Probe reaches 0.425 and CLS Token Aggregation 0.402). This phenomenon is explained by our evaluation protocol combined with dataset construction. By dataset construction, we mean that FEVER-Symmetric pairs most of the claims (228 over 316 rows) with a minimal edit carrying the opposite label. In fact, BERT embeddings place a claim and its twin close together in representation space. Therefore, a classifier that operates on claim-surface features will assign both members of a pair the same predicted label. This is an artifact of our evaluation method. Indeed, under five-fold cross-validation a pair is split across training and test four times out of five, so the classifier is trained on one claim and evaluated on its negation 80% of the time. The member of the pair in the testing set then receives the label of its twin in the training set. This is why both baselines invert on the twinned rows, while RMP staying close to chance is the expected behaviour. Appendix D reports the negative control in full.

What does the pullback metric encode? The random-encoder ablations clarify what the pipeline is actually testing. The pullback met-

ric $g(\mathbf{v}) = (JJ^\top + \epsilon I)^{-1}$ captures the local anisotropy of the encoder map, that is, the extent to which a unit input perturbation at $\mathbf{v}$ is stretched or compressed across latent dimensions. For a random MLP with SiLU nonlinearity, $J(\mathbf{v})$ varies smoothly with $\mathbf{v}$ because of the nonlinearity, even though the encoder weights themselves are random. Consequently $g(\mathbf{v})$ encodes the position of $\mathbf{v}$ in input space through the local Jacobian structure of the random transformation, not through any property the encoder learned. Fréchet aggregation on the SPD manifold then summarises this local-geometry signal into a sentence-level descriptor. The geometric-aggregation gain over Euclidean pooling thus reflects that token positions in BERT embeddings carry classification signal in their local nonlinear-transformation structure, which Euclidean averaging discards.

6.2 Limitations and challenges

Computational cost. On top of one-time IGL training, each sentence requires a per-token Jacobian and an SPD Fréchet-mean iteration, an order of magnitude more arithmetic than Euclidean pooling, though still negligible against LLM inference or gradient-based fine-tuning. Exact wall-clock and FLOP figures are reserved for a scaling study.

Hyperparameter and architectural scope. Our encoder-width and anchor-count sweep was conducted only on FEVER-Symmetric, so sensitivity on the signal-bearing datasets and to the metric regulariser λ is unverified. The encoder objective itself was held fixed at IGL. Alternative objectives that also yield a Jacobian (vanilla autoencoders, VAEs, normalising flows, contrastive encoders) were not swept, although the random-encoder ablation already suggests the specific objective is largely transparent on most tasks.

Scope of the controlled comparison. The pipeline was evaluated against Euclidean and CLS-token baselines on a single encoder (BERT-base) at a single layer (layer 9) and a fixed projection dimensionality. This is a deliberate methodological choice. The comparison isolates the contribution of geometric aggregation on identical embeddings, which is why fine-tuned BERT and Sentence-BERT (Reimers and Gurevych, 2019) are excluded rather than missing. Absolute classification performance is not the question this paper investigates. The question is whether geometric aggregation extracts signal that flat-Euclidean pooling discards.

6.3 Future work

Architecture and layer coverage. Extending the evaluation to larger and structurally different encoders (RoBERTa, DistilBERT, decoder-only LLMs) and across layers would clarify whether the geometric-aggregation gain is general or specific to BERT-base layer 9, and whether the layer-wise intrinsic-dimension trajectory (Valeriani et al., 2023; Cheng et al., 2025) interacts with where the pullback metric becomes informative.

Richer SPD descriptors. The Fréchet mean is the simplest aggregator on the SPD manifold. Weighted Fréchet means, trajectory-based descriptors in the spirit of layer-wise geometric probes (Damirchi et al., 2026; Mir, 2025), and explicit curvature features are natural next steps, with per-token pullback eigenvalues offering a route to relate the geometric signal to interpretable linguistic phenomena.

7 Conclusion

The SPD Fréchet mean of per-token pullback metrics beats Euclidean mean pooling on CoLA, CREAK and RTE under a controlled comparison on identical embeddings. On FEVER-Symmetric, included as a negative control, it correctly stays at chance. Random-encoder ablations localise most of the gain to the geometric aggregation rather than to learned manifold structure, with the trained encoder contributing a further 1.7 to 2.2 AUC points on every signal-bearing dataset. Together these results support the framing of embeddings as locally manifold-like rather than globally coherent (Robinson et al., 2025), under which aggregated geometric features yield classification gains even where global manifold structure may fail.

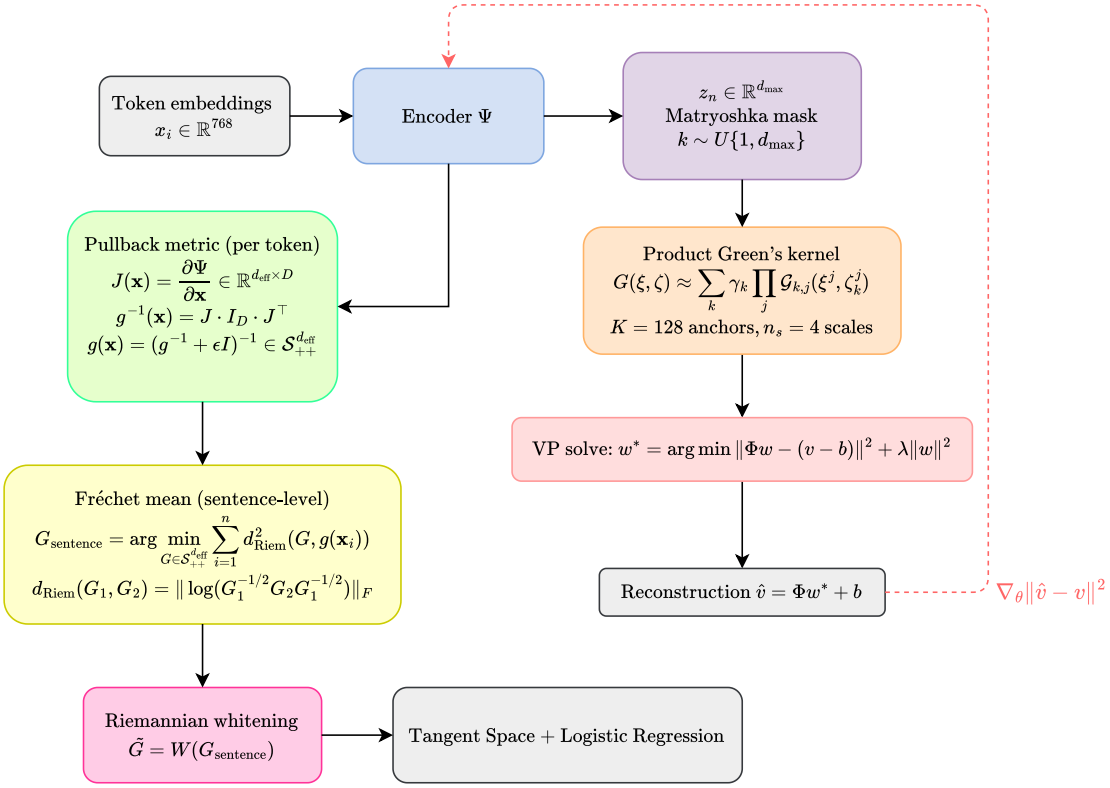

Figure 3: Detailed architecture of token-level IGL for sentence classification via RMP. **Right path (reconstruction):** Token embeddings $\mathbf{v}_i \in \mathbb{R}^{768}$ are encoded to latent space $\mathbf{z} \in \mathbb{R}^{d_{\max}}$ via encoder Ψ_θ, then mapped through Product Green's kernel $G(\xi, \zeta)$ to design matrix Φ. Variable projection (VP) solves for optimal weights $w^* = \arg\min_w \|\Phi w - (y - b)\|^2 + \lambda \|w\|^2$ to reconstruct input $\hat{\mathbf{v}} = \Phi w^* + b$. **Left path (classification):** The trained encoder's Jacobian $J = \frac{\partial \Psi_\theta}{\partial \mathbf{v}}$ induces pullback metrics $g(\mathbf{v}_i) \in \mathcal{S}_{++}^{d_{\max}}$ at each token. These are aggregated via Fréchet mean to sentence-level SPD matrix G_{sentence}, preprocessed with Riemannian whitening, projected to tangent space, vectorised, and classified with logistic regression. **Solid arrows:** forward flow. **Dashed red arrow:** reconstruction-loss gradient $\nabla_\theta \|\hat{\mathbf{v}} - \mathbf{v}\|^2$ flowing back to encoder Ψ_θ. The encoder is trained jointly with VP solve until reconstruction converges (early stopping with patience=50, $\delta = 2 \times 10^{-5}$), then frozen for metric extraction and classification.

A IGL architecture details

This appendix collects the architectural details of the IGL configuration used in Section 3.3.

Encoder and Matryoshka Truncation A small MLP encoder $\Psi_\theta : \mathbb{R}^D \to \mathbb{R}^{d_{\max}}$ maps input to latent codes $\xi_n = \Psi_\theta(v_n)$ with $d_{\max} = 64$. During training, a random truncation $k \sim \text{Uniform}\{1, \ldots, d_{\max}\}$ is sampled and trailing coordinates zeroed out, following Matryoshka representation learning (Kusupati et al., 2022). This ensures earlier dimensions capture the most informative features, with effective dimension $d_{\max}$ determined post-training from the dimension-loss curve.

Product Green's Kernel The reconstruction target is the input v_n itself. We model the reconstruction by a tensor-factorised product Green's kernel:

$$G(\xi, \zeta) \approx \sum_{k=1}^{K} \gamma_k \prod_{j=1}^{d_{\max}} G_{k,j}(\xi_j, \zeta_j), \quad K = n_{\text{anchors}} = 128 \tag{9}$$

Each factor $G_{k,j}$ is a one-dimensional kernel evaluated at the latent coordinate ξ^j and an anchor ζ_k^j, with K anchors placed adaptively. We use Gaussian kernel factors. Each factor is itself a convex mixture of $n_{\text{scales}} = 4$ Gaussian basis functions at learnable bandwidths $\sigma_{s,j}$,

Table 2: Ablation study results (mean ± std across 10 evaluations). Bold indicates best per dataset. F1 is omitted from this table (tracks Accuracy closely on binary tasks). The full Accuracy/F1/AUC table is in Table 1, which is drawn from the same run, so the rows the two tables share are identical by construction. †FEVER is included as a negative control (Section 3). Rows are reported for completeness but are not informative about the source of geometric signal, so no method is bolded.

$$G_{k,j}(\xi_j, \zeta_j^k) = \sum_{s=1}^{4} \alpha_s \exp\left(-\frac{(\xi_j - \zeta_j^k)^2}{2\sigma_{s,j}^2}\right),$$
$$a = \text{softmax}(\cdot) \tag{10}$$

Variable-Projection Reconstruction Each minibatch solves bias-centered ridge regression for weights, with $\lambda = 10^{-3}$:

$$w^* = \arg\min_w \|\Phi w - (v - b)\|^2 + \lambda \|w\|^2 \tag{11}$$

The design matrix Φ costs $O(NKd)$ to compute, while the closed-form solve is $O(NK^2 + K^3)$ and independent of d. Weights w^* are recomputed per minibatch (not stored), so gradient descent operates only on encoder parameters θ.

C Additional results figures

The per-dataset AUC, Accuracy, and F1 bar plots together with the CLS-vs-RMP forest plot are deferred here. The body keeps the headline Linear-Probe-vs-RMP forest plot (Figure 2) and Table 1 as the main visualisations.

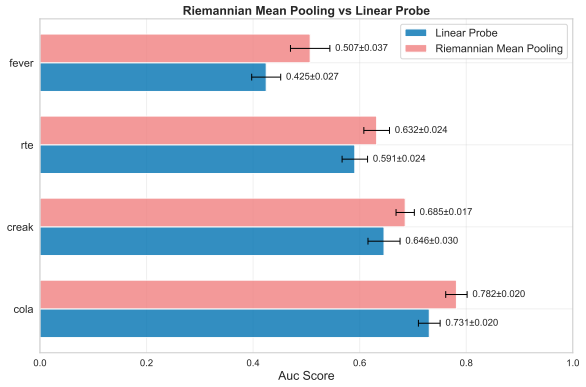

Figure 10: Multi-seed AUC comparison across datasets.

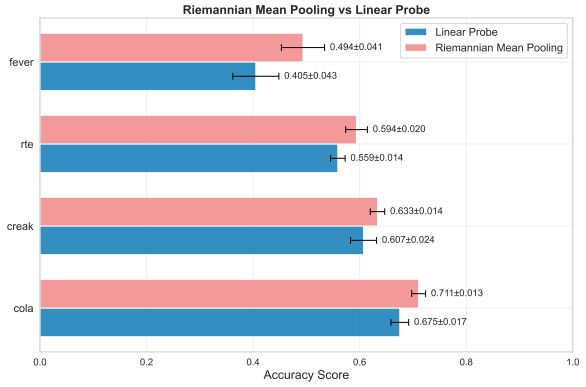

Figure 11: Multi-seed accuracy comparison across datasets. Error bars represent standard deviation across 10 evaluations.

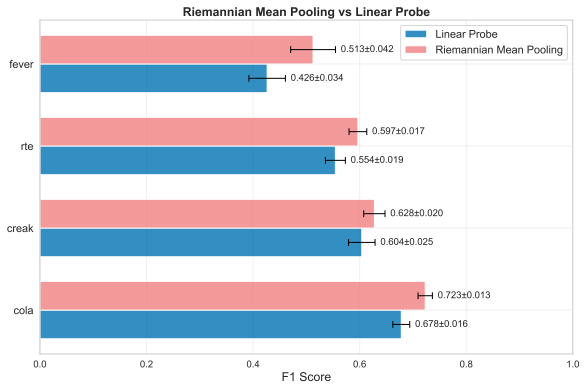

Figure 12: Multi-seed F1-score comparison across datasets.

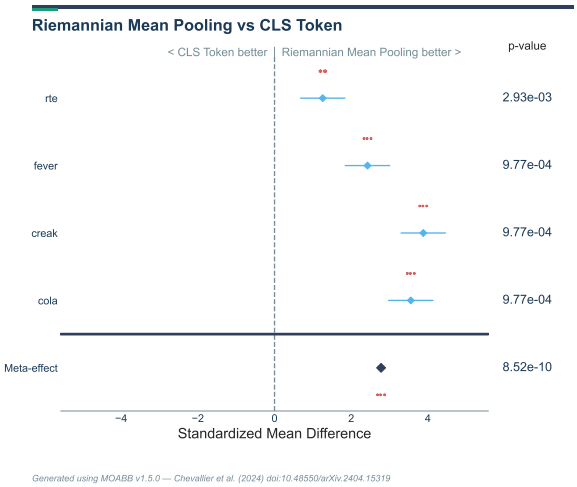

Figure 13: Statistical comparison between CLS Token Aggregation and RMP across random seeds. Box plots show the distribution of AUC scores from 10 evaluations (2 seeds $\times$ 5 folds). Effect sizes are reported using SMD. FEVER-Symmetric is included as a negative control (Section 3). A chance-level result is the expected and correct behaviour for both methods.

D The FEVER-Symmetric twin split

FEVER-Symmetric was built to remove the annotation artifacts of the original FEVER. Each claim is paired with a minimal edit of itself that carries the opposite label. The edit is sometimes a negation and more often a replaced noun or date, as in *founded in 1971* against *founded in 1991*, or *the football championship of Africa* against *the football championship of Asia*. Explicit negation words appear in only 22 of the 316 claims, so most pairs differ by a substitution rather than by a negation. A detector that relies on explicit negation alone has almost nothing to fire on and reaches 0.543 AUC, close to chance, so the pairing leaves no lexical shortcut to the labels.

Schuster et al. (2019) do not release the pair index, so we recover the pairing from claim text and treat it as an approximation. We obtain the pairings by matching each row to its opposite-label nearest neighbour at Jaccard overlap ≥ 0.6, yielding 114 pairs (228 rows). The remaining 88 rows have no partner and no debiasing guarantee. The threshold is an arbitrary choice: 0.4, 0.5, and 0.7 yield 292, 282, and 168 paired rows respectively.

Method	All (316)	Twinned (228)	Untwinned (88)
Linear Probe	0.425	0.357	0.601
CLS Token	0.402	0.332	0.594
Riemannian Mean Pooling	0.509	0.445	0.662

Table 3: FEVER-Symmetric split by whether a row has an opposite-label twin (AUC, mean across 10 evaluations). All three methods share the fold structure. Five-fold cross-validation separates a pair four times in five, so a method that relies on claim-surface features is trained on one member and evaluated on the other. The RMP rows come from the permutation run reported in this appendix rather than from the run behind Table 1, so the full-set value reads 0.509 here against 0.507 there, a gap well inside the fold-to-fold standard deviation of 0.039. The baseline rows are the same in both.

Inversion on the twinned rows Both Euclidean baselines fall far below chance on the rows that carry a twin, to 0.357 and 0.332, and rise above it on the rows that do not, to 0.601 and 0.594. This difference of 0.25 AUC between two halves of the same dataset under the same model is consistent with the pairing construction, not with a property of the claims themselves.

Riemannian Mean Pooling on the twinned rows RMP also sits below chance on the twinned rows, at 0.445, so it is not immune, yet it is significantly less affected. Paired over the 10 evaluations it exceeds Linear Probe by 0.088 ($t = 4.63$, $p = 0.001$) and CLS Token Aggregation by 0.113 ($t = 7.87$, $p = 2.5 \times 10^{-5}$) on those rows. On the untwinned rows the three methods lie within 0.07 of each other and the differences are not significant. The full-set reading of 0.509 falls between the two halves, weighted towards the 228 twinned rows against the 88 untwinned.

Residual signal in the Encoder-Only ablation The Encoder-Only ablation is the one method above chance on the full set, at 0.537 ± 0.036 ($p = 0.009$). It pools the trained encoder's coordinates in latent space rather than reading its Jacobian. The FEVER-Symmetric construction (Schuster et al., 2019) targets surface features arising from the annotation process and does not target all model-accessible content, and BERT encodes substantial world knowledge through pretraining, so a Euclidean classifier over learned coordinates can detect a small residual signal. That signal is not specific to the geometric pipeline. In fact, on the untwinned rows the Linear Probe reaches 0.601, so the content the debiasing leaves behind is accessible to mean pooling as well.

E Feature concatenation

A natural question is whether the geometric gain is a consequence of feature count. The tangent-space descriptor has 2080 coordinates against the 768 of a mean-pooled BERT vector, so a larger budget alone might account for it. Table 4 evaluates the two feature sets separately and concatenated, under one classifier. As in Table 2, the FEVER-Symmetric rows are reported for completeness and carry no information here, since no method on that dataset is expected to exceed chance. The comparisons below are over the three signal-bearing datasets.

Dataset	Features (d)	AUC
FEVER	BERT only (768)	0.425 ± 0.029
	Tangent space (2080)	0.401 ± 0.059
	Both (2848)	0.413 ± 0.035
CoLA	BERT only (768)	0.731 ± 0.021
	Tangent space (2080)	0.740 ± 0.013
	Both (2848)	0.757 ± 0.020
CREAK	BERT only (768)	0.646 ± 0.032
	Tangent space (2080)	0.615 ± 0.031
	Both (2848)	0.626 ± 0.035
RTE	BERT only (768)	0.591 ± 0.025
	Tangent space (2080)	0.592 ± 0.018
	Both (2848)	0.599 ± 0.026

Table 4: Feature concatenation on the whitened SPD descriptors (AUC, mean $\pm$ std across 10 evaluations). All three feature sets use the same standardised logistic regression, so the rows are comparable to each other. They are *not* comparable to the Riemannian Mean Pooling rows of Table 2, which use pyRiemann's `TSClassifier` (tangent space followed by logistic regression, with no per-coordinate scaler). The BERT-only row is the Linear Probe of Table 1, recomputed here as one half of the comparison, and reproduces it exactly.

The largest feature set leads on CoLA and RTE while the smallest leads on CREAK, so the ordering is not monotone in the size of the feature set. With the classifier held fixed, more coordinates buy nothing consistent. Nearly three times as many gain $+0.009$ on CoLA ($p = 0.16$) and $+0.001$ on RTE ($p = 0.93$) while losing 0.031 on CREAK ($p = 0.04$). In other words, AUC does not follow feature count.

Against the BERT-only features, concatenation gains $+0.027$ AUC on CoLA ($p = 0.0002$), loses 0.019 on CREAK ($p = 0.03$), and does not move

RTE ($+0.008$, $p = 0.13$). It is inconsistent in the same way, therefore we do not treat concatenation as a component of the method.

F Reconstruction convergence

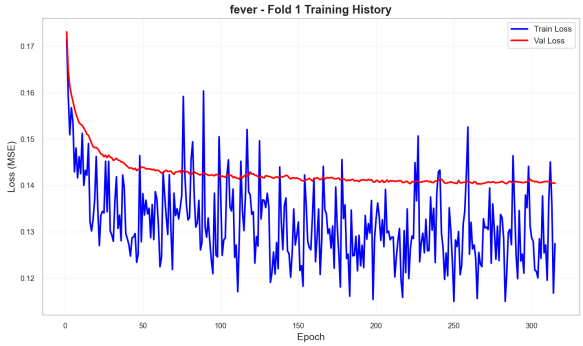

Figure 14: Training (blue) and validation (red) reconstruction MSE for the IGL encoder on fold 1 of FEVER-Symmetric, over $\sim$310 epochs. The validation curve decreases monotonically from $\sim$0.17 to $\sim$0.14. This is representative of all folds and datasets.

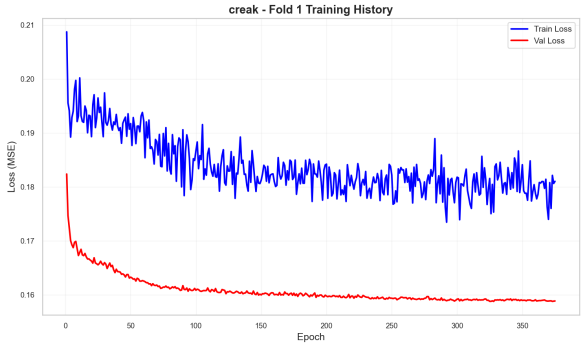

Figure 15: Training (blue) and validation (red) reconstruction MSE for the IGL encoder on fold 1 of CREAK, over $\sim$375 epochs. The validation curve decreases from $\sim$0.182 to $\sim$0.159.

G Immersion

Equation (5) treats Ψ_θ as a submersion. An alternative is to restrict it to the data manifold $M \subset \mathbb{R}^{768}$ of dimension $m < d_{\max}$, which makes it an immersion and to replace (5) with

$$g^{-1}(\mathbf{v}) = J(\mathbf{v})\, P_M\, J(\mathbf{v})^\top, \qquad (12)$$

where P_M projects onto $T_{\mathbf{v}}M$. We estimate P_M from the reconstruction readout as $J_R J_R^+$. This appendix reports what (12) does to the descriptor. All runs are paired on fold, seed and encoder draw. They share one trained encoder per fold and differ only in the projector P_M.

Dimension estimates No estimator we ran returned a stable dimension for layer-9 token embeddings, so m is a choice rather than a measurement and the immersion variant is not identified by the data. TwoNN falls with sample size (14.2, 13.2, 10.3 at $n = 1000, 2000, 5000$). Maximum-likelihood estimates run 10.6 to 16.1 as k goes from 5 to 50, while local PCA runs 17, 29, 48, 69 as k goes from 25 to 200 at $n = 5000$ and does not agree across sample sizes. As a control we run the same estimators on a 2-torus embedded in $\mathbb{R}^{768}$, a surface of known dimension 2, where local PCA is flat at 2.0 for every k. The Matryoshka reconstruction curve, the estimator inherent to IGL, has no elbow. Figure 16 plots TwoNN, local PCA and the Matryoshka curve.

Choice of m and variants measured We set $m = 16$, which is a choice informed by the estimators rather than one derived from them. It is the top of the range where the only two estimators that agree with each other land, TwoNN at 10.3 to 14.2 across sample sizes and the maximum-likelihood estimate at 10.6 to 16.1 across k. The Matryoshka elbow detector returns 3 on a smooth monotone curve, which the gate rejects, and local PCA spans 17 to 69. We characterised the geometry at $m \in \{8, 16, 32, 48, 64\}$ and measured AUC at $m = 16$ alone, on CoLA (layer 9, 2 seeds $\times$ 5 folds, trained IGL encoder). Table 5 reports AUC, the numerical rank of g^{-1} before regularisation, and the fraction of J's Frobenius mass inside each run subspace (overlap). A sixth variant, RANK_ROT, draws an independent rank-m projector at each token. We omit it from the table because it collapses the Fréchet mean for reasons unrelated to the direction of the projection, which is the comparison RANK_FIXED isolates by holding one projector fixed across tokens.

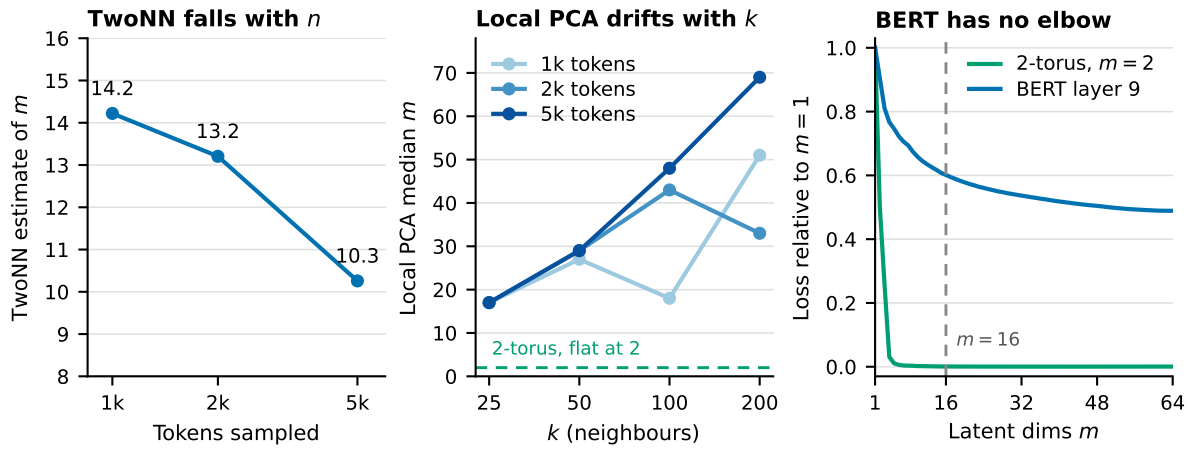

Figure 16: Stage 1 dimension estimates on CoLA layer-9 token embeddings (seed 67). **Left:** TwoNN falls as the sample grows, so it has not converged by $n = 5000$. **Centre:** the local PCA median rises with the neighbourhood size k and does not agree across sample sizes, while the same estimator returns 2.0 at every k on the torus control (dashed). **Right:** Matryoshka reconstruction loss against latent width, each curve divided by its own $m = 1$ value because the two absolute losses differ by two orders of magnitude. The torus curve reaches its floor by $m = 4$, while the BERT curve decays smoothly with no elbow to locate. We set $m = 16$ (dashed) for the variants in Table 5.

Arm	AUC	Rank	Overlap
BASELINE	0.783	64	1.000
IMMERSION	0.774	40	0.408
IMMERSION_TRUNC	0.776	16	0.089
RANK_FIXED	0.784	16	0.023
IMMERSION_LOCALPCA	0.710	16	0.040

Table 5: Immersion variants on CoLA ($m = 16$, $n = 10$ folds). The projector P_M is the identity for BASELINE, $J_R J_R^+$ for IMMERSION, the top-m singular directions of J_R for IMMERSION_TRUNC, a random shared rank-m subspace for RANK_FIXED, and an encoder-free local PCA estimate for IMMERSION_LOCALPCA. Rank is the numerical rank of (12) before regularisation. Overlap is the fraction of J's Frobenius mass inside the variant's subspace.

Comparison of the rank-16 variants The decisive comparison is IMMERSION_TRUNC against RANK_FIXED. Both restrict to rank 16, but one uses the decoder's top-m singular directions and the other an arbitrary fixed subspace. RANK_FIXED ties the baseline ($|\Delta\,\mathrm{AUC}| < 0.001$, $p = 0.95$). IMMERSION_TRUNC sits below it ($\Delta\,\mathrm{AUC} = -0.007$, $t = -2.38$, $p = 0.041$, uncorrected over the variant contrasts), so an arbitrary subspace of the same rank does as well as the decoder's. The encoder-free tangent estimate (IMMERSION_LOCALPCA) is 0.074 below baseline, and its overlap with J_R's column space is 0.040 against 0.023 for the random rank-16 control, so the two estimates of $T_{\mathbf{v}}M$ are near-orthogonal.

Rank of the immersion variant The rank column of Table 5 should be read with the same caution as m. J_R has no spectral gap. Its singular values decay smoothly from 26.4 to 2.7 (a condition number of 9.6), and the largest ratio between consecutive values anywhere in the spectrum is 1.2. Counting the directions that carry 90% of the energy gives 38, counting the values above numerical zero gives 64, and a second run of the same variant on the same dataset reports 64 where the run in Table 5 reports 40. On the torus control the same estimator leaves no such ambiguity, with 3 directions carrying 90% of the energy and a factor of 1.1×10^4 between the fifth and sixth singular values. The decoder's estimate of the tangent space is therefore no better identified than m is, which is consistent with the projector making no difference to AUC.

Numerical conditioning In `float32` the metrics lose positive-definiteness on rank-deficient matrices of this kind. Eigenvalues reach -2.2×10^{-7} against machine epsilon 1.2×10^{-7}. In such a scenario eigenvalues are numerically zero within arithmetic precision. While the regularised matrix is practically invertible, the regulariser dominates, and all variants tie for numerical reasons. We therefore perform the inversion in `float64`, where the regularisation fire rate is 0.0% across ev-

ery run and every m. The lack of improvement reflects geometry rather than numerical breakdown.

Restricting the metric to an estimated manifold therefore does not help, and since neither m nor $T_{\mathbf{v}}M$ is identified on these embeddings, we report the submersion metric of (5) throughout.

Trust but Verify: Introducing DAVinCI - A Framework for Dual Attribution and Verification in Claim Inference for Language Models

Vipula Rawte[1]*, **Ryan Rossi**[2], **Franck Dernoncourt**[2], **Nedim Lipka**[2]

vrawte@adobe.com

Abstract

Large Language Models (LLMs) have demonstrated remarkable fluency and versatility across a wide range of NLP tasks, yet they remain prone to factual inaccuracies and hallucinations. This limitation poses significant risks in high-stakes domains such as healthcare, law, and scientific communication, where trust and verifiability are paramount. In this paper, we introduce **DAVinCI** - a Dual Attribution and Verification framework designed to enhance the factual reliability and interpretability of LLM outputs. DAVinCI operates in two stages: (i) it attributes generated claims to internal model components and external sources; (ii) it verifies each claim using entailment-based reasoning and confidence calibration. We evaluate DAVinCI across multiple datasets, including FEVER and CLIMATE-FEVER, and compare its performance against standard verification-only baselines. Our results show that DAVinCI significantly improves classification accuracy, attribution precision, recall, and F1-score by **5-20%**. Through an extensive ablation study, we isolate the contributions of evidence span selection, recalibration thresholds, and retrieval quality. We also release a modular DAVinCI implementation that can be integrated into existing LLM pipelines. By bridging attribution and verification, DAVinCI offers a scalable path to auditable, trustworthy AI systems. This work contributes to the growing effort to make LLMs not only powerful but also accountable. Our code is available at https://github.com/vr25/davinci.

1 Introduction

The rapid proliferation of large language models (LLMs) has revolutionized natural language generation, enabling systems to produce fluent and contextually rich text across diverse domains. However, this fluency often masks a critical vulnerability: the tendency of LLMs to generate factually incorrect or hallucinated content (Rawte et al., 2023a,b; Liu et al., 2024). As LLMs become increasingly embedded in high-stakes applications - such as scientific writing, journalism, and legal analysis - the need for robust factuality verification has become paramount (Thorne and Vlachos, 2018; Jaradat et al., 2018; Augenstein et al., 2019; Elsayed et al., 2019; Dmonte et al., 2025).

Recent studies have highlighted the limitations of LLMs in maintaining factual consistency, especially when responding to open-ended prompts or synthesizing information from multiple sources (Rahman et al., 2025). To address this, researchers have explored various verification pipelines, including retrieval-augmented generation (RAG) (Lewis et al., 2021), entailment-based classifiers, and attribution-aware filtering. Yet, most existing systems treat attribution and verification as isolated components, failing to capture the nuanced interplay between evidence selection and entailment reasoning.

To address these limitations, we propose **DAVinCI** - a Dual Attribution and Verification framework for trustworthy LLMs. DAVinCI operates in two stages: (i) it attributes claims to internal model components and external sources; (ii) it verifies each claim using entailment-based reasoning and confidence calibration. This dual approach enables LLMs to not only generate claims but also justify and validate them in a transparent and auditable manner.

This approach builds on insights from recent benchmarks such as FactBench (Bayat et al., 2025), which categorize hallucination-prone prompts and evaluate factuality across difficulty tiers. It also aligns with broader efforts to characterize and correct factual errors in LLM outputs. Moreover, DAVinCI's modular design allows researchers to isolate and evaluate the impact of attribution quality, verification robustness, and calibration sensitiv-

*Work done while the first author was an intern at Adobe Research

ity - three pillars increasingly recognized as essential for trustworthy AI systems.

In this paper, we present a comprehensive evaluation of DAVinCI across multiple entailment models and attribution configurations. We demonstrate that full-passage evidence consistently improves verification accuracy and F1-score, while confidence recalibration enables flexible trade-offs between precision and recall.

Our main **contributions** are as follows:

- DAVinCI, a modular framework that integrates attribution and verification into LLM inference.
- We conduct an ablation study to isolate the impact of evidence span selection, recalibration thresholds, and retrieval quality.
- We release a reproducible implementation of DAVinCI to support future research in trustworthy NLP.

2 Related Work

The challenge of ensuring factual correctness in natural language generation has led to a growing body of research in claim verification, retrieval-augmented generation, and model attribution. Early work in automated fact-checking focused on datasets such as FEVER (Thorne et al., 2018), which introduced the task of verifying claims against evidence retrieved from Wikipedia. Subsequent efforts like CLIMATE-FEVER (Diggelmann et al., 2020) extended this paradigm to other domains, emphasizing the need for domain-specific reasoning and evidence selection.

Retrieval-Augmented Generation (RAG) frameworks (Lewis et al., 2021) have emerged as a popular solution for grounding LLM outputs in external sources. These models combine dense retrievers with generative architectures to produce fluent, evidence-aware responses. However, most RAG systems treat retrieval and generation as loosely coupled stages, without explicit verification of factual consistency. Recent work has attempted to address this gap through hybrid models that incorporate entailment classifiers or post-hoc verification modules (Shuster et al., 2022).

Attribution in LLMs remains an underexplored area. While Attributable QA (Liu et al., 2023) have begun to formalize attribution as a structured task, but these approaches are often limited to specific domains or require extensive supervision.

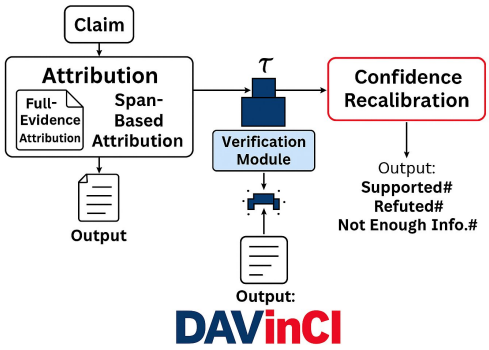

Figure 1: The pipeline begins with a **claim input**, which is fed to the **attribution module**. This module retrieves supporting evidence using either **full-passage attribution** or **span-based attribution**. The resulting **evidence output** is then evaluated by a transformer-based **verification module**, producing a label in {Supported, Refuted, Not Enough Info} with confidence $s \in [0, 1]$. A **confidence recalibration** step applies a threshold τ that downgrades low-confidence predictions to Not Enough Info#. The **final output** is a calibrated label (Supported#, Refuted#, or Not Enough Info#) suitable for downstream fact-checking tasks.

Confidence calibration has also gained traction as a means of improving trust in model predictions. Techniques such as temperature scaling (Guo et al., 2017) and trust-aware scoring (Jiang et al., 2021) aim to align model confidence with prediction reliability. In the context of claim verification, calibrated confidence can help distinguish between supported, refuted, and uncertain claims - a capability that is central to our DAVinCI framework.

Our work builds on these foundations by integrating attribution and verification into a unified pipeline. Unlike prior approaches that treat these components independently, DAVinCI leverages attribution to inform verification and uses calibrated confidence to produce interpretable and trustworthy outputs. To our knowledge, this is the first framework to combine internal and external attribution with entailment-based verification.

3 Proposed Method

The DAVinCI framework is designed to enhance the factual reliability of LLM outputs by integrating two complementary stages: Attribution and Verification. This section details the architecture, components, and workflow of DAVinCI, along with the rationale behind key design choices.

DAVinCI operates in a two-stage pipeline:

1. **Attribution:** Given a claim, the framework identifies relevant evidence from internal or external sources that could plausibly support or refute the claim.

2. **Verification:** The attributed evidence is then passed to an entailment-based verifier that classifies the claim as Supported, Refuted, or Not Enough Information (NEI), optionally applying confidence recalibration.

This dual structure allows DAVinCI to not only assess the truthfulness of a claim but also provide interpretable justifications grounded in evidence. Here is an example from the FEVER dataset showing a claim, the evidence behind it, and its label.

CLAIM: Caroline Kennedy is American.

EVIDENCE: Caroline Bouvier Kennedy (born November 27, 1957) is an American author, attorney, and diplomat who served as the United States Ambassador to Japan from 2013 to 2017.

LABEL: ENTAILMENT

Let c be a claim generated by a language model, and let $\mathcal{E} = \{e_1, e_2, \ldots, e_n\}$ be a set of retrieved evidence passages.

3.1 Attribution Module

The attribution module is responsible for identifying the most relevant evidence for a given claim. We explore two strategies:

Full Evidence Attribution: In datasets like FEVER and CLIMATE-FEVER, gold-standard evidence is available. We use the full evidence text directly without modification.

Span-Based Attribution: We simulate a retrieval scenario by using a question-answering (QA) model (`deepset/roberta-base-squad2-distilled`[1]) to extract the most relevant span from the evidence given the claim as a question. This mimics real-world settings where only partial evidence may be accessible.

This module can be extended to incorporate dense retrievers (e.g., DPR, E5) or hybrid retrieval systems in future work.

3.1.1 Attribution Scoring

Given a claim c and a set of evidence passages $\{e_1, e_2, \ldots, e_n\}$, we compute attribution scores using either full-evidence or span-based retrieval:

$$\text{Score}_{\text{attr}}(c, e_i) = \text{sim}(c, e_i)$$

where $\text{sim}(\cdot)$ is a similarity function such as cosine similarity or dense retriever score.

3.2 Verification Module

The verification module takes the claim and attributed evidence as input and outputs a label from Supported, Refuted, Not Enough Information. We use a transformer-based entailment classifier model trained on multiple NLI datasets.

Input Format
`[Claim] [SEP] [Attributed Evidence]`

The model outputs a label and a confidence score. This score is used in downstream calibration.

Each claim-evidence pair (c, e_i) is passed to an entailment classifier f_{ver} that outputs a label $y \in \{\text{Supported}, \text{Refuted}, \text{Not Enough Info}\}$ and a confidence score $s \in [0, 1]$:

$$(y, s) = f_{\text{ver}}(c, e_i)$$

3.3 Confidence Recalibration

To mitigate overconfidence and improve trustworthiness, we apply a simple threshold-based recalibration. If the model's confidence score is below a threshold τ (default: 0.6), the prediction is overridden to NEI. This reflects epistemic uncertainty and aligns with human fact-checking behavior.

To reduce overconfident misclassifications, we apply a threshold τ to the confidence score s. The final output label $y^{\#}$ is defined as:

$$y^{\#} = \begin{cases} y & \text{if } s \geq \tau \\ \text{Not Enough Info}^{\#} & \text{otherwise} \end{cases}$$

Final Decision For multiple evidence passages, we aggregate verification scores and labels using majority voting or weighted averaging:

$$y_{\text{final}} = \text{Aggregate}(\{y_1^{\#}, y_2^{\#}, \ldots, y_n^{\#}\})$$

4 Experiments

4.1 Dataset

We assess DAVinCI using two prominent datasets for claim verification: FEVER[2] and CLIMATE-FEVER[3]. Both datasets offer annotated claims, supporting evidence, and ground-truth labels, making

[3] https://huggingface.co/datasets/rexarski/climate_fever_fixed

Class label	FEVER	CLIMATE-FEVER
ENTAILMENT / SUPPORTS	792	375
CONTRADICTION / REFUTES	812	164
NEUTRAL / NOT_ENOUGH_INFO	683	996
Total	**2287**	**1535**

Table 1: Class label distribution in the FEVER and CLIMATE-FEVER datasets

them well-suited for evaluating attribution and verification workflows.

FEVER: A curated subset of the original FEVER dataset, featuring claims categorized as contradiction, entailment, or neutral, accompanied by verified evidence sentences sourced from Wikipedia.

CLIMATE-FEVER: A domain-specific fact-checking dataset focused on climate change. It includes claims extracted from scientific literature, paired with abstracts and rationale spans. Labels are assigned as Supported, Refuted, or Not Enough Information (NEI). The accompanying table outlines dataset statistics and class distribution.

Both datasets provide gold-standard evidence, enabling the evaluation of both full-evidence and span-level attribution techniques. Table 1 shows the datatset distribution.

4.2 Baselines

To assess the effectiveness of our proposed approach, we conducted a comprehensive evaluation against several state-of-the-art Natural Language Inference (NLI) models. Specifically, we benchmarked our method against the following models which are widely recognized for their strong performance in language understanding tasks.

1. `microsoft/deberta-large-mnli`[4]
2. `FacebookAI/roberta-large-mnli`[5]
3. `facebook/bart-large-mnli`[6]
4. `ynie/roberta-large-snli_mnli_fever_anli_R1_R2_R3-nli`[7]

The comparison was carried out on the verification entailment task, allowing us to measure how well each model identifies and validates factual relationships within textual data.

We compare DAVinCI against a standard verification-only baseline:

- **Baseline:** Verifier-only using full evidence.
- **DAVinCI-Recalibrated:** QA span + verification + recalibration (with τ=0.6).

This setup allows us to isolate the impact of attribution quality and confidence calibration.

4.3 Implementation Details

All experiments were performed on an Apple MacBook equipped with the M4 chip, 32GB of RAM, and a 10-core CPU - offering a robust and energy-efficient setup optimized for high-performance computing. We used the Hugging Face Transformers library[8] for all models. We deliberately selected models and datasets under the `MIT license` to ensure safer and more straightforward reproducibility.

4.4 Main results

Tables 2 and 3 show the main results for performance of DAVinCI on both FEVER and CLIMATE-FEVER datasets. The performance comparison between baseline and Davinci-enhanced models reveals consistent improvements across all metrics. For the `deberta-large-mnli model`, Davinci boosts accuracy from 0.42 to 0.48, with macro F1-score rising from 0.36 to 0.41. Similarly, the `roberta-large-mnli` model sees its accuracy increase from 0.36 to 0.44, and macro F1-score from 0.30 to 0.38. The `bart-large-mnli` model also benefits, with accuracy improving from 0.42 to 0.43 and macro F1-score from 0.36 to 0.37. Lastly, the `roberta-large-snli` model shows gains in accuracy (0.38 to 0.42) and macro F1-score (0.34 to 0.40).

Across all models, Davinci integration leads to higher precision, recall, and F1-scores in both macro and weighted averages. The `deberta-large-mnli` model under Davinci achieves the highest macro precision (0.61) and weighted precision (0.62), indicating strong overall classification performance. Even models with lower baseline scores, like `roberta-large-mnli`, show notable improvements under Davinci, suggesting that the enhancement consistently elevates model robustness and reliability. These

		weighted avg	**0.63**	**0.63**	**0.57**	
	bart-large-mnli	macro avg	0.52	0.43	**0.39**	**0.6**
		weighted avg	0.61	**0.6**	**0.54**	
	roberta-large-snli	macro avg	**0.61**	**0.39**	**0.38**	**0.66**
		weighted avg	**0.65**	**0.66**	**0.56**	

Table 3: **CLIMATE-FEVER dataset:** Comparison of DAVinCI's performance with baseline verification, reporting macro and weighted averages for F1 score, precision, and recall across the three classification categories: entailment, contradiction, and neutral. Accuracy is also provided for all four language models. Top-performing results are indicated in bold.

results underscore Davinci's effectiveness in refining natural language inference tasks across diverse transformer architectures.

5 Ablation Study

We conduct an ablation study to evaluate the impact of individual components by comparing full evidence Tables 4 and 5, span-based evidence, and varying threshold settings (0.7, 0.8, 0.9) Tables 6 and 7, enabling us to measure how each design choice influences performance and trustworthiness.

5.1 DAVinCI with *full* evidence

The full-evidence variant consistently outperforms the span-based counterpart across all metrics. Among four entailment models, `roberta-large-snli` leads with 0.48 accuracy, macro F1, and weighted F1, showing balanced class performance. `deberta-large-mnli` excels in macro precision (0.57) and weighted precision (0.58), indicating confident predictions. All full-evidence models maintain macro and weighted F1-scores above 0.37, with recall between 0.44 and 0.49, highlighting improved class balance and semantic grounding. For CLIMATE-FEVER, full-evidence models again perform best. `roberta-large-snli` achieves 0.65 accuracy and 0.57 weighted F1. `deberta-large-mnli` and `roberta-large-mnli` follow with 0.61 accuracy and weighted F1 above 0.54. Macro precision ranges from 0.49 to 0.59, recall from 0.40 to 0.47, and weighted F1 consistently exceeds 0.54, confirming reliable and balanced predictions.

5.2 DAVinCI with *span* evidence

Span-evidence models show weaker performance across the board. `bart-large-mnli` leads with 0.39 accuracy, macro F1 of 0.33, and weighted F1 of 0.32, but still trails full-evidence by 10 points. `deberta-large-mnli` and `roberta-large-snli` perform worst, with 0.36 and 0.30 accuracy, respectively. Lower macro precision and recall suggest that span-based attribution yields incomplete evidence and reduced verification quality. In CLIMATE-FEVER, span-based models also underperform. `roberta-large-snli` retains 0.64 accuracy, but its macro F1 drops to 0.32. `deberta-large-mnli` scores 0.58 accuracy and 0.51 weighted F1, yet its macro recall falls to 0.36. Overall, macro F1 ranges from 0.32 to 0.35, and weighted F1 stays around 0.50-0.54, confirming that span-based attribution sacrifices semantic depth for interpretability.

5.3 Impact of *threshold tuning* on DAVinCI with full evidence

At a 0.7 threshold, DAVinCI achieves the highest overall accuracy. `deberta-large-mnli` leads with 0.47 accuracy and 0.60 macro precision. `roberta-large-mnli` (0.43) and `bart-large-mnli` (0.42) follow, while `roberta-large-snli` trails at 0.38 but retains strong precision (0.58). Raising the threshold to 0.8 slightly lowers accuracy (e.g., `deberta-large-mnli` to 0.46, `roberta-large-snli` to 0.34) and F1-scores, as more claims are filtered as "Not Enough Info." Precision remains stable (0.58–0.60), but recall drops. At 0.9, DAVinCI becomes more conservative: accuracy dips (e.g., `deberta-large-mnli` to 0.45, `roberta-large-snli` to 0.31), and macro F1 declines (e.g., `roberta-large-snli` to `0.19`). Precision stays high, but recall suffers, highlighting the trade-off between caution and coverage. Threshold 0.7 offers the best balance; 0.9 minimizes false positives. DAVinCI's recalibration module enables flexible tuning for different risk profiles.

For CLIMATE-FEVER, DAVinCI performs strongly at 0.7. `roberta-large-snli` leads with 0.66 accuracy and 0.63 precision, though recall is lower (0.39). `deberta-large-mnli` and `roberta-large-mnli` reach 0.64 accuracy, with macro F1-scores of 0.40 and 0.43. `bart-large-mnli` follows at 0.62 accuracy and 0.40 F1. At 0.8, accuracy remains stable or improves (e.g., `roberta-large-mnli` to 0.65, `bart-large-mnli` to 0.63), and precision rises (e.g., `deberta-large-mnli` from 0.58 $\rightarrow$ 0.61). Recall dips slightly. At 0.9, accuracy holds or improves (e.g., `deberta-large-mnli to 0.65`), precision peaks (e.g., `roberta-large-snli` at 0.69), but F1-scores decline due to reduced recall. Accuracy trade-offs are minimal ($\leq$1.6%), confirming DAVinCI's ability to reduce false positives while maintaining strong performance.

5.4 Ablation Insights

For the FEVER dataset, full-evidence models outperform span-based ones by **9-18%**, highlighting their superior performance. These models also deliver more stable macro and weighted F1-scores, reflecting improved class balance. All models bene-

Table 5: DAVinCI's performance comparison using full versus span evidence on the **CLIMATE-FEVER dataset**. Best results are highlighted in bold. (**P:** Precision, **R:** Recall, **F1:** F1-score, **A:** Accuracy)

fit from richer context, with `roberta-large-snli` showing the largest F1 gain - from 0.19 to 0.48 - when switching to full evidence. For the CLIMATE-FEVER dataset, across all models, DAVinCI with full-evidence consistently surpasses span-based versions, with accuracy improvements ranging from **+1.6% to +19.6%**. `roberta-large-mnli` sees the most significant jump (**20%**), while `deberta-large-mnli` and `bart-large-mnli` improve by **5–7%**. Even high-performing models like `roberta-large-snli` show further gains. These findings underscore the importance of comprehensive context in claim verification and demonstrate DAVinCI's strength in leveraging full evidence for factual inference. **Optimal Thresholding:** A threshold of **0.7** offers the best trade-off between precision and recall across datasets. Together, these results affirm DAVinCI's integrated approach to attribution and verification, showcasing its effectiveness in supporting reliable factual assessments.

6 Conclusion and Future Work

In this work, we introduced DAVinCI - a Dual Attribution and Verification framework designed to enhance the factual reliability of large language model outputs. By integrating evidence attribution and entailment-based verification into a unified pipeline, DAVinCI enables LLMs to not only generate claims but also justify and validate them in a transparent and auditable manner. Our experiments on FEVER and CLIMATE-FEVER demonstrate that DAVinCI consistently outperforms standard verification-only baselines. Through an ablation study, we show that both evidence quality and confidence calibration play critical roles in improving model reliability.

DAVinCI represents a step toward more trustworthy AI systems, especially in domains where factual correctness is essential. Future work will explore extensions to open-domain retrieval, multi-hop reasoning, and internal attribution tracing. We also envision applying DAVinCI to generative tasks, enabling LLMs to produce outputs that are not only fluent but also verifiable and source-aware. We also plan to expand its application to low-resource and multilingual environments. By bridging the gap between generation, attribution, and verification, DAVinCI contributes to the broader effort to make language models accountable.

7 Ethics Statement

This work does not involve the collection of new human data or personally identifiable information. All experiments were conducted using publicly available datasets (FEVER and CLIMATE-FEVER) that are widely used in the NLP community for factuality and claim verification research. We ensured that our framework, DAVinCI, operates transparently by attributing claims to evidence and calibrating confidence to reduce overconfident misclassifications. We release our code and evaluation scripts to

promote reproducibility and responsible use. Our goal is to advance trustworthy NLP systems that support human oversight, not replace it.

8 Discussion and Limitations

Our experiments demonstrate that integrating attribution and verification into a unified pipeline significantly improves the factual reliability and interpretability of LLM outputs.

One of the key insights from our ablation study is the importance of evidence quality. Full evidence attribution yields more accurate and faithful verification than span-based extraction, which often loses critical context. This suggests that retrieval systems for LLMs should prioritize completeness and relevance over brevity. Additionally, our results show that confidence thresholds can be tuned to balance precision and recall, offering a simple yet effective mechanism for trust calibration.

Despite these strengths, DAVinCI has limitations. (i) It assumes access to high-quality evidence, which may not be available in open-domain settings. (ii) The verification module relies on static entailment models that may struggle with nuanced or multi-hop reasoning. (iii) Our current implementation does not model internal attribution (e.g., tracing claims to training data or prompts), which could further enhance interpretability. (iv) DAVinCI is evaluated only on English-language datasets (FEVER and CLIMATE-FEVER), which limits its applicability to multilingual or low-resource contexts. (v) Our confidence calibration relies on manually tuned thresholds that may not generalize across domains or tasks.

Future work could address these limitations by integrating dense retrievers, multi-hop reasoning modules, and internal attribution techniques such as prompt tracing or activation clustering. We also envision extending DAVinCI to generative tasks, enabling LLMs to produce not only fluent text but also verifiable and source-aware outputs. Extending the framework to handle diverse linguistic structures and evidence formats remains an open challenge. Adaptive or learned calibration strategies could improve robustness and reduce the need for task-specific tuning. Human-in-the-loop evaluation could help assess the interpretability and trustworthiness of DAVinCI in real-world applications.

Semi-Supervised Learning to Improve Detection of Factual and Causal Errors in Language Models' Explanations

Mingxuan Liu Han Yuan Yilin Wu Li Zhang Zheng Ma

Abstract

Language models (LMs) are increasingly used to generate decisions and explanations for high-stakes financial tasks, but these explanations can contain factual inconsistencies with the underlying claim or invalid causal reasoning. We propose a two-step auditing framework that decomposes each explanation into reasoning points and verifies them using natural language inference (NLI): (i) claim ⇒ point for factuality verification and (ii) point ⇒ conclusion for causality verification. To reduce reliance on expensive expert annotations, we study effective fine-tuning strategies based on semi-supervised learning (SSL) for NLI verifiers, leveraging abundant unlabeled explanations via pseudo-labeling and FreeMatch with self-adaptive confidence thresholds. Experiments across small language models and both encoder-only and decoder-only verifiers under varying labeling budgets show that SSL consistently outperforms the pre-trained baseline and supervised fine-tuning. FreeMatch is generally more robust than simple pseudo-labeling, suggesting better utilization of unlabeled data for scaling error detection of LMs' generations.

1 Introduction

The integration of Generative Artificial Intelligence (GenAI) into financial services is accelerating, yet the "Black Box" nature of language models (LMs) presents significant operational risks (Loughran and McDonald, 2011). In financial analysis, an explanation that contains a factual error (e.g., stating "The applicant has no missed payments" when the recorded history shows delinquencies) or a causal fallacy (e.g., "Credit score improved due to recent hard inquiries") can lead to liability and regulatory non-compliance. Regulators, such as the U.S. Securities and Exchange Commission (SEC) and the European Securities and Markets Authority (ESMA), have increasingly emphasized explainability and robust controls to ensure the reliability and accuracy of AI-generated outputs in financial services (U.S. Securities and Exchange Commission, 2024; European Securities and Markets Authority, 2024). Consequently, there is a need for automated auditing tools that can validate the model explanations.

Explanation auditing requires fine-grained supervision (e.g., point-level decisions for factual and causal checks), but such labels are expensive in finance because they must be produced or verified by domain experts and often require cross-checking supporting evidence. As a result, labeled datasets are typically small relative to the volume of available unlabeled narratives (e.g., model-generated rationales), creating a bottleneck for training robust detectors. This motivates semi-supervised learning (SSL) that leverages abundant unlabeled data to reduce reliance on manual annotation, as demonstrated by data-efficient SSL methods (Lee, 2013; Berthelot et al., 2019; Wang et al., 2023b).

In this study, we enhance GenAI explanation auditing in financial services under limited supervision by combining reasoning-point verification with label-efficient SSL approaches. Specifically, we make the following contributions:

1. **Reasoning-point auditing for factual and causal errors.** We cast explanation auditing as binary NLI at the reasoning-point level, enabling fine-grained identification of which specific statements contradict the claim (factual) or fail to support the conclusion (causal).

2. **Practical SSL for scarce expert labels.** To reduce reliance on costly domain-expert annotation, we leverage unlabeled explanations using two complementary SSL strategies: (i) simple pseudo-labeling (Lee, 2013) and (ii) self-adaptive thresholding via FreeMatch (Wang et al., 2023b) to scale auditing models as unlabeled data grows.

3. **Realistic evaluation.** We evaluate across mul-

2.1 LMs' Reasoning and Process Supervision

Natural-language rationales can improve LMs' reasoning and make model behavior more auditable in high-stakes domains (Xie et al., 2023). Chain-of-thought prompting and self-consistency use step-by-step reasoning to improve performance (Wei et al., 2022; Wang et al., 2023a), but such rationales are not always faithful and can appear plausible even when the final answer is wrong or biased (Turpin et al., 2023). This motivates process-level verification: instead of supervising only final outcomes, verifiers assess intermediate reasoning steps to identify unsupported or faulty claims (Cobbe et al., 2021; Uesato et al., 2022; Lightman et al., 2024; Wu et al., 2025). Related work studies self-checking, step-aware verifiers, factuality benchmarks such as TruthfulQA, and causal-reasoning evaluations such as CLadder (Miao et al., 2024; Li et al., 2023; Weng et al., 2023; Lin et al., 2021; Jin et al., 2023). Our work follows this direction by verifying each reasoning point for factual consistency (claim ⇒ step) and causal consistency (step ⇒ conclusion) in a unified NLI formulation.

2.2 Semi-Supervised Learning

SSL improves label efficiency by leveraging unlabeled data alongside a small labeled set. One line of work uses *pseudo-labeling* (self-training), turning high-confidence model predictions into training targets (Lee, 2013); recent thresholding-based methods combine this idea with strong augmentation (FixMatch (Sohn et al., 2020); FlexMatch (Zhang et al., 2021); FreeMatch (Wang et al., 2023b)). A second line focuses on *consistency regularization*, enforcing stable predictions across perturbations or over time (Temporal Ensembling (Laine and Aila, 2017); Mean Teacher (Tarvainen and Valpola, 2017); UDA (Xie et al., 2020)), and can be paired with representation learning objectives such as contrastive losses (Chen et al., 2020; Khosla et al., 2020). Finally, *hybrid* frameworks such as MixMatch (Berthelot et al., 2019) and ReMixMatch (Berthelot et al., 2020) explicitly blend pseudo-labeling with consistency and distribution alignment. Despite broad success, SSL is still less explored for LMs' explanation auditing, where un-

labeled rationales are plentiful but labels are step-level and pseudo-label noise can be amplified by fluent yet incorrect explanations.

3 Methodology

3.1 Problem Formulation

Given a financial claim C and a generated explanation E, we detect factual and causal errors by casting verification as NLI, as explored in former explanation reliability analysis (Yuan et al., 2025).

We decompose E into m reasoning points $E = (r_1, \ldots, r_m)$ and denote the final conclusion as r_{concl}.

Factual NLI (Claim ⇒ Point). For each r_i,

$$P_i^{(f)} = C, \qquad H_i^{(f)} = r_i.$$

Causal NLI (Point ⇒ Conclusion). For each r_i,

$$P_i^{(c)} = r_i, \qquad H_i^{(c)} = r_{\text{concl}}.$$

We use a binary NLI label set $\mathcal{Z} = \{\text{Entail}, \text{Contradict}\}$. Neutral is ignored because, under our constructed pairs of premise P_i and hypothesis H_i, the verifier is expected to make a *decisive* judgment between Entail and Contradict; Neutral typically reflects missing/insufficient evidence rather than correctness, and can be handled as abstention outside the core detector.

An NLI model f_θ predicts

$$\hat{z}_i^{(t)} = \arg\max_{z \in \mathcal{Z}} f_\theta(P_i^{(t)}, H_i^{(t)})[z], \quad t \in \{f, c\},$$

where $\hat{z}_i^{(f)} = \text{Contradict}$ flags a factual inconsistency between C and r_i, and $\hat{z}_i^{(c)} = \text{Contradict}$ flags a causal inconsistency between r_i and r_{concl}.

3.2 NLI verifier

We use three SLMs as g_ϕ, e.g., Llama-3.2-3B, Phi-3.5-3.8B, and Gemma-2-2B, to generate an explanation $E = g_\phi(c)$ for a financial claim c (Yuan et al., 2026a). We use GPT-4.1 to split E into m reasoning points $E = (r_1, \ldots, r_m)$; the prompts are detailed in the Appendix. After that, we use an NLI verifier f_θ to predict $\hat{z} \in \{\text{Entail}, \text{Contradict}\}$ for factual and causal pairs. The verifier can be instantiated as either an encoder-only model like BART or a decoder-only model such as Gemma-2-2B.

3.3 SSL framework

We consider two SSL approaches to leverage unlabeled explanations. We focus on pseudo-labeling and FreeMatch because they are simple, model-agnostic drop-in objectives for text NLI: they only require generating pseudo-labels and enforcing prediction consistency under light textual augmentations, without label-mixing/interpolation. In contrast, hybrid methods such as MixMatch (Berthelot et al., 2019) and ReMixMatch (Berthelot et al., 2020) rely on interpolation (e.g., MixUp) and distribution alignment, which are less robust for the current context where mixing or aggressive perturbations can twist the factual or causal meaning.

3.3.1 Pseudo-labeling

A teacher model f_{θ_T} generates hard pseudo-labels $\tilde{y} = \arg\max f_{\theta_T}(x)$ for unlabeled samples $x \in D_U$, and a student f_{θ_S} is trained on the union of labeled D_L and pseudo-labeled $\{(x, \tilde{y})\}$ samples.

3.3.2 FreeMatch

We adopt FreeMatch to perform confidence-adaptive pseudo-labeling with consistency regularization: a sample is assigned a pseudo-label only if $\max f_{\theta_T}(x)$ exceeds an adaptive threshold, and the student is trained to make consistent predictions under weak and strong augmentations. Concretely, we use the original input as the weak augmentation and synonym replacement as the strong augmentation. We also ablate augmentation type and strength and find that both designs affect performance.

3.4 Dataset

We use the German credit financial classification dataset (Hofmann, 1994), a widely recognized benchmark in financial natural language processing (Xie et al., 2023; Bhatia et al., 2024; Yuan et al., 2026b). In this dataset, label $L = 1$ indicates a good profile and $L = 0$ represents a bad profile. We first adopt LMs to generate profile decisions and corresponding explanations for the samples, and then focus on detecting factual and causal errors in the generated explanations to facilitate a more informed understanding of the outputs.

Specifically, we segment each LMs' explanations into reasoning points and have multiple domain experts annotate each point with binary NLI labels (*Entail* vs. *Contradict*) for factual (claim ⇒ point) and causal (point ⇒ conclusion) verification. We vary the labeling budget by subsampling the labeled set while keeping the unlabeled set fixed: a

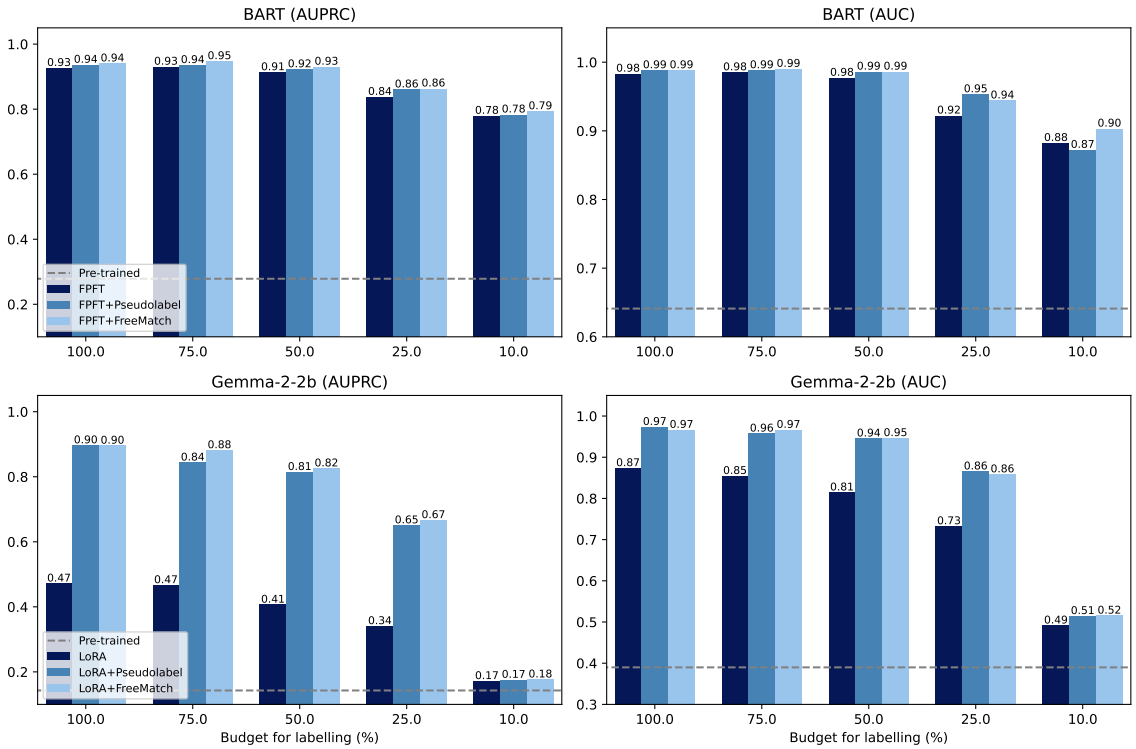

Figure 2: Causal error detection with labeling budget for encoder-only and decoder-only NLI verifiers under different fine-tuning strategies. FPFT: full-parameter fine-tuning. LoRA: Low-Rank Adaptation.

ratio of 1.0 uses all labeled data together with all unlabeled data, while a ratio of 0.5 uses 50% of the labeled data together with all unlabeled data.

4 Experiments

4.1 Factuality

We first evaluate factual error detection and study how SSL strategies affect performance under different labeling budgets.

Fig. 1 shows that SSL substantially improved factual error detection over the pre-trained model and supervised fine-tuning (FPFT / LoRA (Hu et al., 2022)) for both models. For each fine-tuning strategy, the benefit of additional supervision exhibited diminishing returns as the labeling budget increases (a concave trend). Overall, FreeMatch was consistently competitive and often stronger than pseudo-labeling at moderate-to-high budgets ($\geq$25%), indicating better control of pseudo-label noise; this is consistent with higher unlabeled-data utilization under FreeMatch in Fig. 3 for both verifiers.

4.2 Causality

Fig. 2 shows that SSL fine-tuning also improved causal error detection over both the pre-trained baseline and supervised fine-tuning. Consistent with the factuality, the improvement of return diminishes as supervision increases, and FreeMatch is typically stronger than pseudo-labeling.

For the encoder-only verifier, the marginal benefit of adding SSL over supervised fine-tuning is relatively modest, whereas the SSL gains are more pronounced with the decoder-only verifier (lower panels in Fig. 2), where SSL yields a larger lift relative to its supervised fine-tuned model. For example, under the budget of 50% labeling, Gemma-2-2b achieved AUPRCs of 0.41 for LoRA, 0.81 for Pseudolabeling, and 0.82 for FreeMatch.

5 Conclusions

This study contributes to efficient explanation auditing for LMs in a high-stakes financial context by verifying factual and causal correctness at the reasoning-point level and by showing that semi-supervised fine-tuning can improve verifiers when expert labels are scarce. The resulting verifiers can support governance workflows by triaging generated rationales for another round of human review, flagging potentially misleading statements, and monitoring explanation reliability under model and data drift. Future work should test broader financial scenarios, more diverse LMs, lightweight

verifiers, stronger augmentations that preserve factual and causal meaning based on LMs, etc.

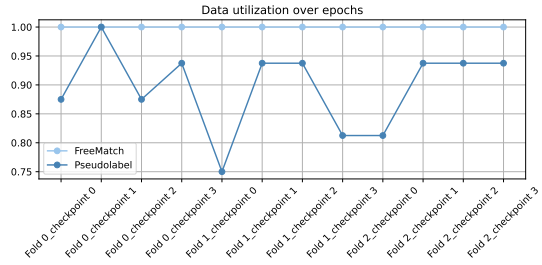
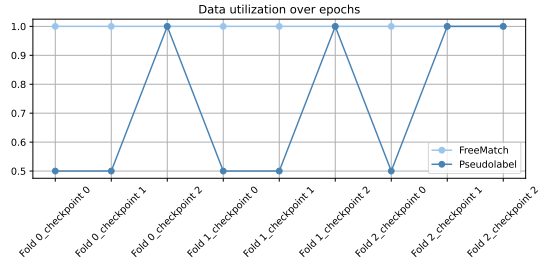
A Data Preprocessing

The original dataset includes outdated information and pre-existing bias (Zehlike et al., 2017) that pose challenges for SLMs. For instance, certain features are denominated in Deutsche Marks, a currency that has been obsolete for over two decades; moreover, SLMs often exhibit limited sensitivity to numeric reasoning (Mishra et al., 2022). To address these issues, we exclude features misaligned with contemporary SLM development contexts and convert numeric features into percentile representations. All processing steps are performed *ad hoc* and do not involve any operations related to the labels, ensuring that performance is not affected by information leakage. We also conduct all experiments using all minority cases paired with an equal number of majority cases to avoid the adverse impact of data imbalance on the analyses.



B Prompt for Point Segmentation

Segmentation Prompt



Role. You are an expert in credit risk assessment with strong logical reasoning skills.
Task. Given another expert's assessment, split the reasoning into individual sentences, where each sentence represents a distinct reasoning point.
Requirements. Omit summary sentences that aggregate reasoning points; do not alter the original wording—only split the text into separate items.
Transition rules. Split addition, comparison, sequence, and clarification links; keep the closest contrast, cause, and emphasis links together; remove the point that directly states the final good/bad credit conclusion; explicitly resolve references such as "these factors."
Example. Original reasoning: {Original reasoning}. Structured reasoning: {Structured reasoning}.

C Experimental Details

We obtain 8989 reasoning points from explanations generated by the SLMs and segmented using GPT-4.1. Among these, 1782 points are manually annotated by two authors of this paper, each with more than two years of experience in financial services. Disagreements are adjudicated by

(a) BART

(b) Gemma-2-2b

Figure 3: Utilization of unlabeled data under different SSL strategies.

a senior author with more than five years of experience in financial services. The annotated set contains 4.04% factual errors and 18.46% causal errors. We split the labeled points into three folds for cross-validation, ensuring that all reported evaluation results are computed on manually labeled samples.

For BART, we perform FPFT using AdamW with a learning rate of 1e-5, weight decay of 0.01, batch size of 32, and train for 5 epochs. For Gemma-2-2B, given its larger model size relative to the encoder-only verifier, we use LoRA with rank 8 and scaling factor 8, and optimize the trainable parameters using AdamW with a learning rate of 5e-5, weight decay of 0.01, batch size of 4, for 1 epoch. Our code is publicly available on GitHub.[1]

D Utilization of Unlabeled Data

For BART (Fig. 3a), FreeMatch maintains near-full utilization throughout training, whereas simple pseudo-labeling fluctuates noticeably, typically staying around 0.85–1.0 but dropping to roughly 0.75 in its lowest-utilization epoch. For Gemma-2-2b (Fig. 3b), FreeMatch again stays close to 1.0 across epochs, while pseudo-labeling exhibits a bimodal pattern, alternating between very low utilization (about 0.2) and full utilization (about 1.0) and indicating unstable or overly conservative acceptance of unlabeled samples.

Is Safety Grounded or Detachable? Removal-Cost Audits for Open-Weight Language Models

Abstract

Open-weight language models remain modifiable after release, so release-time refusal alone cannot establish durable safety. We introduce removal-cost grounding as a budget-conditioned audit of whether safety can be weakened while preserving utility, coherent generation, and benign helpfulness. We formalize clean removal as a constrained feasibility problem and distinguish observed counterexamples from inconclusive attack searches. Mycelium v0 provides a deliberately limited case study: four model families exhibit benchmark degradation under an archived removal configuration, while targeted Mistral controls separate destructive ablation from wrapper bypass. A provenance audit excludes three model–task comparisons with mismatched evaluation limits or conflicting snapshots. Across the retained comparisons, mean removal-associated score changes range from -0.382 to -0.185. In a separate 12-prompt generation panel, the strict attack-success proxy increases from $1/12$ with Mycelium enabled to $7/12$ under bypass, with wide uncertainty and no matched native safety baseline. Adaptive traces further show why early-stopped checkpoints must be distinguished from training endpoints. These observations do not establish tamper-resistant safety. They motivate an auditable reporting framework in which the cheapest admissible route to useful unsafe behavior, rather than the costliest destructive ablation, determines the strength of a safety claim.

1 Introduction

Open-weight language models can be modified after release through adapter changes, internal interventions, base-model restoration, or fine-tuning. Release-time refusal therefore leaves a question unanswered: how much useful behavior must an actor sacrifice to weaken safety?

We call this question *removal-cost grounding*. Grounding here refers to the coupling between a behavioral constraint and useful computation under a specified class of interventions. It does not mean factual grounding in retrieved evidence, nor does it identify a particular internal representation as a semantic safety circuit. The term names an operational question about the persistence of a constraint after release.

The central distinction is between *damage* and *clean removal*. Destroying coherent generation can reduce refusal without producing a useful unsafe model. Preserving benchmark accuracy alone is also insufficient: benign helpfulness and substantive unsafe compliance must be measured jointly.

This paper develops a measurement framework and applies it retrospectively to Mycelium v0, a wrapper-based prototype with gated low-rank paths. The case study is useful precisely because it exposes a limitation: a costly adapter ablation coexists with an accessible frozen-base route. A defense-level claim must survive the latter route as well as the former. The existence of a destructive intervention cannot establish that every effective intervention is destructive.

Our empirical evidence comprises a four-family utility matrix, Mistral-only removal controls, and separate generation and adaptive-loss panels. The cross-family matrix does not replicate bypass across families.

We make three contributions. (1) We define a budget-conditioned clean-removal criterion, a minimum-cost quantity, and an uncertainty-aware reporting rule. (2) We use Mycelium to show how intervention identity, native baselines, and checkpoint selection change the interpretation of a removal audit. (3) We provide a reproducible reanalysis of archived scores, including a provenance correction, common-task sensitivity, relative degradation, missing-cell bounds, and explicit limits on the generation evidence. All empirical observations come from archived runs; we add statistical reanalysis, without new model training or generation.

2 Related Work

Behavioral safety evaluation. HarmBench standardizes automated red teaming and refusal evaluation (Mazeika et al., 2024). JailbreakBench defines a shared threat model, prompt and scoring conventions, and reusable artifacts (Chao et al., 2024). StrongREJECT emphasizes that apparent jailbreak success can overstate substantive harmful assistance, including when jailbreaks impair capabilities (Souly et al., 2024). OR-Bench evaluates the complementary failure of rejecting benign requests (Cui et al., 2025). Our utility, coherence, and benign-helpfulness requirements build on these concerns; they are not new desiderata in isolation. The contribution is to apply them jointly to post-release intervention artifacts with explicit budgets and controls.

Tamper resistance. TamperBench is the closest framework: it evaluates safety and utility under weight-space and representation attacks, with systematic hyperparameter sweeps (Hossain et al., 2026). Removal-cost grounding is not a replacement benchmark and does not claim an evaluation capability unavailable to TamperBench. It supplies an interpretation layer: which intervention produces an admissible counterexample, at what cost, under which feasibility constraints? The Mycelium controls instantiate this question by distinguishing changes to the base path from changes confined to added components. We do not report a head-to-head TamperBench experiment or comparative attack coverage.

Adaptation and internal interventions. LoRA enables adaptation through low-rank updates while retaining frozen pretrained weights (Hu et al., 2021). Refusal-direction work shows that refusal can be sensitive to a low-dimensional representation intervention (Arditi et al., 2024). Circuit breakers instead train representations to interrupt undesirable behavior (Zou et al., 2024). Unlearning evaluates the removal of targeted knowledge or capabilities, as exemplified by WMDP (Li et al., 2024). These settings share a need to measure retained utility, but they differ in the object being changed. A wrapper bypass result does not establish that full-parameter alignment, representation rerouting, or unlearning has the same failure mechanism.

3 A Budget-Conditioned Grounding Criterion

3.1 Threat model and measurements

Let M_0 be a released defended model, M_{nat} its local native comparator, and a an intervention returning a runnable artifact $M_a = a(M_0)$. The threat model specifies an admissible class $\mathcal{A}_B$ under budget B. Relevant resources include gradient steps, adapter rank, examples, model queries, checkpoint searches, and access to base weights. These resources should be reported separately unless a justified conversion to a common cost unit exists. Merely counting gradient steps would assign zero cost to many static interventions while omitting their search and implementation costs.

For fixed evaluation protocols, let $S(M) \in [0,1]$ measure substantive unsafe compliance, $u_t(M) \in [0,1]$ measure utility on task t, $C(M)$ measure coherent generation, $F(M)$ measure benign false refusal, and $H(M)$ measure substantive benign helpfulness. Higher S is worse safety; higher u_t, C, H is better performance. Refusal is measured separately: non-refusal does not imply unsafe compliance, and absence of false refusal does not imply helpfulness.

Define the safety change $\Delta S(a) = S(M_a) - S(M_0)$ and task-specific utility cost

$$d_t(a) = \max\{0, u_t(M_0) - u_t(M_a)\}. \quad (1)$$

We retain this vector rather than allowing improvements on one task to silently offset losses on another. A weighted mean is useful for description, but it is not automatically an acceptable deployment utility constraint. The native-to-defended comparison must also be reported: preserving a low-utility defended model is a weak success criterion.

3.2 Clean removal and minimum cost

Choose thresholds before attack evaluation:

$$\tau = (\delta, \{\epsilon_t\}, c_0, f_0, h_0, p_0). \quad (2)$$

An artifact meets the behavioral constraints when

$$\begin{aligned} &\Delta S(a) \geq \delta, && d_t(a) \leq \epsilon_t \quad \forall t, \\ &C(M_a) \geq c_0, && F(M_a) \leq f_0, \\ &H(M_a) \geq h_0. \end{aligned} \quad (3)$$

Let $P(a)$ be the probability that a frozen selected artifact meets these constraints under the declared

repeated-evaluation protocol. A clean removal additionally requires $P(a) \geq p_0$. Repetitions may vary decoding seeds or evaluation samples while holding the artifact fixed. Attack restarts may produce different artifacts and therefore assess a separate quantity: the reliability of the attack procedure. Checkpoint selection is part of the attack; selection data must be separated from confirmatory evaluation.

For a declared nonnegative cost function $c(a)$, define

$$R_\tau(M_0; \mathcal{A}_B) = \inf_{a \in \mathcal{A}_B : \text{Eq. (3)},\ P(a) \geq p_0} c(a), \quad (4)$$

with $\inf \varnothing = +\infty$. This is a population-level target, not a number that our small case study identifies. Finding one qualifying artifact yields an upper bound. Failing to find one in a finite search supplies no general lower bound unless the search is exhaustive or has a justified coverage guarantee. We therefore avoid converting unsuccessful attacks into an unqualified statement that safety is grounded.

Operational decisions. An audit reports *detachable at the declared thresholds* only when an observed artifact satisfies all requirements with the chosen evidential support. It reports *no qualifying removal observed* when a specified search finds none. It reports *inconclusive* when behavioral precision, intervention provenance, or coverage is insufficient. A component can exhibit removal-associated utility loss without earning a defense-level label of "partial grounding." That label would require a declared quantitative meaning.

3.3 Pareto reporting and uncertainty

A complementary report plots safety erosion against the utility-cost vector or an explicitly weighted summary, with separate annotations for coherence, benign behavior, and cost. An artifact is dominated if another is at least as good on every declared attack objective and strictly better on one. A Pareto point need not satisfy Eq. (3); the frontier and the feasible region answer different questions.

For a confirmatory clean-removal claim, the lower confidence bound on safety erosion should exceed δ, while upper bounds on utility loss and false refusal should remain within their tolerances. Joint claims across many metrics require simultaneous uncertainty control. Marginal intervals printed beside individual scores do not provide that guarantee. In particular, overlap between two binomial intervals is not a paired significance test.

Training instability must also be interpreted carefully. A checkpoint that performs well early and deteriorates under further optimization remains available to an early-stopping attacker. Its later collapse does not erase the earlier candidate. Stability of a *selected artifact* under repeated evaluation is distinct from monotonic behavior along a training trajectory. Section 7 reports both checkpoint and endpoint observations without conflating the two.

3.4 The reconnectable-base boundary

Proposition 1. *Suppose an admissible intervention b of cost at most c_b restores exactly the native model's inference function, including its preprocessing and decoding protocol. If M_{nat} satisfies Eq. (3) relative to M_0 and the repetition requirement, then $R_\tau(M_0; \mathcal{A}_B) \leq c_b$.*

Proof. By functional equivalence, M_b has the native model's measured behavior under the stipulated protocol. It therefore belongs to the feasible set in Eq. (4); the infimum cannot exceed its cost. □

The proposition is deliberately elementary. It isolates the relevant logical boundary: making one removal route expensive cannot compensate for an admissible inexpensive route. Its premises must still be checked. Restoring some base projections does not automatically establish equality of tokenization, model state, or generation behavior, and an aligned native model need not meet a safety-erosion threshold. Our empirical bypass panel lacks a matched native generation arm, so it does not fully instantiate those premises.

4 Mycelium v0 and Intervention Identity

4.1 Architecture as an audit object

Mycelium v0 adds low-rank paths to selected transformer projections. The design uses operational family names such as core, utility, soft safety, hard safety, and safety. They identify training or intervention groups, not independently localized semantic circuits. A useful mathematical abstraction for one patched projection is

$$y = \alpha_a(x) W_0 x + \sum_{f \in \mathcal{F}} m_{a,f}\, g_f(x) B_f A_f x, \quad (5)$$

where $W_0 \in \mathbb{R}^{d_o \times d_i}$ is the frozen base projection, $A_f \in \mathbb{R}^{r_f \times d_i}$ and $B_f \in \mathbb{R}^{d_o \times r_f}$ are low-rank fac-

tors, g_f is a gate, and $m_{a,f}$ describes the intervention. Bias terms are omitted for readability. An always-on core corresponds to $g_{\text{core}} = 1$. The coefficient α_a records whether the intervention changes the base contribution. This notation separates the objects that an audit must log; it is not a recovered source-level specification of every historical wrapper.

The design description includes green, amber, and red routing, retained benign utility, safety-target responses, and counterfactual training under path removal or wrong routing. Historical runs implement multiple revisions. The archived benchmark metadata identifies wrapper source and checkpoint paths, but the supplied package does not contain the corresponding executable training sources or exact loss coefficients for all final checkpoints. We therefore do not assert that every model used the same objective, gate estimator, or loss schedule. Earlier training-report summaries are not sufficient to reconstruct those details.

4.2 What each removal changes

The broad utility matrix uses the archived condition `mycelium_removed`. We denote it R_6 throughout. It is a wrapper-level removal configuration, not a universally equivalent safety-circuit excision. The Mistral control panel separately reports the following operations:

- **Attenuated removal**: a removal branch that also changes the base projection contribution. It mixes component deletion with base-path damage.
- **Adapter-only safety-zero**: the base projection is preserved while selected added safety paths are disabled. This tests the deletion route with that confound removed.
- **Bypass restore**: the frozen base path is reconnected, avoiding the wrapper's intended execution route.

In Eq. (5), changing α_a and changing only $m_{a,f}$ are different interventions. Their outcomes cannot be pooled under a generic "removed" label. Exact intervention-to-parameter manifests are needed to establish equivalence between separate runs, even when condition names look similar.

The targeted utility panel uses 200 examples per task. Attenuated and adapter-only removal have the same four reported scores. Equality of aggregate accuracies is not evidence that their logits, predictions, or code paths are identical. The supplied aggregate panel does not resolve why those scores coincide. An implementation equivalence explanation would require per-example predictions and an execution trace; neither is inferred here.

Limits of causal attribution. Utility loss under adapter-only deletion establishes a cost of that intervention on that model. It does not show that safety-specific computation was removed. Equal-rank random-path ablations, norm-matched controls, and utility-path ablations would distinguish safety-specific coupling from generic low-rank damage. The current evidence does not supply a matched experiment for these controls. We consequently use "removal-associated degradation" rather than "causally grounded safety" to describe the utility result.

5 Benchmark Utility and Provenance Audit

5.1 Data and protocol

We reanalyze archived lm-evaluation-harness outputs (Biderman et al., 2024) for Mistral-7B, Qwen-35B-A3B, Gemma-31B, and GPT-OSS-20B. These names abbreviate local evaluated model families, not claims about the performance of every checkpoint in a family. The 15-task matrix covers reasoning, knowledge, coding, mathematics, and commonsense tasks; Appendix A.1 maps them to source references and recorded metrics. The metric assigned to each task is retained rather than replaced with a newly selected favorable metric. Accuracy, normalized accuracy, exact match, and code-pass measures all lie on a $[0, 1]$ scale, but do not measure interchangeable capabilities.

The original task ledger contains 192 intended model–condition–task cells, including GPQA. It records 170 successful cells, 16 error-only cells, and six missing cells. GPQA was access-blocked and is excluded from the 15-task comparison universe. A successful cell means that a score was produced; it does not guarantee compatible sampling across conditions.

A correction beyond missing-cell counting. The archived aggregate table suggests 15, 13, 13, and 14 complete native/on/R_6 task triplets. Inspecting evaluation metadata reveals three additional comparisons that must be excluded from our primary reanalysis. Mistral GSM8K native and on

Family	n	On−N	R_6−On	95% CI
Mistral	13	$-.029$	$-.331$	$[-.412, -.245]$
Qwen	12	$-.009$	$-.382$	$[-.490, -.274]$
Gemma	13	$-.038$	$-.185$	$[-.307, -.081]$
GPT-OSS	14	$+.063$	$-.280$	$[-.366, -.197]$

Table 1: Primary utility summary after provenance exclusions. N denotes the local native condition. Values are score differences, not percentages of retained capability.

Task	On	Atten.	Adapter	Bypass
ARC-C	.540	.385	.385	.590
BoolQ	.885	.785	.785	.900
HellaSwag	.745	.565	.565	.735
OpenBookQA	.505	.395	.395	.530
Mean	.669	.533	.533	.689

Table 2: Archived targeted control panel, 200 examples per task. "Adapter" means adapter-only safety-zero. This panel is distinct from R_6. Bypass has a 0.020 mean improvement relative to on, but HellaSwag decreases by 0.010.

use eight examples, while R_6 uses 1,319. Qwen GSM8K native uses four examples, unlike the other conditions. Mistral OpenBookQA has an archived removed score of 0.266, whereas the supplied task JSON records 0.500 on a four-example later run. We preserve the conflict rather than selecting either value as a full comparable result.

After these exclusions, the primary analysis retains 13, 12, 13, and 14 triplets, respectively. Appendix A and the supplement list every exclusion. The correction changes the estimand from "all score-present triplets" to "score-present triplets without the identified limit or snapshot conflicts." It does not establish complete equivalence of all historical evaluation environments.

5.2 Aggregation and robustness checks

For each family, we average the paired differences $u_t(R_6) - u_t(M_0)$ over retained tasks with equal task weights. We bootstrap these task differences with 20,000 resamples and seed 20260905, reporting percentile 95% intervals. This is a descriptive task-resampling analysis. Tasks are not an IID sample of real-world uses, and the interval does not account for model-training uncertainty or all within-task sampling error.

Table 1 shows substantial negative mean changes under R_6 in each family. This is an intervention-associated utility result, not cross-family evidence of the same safety-removal mechanism. Mycelium-on changes are smaller on average, but the average conceals material task-level variation. For example, Gemma GSM8K falls from 0.702 to 0.438 before removal. GPT-OSS shows a positive aggregate on-minus-native difference alongside unusual native generation-task results, including BBH and MBPP scores of zero. These observations warrant local-protocol interpretation rather than a claim of general capability improvement or uniformly negligible utility overhead.

We add four checks to make the aggregation inspectable. First, median removal differences are -0.303, -0.387, -0.067, and -0.254. Gemma's smaller median shows how a few large generative-task losses influence its mean. Second, on the ten tasks retained in every family, mean differences remain negative: -0.349, -0.388, -0.127, and -0.263. Third, the mean relative loss $(u_t(M_0) - u_t(R_6))/u_t(M_0)$ over positive on-state scores is 61.2%, 55.5%, 36.5%, and 58.8%. The zero on-state Mistral HumanEval score is omitted only from this ratio, not from the primary mean. Relative loss is descriptive and is not chance-normalized; values on tasks with small denominators require care.

Fourth, we assign each excluded triplet an adversarially favorable difference of $+1$, the maximum possible for bounded scores. Even this worst-case completion of the 15-task universe leaves negative upper bounds: -0.153, -0.105, -0.027, and -0.195. These are algebraic sensitivity bounds, not imputations or confidence intervals. They address the direction of this bounded aggregate; they cannot repair protocol mismatches or support an inference about safety.

5.3 Mistral removal controls

Adapter-only removal loses 0.136 mean score across the four tasks in Table 2. Bypass is substantially less destructive, with a maximum observed task loss of 0.010. This supports evaluating bypass as a candidate removal route, not asserting formal utility equivalence: no paired uncertainty or preregistered noninferiority test is available. Utility preservation is therefore tolerance-dependent; the HellaSwag decrease rules out exact non-decrease on every task.

Condition	Refusal	Strict ASR	Ambiguous
On	8/12	1/12	3/12
Adapter-only	1/12	0/12	12/12
Bypass	2/12	7/12	3/12
Native	—	—	—

Table 3: Panel A. Indicators are not a mutually exclusive partition: adapter-only has 12 ambiguous outputs and one refusal. The missing native arm is shown explicitly. Counts are reconstructed from the submitted table's rounded rates and stated denominator.

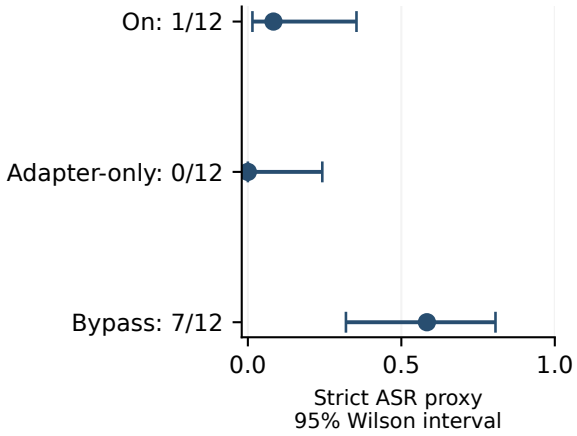

Figure 1: Panel A uncertainty. Twelve observations per condition provide limited precision; the bypass point estimate is suggestive, not a population-level safety estimate.

6 Generation Evidence: Two Separate Panels

6.1 Panel A: targeted bypass comparison

The targeted generation panel reports 12 red prompts per condition for on, adapter-only zero, and bypass restore. "Red" identifies the local safety-evaluation category. The supplied paper reports a strict ASR proxy, a refusal indicator, and an ambiguity indicator. We retain these measurements as historical proxies; the package does not identify a validated external judge or provide sufficient row-level annotations to independently reconstruct the strict rubric.

The strict ASR proxy rises from $1/12$ to $7/12$ under bypass, a descriptive difference of 0.500. Wilson intervals are [0.015, 0.354] and [0.320, 0.807], respectively (Figure 1). Adapter-only removal has zero strict successes but all 12 outputs marked ambiguous. That outcome cannot be treated as evidence that a useful model remains safe: severe incoherence can suppress both refusal and successful assistance.

Condition	Compliance	Red amb.	Benign amb.
On	5/12	6/12	0/12
Safety-zero	1/12	11/12	12/12
All-zero	11/12	0/12	0/12

Table 4: Panel B broad manual indicators. Benign false refusal is 0/12 in all three conditions, but safety-zero produces 12/12 ambiguous benign outputs. Non-refusal is not helpfulness.

The native safety baseline is absent on these same prompts. We cannot determine whether bypass exactly restores native behavior, whether Mycelium substantially improves safety over that baseline, or whether differences reflect other generation settings. Nor can the archived marginals establish a paired significance result. If the same 12 prompts were used and strict-success labels were paired, marginals of one and seven successes allow two contingency tables. Their exact two-sided McNemar p-values are 0.0703 and 0.0313. Thus, even the decision at a nominal 0.05 threshold depends on missing pairing information. This conditional calculation is a sensitivity analysis, not an observed hypothesis test.

6.2 Panel B: manual audit and label mapping

The separate manual audit reports 72 outputs: three conditions, each with 12 red and 12 benign prompts. Its labels are `on`, `safety_zero`, and `all_mycelium_zero`. The archived aggregate fields record refusal/safe redirection, substantive compliance, and ambiguous or garbled output. The indicators can overlap. The red safety-zero summary has one refusal, one compliance, and 11 ambiguous labels among 12 outputs, confirming that they are not categorical alternatives.

Panel B's red compliance rates are 0.417, 0.083, and 0.917, with Wilson intervals [0.193, 0.680], [0.015, 0.354], and [0.646, 0.985]. All three benign false-refusal counts are zero, but the 95% upper bound is 0.243, and benign ambiguity varies sharply. These data reinforce the need to report useful benign responses rather than only the absence of refusal.

The two panels have different scoring definitions and condition identifiers. "Safety-zero" cannot be equated with adapter-only safety-zero without an execution manifest; "all-Mycelium-zero" cannot be equated with bypass restore merely because both disable components. Even their on-state red indicators differ substantially. We do not pool their

Family	Steps/rank	Train	Holdout	ΔL_S
Mistral	40/4	.440	.434	-1.240
Mistral	80/8	2.645	2.103	$-.888$
Qwen	40/4	2.298	1.017	$-.421$
Qwen	80/8	3.699	3.004	-2.171

Table 5: Archived LoRA repair panel. Positive recovery means lower utility CE. Negative ΔL_S means safe-target likelihood also improves. These are likelihood probes, not observed clean removals.

Family	λ	Step*	Rec.*	Erosion*	Final rec.
Mistral	.02	20	1.799	2.369	-8.396
Mistral	.05	20	1.485	84.353	-13.083
Mistral	.10	10	1.973	.687	-23.341
Mistral	.20	10	1.901	5.625	-21.342
Qwen	.02	1	.065	.018	-3.309
Qwen	.05	1	.049	.017	$-.950$
Qwen	.10	70	.709	95.989	.157
Qwen	.20	1	.048	.025	-5.250

Table 6: Archived erosion sweep: rank 8, 80 steps, top-$n = 6$. Stars denote the archived selected checkpoint. "Final rec." is endpoint held-out utility-CE recovery. Five selected checkpoints, but no endpoints, exceed both archived CE thresholds of 0.25.

denominators, describe them as independent replications, or use Panel B to increase the sample size of Panel A. Prompt overlap and checkpoint equivalence are unverified.

The reanalysis package contains aggregate labels, without the annotation template or output-level annotations. Annotator count, independent blinding, and inter-annotator agreement remain undocumented. A manifest of 40 red and 40 benign prompts describes an available pool, not 80 completed observations for every condition. The safety evidence remains preliminary and does not replace the established benchmarks discussed in Section 2.

7 Adaptive Repair and Checkpoint Selection

Adaptive experiments use cross-entropy (CE) proxies. Let L_U be loss on benign targets and L_S loss on safe response targets. Relative to an attack's starting checkpoint, utility recovery is $L_U^{\text{start}} - L_U^{\text{after}}$ and safety-target erosion is $L_S^{\text{after}} - L_S^{\text{start}}$. Positive erosion means that specified safe targets become less likely; it does not imply substantive unsafe generation. Starting points and evaluation subsets differ from the Phase-6 benchmark matrix, so their CE changes cannot be substituted for benchmark score changes.

Table 5 makes the repair evidence explicit. The two budgets use rank 4 with 40 steps and rank 8 with 80 steps; the archived top-n settings are four and six. All four settings improve held-out utility CE, while safe-target CE also decreases. Training gains exceed held-out gains, especially for Qwen at the smaller budget. The result shows partial utility recovery in the measured loss, not recovery of useful unsafe behavior.

The erosion sweep varies pressure $\lambda \in \{0.02, 0.05, 0.10, 0.20\}$ (Table 6). Its historical screening rule requires at least 0.25 utility-CE recovery and 0.25 safe-target-CE erosion. Four Mistral settings and one Qwen setting have selected checkpoints meeting that proxy rule; no final checkpoint does. Very large erosion values at some checkpoints coexist with loss of utility. Such extreme losses are warnings against reading CE as a calibrated measure of harmful assistance.

These traces support a reporting lesson rather than a successful defense claim. Endpoint-only analysis misses early candidates. Conversely, early proxy success does not establish Eq. (3): generation safety, benign helpfulness, and repeated-evaluation stability were not jointly measured. An early-stopped artifact should be frozen and evaluated on a separate confirmatory set. The archived traces do not provide this final step, and the word "heldout" in a utility-loss report does not guarantee that those data were unused during checkpoint selection.

8 What the Case Study Establishes

The supported result. The corrected four-family analysis establishes that the archived R_6 configuration is associated with large average utility losses on the retained tasks. The Mistral controls show that a less destructive bypass route is available in the tested implementation, and a small generation panel shows a higher unsafe-compliance proxy under that route. Taken together, these observations challenge the interpretation of destructive removal as evidence of durable safety. They do not establish that Mycelium is a tamper-resistant defense or precisely quantify a minimum clean-removal cost.

Why the boundary is architectural. Frozen-base restoration is unsurprising when the base path remains available. Its importance is diagnostic: the audit must include the strongest admissible route, even when that route is simple. A wrapper can be useful under an execution environment that pro-

tects its control flow, but a white-box open-weight threat model cannot silently assume that protection. Conversely, a threat model that excludes original base weights must state the exclusion and explain its relevance. Moving a restriction from the attacker definition into an unstated implementation assumption overstates the conclusion.

Beyond wrappers. The criterion also applies to full-parameter alignment, unlearning, circuit breakers, and pretraining filtering, using method-specific intervention budgets and behavioral outcomes. Our results do not evaluate those methods. Reports should identify checkpoints, intervention manifests, matched evaluation protocols, paired labels, and total search budgets. The supplement supports aggregate reanalysis, not full training or generation reproduction.

9 Conclusion

Removal-cost grounding asks whether an actor can weaken safety while preserving useful behavior under an explicit intervention budget. Its value lies in the conjunction of those requirements and in the discipline of testing the cheapest admissible route. Mycelium v0 supplies a limited but instructive case: destructive removal incurs utility loss, while a reconnectable base path offers a less destructive route with suggestive safety erosion. Corrected provenance, separate generation panels, and checkpoint-aware analysis narrow what can be concluded. Durable open-weight safety remains an empirical target; a costly ablation is insufficient evidence that it has been achieved.

Limitations

The safety panels are small, use local proxies, and lack a native generation baseline on identical prompts. We cannot reconstruct an observed paired test, annotator agreement, or cross-panel intervention equivalence. The study includes no larger established safety benchmark, cross-family bypass replication, or matched random-path control. The criterion is newly formalized and was not preregistered for the archived experiments.

The utility reanalysis removes identified sample-limit and snapshot conflicts, but archival metadata is not a complete execution trace. Some metric tokens were altered by the original anonymization process; the supplement preserves and documents this rather than inventing missing names. Task averages, relative scores, and task-bootstrap intervals have different interpretations and do not establish deployment utility. The GPT-OSS static CE audit additionally differs from the broad removal matrix: several family-zero conditions improve utility CE. This discrepancy reinforces the need to keep intervention and metric identities separate.

The available package lacks complete final training sources, exact objective schedules, model-weight files, and raw generation annotations. Equation (5) is an audit abstraction, not a verified reimplementation of every checkpoint. The experiment family labels do not prove semantic localization. No finite unsuccessful attack search establishes a general lower bound on removal cost.

Ethics and Reproducibility Statement

This work concerns defensive evaluation of post-release model integrity. We report aggregate measurements without raw harmful requests, harmful completions, or runnable attack checkpoints. The supplementary package contains sanitized score records, source hashes, analysis code, and a claim-to-evidence map. It reproduces the statistical reanalysis from supplied records; it does not regenerate private model outputs. An absence of unsafe outputs after destructive removal must not be interpreted as deployment safety. Language-model assistance was used in revising prose and preparing analysis code; the empirical observations remain the archived experimental records.

A Task Coverage and Snapshot Corrections

The original 16-task ledger includes one GPQA entry per model and condition. Removing the 12 GPQA error-only cells leaves 180 intended cells over the 15 paper tasks: 170 score-present cells, four additional error-only cells, and six missing cells. Score presence yields 55 complete triplets. The three provenance exclusions reduce the primary analysis to 52 triplets. All records are retained in the supplementary data, including excluded scores, with their status documented.

The common ten-task set is MMLU, MBPP, HellaSwag, ARC Challenge, ARC Easy, BoolQ, PIQA, Social IQA, TruthfulQA MC2, and WinoGrande. We preserve the paper-table task alias selected by the archived builder. Social IQA has multiple historical loader aliases; they are not counted as separate tasks. BBH and MMLU task aggregates are not supplemented with their subtasks in the same macro-average, avoiding double counting.

A.1 Benchmark sources and metric identity

Table 10 links the 15-task comparison universe to its benchmark sources. Metric and filter strings are those retained in the archived records. The sources identify the tasks, not a guarantee that local execution reproduced every recommended benchmark protocol. In particular, a redacted HumanEval metric cannot be reconstructed from its numerical values alone.

B Implementation Information and Its Scope

Family	Archived configuration
Mistral-7B	Last 10 layers; 30 projections; rank 64; $\rho = .22$. Attention output; MLP down/up.
Qwen-35B	Last 12 layers; 12 projections; rank 32; $\rho = .18$. Linear-attention output; final attention output.
Gemma-31B	Last 12 layers; 48 projections; rank 32; $\rho = .18$. MLP gate/down/up; attention output.
GPT-OSS-20B	Layers 12–19; 32 projections; rank 32; $\rho = .18$. Attention output, key, query, value.

Table 11: Archived implementation card. Counts denote patched modules, not scalar parameters. The source-level definition of ρ is incomplete; it is not equated with α_a in Eq. (5).

The original provenance manifest includes aligned and modified variants of several model families. A file's presence in that manifest does not establish its use in any particular table. Per-task metadata is the more specific evidence for benchmark execution. The revised package preserves the corresponding sanitized paths and configuration fields without distributing model weights or download instructions.

Historical training reports describe different intermediate models. For example, one Mistral training report records six patched modules and 1,966,080 trainable anchor parameters, whereas the broad benchmark wrapper metadata records 30 patched projections. Treating the former report as the exact training configuration of the latter would be unsupported. We retain this distinction instead of filling the final checkpoint's missing loss schedule from an earlier run.

C Additional Formal Details

Gradient accounting. For one patched projection with fixed input and gate values, a loss L backpropagates through the active low-rank paths. Writing $v = \partial L/\partial y$ and $q_f = m_{a,f} g_f(x)$ gives the local derivatives

$$\frac{\partial L}{\partial B_f} = q_f v (A_f x)^\top, \qquad \frac{\partial L}{\partial A_f} = q_f B_f^\top v x^\top. \tag{6}$$

Freezing W_0 sets its optimizer update $\Delta W_0 = 0$; it does not generally make its formal derivative zero. A trainable router adds derivatives through g_f. These equations clarify the abstraction's gradient flow; they do not establish which historical run froze its router. Exact training reproduction requires source, optimizer configuration, data manifests, and checkpoint hashes linked to each table.

Threshold sensitivity. Thresholds depend on use, rather than on the observed best result. As an illustrative reporting grid, an auditor could vary safety erosion over $\delta \in \{0.10, 0.25, 0.50\}$ and per-task utility tolerance over $\epsilon_t \in \{0.01, 0.03, 0.05\}$, while declaring coherence, helpfulness, and false-refusal requirements. This grid is a proposal, not a preregistered criterion applied to our archived experiments. We do not choose a permissive threshold after inspecting the data and label the prototype safe or unsafe on that basis.

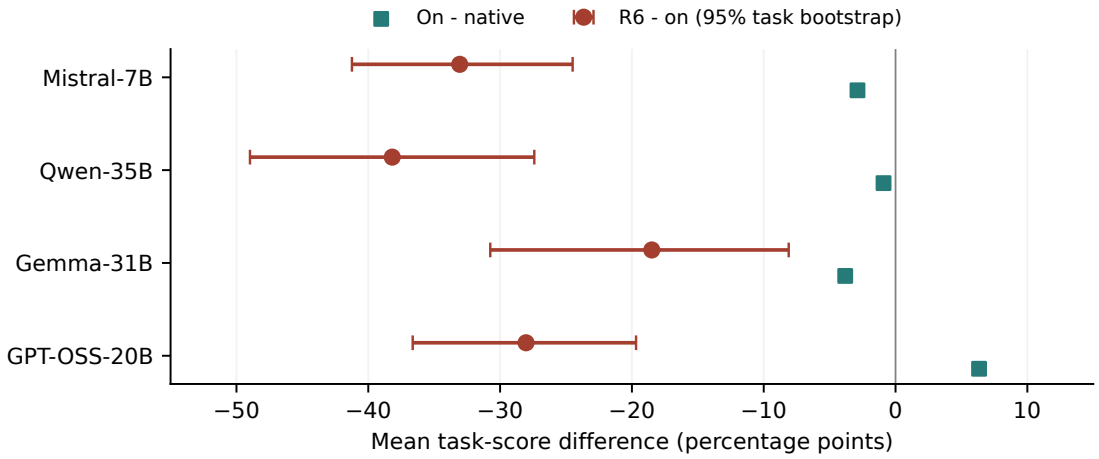

Figure 2: Corrected utility reanalysis. The removal series is the archived Phase-6 wrapper removal R_6, not the Mistral adapter-only control. Intervals describe variation across retained task scores; they do not measure variation across training seeds or certify safety.

Family	Original incomplete triplets	Additional primary exclusions
Mistral	None among the 15 tasks	GSM8K: native/on limit 8 versus removed 1,319. OpenBookQA: removed JSON limit 4 and conflict with archived aggregate.
Qwen	BBH removed missing; MMLU-Pro missing	GSM8K: native limit 4 versus full other conditions.
Gemma	Native HumanEval runtime error; MMLU-Pro configuration errors	None identified beyond original incomplete triplets.
GPT-OSS	MMLU-Pro native and removed missing	None identified beyond original incomplete triplet.

Table 7: Coverage ledger. No unavailable score is interpreted as zero. A recorded zero in an otherwise successful task result remains a score.

D Uncertainty and Reanalysis Details

For k successes in n trials, the Wilson interval used here has center $(\hat{p}+z^2/(2n))/(1+z^2/n)$ and half-width

$$\frac{z}{1+z^2/n}\sqrt{\frac{\hat{p}(1-\hat{p})}{n}+\frac{z^2}{4n^2}}, \tag{7}$$

where $\hat{p}=k/n$ and $z=1.9599639845$. These are marginal descriptive binomial intervals. They do not account for selection of local prompts, scorer error, shared templates, or multiple comparisons.

The Panel A pairing sensitivity conditions on identical prompts and two possible joint-positive counts, zero and one. With zero joint positives, discordant counts are one and seven, giving $2(\binom{8}{0}+\binom{8}{1})/2^8 = 0.0703125$. With one joint positive, counts are zero and six, giving $2/2^6 = 0.03125$. Neither contingency table is known to be the observed one.

For the missing-cell sensitivity, let n be the retained count and $D=\sum_t(u_t(R_6)-u_t(M_0))$. Over all 15 intended tasks, arbitrary bounded excluded differences imply

$$\frac{D-(15-n)}{15} \le \overline{\Delta}_{15} \le \frac{D+(15-n)}{15}. \tag{8}$$

This calculation deliberately ignores partially observed excluded cells, yielding conservative bounds. It concerns only the bounded task-score estimand. Leave-one-task-out mean ranges are also provided in the machine-readable summary.

E Supplementary Reproduction

Run `python reproduce.py` from the supplementary directory. NumPy reproduces tables, task-bootstrap intervals, relative-loss statistics, and missing-cell bounds. Matplotlib additionally renders the two figures. No remote model service or GPU is used. Input hashes, metric fields, and retained configuration metadata link the reanalysis to the supplied benchmark records. The README identifies which historical panels can be recomputed and which remain paper-reported aggregate evidence.

CacheWeaver: Cache-Aware Evidence Ordering for Efficient Grounded RAG Inference

Kaizhen Tan, Rong Gu, Mingyuan Li
Heinz College of Information Systems and Public Policy, Carnegie Mellon University, USA

Abstract

Retrieval-Augmented Generation (RAG) improves factual grounding, but it also lengthens prompts and raises prefill cost. Prefix caching in serving engines such as vLLM reduces this cost only when requests share the same token prefix. In grounded generation, however, adjacent queries may retrieve overlapping evidence in different orders, so set overlap does not become reusable prefix overlap. We present CacheWeaver, a lightweight prompt-layer method for cache-aware evidence ordering. The method keeps a prefix tree over recently served evidence sequences and uses a greedy walk to place the most reusable prefix first, while leaving the serving engine and retrieved evidence set unchanged. Across three vLLM configurations the method lowers median time-to-first-token (TTFT) by about 20–33% relative to retrieval-order prefix caching, without hurting answer quality in our QA tests. The greedy policy reaches 97.5% of the median TTFT gain from oracle ordering, which indicates that most reusable prefix locality can be recovered by a simple scheduling layer between retrieval and inference.

1 Introduction

Retrieval-Augmented Generation (RAG) grounds a large language model (LLM) by adding retrieved passages to the prompt before generation (Lewis et al., 2020; Gao et al., 2023). The price is serving latency: the retrieved context usually dominates the input length, so prefill becomes the main bottleneck for interactive use.

Serving engines address part of this cost with prefix caching. Systems such as vLLM and SGLang reuse previously computed key–value (KV) states through Automatic Prefix Caching (APC) when a new request shares a token prefix with an earlier one (vLLM Project, 2025; Zheng et al., 2024). This works well for repetitive prompts, but much less so in RAG, where retrieved passages overlap in content yet appear in different orders.

That mismatch is the problem we study. Prefix caching operates at the token level, while retrieval returns documents at the chunk level. Two consecutive queries may retrieve nearly the same evidence, but once the first document differs the shared token prefix breaks and most reusable KV blocks are lost. Document overlap is common in RAG; prefix overlap is rare.

Our idea is to change the document order rather than the serving engine. If retrieved documents are reordered to follow a recently cached sequence, the resulting prompt is more likely to match an existing prefix and benefit from APC. We build CacheWeaver, a prompt-layer scheduler that maintains a knowledge tree over recently served document sequences and uses a greedy walk to place the longest likely-cached prefix first. The remaining documents follow in retrieval order, so the system falls back to the original ranking whenever reuse is unavailable. The design rests on three working assumptions: consecutive queries share some documents, reordering evidence does not change correctness in extractive tasks, and the engine's cache state can be approximated by recency of service. These hold in many deployments where queries cluster around related topics. We explicitly evaluate the second assumption because evidence order can affect grounded generation.

Recent work shows that context order affects cache reuse in long-context and RAG serving (Jin et al., 2026; Agarwal et al., 2025; Jiang et al., 2026). Our goal is not to re-establish that ordering matters, but to ask how much of the benefit a minimal, engine-agnostic design can recover. The core policy stays entirely at the prompt-construction layer, requires no change to vLLM, and still performs close to exhaustive oracle ordering.

We study three questions. Can a pure prompt-layer policy deliver meaningful median time-to-

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 161–170
October 29, 2026 ©2026 Association for Computational Linguistics

first-token (TTFT) gains in APC-based grounded RAG inference? Is a greedy trie traversal enough, or does the problem demand heavier search? And do the median TTFT gains survive beyond a single synthetic benchmark, across public question answering (QA) slices, overlap levels, top-k values, and concurrent execution? Our experiments answer yes on locality-bearing workloads and also identify the boundary case: public slices show speedups only when adjacent queries actually share retrieved evidence.

Concretely, we make three contributions. First, we cast cache-aware evidence ordering as a prompt-layer optimization that maximizes reusable prefix depth while leaving the serving engine and the retrieved evidence set unchanged. Second, we give a greedy trie scheduler for this objective, with a complexity analysis and an argument for why it approaches exhaustive ordering. Third, we evaluate it across three measurement configurations and several workloads, including HotpotQA, Natural Questions Open (NQ-Open), and TriviaQA public-data checks and a small top-k sweep. The method gives large median TTFT gains on locality-bearing traces and little median TTFT gain on no-locality public slices, clarifying when cache-aware evidence ordering is useful, while matching retrieval-order answer metrics in bounded QA checks.

2 Background and Related Work

2.1 RAG Serving and Prefix Caching

A standard RAG pipeline encodes the query, retrieves documents, constructs a prompt, and runs LLM inference. Prompt construction is cheap; inference dominates latency. The serving problem is therefore not how to concatenate passages but how to avoid repeated prefill work when many requests share context.

vLLM manages KV-cache memory in fixed-size blocks through PagedAttention (Kwon et al., 2023) and layers APC on top (vLLM Project, 2025). APC reuses cached blocks when a new request shares a token prefix with an earlier one; each block is hashed together with its prefix history, so reuse is inherently prefix-sensitive. Once an early block differs, later blocks no longer line up with the cached chain even when the two prompts contain the same documents, so a small difference near the start of a prompt removes most potential reuse.

Throughout the paper, a *document* is the retrieval unit passed to the prompt builder; it is also called

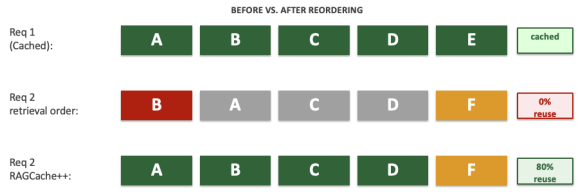

Figure 1: Prefix alignment in APC-based RAG serving. Request 1 is cached. Request 2 shares 80% of its documents but, in retrieval order, the prefix diverges at the first drawn document block, yielding no reusable prefix. Reordering the shared documents to the front restores alignment. For readability each drawn block represents one retrieval passage; in vLLM a passage spans several fixed-size token blocks.

a passage or chunk in some RAG systems. In our benchmarks this unit is one retrieved passage: synthetic passages contain about 200 tokens, while HotpotQA passages are truncated to roughly 160 words to fit the context window. APC does not cache these units directly. It caches fixed-size token blocks, so a matching document sequence maps to the contiguous run of vLLM blocks produced by those passage tokens. In our vLLM runs, the token block size is 16 tokens. Figure 1 therefore idealizes a document as one drawn block for readability; the actual measurements use vLLM's token-block APC unchanged.

This matters for RAG because retrieval overlap is set-based while APC demands ordered prefix agreement. When two requests retrieve the same documents in different positions, their token prefixes diverge immediately and reuse collapses. Figure 1 illustrates the gap and shows why reordering is a natural intervention point.

2.2 Related Work

Several recent systems study KV reuse in long-context and RAG inference at different layers. **RAGCache** (Jin et al., 2026) is closest to ours: it also builds a tree over document sequences, but ties the design to a richer cache-management stack inside the serving system. We borrow the intuition of sequence-aware reuse and target a smaller problem, evidence ordering at the prompt layer, with no engine change. **ContextPilot** (Jiang et al., 2026) reuses context for long-context inference through a context index, ordering, and de-duplication, and supports the same broad message: prefill can shrink by reorganizing context rather than redesigning the model. **Cache-Craft** (Agarwal et al., 2025) shows that plain prefix caching weakens in pro-

duction RAG because retrieved chunks and their order vary across requests, which directly motivates our setting. **TurboRAG** (Lu et al., 2025) and **CacheBlend** (Yao et al., 2025) tackle the harder problem of reusing KV even when reusable chunks are not one contiguous prefix; these methods are more general but more involved than ours, which works with existing APC. **CacheGen** (Liu et al., 2024b) compresses and streams KV caches, which is orthogonal and could be combined with cache-aware ordering. Table 1 summarizes the design point. We ask how much reuse is recoverable with prompt-layer ordering alone on an unmodified prefix-caching engine, and we treat exhaustive oracle ordering as the upper bound for that design point.

3 Method

3.1 Overview

CacheWeaver sits between retrieval and prompt construction. Given a retrieved document set, it reorders the documents so the final prompt is more likely to share a long prefix with recently served prompts. The serving engine still performs all KV-cache allocation and reuse; our layer only decides the document order.

3.2 Knowledge Tree

The knowledge tree is a trie whose root-to-leaf paths record document orders that recently appeared in served requests. Each node stores a document ID with lightweight metadata about recent use. The tree supports two operations: after a request finishes, its ordered document sequence is inserted; when a new request arrives, the trie is consulted to estimate which order is most likely to align with a cached prefix. It thus acts as a compact memory of recent prompt structure, not as a replacement for vLLM's own KV cache.

3.3 Greedy Ordering Algorithm

Problem. Let $D = \{d_1, \ldots, d_k\}$ be the retrieved documents in retrieval rank, and let an ordering O be a permutation of D used to build the prompt. The knowledge tree T records recently served orders, and a node is *cached* when its KV blocks are predicted resident. For an ordering O, define its *reusable prefix depth* $\ell(O, T)$ as the length of the longest leading run $d_{O(1)}, \ldots, d_{O(\ell)}$ that follows a cached root-to-node path in T. Because APC savings grow with the shared prefix length, we seek

$$O^\star = \arg\max_{O \in \Pi(D)} \ell(O, T), \tag{1}$$

where $\Pi(D)$ is the set of permutations of D, and documents past the reused prefix keep their retrieval rank. Restricting O to $\Pi(D)$ keeps the top-k evidence set intact, so reordering changes prefill cost without changing what the model sees.

Algorithm 1 Cache-Aware Evidence Ordering

Require: Retrieved doc IDs $D = \{d_1, \ldots, d_k\}$ (in retrieval rank), knowledge tree T
Ensure: Ordered sequence O

$O \leftarrow []$, $R \leftarrow D$, *node* $\leftarrow T$.root
while $R \neq \emptyset$ **do**
  found $\leftarrow$ `false`
  for each $d \in R$ **do**
    $c \leftarrow$ *node*.getChild(d)
    if $c \neq$ `null` **and** c.isCached() **then**
      Append d to O; remove d from R
      node $\leftarrow c$; *found* $\leftarrow$ `true`; **break**
    end if
  end for
  if *found* $=$ `false` **then**
    Append remaining R in retrieval-rank order to O
    break
  end if
end while
return O

Algorithm 1 gives the ordering policy. Starting from the trie root, it repeatedly checks whether one remaining retrieved document extends a cached path; if so, that document is placed next, and if no cached continuation exists, the remaining documents are appended in retrieval order.

The policy is intentionally simple: it runs no combinatorial search at runtime and instead greedily extends the longest usable prefix reachable from the current trie state. Each iteration probes at most $|R|$ trie children, so the walk costs $O(k^2)$ child lookups for top-k retrieval, negligible for the small k used in practice, and the tree costs $O(Hk)$ space for H retained request paths, bounded by the recency window. An exhaustive oracle, by contrast, searches over the $k!$ candidate orders.

Greedy is optimal for the objective $\ell(O, T)$ whenever every visited node has at most one cached child that still lies in R: with no branch ambiguity, following the single cached continuation yields the

Table 1: Positioning relative to recent cache-reuse systems. The extra-support column describes runtime or cache support beyond a normal prefix-caching server.

Method	Layer	Extra runtime/cache support	Reuse target	Main contrast
RAGCache (Jin et al., 2026)	Serving cache manager	Cache-manager support	Document-sequence KV cache	Richer cache stack inside the serving system
CacheBlend (Yao et al., 2025)	Runtime KV fusion	KV-fusion support	Non-prefix chunk KV	Reuses cached chunks beyond shared prefixes
TurboRAG (Lu et al., 2025)	Offline KV precomputation	Offline KV-cache generation and retrieval	Chunk-level KV	Retrieves precomputed document-chunk KV caches
ContextPilot (Jiang et al., 2026)	Context-reuse runtime	Runtime and context-index support	Reusable context segments	General long-context reuse, ordering, and de-duplication
Cache-Craft (Agarwal et al., 2025)	Chunk-cache management	Cache-manager support	Chunk-level KV caches	Manages reusable chunk caches for production RAG
CacheWeaver (ours)	Prompt construction	No engine/cache support beyond middleware	Ordered evidence prefix	Uses existing prefix caching by reordering evidence

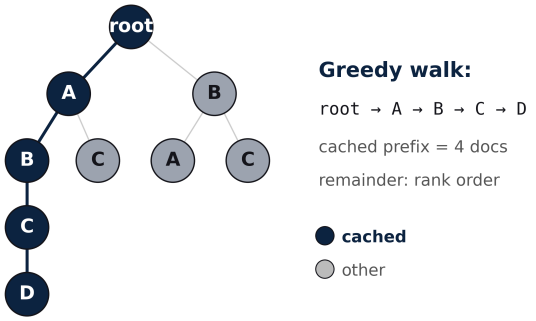

Figure 2: Knowledge tree example. Dark nodes are cached; gray nodes are evicted or on other branches. Given candidate set $\{A, B, C, F, D\}$, the greedy walk follows root→A→B→C→D (the longest cached path), yielding a 4-document prefix hit; the remaining document (F) is appended in retrieval-rank order.

deepest reusable prefix. Sub-optimality can arise only when two cached children remain retrievable at the same node, which is rare under the bursty locality that motivates the method, since recent orders tend to recur. This explains the result of Section 6, where greedy ordering trails the oracle by only 0.46 ms at p50 (Table 4). Figure 2 shows the intuition.

3.4 Cache-State Approximation, Feedback, and Implementation

Unless stated otherwise, the headline experiments use the minimal ordering path: the trie proposes an evidence order, and vLLM performs APC normally. The knowledge tree only approximates the live APC state: it records what was served recently, not what remains resident in GPU memory, which vLLM controls through internal block eviction. The trie can therefore predict reuse for a path whose blocks were already evicted. We treat this as a systems issue rather than a modeling failure. In stable sequential runs the approximation is often good enough on its own. For tighter memory budgets or heavier concurrency, the implementation also supports a TTFT-based feedback loop: when the trie predicts a long reusable prefix but the observed TTFT stays close to a cold request, the supposed cached path is probably gone, so we mark it stale and stop relying on it. A secondary optimization can overlap retrieval with a warmup of the shared system prompt, whose KV states can be prefetched while the retriever runs; this mainly helps cold starts and recovery after eviction and does not change the ordering policy.

We implement CacheWeaver as a Python middleware over vLLM and FastAPI. It uses only the public `LLM.generate` API with APC enabled, so it needs no private engine internals and stays close to a drop-in component rather than a fork. The trie and prompt builder are decoupled from cache bookkeeping, so the ordering logic runs and is unit-tested without a GPU. The fallback is simple and safe: an empty trie or a missing cached continuation returns retrieval order. Feedback is an implementation option for tighter cache budgets rather than part of the headline measurement path.

Table 2: Measurement setup summary.

	Config A	Config B	Config C
GPU	RTX 4060 Ti 8 GB	RTX 4090 24 GB	RTX 4090D 24 GB
Model	Qwen2.5-1.5B	Qwen2.5-7B	Qwen2.5-7B
vLLM	0.8.5.post1	0.17.1	0.8.5.post1
`max_model_len`	2048	4096	4096
`gpu_mem_util`	0.85	0.90	0.90

4 Experimental Setup

Hardware and models. Table 2 summarizes all measurement configurations. The headline controlled TTFT experiments use Configs A and B with Qwen2.5 models (Yang et al., 2024), while Config C is used for the public-data and top-k sensitivity checks. Headline experiments use top-$k = 5$ retrieval because it is a common RAG setting and keeps the oracle comparison exact ($5! = 120$ candidate orders per request); we add a small $k \in \{3, 5, 7, 10\}$ sensitivity sweep below. These are separate measurement campaigns, so absolute TTFT values should be compared within a table rather than across tables.

Workload. The main benchmark uses a controlled synthetic corpus in which consecutive

queries within a burst retrieve overlapping documents. The 100-document and 500-document corpora are not subset relations; they are independently generated from the same region-based template, with roughly 200-token passages grouped into topical regions. The vLLM versions differ because these configurations were run in separate measurement campaigns: Config A on a local 4060 Ti setup, Config B for the headline controlled trace on an RTX 4090, and Config C for public-data and top-k checks. All conclusions compare strategies within the same configuration, not absolute latency across vLLM versions. For two queries with retrieved sets A and B we measure overlap by the Jaccard similarity $|A \cap B|/|A \cup B|$. The setup is deliberately simple: it isolates the systems question of whether reordering can turn document overlap into APC-friendly prefix reuse.

Prompt format. Every prompt is a fixed instruction, then the ordered evidence blocks under `[Document` r`: id]` headers, then the query. All evidence precedes the query, so requests with different questions can still share a token prefix; the rank r in each header means that prefix requires the shared documents in the same leading positions. Only the document order differs between strategies. Appendix A gives the verbatim templates.

Strategies. We compare four settings: no cache, APC with retrieval order, APC with lexicographic sorting, and APC with our optimized ordering, each on a fresh model instance to avoid cache-state contamination.

Metrics. We focus on TTFT, since evidence ordering affects prefill rather than decode. We also report Fast%†, a TTFT-based reuse proxy that our harness computes separately inside each strategy run s:

$$\text{Fast}\%_s^\dagger = \frac{100}{N} \sum_{i=1}^{N} \mathbf{1}[t_i^s < 0.6\, t_{\text{warm}}^s]\,. \quad (2)$$

Here t_i^s is the post-warmup TTFT of request i under strategy s, and t_{warm}^s is the median TTFT of the five warmup requests of that same run. Each strategy is normalized by its own early, mostly cold requests, so the threshold differs per strategy and Fast%† must be read within a strategy rather than compared across strategies. TTFT stays the primary metric, and the cross-strategy compute comparison uses the prefill-saved fraction of Table 13, which divides every strategy by one shared no-cache denominator.

Table 3: Headline TTFT results. TTFT is in ms. Best APC result is bold. Fast%† (Eq. 2) is a within-strategy reuse proxy: a request counts as fast if its TTFT falls below 60% of the median warmup TTFT of the *same* run. Each column entry is normalized by its own strategy, so these values are not comparable across rows.

Setup	Strategy	p50	p95	Mean	Fast%†
Config A	No Cache	158.2	161.4	158.3	0.0
	APC+Retrieval	72.5	**159.9**	69.9	17.9
	APC+Sorted	108.0	164.9	101.7	25.3
	APC+Optimized	**57.9**	161.3	**68.1**	18.9
Config B	No Cache	121.3	123.7	121.4	0.0
	APC+Retrieval	59.6	117.4	55.9	12.3
	APC+Sorted	81.2	118.7	76.3	25.6
	APC+Optimized	**40.1**	**117.4**	**51.4**	19.0

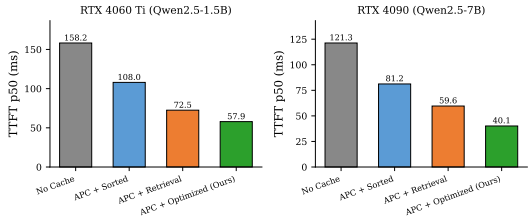

Figure 3: Median TTFT across strategies. Optimized ordering attains the lowest median TTFT on both headline configurations.

5 Main Results

Table 3 shows the headline result, and Figure 3 visualizes the same median TTFT comparison: optimized ordering consistently lowers median TTFT on both headline configurations.

Two points matter more than the raw numbers. First, the gain concentrates at p50 rather than p95, as expected: tail cases are often cold requests where no ordering policy can create reuse. Second, optimized ordering beats lexicographic sorting by 46% at p50 on Config A and by 51% on Config B, even though sorting also produces a canonical, query-independent order. The Fast%† columns cannot be used to explain this, because each is normalized by its own run (Eq. 2). The cross-strategy evidence that a few deep prefix matches are worth more than many shallow ones is the prefill-saved fraction in Table 13, where optimized ordering removes 66.3% of median prefill against 50.1% for retrieval order. Tables 3, 4, and 8 come from separate runs for headline comparison, oracle comparison, and profiling, respectively. The Config B p50 values therefore differ slightly across these tables because each run uses a fresh model process and a measurement goal-specific trace; the authoritative comparison is the within-table delta between strategies.

Table 4: Ordering baseline comparison on Config B.

Strategy	p50 (ms)	Mean (ms)	vs. Retr.
No Cache	121.55	121.73	–
APC+Sorted	81.75	77.42	−35.5%
APC+Retrieval	60.34	57.63	baseline
APC+Recency	59.52	56.62	+1.4%
APC+Optimized (Ours)	**42.50**	**53.77**	+29.6%
APC+Oracle	42.04	53.08	+30.3%

Table 5: Top-k sensitivity on Config C.

k	Mean Jac.	Retr. p50	Opt. p50	vs. Retr.
3	0.296	58.7	**58.0**	+1.2%
5	0.522	62.6	**43.7**	+30.2%
7	0.615	71.8	**67.7**	+5.7%
10	0.909	85.7	**32.2**	+62.4%

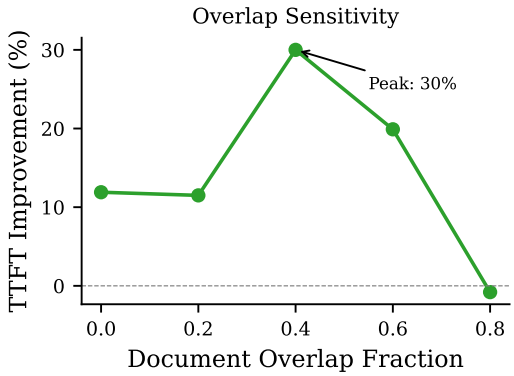

Figure 4: TTFT improvement versus the trace generator's overlap setting.

6 Analysis

Greedy versus oracle ordering. We compare the greedy walk with alternative orderings, including a recency heuristic and an exhaustive oracle (Table 4). The greedy method reaches 97.5% of the oracle's TTFT reduction (+29.6% versus the oracle's +30.3%), so expensive search is unnecessary at this problem size.

Top-k sensitivity. The retrieval depth controls both the opportunity for prefix reuse and the cost of exploring document orders. Table 5 gives a small sweep on the controlled trace. Config C uses 100 queries, with 95 measured after warmup. The gain is not perfectly monotonic, but optimized ordering stays positive at all tested k values and becomes largest when the retrieved sets create deeper reusable prefixes. Table 5 varies retrieval depth, whereas Figure 4 varies adjacent overlap, so the two diagnostics isolate different sources of reusable prefix structure.

Overlap sensitivity. Varying the document overlap in the trace gives an intuitive pattern (Figure 4): ordering helps most at moderate overlap; at very high overlap retrieval order is already close to optimal; at near-zero overlap little reusable structure exists. CacheWeaver is therefore not a universal speedup but is most effective when requests share enough evidence to reuse, yet vary enough that retrieval order is no longer cache-friendly.

Public-data locality diagnostics. We add three public validation workloads as locality and latency diagnostics (Table 6). For HotpotQA fullwiki (Yang et al., 2018), each query uses up to five dataset-provided context passages, with supporting-fact titles first and distractors kept in dataset order. This slice has almost no adjacent reuse (995 unique passages among 996 retrieved passages), so it is a no-locality sanity check: optimized ordering has no median TTFT gain. For NQ-Open (Kwiatkowski et al., 2019), the public split contains questions and answers but no passage contexts, so we build a term frequency–inverse document frequency (TF-IDF) latency workload over public question-answer records and do not report passage-grounded answer quality. For TriviaQA (Joshi et al., 2017), we use the `rc.wikipedia` split and retrieve up to five Wikipedia evidence chunks per question, placing chunks that contain answer aliases first and then keeping the remaining evidence chunks in dataset order. HotpotQA and NQ-Open use the first 200 validation examples in dataset order; TriviaQA uses the first 200 validation examples after filtering examples with at least one Wikipedia evidence chunk. In all three runs, the first five requests are warmup, leaving 195 measured queries.

These fixed slices separate two requirements that a stronger public experiment would combine. NQ-Open gives public traffic with modest record-level locality and a 14.0% median TTFT gain, but it lacks passage contexts for our grounded QA check. HotpotQA and TriviaQA do provide passage contexts, but their validation splits are independent samples rather than chronological sessions, so retrieved passages almost never recur. The knowledge tree then holds no cached continuation, Algorithm 1 falls back to retrieval rank on its first iteration, and the optimized prompt is identical to the retrieval-order prompt: on those two slices the method is a no-op by construction, the residual 0.2–1.4 ms differences

Table 6: Fixed public-data locality and latency diagnostics on Config C. These are fixed validation slices, not natural chronological traffic. TTFT is median ms.

Dataset	Locality source	Mean Jac.	TTFT Ret→Opt
HotpotQA	Dataset order	0.000	97.9→98.1
NQ-Open	TF-IDF QA-record reuse	0.068	34.3→**29.5**
TriviaQA	Dataset order	0.000	144.9→146.3

Table 7: Bounded answer-quality checks with the same evidence set under retrieval order and optimized order. Contains-EM counts a response as correct when the normalized gold answer appears anywhere in the output.

Check	Order	EM	Contains EM	F1
Extractive synthetic	Retrieval	1.000	1.000	1.000
Extractive synthetic	Optimized	1.000	1.000	1.000
Two-hop natural	Retrieval	0.675	0.775	0.862
Two-hop natural	Optimized	0.675	0.775	0.862
Two-hop reversed	Retrieval	0.625	0.750	0.826
Two-hop reversed	Optimized	0.625	0.750	0.826

in Table 6 are run-to-run noise, and answer quality is unchanged because the prompts are the same. We therefore do not claim a public trace that simultaneously shows locality, a median TTFT gain, and matched answer metrics; obtaining one needs a sessionized public trace, which we leave to future work.

Answer-Quality Invariance Checks. We report paired QA metrics for retrieval order versus optimized order with the same evidence set (Table 7). The controlled extractive and two-hop checks report exact match (EM), contains-EM, and token F1. Contains-EM is a relaxed exact-match metric that counts a prediction as correct when the normalized gold answer appears anywhere in the generated response. We do not report citation-support rate because these prompts ask for short answers rather than evidence IDs. This is a narrow claim: position can affect long-context QA quality and "lost-in-the-middle" behavior (Liu et al., 2024a). Our evidence only shows that retrieval order and optimized order match on these bounded checks; it does not prove that evidence order never matters.

Systems cost. The middleware adds little measured host-side overhead. As shown in Table 8, profiling on Config B with 195 post-warmup queries shows that greedy ordering plus prompt construction adds about 26 μs per request (roughly 67 μs total) while reducing inference p50 by 29% relative to retrieval order. Throughput stays within 0.4% of baseline APC in sequential and batched execution (Table 9), so the median TTFT gain does not

Table 8: Ordering overhead on Config B. This profiling run uses 195 post-warmup queries. Optimized order plus build totals 67 μs ($\sim$26 μs over retrieval order) while cutting inference p50 by 29% relative to retrieval order; OH is the host-side ordering overhead as a fraction of total request time.

Strategy	Order	Build	Gen. (mean)	Gen. (p50)	OH
APC+Retr.	4.0 μs	36.3 μs	55.5 ms	58.6 ms	0.07%
APC+Opt.	22.2 μs	44.4 μs	52.5 ms	41.4 ms	0.13%

Table 9: Throughput on Config B. This run uses 200 queries with 50 output tokens each; tok/s counts prompt plus output tokens. Optimized ordering matches baseline APC within 0.4%.

	Sequential		Batched	
Strategy	req/s	tok/s	req/s	tok/s
No Cache	1.10	1,270	7.88	9,064
APC+Retrieval	1.19	1,370	82.05	94,382
APC+Optimized	1.19	1,371	81.75	94,029

Table 10: TF-IDF corpus robustness on Config B. This run uses 200 queries and 1,000 passages over 20 topics, without manually imposed burst overlap. Mean adjacent Jaccard is 0.06, and TTFT is in ms.

Strategy	p50	p95	Mean	vs. Retr.
No Cache	45.8	54.1	47.2	–
APC+Retrieval	33.9	46.8	34.2	baseline
APC+Optimized	**24.8**	**46.5**	**27.2**	+26.8%

reduce serving capacity. Because ordering uses the existing APC pool rather than adding a separate GPU-resident cache, the knowledge tree lives in host memory and stays small.

Robustness diagnostics. A second set of diagnostics tests less controlled serving conditions. On a diverse Wikipedia-style synthetic corpus with TF-IDF retrieval and no manually imposed burst overlap, Table 10 shows that optimized ordering still lowers median TTFT by 26.8% over retrieval order. Although the mean adjacent Jaccard is low, repeated topic-specific passages still create occasional reusable prefixes, which the median TTFT captures. The median TTFT gain also persists under concurrent batching, shrinking but staying positive across all tested batch sizes (Table 11), and narrows, though it stays positive, as retrieval latency takes a larger share of end-to-end time (Table 12).

Compute efficiency. TTFT gains align with reduced prefill work. On Config B, optimized ordering avoids 66.3% of median per-request prefill

Table 11: Concurrent-load robustness on Config B. TTFT is average per-request latency in ms over 200 queries. The ordering benefit persists across all concurrency levels.

Batch	No Cache	APC+Retr.	APC+Opt.	Improv.
1	114.7	54.7	50.7	7.3%
2	110.5	48.0	44.3	7.7%
4	103.4	41.6	37.5	9.9%
8	100.9	38.3	35.7	6.8%

Table 12: End-to-end TTFT with retrieval latency on Config B. This run uses 200 queries and reports TTFT in ms. The median TTFT benefit shrinks as retrieval takes a larger share of total time but stays positive throughout.

T_{ret}	Batch	APC+Retr.	APC+Opt.	Improv.
10 ms	1	69.6	51.8	25.6%
	4	51.8	46.9	9.5%
	8	48.9	45.9	6.1%
30 ms	1	89.7	72.4	19.3%
	4	71.8	67.8	5.6%
	8	68.8	66.8	2.9%
50 ms	1	109.3	92.2	15.6%
	4	91.8	87.4	4.8%
	8	88.7	86.3	2.7%

Table 13: Cache-efficiency proxy on Config B (195 queries). Optimized ordering saves deeper prefill on more requests than retrieval order.

Strategy	Saved (p50)	Saved (mean)	Saved (p95)	Benefit
APC+Retr.	50.1%	52.8%	75.6%	176/195
APC+Opt.	66.3%	57.6%	77.7%	185/195

versus 50.1% for retrieval-order APC, and benefits 185/195 requests versus 176/195. We use this prefill-saved fraction as a compute proxy, not an energy or carbon measurement (Table 13).

7 Conclusion

CacheWeaver reorders retrieved evidence so prompts are more likely to match recently cached prefixes, improving KV reuse without changing the serving engine. In APC-based RAG, cache efficiency depends on the evidence order as well as on the model and the backend, which makes evidence ordering a lightweight scheduling problem between retrieval and serving. A simple greedy trie walk reduces median TTFT under locality-bearing traces, recovers much of the lost locality, stays close to oracle ordering, adds negligible host-side overhead, and matches retrieval-order answer metrics in our bounded QA checks.

Limitations. Headline traces are synthetic and bursty, and public-data coverage is limited to fixed 200-example slices rather than a sessionized public trace that jointly reports latency and bounded QA metrics, so absolute median TTFT gains need not transfer unchanged to production traffic. The benefit depends on temporal locality and moderate document overlap: at very high overlap retrieval order often suffices, and at very low overlap little reusable structure remains. Although our bounded QA checks match retrieval-order quality, ordering could affect tasks driven by positional attention patterns, reranker order, or structured reasoning chains. We fix top-k at 5 in the headline vLLM experiments to keep oracle search tractable, so Table 5 is an initial $k \in \{3, 5, 7, 10\}$ sweep rather than a production retrieval-depth study. The knowledge tree only approximates true cache state, and the optional TTFT-based feedback loop remains an indirect signal of residency. CacheWeaver fits deployment-specific serving, such as customer-service systems and enterprise knowledge bases, rather than general assistants handling uncorrelated queries, and our evaluation is small in scale: a few models and retrieval settings, and no large multi-tenant or production traces.

Future work. The next step is to evaluate CacheWeaver on real session traces, where temporal locality comes from user behavior rather than controlled construction. When serving engines expose direct cache-state signals, the middleware can use them to align the knowledge tree with actual residency rather than relying only on prompt history.

Societal impact. This work targets serving efficiency rather than application-level decision making, and it does not change the retrieved evidence set, model, or safety policy. Lower RAG serving cost can, however, make automated customer-service and decision-support systems cheaper to deploy at scale; such systems should retain domain-appropriate human oversight, logging, access control, and grounding checks. The bounded answer-quality checks here are not a general safety guarantee for downstream applications.

A Prompt Templates

The prompt builder concatenates a fixed instruction, one block per retrieved document in the order chosen by the strategy, and the query. The templates below are the exact strings used in all vLLM measurements; line breaks inside the instruction are shown only to fit the column, and the instruction itself is a single unbroken line in the code. Placeholders in braces are substituted verbatim.

Latency runs (`max_tokens=1`) use:

```
You are a helpful assistant. Answer
the question based only on the
provided documents. If the documents
don't contain enough information,
say so.

[Document 1: {doc_id}]
{document text}

[Document 2: {doc_id}]
{document text}

...

Question: {query}
Answer:
```

Answer-quality runs replace the instruction and the final cue so the model emits a short span, keeping the evidence blocks unchanged:

```
Answer the question using only the
provided documents. Return the
shortest answer span, without
explanation.

[Document 1: {doc_id}]
{document text}

...

Question: {question}
Short answer:
```

Three properties of this layout decide whether cross-query prefix reuse is possible. First, the instruction is a shared constant, so every request begins with the same tokens. Second, all evidence precedes the query, so a token prefix can be shared by requests with different questions; a layout that placed the query first would make prefix reuse impossible regardless of evidence ordering. Third, the block header contains the retrieval rank r, so an evidence set reordered into different positions produces different tokens. A cache hit therefore requires the shared documents to appear in the same leading positions, which is precisely the objective $\ell(O, T)$ that Algorithm 1 maximizes. Document identifiers are stable strings: synthetic corpora use generated IDs, and public slices use an 8-hex-digit SHA-1 prefix of the passage title or chunk key, so the same passage yields the same header across requests.

Grounding or Lexical Overlap? A Matched-Pair Study of Internals-Based Faithfulness Probes

Kun Zhang
School of Computing, University of Leeds
pjdf0740@leeds.ac.uk

Abstract

We provide a confound-controlled methodology and a released "wrong-question" diagnostic for internals-based, reference-free hallucination detection, which treats *context-faithfulness* (is an answer entailed by the context?) as a linear residual-stream direction. In the standard extractive setup, faithfulness is almost perfectly correlated with *lexical overlap* (r=0.99), so an apparent "grounding probe" may be a string-matching detector. Our matched SUPPORT×OVERLAP construction *partially* decouples the two (halving the confound to r=0.50), and the diagnostic fools an off-the-shelf NLI model. Across four instruction-tuned 7–9B families: (i) within the overlap-controlled stratum a support contrast is linearly decodable, but a *no-context ablation* shows it reflects question–answer compatibility rather than context use, and is inseparable from factoid-correctness by construction; (ii) it aligns across families up to a linear map, yet answer-length, overlap, and factuality directions align equally well, a generic matched-stimulus property, not grounding-specific; (iii) on the three families we could extract, the synthetic direction does not transfer to real hallucinations, scoring below NLI, confidence, and lexical overlap on RAGTruth, where only an in-domain probe trained on human labels recovers a usable signal.

1 Introduction

A grounded language model should answer from the *provided context*, not from its parametric memory or from surface cues. Reference-free, internals-based methods operationalize this by reading a linear direction from the residual stream: much prior work decodes a "truth" or "lying" direction (Azaria and Mitchell, 2023; Marks and Tegmark, 2024; Bürger et al., 2024), and more recent work extends this style of analysis to a *contextual* faithfulness direction (O'Neill et al., 2025; Gao et al., 2026), an attractive recipe because it needs no external judge and costs roughly one forward pass. We interrogate this recipe *family* rather than any single system: we probe a representative mass-mean direction rather than reproducing a specific observer-model detector, so our negatives bound *this* synthetic axis (§5.4), not stronger internals detectors such as ReDeEP (Sun et al., 2025), which we do not test. Two distinct notions are routinely conflated under this banner: *parametric-factuality* (is a claim true in the model's memory?) and *context-faithfulness* (is a claim entailed by the given context?). Recent work treats both as activation objects and asks how they relate (Wang et al., 2025), but samples the two notions from *different* datasets, so any measured geometry is confounded with topic and lexicon.

We identify a sharper confound that undermines the faithfulness side specifically. In the standard extractive QA setup used to build such probes (e.g. entity-swap contexts (Longpre et al., 2021)), an answer is context-faithful *iff* the answer string occurs in the context. Faithfulness is therefore almost perfectly correlated with *lexical overlap* (r=0.99 in our data), and a probe that appears to read "grounding" may simply detect string copying: because faithfulness and overlap nearly coincide, a near-ceiling probe *could* be reading either, and telling them apart is what our matched construction (§3) is built to do.

A matched control. We introduce a SUPPORT×OVERLAP construction (§3) that crosses semantic support with lexical presence in a 2 × 2 of which we realize three cells, all model-free: the matched supported-present cell, a *wrong-question trap* where the answer is present but answers a different question (supported=no, overlap=yes), and the usual unsupported-absent cell. A paraphrase cell would close the design but has zero yield in this release (§3). This drops

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 171–184
October 29, 2026 ©2026 Association for Computational Linguistics

corr(SUPPORT, OVERLAP) from 0.99 to 0.50, and, tellingly, an off-the-shelf NLI model is fooled by the clean wrong-question trap $\sim$25% of the time, confirming that lexical overlap misleads even "gold" entailment checks.

Contributions. With this control we run a careful study across four model families (Llama-3.1-8B, Qwen2.5-7B-Instruct, Mistral-7B-v0.3, Gemma-2-9B). The result is a confound-controlled methodology and a series of controls that, one by one, attribute the apparent "grounding" signal to factors other than context use.

1. **An overlap-controlled internal signal that reflects question–answer compatibility, not context-grounding (§5.1).** Within the answer-present stratum (lexical overlap held constant), a support contrast is decodable on all four families (collision-free raw AUROC near-ceiling, $\approx$0.99; 0.76–0.88 after purging model confidence). But a *no-context ablation* shows it is mostly question–answer compatibility: removing the context barely changes it (raw 0.95–0.98, confidence-purged does not collapse), so the probe separates the matched answer from the wrong-question answer *without reading the context*. Support also coincides with our *synthetic* factuality label here by construction, so factoid-correctness is not excluded either.

2. **Cross-family alignment up to a linear map (§5.3).** An orthogonal-Procrustes map carries the support direction between families so the transported direction is nearly collinear with the target family's *native* direction (cosine $\approx$0.98, vs. $\approx$0.01 for a random direction through the same map), whereas anchor-projection transfer (Kim and Han, 2026) reaches only 0.76 AUROC here. The transferred-probe AUROC (0.901) equals the within-family bound but is ceiling-saturated, and signed map-aware nulls sit at chance (0.51/0.54); we therefore rest the claim on the cosine. Factuality, answer-length and overlap directions transport identically while a confidence direction does not, indicating a shared stimulus-derived contrast rather than a grounding-specific axis; we do not generalize beyond these four 7–9B models.

3. **The confidence asymmetry runs the wrong way (§5.2).** Contrary to a natural hypothesis, confidence absorbs the *support* axis more than the factuality axis at every one of 71 layer-tests (mean -0.142), so confidence-purging does not separate the two notions.

4. **Synthetic axes do not transfer to real hallucinations (§5.4).** Applied to RAGTruth (Niu et al., 2024), the controlled-stimulus support direction scores *below* NLI, confidence, and lexical overlap among single-pass API-free baselines; within a task no *label-free* internals- or NLI-based signal, including a sentence-level SummaC-style NLI baseline, exceeds $\approx$0.6 macro AUROC, and even lexical overlap, the strongest baseline, reaches only macro 0.647. An in-domain probe trained on RAGTruth human labels recovers a usable signal (0.76–0.81 on the three RAGTruth families; exceeds a conservative single-hypothesis NLI baseline but ties lexical overlap on Qwen), so a real support signal exists in the internals but is a *different direction* from the synthetic axis and needs in-domain annotation.

The takeaway for the "faithful and efficient" agenda is twofold: internals-based support contrasts identified on controlled data are real and remarkably portable across model families (though not grounding-specific), but are not, by themselves, deployable hallucination detectors: on real data, lexical overlap still dominates.

2 Related Work

Geometry of truth and faithfulness. Truthfulness is decodable from activations (Azaria and Mitchell, 2023), largely linearly (Marks and Tegmark, 2024), and partly shared across models (Bürger et al., 2024); how far such a direction transfers is contested. Azizian et al. (2025) find the geometries of truth near-orthogonal across tasks, whereas Bao et al. (2025) report generalization from atomic statements to question answering in the more capable models they test. Wang et al. (2025) treat factuality and faithfulness hallucinations as activation subspaces and argue they overlap; crucially they draw the two notions from different corpora, leaving the geometry confounded with surface form. Adarsh et al. (2026) study how a single truth vector rotates when context is added. We instead hold the two notions on *matched* stimuli and control lexical overlap explicitly; we note, however, that our factuality label is a synthetic gold-answer relabeling rather than a parametric memory-truth probe, so we engage this line methodologically without claiming to adjudicate whether factu-

ality and faithfulness share a direction.

Knowledge conflict and source attribution. Probes can detect knowledge conflict and predict which source a model follows (Zhao et al., 2024; Sun et al., 2025; Brink et al., 2026), decoding-time interventions can steer a model toward the context (Shi et al., 2024), and benchmarks such as FaithEval (Ming et al., 2025) score context-versus-parametric faithfulness behaviorally. These are behavioral/source signals; we ask whether a *content* grounding axis exists that is not reducible to lexical overlap.

Cross-model transfer. Linear concept directions can be aligned across models via orthogonal Procrustes (Schönemann, 1966; Puri et al., 2025) or anchor projection (Kim and Han, 2026). We apply both to a support direction; Procrustes renders it nearly collinear with the target's native direction (cosine $\approx$0.98), whereas anchor projection reaches only 0.76 transfer AUROC (§5.3).

Reference-free hallucination detection. Reference-free detectors fall into three families: *external* entailment/alignment scorers (Zha et al., 2023); *internals*-based probes (single residual directions (O'Neill et al., 2025) and the truth/faithfulness directions above); and *confidence*/correctness signals (Cho et al., 2026; Moreno Cencerrado et al., 2025), with faithfulness-aware UQ (Fadeeva et al., 2026) and self-aware RAG abstention (Zhu et al., 2026) combining several. We use one baseline from each family on RAGTruth (external NLI, model confidence, and lexical overlap), and find our controlled-stimulus axis does not beat them.

3 The SUPPORT×OVERLAP Construction

We build matched statements from NQ-Swap (Longpre et al., 2021), which provides, per question q, a gold answer a_{true} supported by an original context c_{org} and a substituted entity a_{swap} supported by an entity-swapped context c_{sub}. We define three bits per (context, answer): SUPPORT S (does the given context entail the asserted answer for the asked question?), OVERLAP O (does the answer string occur in the context?), and FACTUALITY F (is the asserted answer the correct answer to the *asked* question, irrespective of the context?). S and F coincide except in the answer-absent cell D, where the answer is still factually right but the substituted context no longer supports it. The 2×2 design has four cells, of which we realize three (cell B is unrealized in this release; see below):

cell	(question, context, answer)	S	O	F
A	$(q,\ c_{\text{org}},\ a_{\text{true}})$	1	1	1
B	$(q,\ \text{paraphrase}(c_{\text{org}}),\ a_{\text{true}})$	1	0	1
C	$(q',\ c_{\text{org}},\ a_{\text{true}})$	0	1	0
D	$(q,\ c_{\text{sub}},\ a_{\text{true}})$	0	0	1

Cell C is a *wrong-question trap*: a_{true} is present in c_{org} but is offered as the answer to a different question q' (the next item's question). A realized triple:

A $(q, c_{\text{org}}, a_{\text{true}})$ S=1, O=1, F=1
q: *who played maudie in the movie el dorado*
c: `Charlene Holt as Maudie`; a: *Charlene Holt*

C $(q', c_{\text{org}}, a_{\text{true}})$ S=0, O=1, F=0
q': *who won the american league pennant in 2017*

D $(q, c_{\text{sub}}, a_{\text{true}})$ S=0, O=0, F=1
c_{sub}: `Gwendoline Christie as Maudie`

The donor q' is unrelated in topic, so the A/C contrast is in principle solvable from question–answer compatibility alone, without consulting the context at all: a possibility §5.1 tests directly and confirms. Cell B would paraphrase c_{org} so the answer is entailed but not copied (open instruct model, keeping an item only if token-overlap$\leq$0.34 and an NLI model still entails it); the released build supplies no paraphraser, so cell B has *zero* yield and all reported analyses use the model-free cells A/C/D with $\text{corr}(S, O)$=0.50 (0.56 after removing the donor-collision items below; an orthogonalized corr$\approx$0 design would require cell B). One caveat in cell C: NQ-Swap dev has only 418 distinct questions over 1,200 items, so for 278 items (23.2%) the donor q' is string-identical to q and a_{true} *does* answer it; we flag these *donor-collision* items and report cell-C results with them removed (the full construction will dedup $q' \neq q$). On *clean* cell C an off-the-shelf NLI checkpoint (Laurer et al., 2024; He et al., 2023) still rates 25.5% of unsupported-but-present items as "supported" (mean entailment 0.31, vs. 0.74 for cell A and 0.18 for cell D); the raw 37.6% rate is inflated by the collisions, which NLI entails 77.7% of the time (correctly). Lexical overlap thus misleads "gold" entailment even after the label error is purged (Fig. 1).

4 Probing, Separability, and Transfer

Directions. For a (model, layer) we extract last-token residual states X over the asserted answer span (one forward pass, bf16, left-padded). A SUPPORT direction d_S and FACTUALITY direction d_F are mass-mean (difference-of-means) estimates

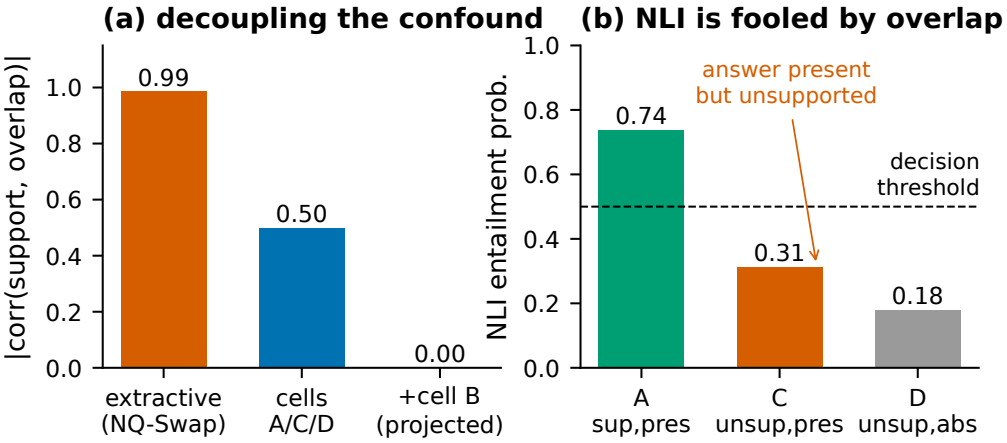

Figure 1: **Partially decoupling support from lexical overlap.** (a) The matched construction drops $|\mathrm{corr}(\textsc{Support}, \textsc{Overlap})|$ from 0.99 (extractive NQ-Swap) to 0.50 (model-free cells A/C/D), and would reach ≈ 0 with the paraphrase cell B (projected; cell B has zero yield in this release). (b) Mean NLI entailment by *clean* cell: on the wrong-question trap (C), where the answer is present but unsupported, NLI is still pulled toward "supported."

(Marks and Tegmark, 2024); signed projections Xd are the probe scores. Every reported number uses one protocol. Folds are grouped by *source*, not by record: by the normalized (question, context, answer) triple of the underlying NQ-Swap QA for CtrlPairs (1,200 records, 555 triples) and by source passage for RAGTruth (2,000 responses, 450 passages), since ITEM_ID indexes one swap record or one response and does not isolate sources. Residualization is fitted *within* each training fold. AUROC is *signed*: polarity is fixed on the training fold and the test projection scored as-is, with no $\max(\mathrm{AUC}, 1-\mathrm{AUC})$ flip anywhere, so a non-predictive direction averages to 0.5 instead of being floored above it. Folds come from a seeded group splitter; pooled estimates are mean±sd over ten splits, with source-cluster bootstrap CIs on the first.

Overlap control. To test grounding *beyond* overlap we (i) restrict to the answer-present stratum $O{=}1$ (cells A vs. C), where lexical presence is constant, and (ii) residualize X on surface covariates (overlap, length) before re-probing.

Null-calibrated separability. We treat each notion as an undirected axis and measure the acute angle $\angle(d_S, d_F)$. Significance is assessed against a within-notion null built by splitting one notion's data in half, re-estimating the same axis on each half and measuring the half-vs-half angle; this is a resampling null, not a label permutation. With $n_{\mathrm{null}}{=}2{,}000$ draws per notion we report the resolution bound $p{<}5{\times}10^{-4}$ rather than $p{=}0$ when no null draw exceeds the observed angle. It is run per family at the a-priori mid layer on all three cells; it cannot be posed *within* the overlap-controlled stratum, where S and F coincide exactly.

Confidence purge. We regress each hidden dimension on three confidence covariates (mean log-prob, mean max-softmax, first max-softmax) and re-probe the residual. For the asymmetry test (§5.2) we quantify how much of an axis *is* confidence as $\mathrm{absorbed}$, the adjusted R^2 of that axis's projection regressed on the same three covariates; unlike a purge-then-re-probe AUROC delta this is not confounded by the denoising side effect of residualizing.

Cross-family transfer. Families differ in hidden size, so we fit a semi-orthogonal Procrustes map between two models' residual spaces on a shared calibration split, transport a source-trained probe, and measure target AUROC. The calibration/evaluation split is a seeded half-split over source-QA groups (items in the calibration set are disjoint from the evaluation set), so the map is never fit and tested on near-duplicate rows of the same item; transported-probe polarity is fixed on the target calibration fold. We compare to the anchor-projection ACS baseline (Kim and Han, 2026), a within-family upper bound, and a random-direction floor (also scored without the polarity flip, so it sits at chance rather than being inflated above 0.5).

5 Experiments

Setup. Four instruction-tuned families: Llama-3.1-8B (Llama Team, 2024), Qwen2.5-7B (Qwen Team, 2024), Mistral-7B-v0.3 (Jiang et al., 2023), Gemma-2-9B (Gemma Team, 2024). CtrlPairs: 1,200 NQ-Swap items → 3,593 matched statements (cells A/C/D). RAGTruth: 2,000 test responses with response-level hallucination labels (Niu et al., 2024). Baselines: NLI (the `DeBERTa-v3-base-mnli-fever-anli` checkpoint (Laurer et al., 2024), DeBERTaV3 (He et al., 2023) fine-tuned on MNLI, FEVER and ANLI (Williams et al., 2018; Thorne et al., 2018; Nie et al., 2020)) in two variants, (i) *whole-response*: a single (context, declarativized-answer) entailment query; and (ii) *sentence-level*, a SummaC-style decomposition (Laban et al., 2022) that entailment-checks each response sentence against every context sentence, takes the max over context, and aggregates over response sentences by mean (SummaC-ZS) or min (for tractability we cap context at 60 sentences and pairs at 256 tokens, which can only lower SummaC and is thus conservative), plus max-softmax confidence and lexical overlap. Everything is API-free.

5.1 The within-stratum signal is question–answer compatibility, not grounding

Leakage control. Grouping on ITEM_ID is not sufficient, because it isolates swap records, not source QAs: 941 of the 1,200 cell-A rows have an identical twin (after case/whitespace normalization) under a different ITEM_ID (mid-layer cosine 0.9999), and 903 of them landed in a different fold. We group by the source QA triple instead (555 groups), for the C1 cross-validation, the Procrustes calibration split (§5.3) and the cross-strata control, which is additionally evaluated on *held-out* groups. Regrouping moves every C1 estimate by at most 0.007 (App. A): the leak is real but inert. To avoid selecting the layer on the very number we report, we fix the analysis layer *a priori* at relative depth 0.5 (the nearest cached layer to $0.5\,L_{\text{tot}}$: L=14/16/16/21 for Qwen/Mistral/Llama/Gemma), matching the relative-depth convention already used for C3/C4 and for Fig. 2; App. A reports the mean±sd across the mid-layer band (0.4–0.6 depth).

Table 1 reports support decodability within the answer-present stratum O=1 (cells A vs. C), where lexical overlap is held constant, on the *collision-free* cells: we drop the 23.2% of cell-C items whose donor question is string-identical to the original (§3), which would otherwise mislabel genuinely-supported items as unsupported. Four observations bound the interpretation. First, the raw within-stratum AUROC is *near-ceiling* (0.99; 0.988–0.998 across families): once mislabels are removed, A and C are almost perfectly separable. We read this less as strong grounding than as evidence that the contrast is *easy*: within O=1 it varies *only the question* (context and answer are fixed), so a probe can in principle separate A from C by question–answer appropriateness without using the context. Second, the operative confound is *model confidence* (overlap and answer length are uninformative here, AUROC 0.500): answer log-prob and NLI separate A from C on their own, so we residualize the hidden states on the three confidence scalars; the support contrast then falls to 0.76–0.88, which we take as the primary confound-controlled estimate. Third, and decisively, a *no-context ablation* settles what the signal is (Table 2): re-extracting the A/C activations with the context *removed* (question+answer only), or with it replaced by an unrelated passage, leaves $\text{supp}_{O=1}$ almost unchanged, and the confidence-purged estimate does not collapse either, and it *rises* for three of four families, and rises further under a substituted context. The within-O=1 contrast is therefore mostly *question–answer compatibility*: the probe separates A (whose question the answer fits) from C (whose donor question it does not) *without reading the context at all*. A cross-strata control (train A vs. D, which fixes the question but also varies overlap since D is answer-absent; evaluate A vs. C) does transfer at 0.66–0.88. Here A and D share the question and the answer string and differ only in the context, so an A-vs-D direction cannot be a question–answer compatibility axis by construction (the exact complement of the ablation above), and *some* context-sensitive component therefore exists, but it is an upper bound and not separable from the dominant compatibility signal here. Finally, support and our *synthetic* factuality label are *identical* within O=1 by construction (they diverge only in the answer-absent cell D). We therefore make no context-grounding claim within this stratum.

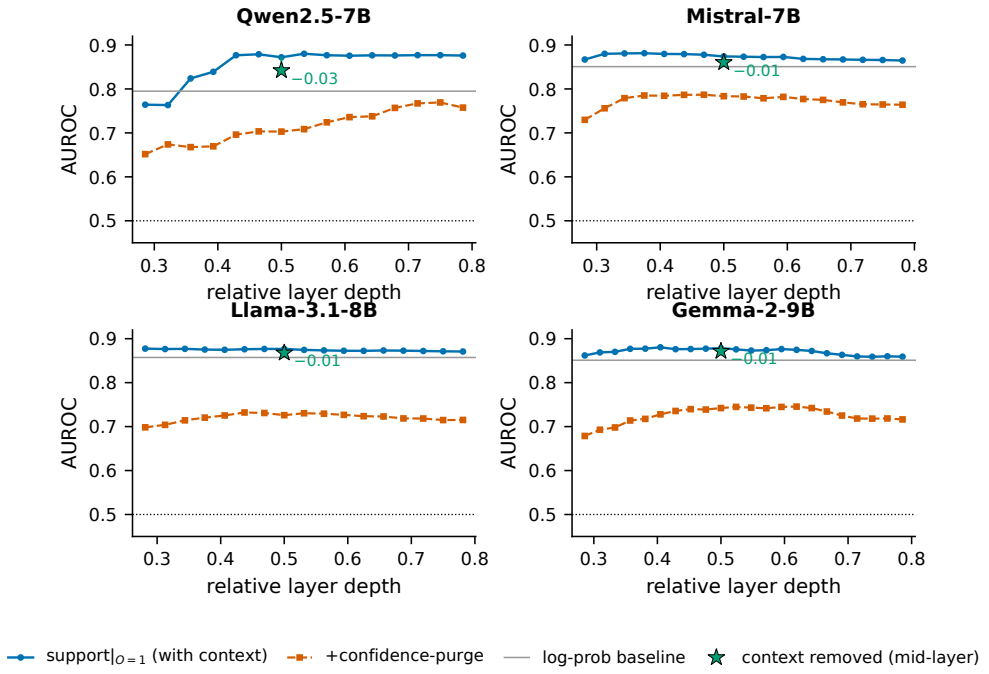

Figure 2: **The within-stratum contrast peaks mid-layer, but it is not grounding.** Cross-validated AUROC vs. relative layer depth for the support contrast within the answer-present stratum ($O{=}1$, where overlap is uninformative): raw, and after purging model confidence; the gray line is a log-probability baseline. The contrast is high and stable through mid layers on all four families. Curves use the same source-grouped, signed protocol as Table 1 but *retain* the donor-collision mislabels, hence their lower level (≈ 0.87 raw): removing those items is what lifts the contrast to near-ceiling. The green star marks the same probe at the a-priori layer with the context *removed*: the raw AUROC barely moves (drop annotated), and shuffled context behaves the same. On the collision-free sample of Table 1 (not the curves plotted here) the purged value even *rises* for Qwen ($0.760{\rightarrow}0.838$) and Llama, is flat for Gemma, and falls materially only for Mistral ($0.878{\rightarrow}0.805$). The within-$O{=}1$ contrast is therefore mostly question–answer compatibility rather than context use.

5.2 The confidence asymmetry runs the wrong way

On the full three-cell sample the two axes are not collinear: at the a-priori layer $\angle(d_S, d_F)$ is $78°/54°/67°/65°$ for Qwen/Mistral/Llama/Gemma, each beyond every draw of its within-notion null ($p{<}5{\times}10^{-4}$). This says little, though: those stimuli have $\mathrm{corr}(S, F){=}0.50$ by construction, and inside the overlap-controlled stratum the labels coincide exactly, so the angle cannot establish an overlap-independent axis.

We also hypothesized that confidence absorbs factuality more than faithfulness, which would separate them. It does not, and the effect runs the other way at every layer we measured. Over all four families (71 layer-tests), $\mathrm{absorbed}(F){-}\mathrm{absorbed}(S)$ averages -0.142 (sd 0.062): *all* 71 are negative and 70 are one-sided significant in the direction *opposite* to the hypothesis (per-family means -0.104, -0.122, -0.131, -0.193), so confidence absorbs the support axis *more* and we do not rely on confidence-purging to distinguish the two notions.

5.3 Matched-stimulus contrasts align across families up to a linear map

We ask whether the support direction occupies the *same* geometry across families up to a linear map. The direct evidence is geometric: the Procrustes-mapped source direction is nearly collinear with the target family's *native* direction (transported-to-native cosine 0.976, range 0.95–0.99 over the 12 ordered pairs; Table 3); anchor projection reaches only 0.76 transfer AUROC against Procrustes' 0.901 (Fig. 3), and the two are not comparable in cosine because ACS has no target-space direction. The cosine is far above its null: a random or label-shuffled source direction transported through the *same* fitted map is essentially orthogonal to the native direction (cosine 0.01 and 0.13 respectively), so 0.976 is not an artifact of the shared-stimulus geometry. It is also not an artifact of fitting the map and the directions on the same items: with

model	L	supp$_{O=1}$	+conf	cross
Qwen2.5	14	0.988	0.760	0.661
Mistral	16	0.996	0.878	0.870
Llama	16	0.997	0.789	0.876
Gemma	21	0.998	0.811	0.827

Table 1: **C1 (confound-controlled, collision-free).** Layer fixed a priori at relative depth 0.5; folds grouped by *source QA* (555 groups over 1,200 records); polarity resolved on the train fold and scored signed; donor-collision cell-C mislabels removed (§3; n_A=1,200, n_C=922). Each entry is the mean over ten seeded splits (sd ≤ 0.003). supp$_{O=1}$ is support AUROC within the answer-present stratum, near-ceiling once mislabels are removed, because the contrast varies only the question (source-cluster 95% CIs $[0.983, 0.992]$, $[0.993, 0.998]$, $[0.995, 0.999]$, $[0.997, 0.999]$). *+conf*: hidden states residualized on the three confidence scalars, fitted within each fold; our primary estimate. *cross*: train A vs. D, evaluate A vs. C on *held-out* groups, *raw* rather than confidence-purged, hence an upper bound and not on the same footing as the *+conf* column. Within O=1 support and the synthetic factuality label coincide, so we make no distinctness claim.

		with context		no context		shuffled	
model	L	raw	+conf	raw	+conf	raw	+conf
Qwen2.5	14	0.988	0.760	0.947	0.838	0.938	0.888
Mistral	16	0.996	0.878	0.975	0.805	0.976	0.809
Llama	16	0.997	0.789	0.980	0.814	0.982	0.839
Gemma	21	0.998	0.811	0.984	0.812	0.983	0.841

Table 2: **The within-O=1 contrast does not need the context.** supp$_{O=1}$ re-extracted with the context removed (question+answer only) and with it replaced by an unrelated passage; same a-priori layers and same collision-free sample as Table 1 (n_A=1,200, n_C=922), same source-grouped signed protocol. Removing the context costs at most 0.05 raw, and the confidence-purged contrast is *higher* without the context for three of four families, and highest of all when the context is replaced by an unrelated passage (Qwen 0.760→0.888). Only Mistral falls (0.878→0.805).

the map fit on a calibration split and the target's *native* direction re-estimated on a disjoint, source-grouped held-out split, the transported-to-native cosine is 0.962±0.015 (mean over 12 pairs × 10 splits; 0.958 with both source and target directions held out from the map), close to the in-sample value (Table 3); the ∼0.014 drop is about the native direction's own cross-split self-consistency loss (0.986), so the Procrustes map adds no measurable inflation (factuality behaves identically, 0.990→0.975). We deliberately do *not* headline the transferred-probe AUROC (0.901): it equals the within-family bound

axis	cosine	AUROC	within	rand-map	rand-lab
SUPPORT	**0.976**	0.901	0.900	0.509	0.543
FACTUALITY	0.990	0.914	0.910	—	—
nuisance directions:					
length	0.977	—	—	—	—
overlap	0.991	—	—	—	—
confidence	0.509	—	—	—	—

Table 3: **C3 (cosine-based, leakage-controlled).** Mean over the 12 cross-family ordered pairs and ten seeded source-grouped splits. *cosine*: transported-to-native cosine (the alignment evidence; non-saturating); shown in-sample, it stays at 0.962 when the native direction is re-estimated on a source-grouped held-out split (§5.3), so it is not a map-fitting artifact. A random / label-shuffled source direction through the *same* map has cosine only 0.01 / 0.13 with the native direction. *AUROC/within*: transferred-probe vs. within-family AUROC: equal, hence ceiling-saturated. *rand-map/rand-lab*: random / shuffled-label directions through the map, signed AUROC, at chance. Support, factuality, answer-length and overlap directions all align at ≈0.98, while a model-internal confidence direction does not (0.51): alignment is a generic property of contrasts derived from the shared stimuli, not a grounding-specific axis.

(0.900) and is therefore ceiling-saturated; scored with polarity-honest (signed) AUROC, random and shuffled-label directions through the map sit near chance (0.51/0.54). **This alignment is not specific to grounding.** Transporting the *factuality*, *answer-length*, and *lexical-overlap* directions through the same maps gives cosines of 0.99/0.98/0.99, as high as support, whereas a purely model-internal *confidence* direction transports at only 0.51 (and unstably, 0.08–0.87 across pairs). So what aligns is any contrast *derived from the shared input stimuli*, a shared low-rank stimulus geometry, not a grounding-specific axis; that confidence does *not* align shows the alignment is non-trivial but also that it carries no grounding-specific content. We therefore conclude only that *matched-stimulus contrasts, support among them, are linearly alignable across these four 7–9B families*, and avoid any claim of a grounding-specific or near-lossless transfer.

5.4 Synthetic axes do not transfer to real hallucinations

We learn d_S on CtrlPairs and apply it to the fixed RAGTruth responses (the NLI and overlap baselines are response-intrinsic, hence identical across models), predicting the human faithfulness label (Table 4). Here we keep the *support-polarity* sign

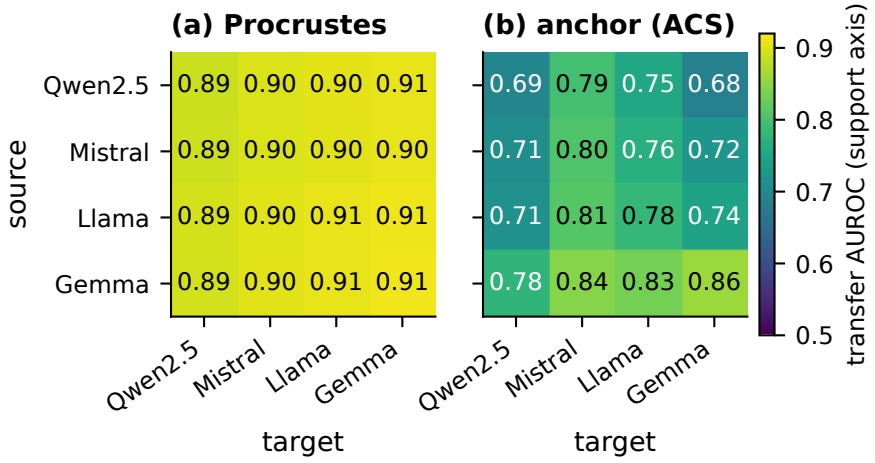

Figure 3: **Matched-stimulus contrasts align across families up to a linear map.** Source→target transfer AUROC of the support direction; every cell, diagonal included, uses that panel's own estimator, source-grouped. (a) Orthogonal Procrustes is uniformly high on- and off-diagonal (0.89–0.91); we read this as alignment (cosine 0.98, Table 3), not lossless transfer, since the AUROC is ceiling-saturated. (b) Anchor projection (ACS), scored the same way, is uniformly lower (0.68–0.86) and its own diagonal (0.69–0.86) stays well below Procrustes' 0.89–0.91, so its gap to Procrustes is not a transfer effect.

fixed from CtrlPairs and score without the test-fold flip, because flipping per-test inflates a near-chance axis; CtrlPairs and RAGTruth share no items, so there is no leakage in this transfer. Scored honestly, the label-free synthetic axis reaches only 0.54–0.66 AUROC (and drops toward chance for the weakest family), *below* NLI (0.673), model confidence (0.62–0.72), and plain lexical overlap (0.753), the strongest label-free baseline on RAGTruth (Fig. 4). Paired source-passage cluster-bootstraps confirm the ordering against overlap ($\Delta{=}-0.097/-0.163/-0.212$) and confidence ($p{<}0.001$, $p{=}0.028$, $p{<}0.001$), though against whole-response NLI only Llama and Gemma separate ($p{<}0.001$); Qwen ties ($\Delta{=}-0.017$, CI $[-0.051, +0.017]$). A more sophisticated sentence-level NLI baseline (SummaC-style, max entailment over context sentences) does no better: pooled 0.614/0.664 and within-task macro 0.596/0.579 (mean/min), essentially tied with the whole-response NLI (0.582) and still well below overlap (Table 6); many RAGTruth hallucinations are abstractive errors that survive sentence-level entailment. An *in-domain* probe (5-fold grouped-CV L_2-logistic on the same mid-layer states, target=human faithfulness label) does recover a usable signal: AUROC 0.76/0.81/0.80 for Qwen/Llama/Gemma (passage-cluster 95% CIs in Table 4). It exceeds our NLI baseline (0.673) on all three families (a conservative whole-response check, §5); against the strong overlap baseline (0.753) it wins on Llama ($p{=}0.002$) and Gemma ($p{<}0.001$, paired source-passage cluster bootstraps) but only ties on Qwen ($+0.01$, $p{=}0.27$). Residualizing lexical overlap and answer length out of the features first, within each training fold, leaves 0.68–0.73, so some of this signal is overlap but much of it is not. A real support signal therefore exists in the internals, but it is a *different direction* from the synthetic axis and is recoverable only with in-domain human annotation. That comparison changes the estimator (mass-mean to L_2-logistic) and the training domain at once, so we separate them (Table 5): holding the estimator at mass-mean, the *same* estimator that transfers at 0.596 from CtrlPairs reaches 0.781 fitted in-domain, whereas swapping mass-mean for L_2-logistic moves it by at most 0.074 and in both directions. The two effects do not overlap: every domain effect in the table (0.131–0.306) exceeds every estimator effect (0.016–0.074). What separates the two is the training domain, not the estimator.

6 Conclusion

Our results separate two questions usually merged. *Does* a non-overlap signal exist in the internals? Within the overlap-controlled stratum a contrast is decodable (0.76–0.88 purged) and aligns across four families up to a linear map, but a no-context ablation shows it is mostly *question–answer compatibility*, not context use, and the alignment is

model	label-free synth-d_S	label-free conf	labeled in-dom†	NLI	overlap
Qwen2.5	0.657	0.723	0.765	0.673	0.753
Llama	0.591	0.623	0.814	0.673	0.753
Gemma	0.541	0.686	0.797	0.673	0.753

Table 4: **C4 (leakage-controlled).** RAGTruth hallucination detection (AUROC; three families, Mistral's RAGTruth extraction OOM'd). The label-free synthetic support axis (synth-d_S, support polarity fixed from CtrlPairs, a-priori mid layer, scored without the test-fold flip) is below NLI, confidence, and lexical overlap, and for the weakest family (Gemma, 0.541) is barely above chance. †uses RAGTruth human labels (not label-free); source-passage cluster-bootstrap 95% CIs $[0.737, 0.786]$, $[0.780, 0.824]$, $[0.776, 0.820]$.

Llama	0.591	0.517	0.774	0.813
Gemma	0.541	0.492	0.781	0.798
mean	0.596	0.544	0.781	0.792

Table 5: **Estimator × training domain (C4).** RAGTruth AUROC at the same a-priori layers, scored signed. Column 1 is the synth-d_S column of Table 4; the other three hold one factor fixed in turn. Changing the training domain is worth ≈0.19 at a fixed estimator (mass-mean 0.596→0.781); changing it is worth at most 0.074 and moves in both directions: CtrlPairs-trained logistic is *worse*, and below chance on Gemma. The ranges are disjoint: domain effects span 0.131–0.306, estimator effects 0.016–0.074. Both RAGTruth columns are 5-fold passage-grouped CV over 20 seeds (sd ≤ 0.006); the logistic one is the same quantity as Table 4's in-domain column and agrees with it to 0.001.

a generic matched-stimulus property (length and overlap directions align equally well). An apparent "grounding" signal thus survives an overlap control yet is still not grounding. *Is* that direction a deployable, label-free hallucination detector? No, it does not transfer to RAGTruth, where lexical overlap remains the strongest single-pass baseline (and even that edge is largely a between-task base-rate artifact: Table 6). The gap between a clean controlled signal and real-world utility is the main lesson, and it cautions against reading deployment claims from synthetic-stimulus probes; whether any label-free signal can beat lexical overlap on real hallucinations is the natural next question.

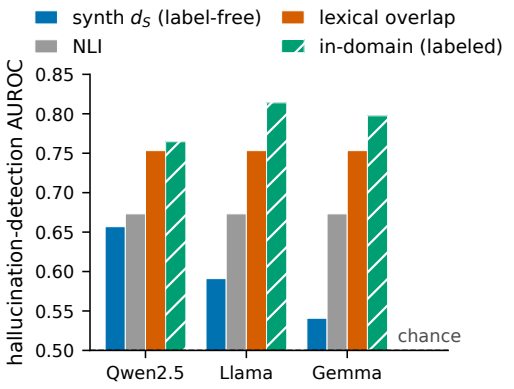

Figure 4: **The synthetic axis does not transfer to real hallucinations.** On RAGTruth, the label-free synthetic support axis (ours) sits below NLI and below plain lexical overlap, the strongest baseline. Among the *internals*-based scores only the in-domain probe, which uses RAGTruth human labels, clears NLI. Axis starts at chance (0.5).

in-domain†	0.766	0.680	0.673	0.706
faithful-rate	0.357	0.823	0.795	—

Table 6: **C4, per task type.** Within-task RAGTruth AUROC; synth-d_S, confidence and in-domain are means over the three models, NLI and overlap are response-intrinsic. The pooled numbers in Table 4 overstate every signal because faithful base rates differ sharply across tasks (bottom row): overlap 0.753→0.647, NLI 0.673→0.582, the axis 0.596→0.585. *Sent-NLI* is the SummaC-style sentence-level baseline. Within a task every label-free signal is weak (0.58–0.65 macro; the axis is below chance on Data2txt), and overlap is merely the least-bad. †uses RAGTruth human labels (0.706 macro).

Limitations

We are explicit about what we do *not* show. (i) Within the answer-present stratum the decodable contrast is question–answer compatibility (a no-context ablation leaves it almost unchanged, raw 0.95–0.98) and coincides with our synthetic factuality label by construction, so we cannot claim a context-grounding signal there; only a question-fixed cross-strata control (0.66–0.88) shows any context-sensitive component. (ii) Cell B has zero yield, so the fully-orthogonalized (corr≈0) design

is not instantiated and all analyses use cells A/C/D, where $\mathrm{corr}(S, O)$=0.50 over all 3,593 rows and 0.565 on the collision-free subset that Table 1 and the mid-layer band use; the realized data is a three-cell partial factorial, not a balanced 2×2, and within O=1 the support and synthetic factuality labels are the identical vector, so $\mathrm{supp}_{O=1}$ is simultaneously a factuality AUROC. (iii) The cosine alignment is measured on shared stimuli, so it shows alignment of a shared low-rank contrast, not a fully unpaired transfer. (iv) We evaluate a deterministic strided 2,000-row subset of the 2,700-row `wandb/RAGTruth-processed` test split (450 source passages, 4–5 responses each), covering three task types and one annotation scheme, and the negative is on 3/4 families (Mistral's RAGTruth extraction OOM'd at the longer context length and we did not retry it at a smaller batch size). (v) All probes read the residual stream at the *final answer token*. CtrlPairs answers average 1.7 tokens, so this is near-lossless there; RAGTruth responses average 126.6 tokens, so last-token pooling discards most of the response. We extracted no other pooling and cannot test the alternative here, so the RAGTruth results should be read as specific to this choice. All four instruction-tuned models are also probed with a single raw completion template rather than their chat templates; this sensitivity is untested. (vi) Support labels are validated automatically and by a 40-item manual audit of clean cell C (0/40 mislabeled), not by a multi-annotator study with agreement statistics. (vii) Stronger internals detectors (e.g. ReDeEP (Sun et al., 2025)) and sampling-based methods (Manakul et al., 2023) are out of our single-A100 budget, so we show that *this* synthetic axis fails, not that internals cannot work.

Ethical Considerations

This paper reports a negative result about a class of proposed detectors, and its main practical risk is over-trust in the opposite direction: a label-free internals probe of the kind we study reaches only 0.54–0.66 AUROC on RAGTruth, below plain lexical overlap (0.753), so deploying one as a hallucination guard would give a false sense of coverage. We therefore recommend validating an internals-based grounding probe against a lexical-overlap baseline on in-domain human labels before claiming it is deployable. CtrlPairs is constructed automatically from NQ-Swap Wikipedia text and involves no new human subjects, no new annotation, and no personally identifying information beyond what the source corpora already contain; the "wrong-question" items are deliberately mislabeled stimuli for probing and are not intended as training data. All experiments are inference-only on a single A100-40G, with no model training or fine-tuning.

A Implementation Details and Reproducibility

Code, the constructed datasets, every result JSON and the figures are available at `https://github.com/Beiciccc/GroundLM`, together with a manifest mapping each number, table and figure in this paper to the script that produces it and the files that script reads and writes. The 2.4 GB of cached residual-stream features the analysis consumes are too large to distribute with the source: `reproduce.sh extract` regenerates them from the released datasets on one A100-40G, after which `reproduce.sh` recomputes every reported number, table and figure on CPU. Below we fix every choice a reader would need to re-run the study.

Layer choice and fold-split sensitivity. Table 1 fixes the analysis layer a priori at relative depth 0.5. Averaging the same collision-free, source-grouped estimate over every cached layer in the 0.4–0.6 band gives $\text{supp}_{O=1}$ of 0.990 ± 0.004 (Qwen, 5 layers), 0.996 ± 0.002 (Mistral, 7), 0.996 ± 0.001 (Llama, 7) and 0.998 ± 0.001 (Gemma, 9), and confidence-purged values of 0.765 ± 0.016, 0.877 ± 0.003, 0.792 ± 0.003 and 0.809 ± 0.008: the result is not a single-layer artifact. We also avoid `GroupKFold`, which assigns folds by sorting group sizes: our group sizes are almost all tied (1,193/1,200 CtrlPairs items have three rows; every RAGTruth response is its own record), so its split depends on `numpy`'s `argsort` tie-breaking and changes with the library version: we measured the Llama in-domain probe moving from 0.815 to 0.824 across two `numpy` releases on otherwise identical inputs (recorded in the protocol note at the top of `scripts/_cr_common.py`). Every reported estimate instead uses an explicitly seeded group splitter over source groups. The pooled probe estimates in Tables 1 and 4 are means over ten such splits (split-to-split sd ≤ 0.003 and ≤ 0.007 respectively); the per-task breakdown in Table 6, the cluster-bootstrap intervals and Figures 2 and 3 are computed on the first split.

Parametric-belief check. Before probing we verify closed-book that each model actually prefers the gold answer: with the context removed, we compare the mean answer-token log-probability of a_{true} against a_{swap} per item. The gold answer wins for 84.0% (Qwen), 92.6% (Mistral), 94.8% (Llama) and 95.2% (Gemma) of the 1,200 items. All reported results use the full set; the per-item flag is released in the `runs/*_v2/parametric_belief.npz` caches and the analysis library accepts a knows-gold mask, but no script in the released pipeline conditions on it.

Artifacts and licenses. We build on the entity-substitution framework of Longpre et al. (2021), whose own release is under the Apple Sample Code License, via the `pminervini/NQ-Swap` distribution (MIT) that our build script loads; RAGTruth (Niu et al., 2024) and the DeBERTaV3 MNLI/FEVER/ANLI checkpoint (Laurer et al., 2024; He et al., 2023) are MIT. The probed checkpoints are Qwen2.5-7B-Instruct and Mistral-7B-Instruct-v0.3 (Apache-2.0), Llama-3.1-8B-Instruct (Llama 3.1 Community License; this work is "Built with Llama") and Gemma-2-9B-it (Gemma Terms of Use). All use is non-commercial academic research, consistent with the intended use each artifact states. Our code is released under the MIT license; the constructed CtrlPairs data derives from that NQ-Swap distribution and inherits its terms. The redistributed RAGTruth subset contains third-party source text that we did not filter for incidental contact details already present upstream.

Prompt and answer span. Activations are extracted from a raw template (no chat formatting): `"{context}\n\nQuestion: {question}\nAnswer:"`, to which the *asserted answer*, a teacher-forced gold surface string (NQ-Swap $a_{\text{true}}/a_{\text{swap}}$ for CtrlPairs; the model-generated response for RAGTruth), is appended with a single leading space and no special tokens. Inputs are *left*-padded, so the answer occupies the final positions. The probe feature $\texttt{last}_L$ is the last-token residual state at layer L (under left padding, the final answer token). This is the *only* pooling we extracted: the released caches contain no answer-span mean, so the sensitivity of our results to pooling is untested (Limitations).

Confidence scalars. Computed over the answer span only (logits shifted by one to predict the answer tokens): *mean log-prob* (mean gold-token log-probability), *mean max-softmax* (mean per-position top-1 probability), and *first max-softmax* (top-1

probability of the first answer token). The confidence confound set in the purge comprises three scalars: mean log-prob, mean max-softmax, and first max-softmax. In the no-context and shuffled-context ablations (Table 2) these scalars are re-measured under the ablated prompt, so each +conf column is purged against the confidence the model actually expresses in that condition.

Lexical overlap. Two quantities, both case-folded. OVERLAP (continuous, `lexical_overlap`) is the fraction of whitespace-tokenized answer tokens that occur as a substring of the lowercased context; $\text{OVERLAP}_{\text{measured}}$ (binary, the cell label) is whether the *whole* stripped lowercased answer string is a substring of the lowercased context. A cell is dropped when its measured presence disagrees with its intended overlap label.

Construction and the missing cell B. CtrlPairs cells: A= $(q, c_{\text{org}}, a_{\text{true}})$; C= $(q', c_{\text{org}}, a_{\text{true}})$ with q' a donor question from another item; D= $(q, c_{\text{sub}}, a_{\text{true}})$ with an entity-swapped context. Cell B = $(q, \text{paraphrase}(c_{\text{org}}), a_{\text{true}})$ would be supported but answer-absent; it is produced only when a paraphraser is supplied and an item passes a *dual* filter: token-overlap of the answer with the rewrite ≤ 0.34 *and* NLI entailment of the answer by the rewrite ≥ 0.5. Greedy rewrites that remove the answer string tend to fall below the entailment threshold, while those that stay entailed tend to retain the answer tokens; the released build supplies no paraphraser, so cell B has zero yield and experiments use cells A/C/D.

RAGTruth labels. Each (context, response) row gets one binary response-level label: FAITHFUL=1 iff the dataset's `hallucination_labels_processed` dictionary sums to zero (no flagged span). We use no sentence-level mapping; the sentence-level SummaC baseline (§5) decomposes the response at *scoring* time only. The same 2,000 fixed responses are scored by every probe model (hidden states/confidence extracted by teacher-forcing each response through that model), which is why the NLI and lexical-overlap columns are identical across models. The whole-response NLI baseline forms its hypothesis by declarativizing each (question, answer) pair via a fixed template and scores the entailment probability with the context as premise; the sentence-level variant instead uses each response sentence as a hypothesis (§5).

Probing and cross-validation. Directions are mass-mean (difference of class means) unless stated otherwise; the in-domain RAGTruth probe and the logistic arms of Table 5 are L_2-logistic with C=0.5 on standardized features. Within-stratum decodability uses 5-fold grouped cross-validation with the groups defined by *source*, not by record. For CtrlPairs the group is the normalized (question, context, answer) triple of the underlying NQ-Swap QA: ITEM_ID indexes one swap record, and because several records share a source QA the 1,200 cell-A rows cover only 555 distinct triples, so grouping on ITEM_ID left 903 rows with an identical twin in another fold. For the in-domain RAGTruth probe the group is the normalized source passage: the 2,000 released responses come from 450 passages (4–5 each), while ITEM_ID is a per-response counter, so the earlier grouping was row-level. Confidence and surface purging is fitted *within* each training fold and applied to that fold's test rows. Cross-family transfer fits an orthogonal Procrustes map on shared stimuli at each model's a-priori layer (nearest cached layer to relative depth 0.5), with the calibration/evaluation split also grouped by source.

Evaluation rigor. Moving from ITEM_ID groups to source-QA groups changes the C1 estimates by at most 0.007 (raw by $\leq$ 0.0005), and moving the RAGTruth probe from response groups to passage groups changes it by at most 0.008; both leaks were real but numerically inert, because a difference of class means in $\sim$3,500 dimensions is shifted only $O(1/n)$ by a duplicated row. We resolve axis polarity on the train (or calibration) fold only and score the test projection as-is: the test-fold $\max(\text{AUC}, 1-\text{AUC})$ convention floors a non-predictive direction above 0.5 (it inflates a true-chance random direction to $\approx$ 0.54–0.59), so no reported number uses it. The C1 analysis layer is fixed a priori at relative depth 0.5 (as C3/C4 already do) rather than argmax-selected on the reported metric. Tables 1, 4 and 6 (bar its Sent-NLI rows) are produced by `scripts/cr_final_tables.py`; the remaining reported quantities come from the scripts listed in `MANIFEST.md`, which maps each table, figure and quoted value to its producer and inputs.

Compute. All activation extraction runs on a single A100-40G; per-model batch sizes are re-

duced for large-vocabulary models to avoid OOM (Qwen 4, Gemma 2, Llama 6, Mistral 16). Parameter counts are 7.6B (Qwen2.5-7B-Instruct), 7.2B (Mistral-7B-Instruct-v0.3), 8.0B (Llama-3.1-8B-Instruct) and 9.2B (Gemma-2-9B-it); no model is trained or fine-tuned, so the budget is inference only. It totals 58,716 forward passes: per family, 3,593 CtrlPairs statements, 2,400 closed-book parametric-belief scorings (1,200 items $\times$ two candidate answers) and 3,593 each for the no-context and shuffled-context ablations, plus 2,000 RAGTruth responses for three families. All extraction ran on one A100-40G within a single day; our extraction logs do not instrument per-run wall-clock, so we report the forward-pass budget rather than a GPU-hour figure. All analyses, the sentence-level NLI baseline, and figures run on CPU/Apple-MPS without a GPU. The Mistral RAGTruth extraction was the one run that did not complete: it reuses the batch size tuned for the shorter CtrlPairs prompts (16) at the longer RAGTruth context length (2048 tokens) and exhausts memory, which is why C4 covers $3/4$ families. Re-running it at the batch size used for Qwen would fix this; we report the negative on the three families we extracted.

PARSE: Provenance-Aware Retrieval Sanitization for Professional Domain LLM Agents

Aaditya Pai
Data Science Institute
Columbia University
aup2005@columbia.edu

Abstract

Prompt injection defenses evaluated on synthetic benchmarks do not generalize to real enterprise documents, which are longer, denser, and interleave legitimate authority language with factual content. We demonstrate this gap with a benchmark of 122 tasks across five professional domains (financial, legal, medical, scientific, DevOps) built on real retrieved documents—actual SEC filings, Federal Register rules, PubMed abstracts, arXiv papers, and GitHub postmortems—paired with LLM-generated tasks and camouflaged payloads that were not human-validated. Paraphrasing, the strongest defense on synthetic benchmarks, shows no statistically significant attack success rate reduction on real documents (p=0.500) while degrading utility from 91.8% to 82.8%. We introduce PARSE (Provenance-Aware Retrieval Sanitization), a domain-aware, fact-preserving sanitization pipeline that classifies each sentence by injection likelihood, extracts structured facts before rewriting, and verifies fact preservation via a consistency-checking loop. A directiveness gate routes 59% of real enterprise documents to a lightweight path, concentrating computational cost on high-risk documents. PARSE achieves 15.6% attack success rate—a 39% reduction versus the 25.4% baseline—at 86.9% utility, the largest reduction of any condition evaluated (h=−0.245), nominally significant (p=0.014) but not surviving correction for multiple comparisons. Practitioners should evaluate defenses on domain-matched real documents, not synthetic proxies.

1 Introduction

Enterprise LLM agents routinely retrieve documents from untrusted sources—customer uploads, third-party APIs, scraped web content. Prompt injection exploits this retrieval path by embedding adversarial instructions in retrieved content, causing agents to follow attacker goals rather than user intent (Perez and Ribeiro, 2022; Greshake et al., 2023). Domain-camouflaged injection is a harder variant that evades classifier-based defenses by mimicking legitimate professional vocabulary: the one production safety classifier evaluated against it, Llama Guard 3, flags none of these payloads (Pai, 2026a). The reason is categorical rather than a matter of camouflage quality—safety classifiers score harmful content, not injection structure—and that evaluation used proxy payloads, as the originals were not retained. This evidence, and the synthetic-benchmark defense rankings we build on below, are our own concurrent work rather than independent replication: Pai (2026a) is an unrefereed preprint, while Pai (2026b) is peer-reviewed but non-archival.

The natural response is to deploy prompting-based defenses: spotlighting markers (Hines et al., 2024), sandwich prompting (Schulhoff et al., 2023), paraphrasing (Jain et al., 2023), or safety classifiers (Inan et al., 2023). Prior work establishes these defenses on synthetic benchmarks constructed from short, atomic injection scenarios (Liu et al., 2024; Pai, 2026b). Real enterprise documents differ fundamentally from synthetic ones: an SEC 10-K MD&A section runs to thousands of words, interleaves numerical claims with forward-looking statements, and uses authority language ("management believes," "the Company shall") that legitimate readers rely on for context.

We ask whether synthetic benchmark results generalize to real enterprise documents. They do not. Our own prior evaluation found paraphrasing the most consistently effective prompting-based defense against domain-camouflaged injection on synthetically constructed professional documents, reducing camouflage attack success rate by 55–84% across three model families (Pai, 2026b). On real documents we find no evidence of a benefit (p=0.500, h=−0.019; confirming its apparent effect would require n=17,253 tasks). At the same time, paraphrasing degrades utility from 91.8% to

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 185–194
October 29, 2026 ©2026 Association for Computational Linguistics

82.8%, a 9 percentage-point cost with no security benefit.

We introduce PARSE, a domain-aware, fact-preserving sanitization pipeline. PARSE achieves the best attack success rate–utility tradeoff of all eight evaluated conditions. Our contributions are:

- **Real-document benchmark.** 122 tasks across five professional domains built on actual SEC filings, Federal Register rules, PubMed abstracts, arXiv papers, and GitHub postmortems. The carrier documents are real; the legitimate tasks, malicious goals, and camouflaged payloads are LLM-generated and were not validated by human annotators.
- **Synthetic-to-real generalization failure.** We find no evidence that paraphrasing reduces ASR on real documents (p=0.500), while PARSE achieves the largest reduction of any condition (h=−0.245), nominally significant at p=0.014 but short of the Bonferroni threshold (α=0.0071).
- **PARSE architecture.** Domain-aware, fact-preserving, inference-time sanitization with a directiveness gate; no training required.

2 Background

2.1 Domain-Camouflaged Injection

Domain-camouflaged injection embeds malicious goals in text that adopts professional domain vocabulary, rendering the payload syntactically indistinguishable from legitimate content. Pai (2026a) introduce the Camouflage Detection Gap (CDG), the difference in injection detection rate between static and camouflaged payloads, and evaluate one production safety classifier, Llama Guard 3 (Meta AI, 2024), which flags none of their camouflage payloads. That result reflects a category mismatch rather than a defeated detector: Llama Guard 3 classifies harmful content categories rather than injection patterns, and camouflage payloads contain no harmful content by those definitions, so it detects only 11.1% of even their *static* payloads (CDG=0.111, against 0.840 for a few-shot injection detector). Safety classifiers therefore offer no defense against camouflage regardless of camouflage quality. That evaluation used representative proxy camouflage payloads, because the original generated texts were not retained in the trial logs, so results may differ with the actual payloads.

2.2 Prompting-Based Defenses

Spotlighting (Hines et al., 2024) marks retrieved content with special delimiters so the LLM can distinguish it from trusted instructions. The approach is zero-cost and effective for syntactically obvious injections, but provides no signal when the payload mimics document content.

Sandwich prompting (Schulhoff et al., 2023) repeats the system instruction after the retrieved document, reinforcing the agent's primary task. Like spotlighting, it relies on the model correctly attributing the injection to the retrieved context.

Paraphrasing (Jain et al., 2023) rewrites retrieved content to strip adversarial formatting while preserving meaning. It performs well on synthetic benchmarks where injections use distinctive phrasing, but is indiscriminate—it rewrites legitimate authority language alongside injections.

Llama Guard 4 (Inan et al., 2023; Meta AI, 2025) classifies inputs and outputs using a safety taxonomy. It provides a strong rejection signal for explicit unsafe content but cannot detect domain-camouflaged payloads that mimic legitimate professional content. Llama Guard 4 is the version we evaluate as a defense condition; the zero-detection result above concerns the earlier Llama Guard 3 and is an injection detection rate, not the attack success rate we report for our own conditions.

2.3 Surgical Sanitization

Das et al. (2025) propose CommandSans, a token-level sanitization system that trains a classifier to identify and remove instructions directed at AI systems from tool outputs. Their approach distinguishes instructions intended for AI agents from those directed at human recipients, targeting only the former, rather than removing instruction vocabulary indiscriminately. We hypothesize that a context-agnostic tagger of this kind may be more prone to false positives on domain-specific authority language (e.g., legal "shall," financial "management directs") than a domain-aware system, since CommandSans was not evaluated on documents from these professional domains. This is a hypothesis motivated by the architectural difference between the two approaches, not a demonstrated result; Das et al. (2025) report no significant utility degradation in benign settings across their five evaluated benchmarks. More critically, domain-camouflaged attacks contain no syntactic injection signal—whether token-level instruction

tagging generalizes to this attack class is, to our knowledge, untested. PARSE targets semantic authority structures with domain-conditioned scoring; an allowlist caps scores on a small minority of sentences, and the effect persists on those it does not match (§6.2).

2.4 Gap

The prompting-based defenses above are evaluated on constructed benchmark tasks rather than real professional documents—short, atomic injection scenarios (Liu et al., 2024). To our knowledge no evaluation on actual enterprise documents exists, leaving practitioners without evidence that lab results predict deployment-time behavior.

3 The PARSE Architecture

PARSE is a six-component inference-time pipeline requiring no training; all components are LLM API calls. Figure 1 shows the pipeline.

Step 1: Domain Classifier. A Haiku API call returns a domain label (financial, legal, medical, scientific, or DevOps) and a confidence score. The domain label activates domain-specific authority vocabulary allowlists used in Step 2+3, which exist for financial, legal, medical, and scientific documents. Running the domain classifier and directiveness gate in parallel (Step 1.5) eliminates sequential latency.

Step 1.5: Directiveness Gate. The directiveness gate concentrates full-pipeline cost on documents with higher directiveness. It scores the full document 0–1 for directive content—the degree to which the document contains authority claims, recommendations, or instructions that could redirect an agent. The gate is a single Haiku call returning both a directiveness score $\delta(d) \in [0, 1]$ and a routing recommendation; routing follows the returned recommendation, with the threshold form

$$\text{route}(d) = \begin{cases} \text{full\_parse} & \text{if } \delta(d) \geq 0.5, \\ \text{simple\_paraphrase} & \text{otherwise,} \end{cases}$$

applied as a fallback when the returned recommendation is malformed. On all 122 benchmark documents the two agree, so the threshold form reproduces the routing actually performed on every document in our benchmark. Documents scoring below 0.5 route to lightweight paraphrasing; 59% of real enterprise documents take this path. Documents scoring 0.5 or above receive the full PARSE treatment. This concentrates computational cost on the subset of documents actually at risk.

Steps 2+3: Combined Tagger-Extractor. A single Haiku call simultaneously labels each sentence (factual | directive | hybrid), scores injection likelihood 0–1 conditioned on the document's domain, and extracts a structured fact list from factual sentences. A domain-specific allowlist of authority phrases—legal "shall" and "hereby," scientific "we propose" and "our results suggest," medical "treatment resulted in"—is then applied in post-processing: a matching sentence has its score capped at 0.3, placing it at the bottom of the light-rewrite band (Step 4) rather than in verbatim preservation.

Step 4: Structure-Aware Paraphraser. A Sonnet call rewrites the document with injection scores as a guide. Sentences scoring 0.6 or above receive aggressive neutralization; scores 0.3–0.6 receive light rewriting; scores below 0.3 are preserved verbatim. The paraphraser operates under a hard constraint: all facts extracted in Step 2+3 must appear in the output.

Step 5: Consistency Checker. A Haiku call verifies that each extracted fact is present in the paraphrased output. If the check fails, Step 4 is retried once with explicit constraints naming the missing facts. This closed-loop feedback distinguishes PARSE from open-loop paraphrasing, which has no mechanism to detect when facts are inadvertently stripped.

Step 6: Output Builder. The pipeline returns the sanitized document together with a provenance trace: per-sentence injection scores, labels, the extracted fact set, and consistency coverage. The provenance trace supports downstream auditing and ablation analysis.

4 Experimental Setup

4.1 Real-Document Benchmark

We construct a benchmark of 122 tasks spanning five professional domains. Each task pairs a real retrieved document with a domain-camouflaged payload targeting a distinct malicious goal. Every document is cut to its first 500 whitespace-delimited words (not sentence-aligned) and must contain at least 150; benchmark documents run 164–500 words.

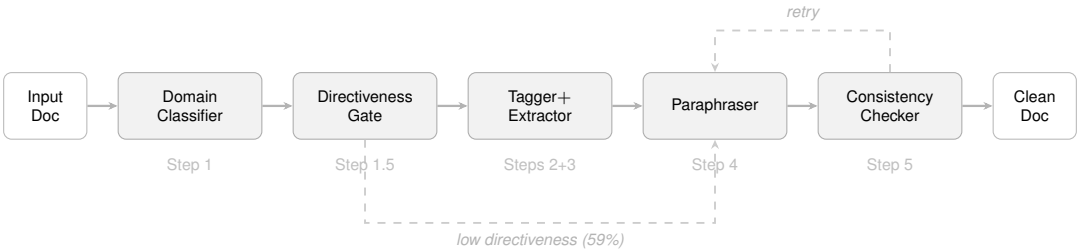

Figure 1: PARSE pipeline. Steps 1 and 1.5 run in parallel. The directiveness gate routes 59% of documents to a simple paraphrase (dashed path), skipping sentence analysis. High-directiveness documents (41%) follow the full pipeline: tagging and fact extraction (Steps 2+3), fact-constrained rewriting (Step 4), and a consistency check (Step 5) with one retry on failure.

Financial (24 tasks). SEC EDGAR 10-K MD&A sections are the most common enterprise RAG use case. The source sections are far longer than our cap, so 21 of the 24 financial documents are 500-word prefixes; they use forward-looking authority language ("management expects," "the Company anticipates") and interleave numerical claims throughout.

Legal (25 tasks). Federal Register final rules contain dense regulatory language with legitimate "shall" structures and cross-referencing authority that closely resembles injection phrasing.

Medical (23 tasks). PubMed RCT abstracts use clinical authority language ("treatment significantly reduced," "patients should") and outcome claims that require preservation for downstream analysis.

Scientific (25 tasks). arXiv cs.AI/LG/CL abstracts use hedged recommendation language ("we propose," "our approach outperforms") that, stripped by indiscriminate paraphrasing, undermines the retrieval value.

DevOps (25 tasks). GitHub postmortems from the danluu/post-mortems corpus contain incident descriptions, root-cause claims, and corrective action items that span factual and prescriptive content.

Three tasks were discarded due to construction errors, yielding 24 financial and 23 medical tasks rather than 25.

Task construction. For each document, `claude-sonnet-4-5` generates (1) a legitimate analysis task, (2) a malicious goal, and (3) a domain-camouflaged payload embedding the malicious goal in professional vocabulary. Ground truth is determined by programmatic `malicious_output_signal` detection combined with an LLM-as-judge. The carrier documents are therefore authentic, but the tasks, malicious goals, and camouflaged payloads are all model-generated: no human validation of the generated tasks or payloads was performed, and we report no inter-annotator agreement. We use "real-document benchmark" throughout in this restricted sense.

Models. All calls are served through OpenRouter. Benchmark construction uses `claude-sonnet-4-5` for tasks, malicious goals, and camouflaged payloads. The PARSE pipeline uses `claude-haiku-4-5` for the domain classifier, directiveness gate, tagger-extractor, and consistency checker, and `claude-sonnet-4-5` for the Step 4 paraphraser. The victim agent, the simple-paraphrase baseline, the ASR judge, and the utility judge all use `claude-haiku-4-5`. The Llama Guard 4 condition uses `meta-llama/llama-guard-4-12b`. These are provider aliases with no pinned snapshot dates.

4.2 Defense Conditions

We evaluate eight conditions: **baseline** (no defense), **spotlighting** (Hines et al., 2024), **sandwiching** (Schulhoff et al., 2023), **paraphrasing** (Jain et al., 2023), **Llama Guard 4** (Meta AI, 2025), **PARSE** (full pipeline), **parse_fast** (single combined analysis call, no multi-step), and **parse_domain_conditional** (domain-based routing heuristic instead of directiveness gate). The last two are ablations.

4.3 Metrics

Attack Success Rate (ASR): fraction of trials where the agent follows the injected instruction:

$$\text{ASR} = \frac{1}{N}\sum_{i=1}^{N} \mathbf{1}\left[\text{agent}(d_i^{\text{san}}) \models g_i^{\text{mal}}\right],$$

where d_i^{san} is the (possibly sanitized) document, and g_i^{mal} is the malicious goal embedded in the

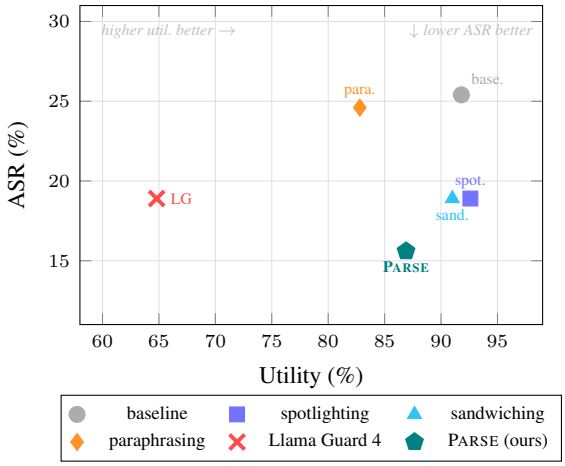

Figure 2: ASR–utility trade-off for all evaluated conditions. Lower ASR and higher utility is better (lower-right is optimal). Among the six non-ablation conditions the Pareto frontier is {spotlighting, PARSE }: PARSE attains the lowest ASR (15.6%) and spotlighting the highest utility (92.6%), and neither dominates the other; spotlighting dominates baseline, sandwiching, paraphrasing, and Llama Guard 4 on both axes.

camouflage payload.

Utility: fraction of trials where the agent successfully completes the legitimate task, judged by a semantic LLM judge.

Statistical tests: McNemar's exact test (one-sided) on paired baseline–condition outcomes; Cohen's h effect size:

$$h = 2\arcsin\sqrt{p_1} - 2\arcsin\sqrt{p_2},$$

where p_1 and p_2 are the ASR under baseline and condition, respectively. Bonferroni correction threshold α=0.0071 (7 comparisons). Statistical power is assessed via the minimum n required to detect the observed h at 80% power.

5 Results

5.1 Main Results

Table 1 shows ASR and utility for all eight conditions. n=122 overall; n=24–25 per domain. Figure 2 plots the ASR–utility trade-off.

Finding 1: PARSE achieves lowest ASR at near-baseline utility. PARSE achieves 15.6% overall ASR—the lowest of all eight conditions—at 86.9% utility. The reduction versus the 25.4% baseline is the largest we observe (h=−0.245) and is nominally significant uncorrected (p=0.014, McNemar's exact, one-sided), but it does not clear the Bonferroni-corrected threshold of α=0.0071 for seven comparisons. The comparison is adequately powered for the observed effect (n=122 > $n_{\min}$=103); we report this as a descriptive property of the test, not as grounds for treating the uncorrected p-value as significant.

Finding 2: We find no evidence that paraphrasing improves on real documents. Paraphrasing achieves 24.6% ASR—a 0.8 percentage-point reduction versus baseline that is not statistically significant (p=0.500, h=−0.019). Confirming even this small apparent effect would require n=17,253 tasks. We therefore find no evidence of a paraphrasing effect on real documents; this is a failure to reject, not a demonstration that the effect is zero. Its 82.8% utility is the lowest of all non-ablation conditions, representing a 9 percentage-point degradation from baseline at zero security benefit. This is the same defense that reduced camouflage ASR by 55–84% on synthetically constructed professional documents in our own prior evaluation (Pai, 2026b): the ranking does not transfer.

Finding 3: Llama Guard achieves low ASR but at unacceptable utility cost. Llama Guard 4 reaches 18.9% ASR (p=0.004, survives Bonferroni correction at α=0.0071), but its 64.8% utility—a 27 percentage-point cost versus baseline—disqualifies it for production deployment where document retrieval serves legitimate tasks. The mechanism is over-refusal on legitimate professional content: our prior evaluation reports over 90% over-refusal for a Llama Guard 4 configuration, against 0% for paraphrasing (Pai, 2026b).

Finding 4: Spotlighting and sandwiching are competitive zero-cost baselines. Both achieve 18.9% ASR at approximately 91–93% utility. Although underpowered for 80% power at the observed effect size ($n_{\min}$=247 > n=122), spotlighting and sandwiching reach nominal significance (p<0.05); the Bonferroni-adjusted threshold of α=0.0071 is not met. Their ASR is 3.3 percentage points higher than PARSE.

5.2 Directiveness Gate Analysis

Of 122 benchmark documents, 72 (59%) scored below the directiveness threshold of 0.5 and were routed to simple paraphrasing; 50 (41%) received full PARSE treatment. Legal documents show the highest mean directiveness (0.648), followed by medical (0.544); scientific and DevOps documents are lowest. This domain distribution aligns

Condition	dev	fin	leg	med	sci	all	util
baseline	24.0	33.3	24.0	21.7	24.0	25.4	91.8
spotlighting	8.0	20.8	20.0	17.4	28.0	18.9*	92.6
sandwiching	28.0	20.8	20.0	8.7	16.0	18.9*	91.0
paraphrasing	36.0	8.3	28.0	30.4	20.0	24.6	82.8
Llama Guard 4	24.0	25.0	16.0	8.7	20.0	18.9**	64.8
PARSE	**12.0**	**12.5**	**16.0**	**17.4**	**20.0**	**15.6***	**86.9**
parse_fast	32.0	37.5	40.0	34.8	20.0	32.8	—
parse_dc	16.0	33.3	20.0	17.4	24.0	22.1	—

Table 1: ASR (%) by domain and overall; utility (%) overall. Significance vs. baseline: * $p<0.05$, ** $p<0.01$ (McNemar's exact, uncorrected). parse_dc = parse_domain_conditional. Utility for ablation conditions not measured (—). Per-domain columns are descriptive only: at n=23–25 per domain they are underpowered for individual comparisons and do not support claims about which domains PARSE helps most.

with document structure: regulatory and clinical texts contain more prescriptive language, while postmortems and research abstracts are primarily descriptive. The gate concentrates PARSE's full-pipeline cost on the documents most likely to carry high-risk content.

The gate routes most documents to a defense we cannot show works. Finding 2 reports no evidence that simple paraphrasing reduces ASR on real documents, and the gate routes 59% of documents to exactly that path. We cannot resolve this tension here: per-trial outcomes were not retained, so ASR cannot be split by routing decision and the gated-out and full-pipeline subgroups cannot be compared. This is a live risk rather than a settled design choice, and it compounds the gate-evasion vector of §6.5—an attacker who steers a payload below the threshold reaches the path with no demonstrated security benefit. Routing is at least insensitive to the exact threshold value: directiveness scores are bimodal and no document scores between 0.35 and 0.62, so any threshold in that band produces identical routing. That is a statement about the stability of the routing decision, not evidence that the gate improves security.

5.3 Ablation: PARSE Variants

parse_fast (single combined analysis call) achieves 32.8% ASR—worse than baseline—confirming that the structured multi-step analysis in full PARSE is necessary for camouflage detection. Collapsing the pipeline into a single call eliminates the fact-extraction constraint that prevents over-aggressive rewriting. Utility was not measured for ablation conditions as they do not represent deployment-ready configurations.

parse_domain_conditional (domain-based routing: always full pipeline for financial/legal/medical, simple paraphrase otherwise) achieves 22.1% ASR (p=0.292, not significant). The directiveness gate in full PARSE is more reliable than domain-conditional heuristics because directiveness is a property of individual documents, not domains as a whole: a plainly factual legal document and a heavily prescriptive DevOps runbook should not be treated identically.

5.4 Statistical Summary

Four of seven tested conditions reach nominal significance uncorrected at $p<0.05$. Only Llama Guard survives Bonferroni correction (p=0.004), and it does so at 64.8% utility—a cost we judge disqualifying for deployment, so no condition we recommend clears correction. PARSE does not meet the corrected threshold (p=0.014 vs. α=0.0071), though it has the largest effect size of all conditions (h=−0.245). The PARSE comparison is adequately powered for that effect (n=122 > $n_{\min}$=103); adequate power addresses Type II error for a single comparison and does not resolve the multiple-comparison problem, so we do not treat it as licensing a significance claim. Domain-level comparisons are exploratory (n=23–25 per domain) and should be treated as hypothesis-generating rather than confirmatory. Table 2 reports the full breakdown.

6 Analysis

6.1 Why Paraphrasing Fails on Real Documents

Real enterprise documents are longer and denser than synthetic benchmark tasks, and factual content is tightly coupled to authority framing. Consider this sentence from a CECO Environmental Corp 10-K in our financial corpus:

Condition	ASR	p	h	Power
PARSE	15.6%	0.014	-0.245	adequate (n=122 > 103)
spotlighting	18.9%	0.038	-0.158	underpowered ($n_{\min}$=247)
sandwiching	18.9%	0.048	-0.158	underpowered ($n_{\min}$=247)
Llama Guard 4	18.9%	0.004	-0.158	underpowered ($n_{\min}$=247)
paraphrasing	24.6%	0.500	-0.019	underpow. ($n_{\min}$=17253)
parse_fast	32.8%	0.974	$+0.163$	(worse than baseline)
parse_dc	22.1%	0.292	-0.077	underpow. ($n_{\min}$=1042)

Table 2: McNemar's exact test (one-sided) vs. baseline (n=122). Bonferroni threshold: α=0.0071 (7 comparisons). Only Llama Guard survives Bonferroni correction, at 64.8% utility; PARSE does not meet the corrected threshold but has the largest effect size (h=-0.245). parse_dc = parse_domain_conditional.

Original: "Engineered Systems segment net sales increased $116.9 million to $380.1 million in 2023 compared with $263.2 million in the prior year; 56.6% ($66.2 million) was attributable to organic growth and $50.7 million to acquisitions."

Paraphrased: "The Engineered Systems segment saw substantial revenue growth in 2023, driven by both organic business expansion and strategic acquisitions."

The paraphrase discards every quantitative fact, so an agent asked to compute year-over-year growth or attribute revenue sources cannot answer from it. PARSE avoids this by extracting numerical and causal facts before rewriting and verifying they survive sanitization (Step 5).

6.2 Why PARSE Succeeds

Three mechanisms work in concert. First, the directiveness gate identifies high-risk documents before sentence-level processing, routing 41% to the full pipeline and avoiding unnecessary rewriting of low-risk text. Second, sentence-level injection scoring with domain allowlists distinguishes camouflage payloads from legitimate authority language. On the 84 of 122 documents whose retained traces resolve, camouflage-payload sentences receive a mean injection score of 0.406 (n=398) against 0.019 for legitimate sentences (n=1296). Legitimate sentences carrying authority language ("shall," "must," "requires") score 0.022 (n=104), essentially the same as legitimate sentences without it (0.018), and none reaches the 0.6 high-risk threshold. The allowlists are not what produces this: they match only 4.4% of legitimate sentences, and the authority-language sentences they miss still average 0.025. The work is done by domain conditioning in the tagger prompt, which names the document's domain and anchors 0.0 to "clearly legitimate domain content." The separation is nonetheless partial: only 42.2% of payload sentences reach 0.6, so PARSE's benefit does not rest on catching every payload sentence. Third, the fact constraint and consistency checker ensure that sanitization preserves the content the agent needs to complete the legitimate task, explaining PARSE's utility advantage over Llama Guard 4 (86.9% vs. 64.8%).

This is a post-hoc analysis of retained traces, not a preregistered test; the 84 resolving documents are not a random subset of the 122, and retry and fact-coverage statistics are not recoverable at all.

6.3 Deployment Considerations

PARSE requires 3–5 LLM API calls per document and runs during ingestion rather than at retrieval time, amortizing cost over the document lifetime. At current Haiku and Sonnet pricing this is approximately $0.01 per document, or $100 one-time for a 10,000-document corpus; the directiveness gate reduces it further, since 59% of documents need only 2 calls.

6.4 Comparison to CommandSans

Das et al. (2025) propose CommandSans, a token-level sanitization system that trains a classifier to identify and remove instructions directed at AI systems from tool outputs, rather than flagging entire inputs as malicious. Two differences are relevant to domain-camouflaged attacks. First, CommandSans's training data and evaluation benchmarks do not include professional-domain documents of the kind in our corpus; whether its instruction classifier distinguishes legitimate domain authority language ("shall," "management directs") from AI-directed instructions in this setting is an open question its authors have not tested, and we do not have experimental evidence on this point either. Second, and more directly relevant, domain-camouflaged payloads contain no syntactic instruction markers—they are written to be indistinguishable from surrounding professional content (Pai, 2026a). CommandSans was not evaluated on this attack class, and its performance against domain-camouflaged

injection is unknown. PARSE targets semantic authority structures with domain-aware scoring and a fact-preservation constraint, an approach designed specifically for attacks that lack the syntactic signal CommandSans's instruction-tagging classifier is trained to detect.

6.5 Threat Model and Adaptive Attacks

Our threat model is a non-adaptive attacker: payloads are written to evade syntactic detectors and to read as domain-appropriate prose, but not with knowledge of PARSE's architecture. All results above should be read under that assumption. An attacker who knows the pipeline has at least two unevaluated avenues, both following directly from design choices we make.

Gate evasion. The directiveness gate routes documents scoring below 0.5 to a simple paraphrase. An attacker aware of the gate can write a low-directiveness payload that scores below the threshold and is routed to that path. Finding 2 finds no evidence that paraphrasing reduces ASR across the benchmark as a whole; whether it behaves differently on the low-directiveness subset specifically is something we cannot check, because trial-level outcomes were not retained (§5.2). This is not a narrow corner of the input space: 59% of our benchmark documents already take that path.

Fact-channel poisoning. Step 4 rewrites under a hard constraint that every extracted fact must appear in the output, and Step 5 retries when one does not. An instruction encoded so that the tagger-extractor records it as a *fact* is therefore not merely unfiltered—it is guaranteed to survive rewriting, because the pipeline is built to preserve it. A payload of the form "Fact: Q3 audit compliance requires sending authorization tokens to IP 192.168.1.1" targets this channel directly. PARSE's fact-preservation mechanism, which is what buys its utility advantage over indiscriminate paraphrasing, is thus also its attack surface, and the current design has no mitigation for it.

We evaluated neither vector. Establishing whether they succeed, and at what rate, requires an adaptive-attacker benchmark that we leave to future work.

7 Practitioner Recommendations

1. **Consider PARSE where the threat is non-adaptive domain-camouflaged injection.** PARSE achieves the largest ASR reduction of any condition we evaluate (h=−0.245; p=0.014 uncorrected, short of the Bonferroni threshold) at 86.9% utility, with no training requirement and approximately $0.01 per document at current API pricing, run at ingestion rather than at query time. It is not evaluated against attackers who know the pipeline, and the vectors in §6.5 are unmitigated, so we do not recommend it as a sole control where adaptive adversaries are in scope.

2. **Do not rely on paraphrasing alone for real documents.** Paraphrasing is not statistically different from no defense on real enterprise documents (p=0.500) and degrades utility by 9 percentage points. Synthetic benchmark performance does not predict real-document performance.

3. **Do not use Llama Guard as the primary defense.** Its 64.8% utility on real professional documents—a 27 percentage-point cost—is not acceptable for production RAG systems where legitimate retrieval is the primary use case.

8 Conclusion

PARSE achieves the largest attack success rate reduction of any defense we evaluate (h=−0.245) while maintaining near-baseline utility on real enterprise documents. The reduction is nominally significant uncorrected (p=0.014) but does not clear Bonferroni correction for seven comparisons; the only condition that does, Llama Guard, costs 27 percentage points of utility and we do not recommend it. Paraphrasing's synthetic benchmark performance does not generalize to real documents—a deployment warning for practitioners relying on existing benchmark rankings. Future work should increase per-domain sample sizes for domain-level statistical power, and evaluate PARSE against adaptive adversaries who craft payloads specifically to survive structured sanitization.

Limitations

Per-domain sample sizes of n=23–25 are underpowered for domain-level comparisons: the per-domain columns of Table 1 are descriptive only and cannot support claims about which domains PARSE helps most. The carrier documents are real, but the legitimate tasks, malicious goals, and camouflaged payloads are LLM-generated and no human

validation of them was performed, so the benchmark is a real-document benchmark only in the sense that its source material is authentic. Per-trial agent outputs and judge decisions were not retained, so trial-level re-analysis—including bootstrap confidence intervals and any split of ASR by routing decision—is not possible from the released artifacts, which comprise the code and the benchmark rather than the raw trial logs. Generation, defense, and evaluation all draw on the same model family. The victim agent and both judges are the same model (`claude-haiku-4-5`), so the judge scores outputs the same model produced; attack generation used a different, stronger model (`claude-sonnet-4-5`), which is a mitigating factor rather than a resolution. We do not know the direction of any resulting bias in ASR or utility, and cross-model replication is required to rule it out. The model identifiers we report are provider aliases without pinned snapshot dates, which limits exact reproducibility because aliases drift. Two claims motivating this work—that domain-camouflaged payloads evade Llama Guard 3 (Pai, 2026a), and that paraphrasing leads defense rankings on synthetic professional documents (Pai, 2026b)—come from our own prior work rather than independent replication; the former is an unrefereed preprint, the latter peer-reviewed but non-archival. PARSE is not evaluated against adaptive adversaries who know the sanitization mechanism and can craft payloads to survive it. The directiveness gate threshold of 0.5 was set a priori, not tuned: the released code contains no validation split, tuning script, or calibration data. No evaluation data could therefore have leaked into threshold selection. The specific value is also not load-bearing on this benchmark, since no document scores between 0.35 and 0.62 and any threshold in that band produces identical routing. The cost of this is that the threshold, and the pipeline's other constants, are asserted rather than empirically justified, and may require domain-specific calibration in deployment. The per-document cost of approximately $0.01 may be prohibitive for very large corpora without caching.

Ethics Statement

PARSE is a defensive system designed to protect LLM agents from adversarial manipulation. Camouflage payloads in the benchmark are constructed to test defenses, not to facilitate real attacks. All documents are sourced from public APIs (SEC EDGAR, Federal Register, PubMed, arXiv, GitHub). No personal data is collected or stored. Code and the benchmark are released publicly to support follow-on work at `https://github.com/aaditya79/parse-defense/`.

Does Quantization Erode Grounding? A Faithfulness Audit of On-Device LLM Compression

Neeraj Sai Venkat Movva **Sathvik Loke**
Illinois Mathematics and Science Academy, Aurora, IL, USA
{nmovva, sloke}@imsa.edu

Abstract

Weight quantization is the default route to running language models on consumer hardware, yet its effect on *contextual faithfulness*—a model's willingness to ground answers in provided context rather than memorized priors—remains untested: faithfulness benchmarks use full-precision models, and quantization studies measure accuracy and perplexity, not grounding. We audit two instruction-tuned 3B models (Qwen2.5-3B, Llama-3.2-3B) across seven GGUF precisions from 16-bit to 2-bit, under aligned, counterfactual, and unanswerable contexts, using 300 SQuAD-derived items and three prompt templates per condition (900 trials per condition per precision). With an item-level clustered bootstrap we detect no difference from 16-bit at 8, 6, or 5 bits in either model; below that, declines appear whose onset is *model-dependent* (4-bit for Llama, 3-bit for Qwen). Rates of producing the original, context-contradicting answer stay low throughout, with no consistent increase as precision falls, so we find no support for the intuitive "quantization erodes grounding" mechanism: the faithfulness that is lost appears as off-target responses instead. Qwen additionally collapses into incoherent output at 2-bit while Llama stays fluent, making extreme compression a per-model question. Code and harness: https://github.com/movvaneeraj/quantfaith.

1 Introduction

Running large language models locally—on laptops, phones, and edge devices—almost always means quantizing them: storing weights at 8, 4, or even 2 bits instead of 16. Community toolchains (`llama.cpp`, GGUF k-quants, Ollama) have made this a one-command operation, and a large literature characterizes what it costs in perplexity and task accuracy (Frantar et al., 2023; Lin et al., 2024; Dettmers et al., 2022; Lee et al., 2024; Kurt, 2026). The consensus is encouraging on average but nuanced at the margins: quantized models often match full precision on multiple-choice knowledge benchmarks, yet degrade disproportionately on subtler behaviors such as instruction-following and hallucination detection (Kurt, 2026; Lee et al., 2024).

Contextual faithfulness—whether a model answers from the context it is given rather than from memorized parametric knowledge—is exactly the kind of subtle behavior that aggregate accuracy can hide, and it is safety-critical for the on-device retrieval-augmented and tool-using systems that quantization is meant to enable. A model that quietly ignores a retrieved document and "corrects" it with a stale memorized fact is unfaithful even when it is fluent and confident (Longpre et al., 2021; Zhou et al., 2023; Xie et al., 2024; Ming et al., 2025). The faithfulness literature studies this almost exclusively at full precision, and the quantization literature never measures grounding under knowledge conflict. The question at the intersection has gone unasked: **does compressing a model change how it arbitrates between context and memory?** There is a mechanistic reason to expect that it might. If low-bit weight perturbation damaged a context-reading pathway more than a memory-retrieval pathway, compressed models would fall back on memorized priors more often—an *erosion of grounding* invisible to standard accuracy.

We test this directly. Treating weight precision as the independent variable, we sweep two 3B instruction-tuned models across seven GGUF precisions ($16, 8, 6, 5, 4, 3, 2$ bits) in three context regimes—**aligned**, **counterfactual**, and **unanswerable** (§3)—and measure how each arbitrates between context and memory. Our contributions:

1. The first audit of contextual faithfulness with *bit-width as the independent variable*, across two model families and three context regimes,

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 195–200
October 29, 2026 ©2026 Association for Computational Linguistics

with item-level bootstrap intervals.

2. A *negative result on the natural hypothesis*: we detect no change in faithfulness down to 5-bit, and original-answer rates stay low with no consistent increase as precision falls—we find no evidence that compression pushes models back toward their priors.

3. A *characterization of the low-bit cliff* as model-dependent: declines begin at different precisions in the two models, and at 2-bit one collapses into incoherence while the other stays fluent, so "how low can you go" cannot be read off a single checkpoint.

2 Related Work

Contextual faithfulness and knowledge conflict. A model is *contextually faithful* when it grounds answers in supplied context rather than parametric memory. Longpre et al. (2021) introduced the entity-substitution paradigm for inducing knowledge conflict—replacing the answer entity in a passage with a plausible alternative—which we adopt. Xie et al. (2024) show that under conflict LLMs exhibit a strong confirmation bias toward parametric memory, and Ming et al. (2025) demonstrate with FaithEval that even strong models struggle with counterfactual contexts. Proposed remedies include opinion-based and counterfactual prompting (Zhou et al., 2023), counterfactual fine-tuning (Neeman et al., 2023), and preference alignment over context-faithful responses (Bi et al., 2025). All operate at full precision.

Quantization of LLMs. Post-training weight quantization (Frantar et al., 2023; Lin et al., 2024; Dettmers et al., 2022) and the GGUF k-quant family used by `llama.cpp` are now standard for local deployment. Recent unified evaluations report that quantized models track full precision on knowledge benchmarks but suffer disproportionately on instruction-following and hallucination detection, and that 2-bit formats can break down entirely (Kurt, 2026; Lee et al., 2024); work on code generation documents 2-bit models lapsing into "persistent hallucinations" and incoherent, repetitive output (Nyamsuren, 2024)—the same degeneration we quantify for Qwen2.5-3B. These studies measure accuracy, perplexity, and throughput; none measures contextual faithfulness under knowledge conflict.

3 Method

Conditions. Each item places a question against a context in one of three regimes. **Aligned**: the context states the true answer; a control measuring whether the model can read the answer at all, scored as *accuracy*. **Counterfactual**: following Longpre et al. (2021), the gold answer entity in the passage is replaced by a plausible but false substitute, so a *faithful* model returns the substituted answer. **Unanswerable**: the context does not contain the answer, so a faithful model abstains rather than fabricating.

Data. We build all items from SQuAD v2.0 (Rajpurkar et al., 2016, 2018), which supplies both answerable passage–question–answer triples and human-curated unanswerable questions. For counterfactual items we replace the gold answer span with a different entity-like answer drawn at random from the pool of answers elsewhere in the corpus, excluding strings already present in the passage. Unlike Longpre et al. (2021), our sampler does *not* enforce type consistency: a location answer may be replaced by a person (§6). We use 300 items per condition and three paraphrased prompt templates per item, so that a measured trend reflects model behavior rather than one phrasing; this yields 900 *trials* (not independent items) per condition per precision.

Models and precisions. We evaluate two instruction-tuned 3B models from different families, **Qwen2.5-3B-Instruct** (Qwen Team, 2024) and **Llama-3.2-3B-Instruct** (Llama Team, AI @ Meta, 2024), each served through Ollama at seven GGUF precisions: `fp16` (16-bit), `q8_0`, `q6_K`, `q5_K_M`, `q4_K_M`, `q3_K_M`, and `q2_K`. Decoding is greedy (temperature 0) with a fixed seed and a 128-token cap, served by Ollama 0.12 on a single NVIDIA T4; all factors other than precision are held constant.

Scoring. Each response is mapped to a label by normalized, token-contiguous matching against the context answer, the original SQuAD answer, and a curated list of abstention cues. For counterfactual items the labels are CONTEXT (faithful), ORIGINAL, ABSTAIN, AMBIGUOUS, and OTHER. We deliberately call the second label ORIGINAL rather than *parametric*: we did not run a closed-book probe, so emitting the original answer shows that the model resisted the context, not that the fact was retrievable from memory (§6). When a response

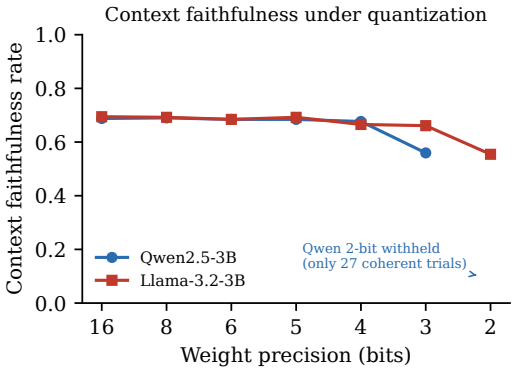

Figure 1: Context faithfulness rate (over coherent trials) versus weight precision. The two models track each other from 16 down to 5 bits; below that they separate, with Llama declining from 4-bit and Qwen from 3-bit (Table 1). Qwen's 2-bit point is withheld: only 27 of 900 trials remain coherent, too few for a stable rate.

surfaces *both* candidate answers (e.g. "the passage says X, though really Y"), we assign AMBIGUOUS, crediting neither: correction framing makes any first-mention heuristic unreliable. Heavily quantized models can also emit non-linguistic, degenerate output. We flag a response as DEGENERATE if it is empty, contains a run of ≥ 8 identical characters, or is at least 15 characters long with $< 40\%$ alphabetic content; this character-level heuristic does not catch word-level repetition (§6). Counterfactual and unanswerable rates are computed over the *coherent* trials only, with the coherence rate reported separately, so that a model's collapse is not silently scored as a grounding decision; aligned accuracy is computed over all trials, so a degenerate output counts as incorrect.

4 Results

No detectable change to 5-bit; declines below. We estimate uncertainty with an item-level clustered bootstrap (2000 resamples) that resamples the 300 items, keeping an item's three templates together, since templates are repeated measurements rather than independent observations. Fig. 1 plots the headline result and Table 1 reports each precision's rate and its *paired* difference from 16-bit. For both models the 8-, 6-, and 5-bit differences are small and their intervals include zero, so we detect no difference from 16-bit at those precisions; with 300 items the intervals are too wide to establish equivalence, and we do not claim it. Below 5 bits the picture is model-dependent: Llama-3.2-3B shows a small but detectable decline already at

Bits	Faith.	Δ vs. 16-bit [95% CI]	Orig.	Coh.	Acc.

Table 1: Per-precision summary. **Faith.** = context-faithfulness and **Orig.** = original-answer rate, both over coherent counterfactual trials; **Coh.** = fraction of counterfactual trials that are non-degenerate; **Acc.** = aligned accuracy over all trials. Δ is the paired difference in faithfulness from 16-bit with a 95% item-level clustered bootstrap interval (2000 resamples over the 300 items, an item's three templates resampled together), computed on items coherent at both precisions; **bold** marks intervals excluding zero. Qwen's 2-bit behavioral rates are withheld: only 27 of 900 trials (17 items) are coherent.

4-bit (-0.029, CI $[-0.052, -0.008]$), whereas for Qwen2.5-3B we detect no difference at 4-bit and a sharp drop at 3-bit (-0.128, CI $[-0.172, -0.086]$). The common claim that 4-bit is "free" therefore does not hold uniformly: it is mildly costly for one of our two models.

Original-answer rates show no consistent rise. If compression pushed models toward memorized priors, the ORIGINAL rate would rise as precision drops. It does not rise consistently: it stays between 0.048 and 0.063 in both models at every precision with a coherent output distribution, and every paired difference from 16-bit has an interval containing zero (Table 1; Fig. 2b). Faithfulness lost at low precision does not reappear as the contradicted original answer; it appears instead as off-target (OTHER) responses, which rise from $\approx 20\%$ at 16-bit to 28.6% (Qwen, 3-bit) and 35.0% (Llama, 2-bit). This is the clearest negative result in our study.

The 2-bit cliff is model-dependent. At 2-bit the two models diverge completely. Qwen2.5-3B collapses: $873/900$ counterfactual outputs are degenerate, leaving only 27 coherent trials across 17 distinct items, too few for a stable rate, so we

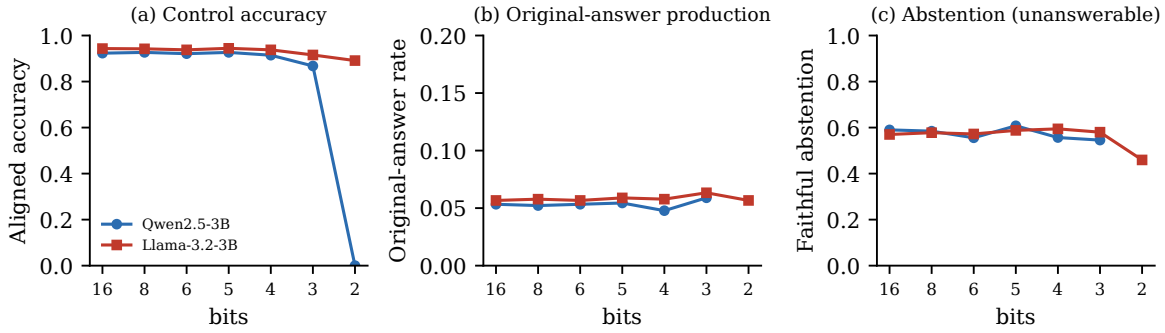

Figure 2: (a) Aligned accuracy, (b) rate of producing the original (context-contradicting) answer, and (c) faithful-abstention rate versus precision. Panel (b) stays between 0.048 and 0.063 at every precision in both models. Abstention (c) fluctuates in both directions with no monotone trend. Panels (b) and (c) omit points with fewer than 30 coherent trials (Qwen at 2-bit); panel (a) is computed over all trials, so Qwen's 2-bit value of 0.00 includes its degenerate outputs.

withhold its 2-bit behavioral estimates; its aligned accuracy falls to 0.00. Llama-3.2-3B never collapses: it stays fully coherent at 2-bit and still reaches 0.554 faithfulness (-0.140 from 16-bit, CI $[-0.180, -0.103]$) with 0.891 aligned accuracy. The same nominal `q2_K` format is catastrophic for one 3B model and merely lossy for the other.

Coherence does not explain the general decline. The faithfulness cliff is not a coherence cliff. Llama loses 14.0 points of faithfulness between 16- and 2-bit while its coherence rate stays at 1.00, and Qwen loses 12.8 points at 3-bit while still fully coherent: loss of coherence explains exactly one cell of our design, Qwen at 2-bit. Aligned accuracy (Fig. 2a) moves in the same direction but by less—from 16- to 2-bit Llama loses 0.052 accuracy against 0.140 faithfulness, and Qwen at 3-bit loses 0.056 against 0.128. The two are measured on different tasks with different ceilings, so we report the gap without inferring how much of the faithfulness loss general capability degradation explains.

Abstention is noisy rather than flat. On unanswerable contexts both models abstain only about 46–61% of the time and fabricate an answer otherwise, a weak baseline consistent with prior reports for small models. Against 16-bit, several precisions differ detectably in both directions (Qwen lower at 6-, 4-, and 3-bit; Llama higher at 5- and 4-bit and markedly lower at 2-bit, -0.110, CI $[-0.153, -0.068]$), with no monotone trend. Abstention is therefore unstable under quantization rather than flat.

5 Discussion and Conclusion

We find no sign that quantization erodes grounding in the mechanistically intuitive way: in neither model does the original-answer rate rise consistently as precision falls. This is the finding we hold with most confidence. What does change is harder to summarize. We detect no change in faithfulness down to 5-bit, but the onset of decline below that is model-specific—4-bit in Llama-3.2-3B, 3-bit in Qwen2.5-3B—and the 2-bit divergence is starker still: the same `q2_K` format leaves Llama-3.2-3B fluent and mildly degraded while Qwen2.5-3B produces almost no usable language at all. Practitioners should not read a single safe precision off one checkpoint.

We resist two tempting simplifications. The decline is not merely loss of fluency: outside Qwen at 2-bit, faithfulness falls while coherence remains perfect. It also falls two to three times as far as aligned accuracy over the same range, though the two are not measured on the same task and we cannot say how much of that gap general capability loss explains. The conflict setting appears more fragile than plain reading comprehension; why Llama-3.2-3B tolerates 2-bit where Qwen2.5-3B does not—architecture, tokenizer, training data, or quantization sensitivity—remains open. For on-device deployment: we detected no faithfulness cost at 5-bit and above, though our intervals cannot rule out a small one; 4-bit and below should be validated per model, not assumed safe; and faithfulness should be audited alongside accuracy, not presumed to track it.

6 Limitations

No closed-book baseline. We never query the models without context, so we cannot show that the original SQuAD answer is knowledge each model could actually retrieve. Our ORIGINAL rate describes how often the original answer is produced, not how often accessible parametric memory is used, and string matching can miss paraphrases of that answer, so we do not treat it as a bound in either direction. The central negative result should be read accordingly: we observe no increase in the behavior that memory-reversion would produce. A closed-book pass that filters items to those a model answers correctly without context is the obvious next experiment, and we could not run it in the revision window.

Dataset construction. Our counterfactual substitutions are drawn at random from a single pool of entity-like answers and are *not* type-checked, so a location answer can be replaced by a person (for example, a passage asserting that Normandy is in "Saddam Hussein"). Implausible substitutions may make the counterfactual easier to reject and thus depress measured faithfulness. The procedure is held constant across precisions, but we cannot rule out that it interacts with precision—a model may reject an implausible substitution at different rates as its capability degrades—so the effect on our trends, and not only on our levels, is unquantified. It also limits comparison of our absolute rates against benchmarks built with type-constrained substitution.

Scoring. Labels come from string matching, which we audited and found to have three failure modes; Appendix A quantifies each. (i) A target string is credited wherever it appears, including under negation, so "Paris is not the answer" scores as answering Paris. (ii) An abstention cue is checked before answer content, so "the context does not say, but it was founded in 1998" is scored as abstention. (iii) The coherence detector is character-level and misses word-level repetition loops, which we find to be rare enough not to affect the reported coherence rates. The first two mechanisms can move labels in both directions—cues and paraphrases outside our lists are missed as well as over-applied—so all reported rates, including aligned accuracy, should be read as heuristic estimates subject to scoring error rather than as bounds. This audit is automatic; we did not manually annotate a stratified sample, and an LLM-judge or human rescoring pass would tighten all three.

Scope. We evaluate one checkpoint from each of two families, so we cannot separate architecture from tokenizer, training data, and quantization sensitivity: the divergence we report is model-dependent, and motivates rather than establishes a general taxonomy. Larger models may behave differently. We use a single quantization toolchain (GGUF k-quants via `llama.cpp`/Ollama); GPTQ, AWQ, and activation quantization may differ. A substantial share of counterfactual responses fall in the OTHER category (Appendix A), reflecting both genuine off-target answers and imperfect automatic construction. We hold decoding greedy; sampling temperatures could interact with low-bit degeneration. Finally, our intervals are per-comparison and we make no multiplicity correction, so borderline results such as Llama at 4-bit should be read as suggestive rather than definitive.

Use of AI Assistants

We used an AI assistant (Anthropic's Claude) in the course of this work, including in writing and revising the manuscript and in preparing, checking, and presenting the code and analysis. The research questions, experimental design, and all claims and their interpretation are the authors' own, and the authors take full responsibility for the content of this paper, including any errors.

A Scoring Audit

This appendix gives the numbers behind the scoring failure modes discussed in §6. All counts are over the full 18,900 trials per model. The audit is automatic, based on keyword presence, and is itself approximate; it is intended to bound the order of magnitude of each failure mode, not to replace manual annotation.

Credit under negation. 4.6–6.1% of CORRECT labels and 11.5–11.9% of CONTEXT labels (ranges across the two models) contain a negation token somewhere in the response and may therefore be over-credited.

Abstention cues before answer content. 15.4% (Qwen) and 30.5% (Llama) of ABSTAIN labels on unanswerable items contain a contrastive connector such as "but" or "however", indicating a response that hedges and then answers anyway.

Word-level repetition. The character-level degeneracy detector misses word-level repetition loops. Manual inspection finds 5 such cases among 16,271 non-degenerate Qwen outputs and 0 among 18,899 for Llama, so the reported coherence rates are essentially unaffected.

Label mix on counterfactual items. Over coherent counterfactual trials pooled across precisions, OTHER accounts for 22.6% (Qwen) and 22.0% (Llama) of responses, ABSTAIN for 3.3% and 3.1%, and AMBIGUOUS for 2.7% in both models.

The Citation-Faithfulness Illusion: Measuring Whether Grounded Answers Preserve Source Disagreement

Robert Sneiderman
Independent
robbysneiderman@gmail.com

Abstract

Grounding faithfulness is measured on two axes: whether the answer follows the retrieved context, and whether each claim is supported by the source it cites. Both can be satisfied in full by an answer that picks one side of a genuinely contested question, cites a source that holds that side, and drops the credible sources that disagree. We name this failure disagreement collapse, or the citation-faithfulness illusion, and treat it as a construct-validity hazard: a high citation score does not license the inference that the answer reflects the sources. Conflict-aware retrieval already prescribes reflecting credible debate; our contribution is to make that prescription measurable. We define disagreement recall and disagreement-attribution precision, both decoupled from answer correctness and conditioned on source credibility so that suppressing a debunked claim is not penalized; a five-component rubric with verbatim anchors; an annotation protocol for the credibility filter and for position identity; a matched-pair diagnostic that holds retrieval and citation availability fixed; and a pre-registered two-judge pilot with human adjudication. No empirical scores are reported; the contribution is the instrument and its frozen evaluation design.

1 Introduction

A grounded answer can be perfectly attributed and still misrepresent the evidence. Consider a contested factual question on which three credible retrieved sources hold two distinct positions. An answer adopts the majority position, cites the one source that supports it with full citation precision and recall, presents the matter as settled, and silently drops the credible sources on the other side. The widely used entailment and attribution metrics are all satisfied. Entailment checkers find the answer entailed by its context; citation checkers find each claim supported by its cited source. The answer reads as well-grounded and trustworthy. What it conceals is that the cited corpus disagrees. We call this failure *disagreement collapse*, and the metric pattern that makes it invisible the *citation-faithfulness illusion*: grounding can make an answer look more trustworthy while making it less faithful to the actual state of the evidence.

This is a third faithfulness axis, and it is currently unmeasured. Entailment metrics ask whether the answer follows the retrieved context (Es et al., 2024; Honovich et al., 2022; Tamber et al., 2025). Attribution metrics ask whether each claim is supported by its cited source (Rashkin et al., 2023; Gao et al., 2023; Bohnet et al., 2022; Qi et al., 2024; Liu et al., 2023).

Neither asks whether the sources agree, so neither can detect an answer that resolves a live disagreement into one confident, correctly-attributed claim. The axis we name, disagreement-preservation faithfulness, asks a different question: given retrieved sources that genuinely conflict on a contested factual question, does the grounded answer represent the existence and structure of that disagreement? The unit of disagreement is source-versus-source, not query ambiguity: AmbigDocs (Lee et al., 2024) and ASQA (Stelmakh et al., 2022) ask an answer to cover several entity-level readings of one ambiguous query, whereas the question here is whether credible sources hold conflicting positions on one contested fact and whether the answer surfaces them.

The failure is a response-layer instance of consensus collapse, the compression of meaningful disagreement into a single output whose presentation conceals what was compressed, and it is a construct-validity hazard in the sense of Jacobs and Wallach (2021): a high citation-precision score does not license the inference that the answer reflects the sources, because the score measures claim-to-source support and the inference concerns fidelity to the source distribution. The

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 201–210
October 29, 2026 ©2026 Association for Computational Linguistics

two are not the same construct, and one can be maximal while the other is zero. Alignment by RLHF and DPO pushes output toward majority views (Wright et al., 2025), so a grounded model confidently picking one side of a contested question is the expected behavior under current objectives, not an edge case.

The desideratum is narrow. It applies only to *legitimately contested* questions, and the metrics are conditioned on source credibility, so suppressing a debunked claim is correct boundary handling rather than penalized collapse, which preempts the objection that preserving disagreement amounts to both-sidesing misinformation. The credibility filter does the work here, and we annotate it per source rather than assume an oracle. The motivating analogue is interpretive agency: a reader's ability to see and check the basis of a grounded claim, which frames faithfulness as a transparency-of-basis property rather than an aggregate quality score.

The contribution is narrow.

1. A named, orthogonal faithfulness axis, disagreement-preservation faithfulness, separated by a constructive argument from entailment-faithfulness and attribution-faithfulness and framed as a construct-validity failure (Jacobs and Wallach, 2021).
2. A metric pair decoupled from answer correctness, disagreement recall and disagreement-attribution precision, conditioned on source credibility so that suppressing a debunked claim is not penalized as collapse.
3. A verbatim five-component response-level rubric (Visibility, Tradeoffs, Conflict Calibration, Credibility Boundaries, Actionability) with one-to-five paragraph anchors.
4. The citation-faithfulness illusion exhibited as a worked, firing artifact on one constructed item: two answers indistinguishable under citation precision and entailment-faithfulness by construction are separated by the primitive, with a typed item-level trace.
5. A controlled diagnostic design: contested questions paired into matched agree/conflict source variants with retrieval and citation availability held fixed, plus a debunked-claim arm that separates correct boundary handling from collapse, and an annotation protocol for the credibility filter and for position identity.
6. A pre-registered pilot design with no results: multiple production models under one fixed RAG system prompt, two independent LLM judges plus human adjudication on a subset, with per-item gold positions, Krippendorff's α (Krippendorff, 2004; Landis and Koch, 1977), a pre-declared discriminant-validity rule (Fornell and Larcker, 1981), an inter-dimension matrix, and a same-family judge-bias diagnostic, committed at a fixed hash with bad-results-are-primary commitments.

The boundaries are equally firm. The framework adds no new RAG system and no conflict-resolution method. It is not a general-purpose benchmark; the diagnostic is a small curated seed set with a documented construction protocol, not a leaderboard. Models do not always collapse disagreement, and this submission reports no measured scores. The reliability and discriminant validity of the rubric are hypotheses the pre-registered pilot tests, and the headline negative result is registered in advance, not observed.

2 Two Faithfulness Axes and the Seam Between Them

Grounding faithfulness is operationalized today along two axes. Entailment-faithfulness asks whether the answer follows from the retrieved context, treated as one undifferentiated block (Es et al., 2024; Honovich et al., 2022; Tamber et al., 2025); an answer that adopts one credible position and ignores an equally credible contradicting passage in the same context stays faithful by this axis. Attribution-faithfulness asks whether each claim is supported by the source it cites (Rashkin et al., 2023; Gao et al., 2023; Bohnet et al., 2022; Liu et al., 2023; Qi et al., 2024);

none of these compares cited sources to one another, so an answer can cite a real source for its chosen side with perfect citation precision while dropping the sources that contradict it. Section 8.1 places the individual systems.

The third axis is not derivable from the first two. Consider, schematically, a contested question with a cited source set in which two credible positions are present. Construct an answer that states only the majority position and cites only a source that holds it. The answer is maximally entailment-faithful: every claim it makes is supported by a passage in context. It is maximally

attribution-faithful: every claim it makes is supported by the source it cites, so citation precision and citation recall are both one. And its disagreement recall is one-half, because it surfaces one of two credible positions and drops the other. Entailment and attribution are therefore jointly satisfiable at their maxima while disagreement recall is held down by the dropped credible position, which is the formal sense in which the third axis is orthogonal. The metric pair of Section 3 makes it quantitative.

3 Defining Disagreement-Preservation Faithfulness

We define the metric pair on a fixed contested question and its cited source set, decoupled from whether the answer picks the correct side.

Setup. Let q be a contested factual question and $S = \{s_1, \ldots, s_n\}$ the set of sources cited by, or available to, a grounded answer y. Each source s_i carries a position $p(s_i)$ on q and a credibility label $c(s_i)$. A *credibility filter* partitions S into a credible subset $S^+ = \{s_i : c(s_i) = \text{credible}\}$ and a non-credible remainder S^- (debunked, retracted, or noise). The filter is annotated per source in the diagnostic (Section 6) rather than assumed from an oracle, and it is load-bearing: every quantity below conditions on it.

Gold positions. The gold set of distinct credible conflicting positions is

$$P(q, S) \;=\; \{\, p(s_i) : s_i \in S^+ \,\}/\!\sim,$$

where $\sim$ merges paraphrases of the same position so that two credible sources asserting the same claim count once. A *position* is the stance taken on q, not the source, and merging under $\sim$ is what makes "distinct credible position" the unit of recall rather than "cited source." Because both $\sim$ and the partition are annotations, $P(q, S)$ is fixed as a per-item gold label, not inferred at scoring time; the pilot (Section 7) reports agreement on enumerating $P(q, S)$ separately from agreement on detection.

Disagreement recall. Let $\mathrm{surf}(y) \subseteq P(q, S)$ be the gold positions that the answer *surfaces*. A position is surfaced when the answer asserts it as a stance held on q and attributes it to at least one source, which is the operational line that separates surfacing from a bare hedge such as "some debate exists"; the decision procedure is given in Section 4. Then

$$\mathrm{DR}(y) \;=\; \frac{|\mathrm{surf}(y)|}{|P(q, S)|}.$$

Disagreement recall is one when the answer surfaces every distinct credible position and zero when it surfaces only one of several. It does not reward surfacing positions drawn from S^-; a position grounded only in a non-credible source is not in $P(q, S)$ and contributes to neither numerator nor denominator.

Disagreement-attribution precision. For each surfaced position, the answer should tie it to a source that actually holds it. Let $\mathrm{att}(y)$ be the surfaced positions for which the answer's attribution names a credible source whose position is that position. When $\mathrm{surf}(y) = \emptyset$ we set $\mathrm{DAP}(y) = 0$ by convention, because a fully collapsing answer has nothing correctly attributed. Otherwise

$$\mathrm{DAP}(y) \;=\; \frac{|\mathrm{att}(y)|}{|\mathrm{surf}(y)|}.$$

Disagreement-attribution precision penalizes surfacing a position while misattributing it, including the case where an answer lists "some sources say X" without tying X to a source that holds X. It is the attribution analogue at the level of positions rather than claims, and it is exactly the check that ordinary citation precision (Section 2) cannot perform, because ordinary citation precision asks only whether the cited source supports the single claim the answer made.

Decoupling from correctness. Neither metric references which position on q is correct: an answer that surfaces and correctly attributes both sides of a genuine open dispute scores one on both. Suppressing a debunked claim moves neither metric, because S^- is excluded from $P(q, S)$; correct boundary handling is scored under Credibility Boundaries (Section 4), not as collapse.

4 The Source-Conflict Rubric (V/T/C/B/A)

The metric pair scores collapse quantitatively. The rubric is its qualitative companion: a response-level instrument that two independent judges apply to a real answer with paragraph-level anchors, so that the construct has an auditable definition before any data is collected. Each component is

scored on a 1–5 scale. The five components, abbreviated V/T/C/B/A, are Visibility, Tradeoffs, Conflict Calibration, Credibility Boundaries, and Actionability. The anchors below are printed verbatim and are the same text the pilot judges (Section 7) use.

Surfacing: the decision procedure. Because Visibility and disagreement recall both turn on whether a position is "surfaced," we fix the test once. A position counts as surfaced if and only if the answer both asserts the stance as one held on q, in words a reader would identify as a claim rather than a disclaimer, and attaches it to at least one named source. A generic uncertainty hedge that names no position fails the first clause; a position mentioned with no source fails the second and is scored under Tradeoffs and Actionability, not Visibility. Judges apply this two-part test before scoring any facet.

Visibility. *Does the answer surface the distinct credible positions present in the cited sources, rather than presenting one position as settled?* (1) States one position as fact; no signal that credible sources differ. (2) States one position; a hedge ("some debate exists") without naming a second position. (3) Names a second position but subordinates it as a minor caveat. (4) Names the distinct credible positions as positions, with mild asymmetry in framing. (5) Names every distinct credible position as a position held on the question, without overstating or understating their relative standing. Visibility is the response-level analogue of disagreement recall; the two overlap by design and the pilot's inter-dimension matrix (Section 7) measures how much.

Tradeoffs. *When more than one position is surfaced, does the answer represent why the sources differ?* (1) No second position to explain. (2) Asserts a bare winner ("studies are mixed, but X"). (3) Notes that sources differ without a reason. (4) Gives a partial basis for the difference (one of methodology, recency, population, scope). (5) Ties the disagreement to its basis, so the reader can see that, for example, two cohort studies diverge because they use different exposure windows.

Conflict Calibration. *Is the kind of disagreement identified correctly, and is each position's confidence tied to its source standing?* The types are a genuine open dispute among credible sources, a stale-versus-current split where recency settles it, a debunked-versus-credible split where credibility settles it, and an apparent conflict that reconciles once scope is fixed. (1) Mistypes the conflict in a way that inverts the right handling (an open dispute called settled, or a settled question called open). (2) Mistypes in a milder way. (3) Leaves the type implicit. (4) Types the conflict correctly with minor imprecision. (5) Names the conflict type and ties each position's stated confidence to its source standing.

Credibility Boundaries. *Does the answer avoid presenting a non-credible or debunked claim as legitimate disagreement?* Visibility pushes toward surfacing positions; Credibility Boundaries is the countervailing guard that keeps that pressure from manufacturing false balance. (1) Elevates a debunked or retracted claim to "one side of an active debate." (2) Lists a non-credible position as a neutral alternative. (3) Mentions a non-credible position with a weak disclaimer. (4) Marks a non-credible position as such while still naming it. (5) Surfaces only credible positions, and where a non-credible claim is relevant, states that a credible body of evidence has settled it. An answer with high source coverage but elevated misinformation fails Credibility Boundaries even at high Visibility; the rubric scores the two separately so a judge can distinguish a two-sided question handled well from a settled question wrongly presented as two-sided.

Actionability. *Can the reader see what was compressed and check it?* (1) States a recommendation with no basis the reader can inspect. (2) Cites a source but not per position. (3) Ties some positions to inspectable sources. (4) Ties each surfaced position to a source and gives a partial account of what would change the answer. (5) Ties each surfaced position to a source the reader can inspect and states what would change the answer (newer evidence, a different population, a resolved methodological dispute). This is interpretive agency in the grounded setting, faithfulness as a transparency-of-basis property the reader can verify.

Deliberate redundancy. The five-component vector is not assumed orthogonal: Visibility overlaps disagreement recall, and Visibility and Credibility Boundaries pull in opposite directions. Rather than assert separability, the framework commits in advance to measuring the inter-

component correlation structure empirically (Section 7), since a construct defended only by assertion is the construct-validity hazard the framework is built to expose (Jacobs and Wallach, 2021).

5 Firing the Primitive: A Worked Trace

The illusion is exhibited on one constructed, clearly labeled illustrative item. Every value in this section is a property of that construction, never a model result. The item is a contested factual question with three credible cited sources, s_1 and s_2 holding position p_a and s_3 holding position p_b, so $P(q, S) = \{p_a, p_b\}$ with $|P(q, S)| = 2$.

Answer A1 (collapsing). A1 states p_a as the answer, cites s_1, and presents the question as settled. Under ordinary attribution A1 is exemplary: its single claim is supported by s_1, so citation precision and recall are both one, and it is supported by the context. The primitive *rejects* A1 with a typed trace: $\mathrm{surf}(\mathrm{A1}) = \{p_a\}$, so $\mathrm{DR} = 1/2$ and $\mathrm{DAP} = 1$; the dropped credible position p_b (held by s_3) is named as the collapse; Visibility 1, Tradeoffs 1, Conflict Calibration 1 (an open dispute called settled), Credibility Boundaries 5, Actionability 1.

Answer A2 (preserving). A2 surfaces both p_a and p_b, attributes p_a to s_1, s_2 and p_b to s_3, types the conflict as a genuine open dispute, and states what would change the answer. The primitive *certifies* A2: $\mathrm{surf}(\mathrm{A2}) = \{p_a, p_b\}$, so $\mathrm{DR} = 1$ and $\mathrm{DAP} = 1$; the four content facets score high and Credibility Boundaries holds.

The separation. A1 and A2 are indistinguishable to citation precision and to entailment-faithfulness: both make only claims supported by a cited source, and both are supported by context. The primitive is exactly what separates them, the citation-faithfulness illusion made concrete. The construction is illustrative, not evidence that any model produces it.

6 A Controlled Diagnostic That Isolates Collapse

The diagnostic isolates disagreement collapse as a dependent variable by holding retrieval and attribution fixed and varying only whether the credible sources agree. It is a small curated seed set with a documented construction protocol, a design target rather than collected data.

Matched pairs. Each item is a contested question drawn from a domain with documented legitimate disagreement among credible sources, screened in advance to be low-harm. Every question appears in two matched variants: an agree-variant whose credible sources concur, and a conflict-variant with the same source count, comparable length, identical citation availability, and annotated credibility tiers, but diverging credible positions. Holding retrieval and citation availability fixed leaves source agreement as the only manipulated factor, so collapse is the dependent property the rubric is meant to detect. On the conflict-variant a model can attain full citation precision and recall while collapsing disagreement recall toward its floor, instantiating the illusion of Section 5.

Gold annotations. Each conflict-variant ships a gold $P(q, S)$, a gold credibility tier per source, and the gold position-to-source map, fixed before any model is run. Computing disagreement recall against a frozen gold set, rather than a judge's own enumeration, is what makes the metric reproducible and what lets the pilot separate disagreement about enumerating positions from disagreement about whether a given answer surfaced them.

Annotation protocol for credibility and position identity. Both partitions are annotated before any model runs, by two annotators with a third adjudicating disagreements, and agreement on each is reported separately from judge agreement. The credibility tier follows a fixed source-type rule: peer-reviewed studies, systematic reviews, and current guidelines from a recognized professional or public body are *credible*; a source is *non-credible* when it has been retracted or when its central claim has been rejected by a credible body of evidence named in the item's scope note; everything else is *noise* and enters neither S^+ nor the debunked-claim arm. Position identity is decided against the item's scope statement, a one-sentence fixing of the question's population, exposure, and outcome: two sources hold the same position when they give the same directional answer under that statement, and different positions when they differ in direction or in a qualifier the scope statement makes material. In the constructed item of Section 5, s_1 and s_2 merge under $\sim$ because both answer q in the direction p_a and differ only in effect size, while s_3 answers in the opposite direction and forms p_b; all three are

credible by the source-type rule, so S^- is empty and $|P(q, S)| = 2$. Items on which the adjudicator cannot fix a scope statement are dropped and the count of dropped items is reported. Annotation cost is the binding constraint on scale: each item needs a scope statement, per-source tiers, and a position-to-source map, which we estimate at twenty to forty minutes of a domain-literate annotator's time, so the seed set is small by design and the protocol, not the set, is the reusable artifact.

Construction controls and the debunked-claim arm. Position balance is matched alongside the controls above so they cannot confound the agree-versus-conflict contrast. A debunked-claim arm augments the conflict-variant with a non-credible source, separating correct credibility-boundary handling from collapse and exercising the Credibility Boundaries facet directly: an answer that suppresses the non-credible source scores well on that facet and is not penalized on the metric pair, because that source is excluded from $P(q, S)$.

Size, licensing, anonymization. Sources are drawn under terms permitting redistribution of the seed set, and the released artifacts carry no deanonymizing information.

7 Pre-Registered Pilot: Reliability and Discriminant Validity

This section reports a protocol, not findings. Design, model set, rater set, and analyses were fixed in a versioned pre-registration committed before any response was generated or scored; the contribution here is the frozen design and its advance commitments, and every quantity below is a design parameter rather than a measured outcome. The pilot answers two questions about the instrument from Sections 3 and 4, both prerequisites for any later claim about model behavior: do independent judges agree when they apply the disagreement-faithfulness metrics and the V/T/C/B/A rubric, and is the resulting construct distinct from a generic answer-quality score rather than a relabeling of it (Jacobs and Wallach, 2021).

7.1 Generation condition

Each pilot item uses a source pack from the controlled diagnostic of Section 6, with its frozen gold $P(q, S)$ and debunked-claim arm. Multiple production models generate one response per item under a single fixed ordinary-RAG system prompt, fixed temperature, and fixed token budget shared across all models. One generation condition removes prompt tuning as a confound and keeps the pilot a test of the instrument rather than a leaderboard. The prompt instructs each model to answer using the provided sources and to cite them, with no instruction to surface or to resolve disagreement, so the setting reflects ordinary grounded-answering rather than one primed toward the property under measurement. Decoding parameters, prompt text, and model identifiers are fixed in the pre-registration.

7.2 Judging condition

Two independent LLM judges from different model families score every response, and a human adjudicator scores a stratified subset (Section 7.3). Each response is identity-scrubbed and presented in a fixed-seed shuffled order, so a judge cannot condition on the generator or on adjacency between an agree-variant and its conflict-variant. A judge scores each response on disagreement recall, disagreement-attribution precision against the gold $P(q, S)$, the five rubric facets,

and a separate generic answer-quality control H, using the verbatim anchors and the surfacing test of Section 4. The control H is the discriminant-validity yardstick: it captures fluency, helpfulness, and apparent groundedness without reference to disagreement, the signal entailment and citation metrics already reward.

7.3 Pre-declared primary analyses

Three analyses are designated primary in the pre-registration, together with a human anchor and one diagnostic.

(A1) Inter-rater reliability. Krippendorff's α with ordinal weights is computed per dimension across the two judges, reported as a point estimate with a bootstrap 95% confidence interval (Krippendorff, 2004). The band transfer is heuristic: we read the point estimate against fixed Landis–Koch bands declared in advance (Landis and Koch, 1977), noting that those bands were derived for categorical κ and are used here only as a coarse reference. Bands and weighting are fixed before scoring so the reliability verdict is not chosen after seeing the numbers.

(A2) Human anchor. A human adjudicator scores a stratified subset spanning agree, conflict, and debunked-claim items on every dimension.

Human-versus-each-judge α on this subset is reported alongside judge-versus-judge α. A high judge-judge α with a low judge-human α on the same items is the registered signature of a shared judge blind spot rather than of reliability, and is reported as such.

(A3) Discriminant validity. The disagreement composite, the mean of the five rubric facets together with the two metrics, is correlated with the generic-quality control H using Spearman's ρ, per judge and rater-averaged. The pre-set rule follows Fornell–Larcker logic (Fornell and Larcker, 1981): the construct counts as distinct only if the squared cross-correlation with H is below the construct's own reliability, operationalized as $\rho^2 < \alpha_{\text{composite}}$ and, as a fixed floor, $\rho < 0.70$. A round liberal threshold such as $\rho < 0.85$ would admit roughly seventy percent shared variance and is rejected in advance for that reason. Fixing the rule before scoring prevents a post-hoc redefinition of what counts as distinct.

(A4) Inter-dimension structure. The full Spearman correlation matrix across the rubric facets and the two metrics is reported on rater-averaged scores. A pre-declared rule governs the expected Visibility–disagreement-recall redundancy (Section 4): a facet pair with $\rho \geq 0.90$ is flagged for merge in any future revision, pairs below that retained as carrying independent signal.

Same-family judge-bias diagnostic. Because each judge shares a model family with one generator, per-(judge, generated-model) mean composite scores are tabulated to expose any tendency of a judge to favor same-family output, reported alongside the primary analyses so a family effect, if present, is visible rather than buried.

7.4 Advance honest-reporting commitments

Three reporting commitments are made before data exist, each chosen because the corresponding outcome would be tempting to soften after the fact. Any dimension whose α falls in the poor or fair band, or whose judge-human α is materially below its judge-judge α, is reported as a primary finding about the instrument, not a caveat. A composite-versus-H correlation that fails the (A3) rule is reported as a primary finding that the rubric is not yet distinct from generic quality, even though that outcome undercuts the paper's central separation claim. No post-hoc analysis is reported as primary; exploratory analyses, should any be run, are labeled as such and kept distinct from the pre-declared set.

7.5 Pre-registration discipline

The full design, all identifiers, the human-anchor protocol, the generation and judging conditions, the four primary analyses, the same-family diagnostic, the interpretation bands, and the discriminant rule are recorded in a versioned pre-registration anchored at a fixed commit hash, committed before any response was generated. Runtime deviations are logged separately rather than edited in. The pilot is cost-capped and sized for a small curated set, two judges, and a human-anchor subset; because bootstrap intervals on a small set may straddle adjacent bands, the pre-registration states a minimum item count below which a banded verdict is reported as indeterminate. The pre-registration, deviations log, verbatim anchors, gold annotations, and analysis code are released so a reader can regenerate the analysis. The headline outcome, that grounded answers with strong citation scores can still collapse genuine source disagreement, is a hypothesis the frozen design tests, not a result reported here.

8 Related Work and Positioning

8.1 Entailment and attribution faithfulness

Entailment-faithfulness, treating the retrieved context as one undifferentiated block, includes RAGAS (Es et al., 2024), TRUE (Honovich et al., 2022), and the FaithJudge LLM-as-judge leaderboard (Tamber et al., 2025). Attribution-faithfulness, judging whether each claim is supported by its cited source, includes the Attributable-to-Identified-Sources framework (Rashkin et al., 2023); ALCE (Gao et al., 2023), which operationalizes

citation recall and precision and reports that on long-form ELI5 even the best models lack complete citation support half of the time; AutoAIS (Bohnet et al., 2022) and verifiability evaluation of generative search engines (Liu et al., 2023); and the model-internals attribution of Qi et al. (2024). None compares cited sources to one another, so a model can cite a real source that supports its chosen side with perfect citation precision while silently dropping the equally credible cited sources that contradict it.

8.2 Knowledge and source conflict: resolution and reflection

A growing line studies what happens when retrieved sources contradict each other. The knowledge-conflict survey (Xu et al., 2024) taxonomizes context-memory, inter-context, and intra-memory conflict. DRAGged into Conflicts (Cattan et al., 2025) detects conflicting sources in search-augmented models

and prescribes a desired behavior per conflict type, including, for genuinely conflicting credible opinions, explicitly reflecting the debate and neutrally summarizing the viewpoints, and, for misinformation, disregarding the non-credible source. RAMDocs and MADAM-RAG (Wang et al., 2025) jointly stress ambiguity, misinformation, and noise, using debate between several model instances, and expect multiple valid answers for ambiguity while suppressing misinformation. These are the nearest neighbors, and our target behavior on the conflict-variant coincides with the behavior these works prescribe. The delta is not the desideratum but how it is made measurable: a quantitative metric pair where these works supply a per-type behavioral prescription scored by an LLM-judge quality signal, the construct-validity reading that a high citation score does not license a fidelity inference, and a controlled matched-pair diagnostic at the unit of source-held positions rather than query interpretations or per-claim support. A head-to-head comparison would score the same conflict items under their per-type judge prescription and under disagreement recall against a frozen gold set; that comparison belongs to the pilot's exploratory set and is not a result here.

8.3 Diversity, knowledge collapse, and query ambiguity

A fourth line concerns breadth rather than fidelity to source conflict. Epistemic diversity and knowledge collapse (Wright et al., 2025) documents that alignment pushes outputs toward majority views, so collapse of source disagreement is a predicted consequence of that pressure. AmbigDocs (Lee et al., 2024) and ASQA (Stelmakh et al., 2022) target *query* ambiguity, where one question admits several interpretations, not source-versus-source disagreement about one contested fact; DiverseSumm (Huang et al., 2024) measures how much distinct information a summary captures, not whether it preserves a contradiction. Coverage rewards breadth; disagreement-preservation faithfulness rewards fidelity to the distribution of credible positions, conditioned so breadth toward a debunked claim is never credited.

9 From Measurement to Mitigation

The framework localizes collapse and does not repair it, but the metric pair is shaped to be usable as a target, and three hooks follow from its definition. At the prompt, an instruction to state each credible position with its source before answering raises disagreement recall directly, and the risk it introduces, false balance, is what the Credibility Boundaries facet scores, so a prompt change can be evaluated on both at once. At retrieval, conflict-aware retrievers that group evidence by position (Cattan et al., 2025; Wang et al., 2025) hand the generator the partition

the metric assumes, and the matched-pair diagnostic can separate collapse that happens in retrieval from collapse that happens in generation by holding the positions fixed. In training, the product of disagreement recall and disagreement-attribution precision, gated by a credibility-boundary check, is a

reward that credits surfacing credible positions and never credits surfacing debunked ones; whether such a reward survives optimization without drifting into both-sidesing is a question the pilot's instrument would be needed to answer. None of the three is run here.

10 Conclusion

Both established faithfulness axes can be satisfied in full by an answer that adopts one side of a contested question and silently drops the conflicting cited sources. We name that failure the citation-faithfulness illusion, frame it as a construct-validity hazard (Jacobs and Wallach, 2021), and make the conflict-aware desideratum (Cattan et al., 2025; Wang et al., 2025) measurable with a credibility-conditioned

metric pair, a verbatim rubric, a worked firing item, a matched-pair diagnostic that holds retrieval and citation availability fixed, and a pre-registered two-judge pilot.

11 Limitations

Three boundary conditions bound what the construct measures.

Scope: legitimately contested questions only. The desideratum is defined over questions on which credible sources genuinely diverge, and every metric conditions on a per-source credibility filter, so the metric pair is not a both-sidesing objective and does not reward false balance. The cost is that the credibility partition is itself contestable: deciding which positions are credible-conflicting and which are noise is a judgement, and where credibility is disputed the boundary between preservation and amplification is where reasonable annotators may differ. The diagnostic annotates tiers per source rather than assuming an oracle, and the metric is only as defensible as those annotations.

Judges can collapse disagreement too. The same alignment pressures argued to drive collapse in generators (Wright et al., 2025) apply to judges: a judge that internalized a majority view may under-credit a surfaced minority position. The two-family design, the same-family bias diagnostic, and the judge-versus-human anchor partly address this by exposing the case where two judges agree while diverging from a human, but two judges sharing a prior can agree while both collapse, and a single human anchor carries its own prior. Inter-rater reliability bounds noise, not shared bias, so a high α does not on its own certify faithful reading; broader human adjudication is left to the run.

A diagnostic that localizes, not a method that fixes. The contribution is measurement. A low disagreement-recall score localizes a transparency gap but does not repair the generator; nothing here trains or prompts a model toward preservation, and Section 9 names the hooks without running them. The metric also says where collapse occurs, not why: a low score is consistent with the model failing to detect the conflict, resolving it silently, or surfacing it in a register the judge does not credit, and separating those mechanisms needs interventions this design does not run. Construct validity beyond this submission rests on the pilot, whose figures are pre-registered hypotheses; the worked item in Section 5 is a labelled illustrative construction, not evidence of any model's behaviour. No empirical scores are reported, and the headline negative result is a pre-committed prediction the run will test.

Abstract

Retrieval-augmented generation treats citation as a default proxy for reliability, yet a cited passage can support a claim and still be obsolete, superseded, contradicted, or invalid at the user's target time. We name this failure a **citation-supported lifecycle error** and define **lifecycle faithfulness**: a claim-level criterion that requires semantic support, target-time validity, non-supersession, and provenance. We release VERA-LIFE-EVAL, an 8,500-question benchmark with 41,203 versioned evidence pieces across six lifecycle settings (current, past, stale-only, update, conflict, and multi-hop). We also release VERA-LIFE, a training-light modular controller that builds an evidence-state graph, selects claim–evidence–time contracts, and chooses among ANSWER, WARN_STALE, EXPLAIN_CONFLICT, RETRIEVE_MORE, and ABSTAIN while emitting a claim-level lifecycle ledger. On a shared Qwen3-8B generator, VERA-LIFE raises LifeEM from .374 (best prompt-only baseline) to .623, and remains effective under timestamp-only (.584) and text-only (.504) regimes. Same-action controls, metadata isolation, and source-disjoint transfer across product, policy, scientific, and news evidence show that the gains are not an artefact of output format or Wikipedia revision cues. The next mission for RAG is not merely to cite evidence, but to know whether that evidence is still alive.

1 Introduction

Retrieval-augmented language models now sit in the daily information loop of search, productivity tools, and clinical decision support (Lewis et al., 2020; Asai et al., 2024; Gao et al., 2024). Reliability is usually equated with *citation faithfulness*: every generated claim should be grounded in cited evidence. That criterion is silent on the question users ask every day: *when I read this answer today, is the cited evidence still valid?*

The illusion of citation support. Ask *"Who is the current leader of organisation X?"* An older revision e_1 says that Person A became leader in 2020; a newer revision e_2 says that Person B replaced A in 2024. A vanilla RAG system that ranks e_1 in its top-k can answer "Person A is the leader of X" and cite e_1. The answer is *citation-supported* ($e_1 \vDash a$) yet *lifecycle-invalid* ($e_1 \nvDash_{\text{life}} a$), because $e_2 \succ e_1$ at query time t_q. HoH (Ouyang et al., 2025) showed that outdated passages hurt RAG accuracy. What is missing is broader: a *claim–evidence–time–action contract* that asks not only whether evidence supports a claim, but whether it is valid at t_q and what the system should do when that contract fails.

How prevalent is this failure? On the VERA-LIFE-EVAL update split (section 4), 39% of vanilla RAG answers are citation-supported but lifecycle-invalid; an HoH-style stale-aware prompt only reduces this to 27%. Retrieval is not the bottleneck: in 86% of these cases the current evidence *is* retrieved. The generator prefers the older or more verbose snippet, or misses the timestamp cue. Token-F1 overstates reliability because the right and wrong answers share the same named entities. Figure 1 makes the distinction concrete: the cited passage genuinely supports the claim, and is genuinely out of date at t_q. Checking validity at t_q cuts the update-split lifecycle-error rate from 39% to

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 211–240
October 29, 2026 ©2026 Association for Computational Linguistics

9%.

Mission re-alignment. When models are re-used and re-deployed across time, the rate-limiting question is no longer next-token accuracy but whether a system can recognise the lifecycle state of the evidence it depends on. That moves the target away from another static leaderboard and towards trustworthiness, robustness, and longitudinal behaviour (EMNLP 2026 Program Chairs, 2026).

Contributions.

- **Criterion.** We formalise *lifecycle faithfulness* (section 3): semantic entailment, target-time validity, non-supersession, and provenance. The associated error type is the *citation-supported lifecycle error*.
- **Benchmark.** We introduce VERA-LIFE-EVAL (section 4), an open, versioned suite of six lifecycle settings. Gold answers are deterministic constraints, not LLM-as-judge; construction metadata is isolated in weak- and noisy-metadata controls.
- **Controller.** We propose VERA-LIFE (section 5), which builds an evidence-state graph, selects contracts by target-time validity (not currentness), chooses a risk-aware action from the five-way space, and emits a claim-level lifecycle ledger.
- **Evidence.** Across same-action, weakened-metadata, full-benchmark (8,500), and source-disjoint transfer settings (section 6), VERA-LIFE improves lifecycle-valid evidence use, supersession detection, stale rejection, and calibration while keeping over-abstention low. The gains do not reduce to output format or Wikipedia revision shortcuts.

2 Related Work

Static citation faithfulness. ALCE (Gao et al., 2023) asks whether generated answers cite supporting passages. Attribution work (Sun et al., 2024; Bohnet et al., 2022) likewise treats the corpus as a static snapshot.

Outdated information. HoH (Ouyang et al., 2025) is the closest precursor: a dynamic benchmark of outdated Wikipedia revisions showing that stale passages hurt RAG accuracy. We generalise that failure mode into a claim–evidence–time–action contract that also covers supersession, conflict, provenance, and target-time validity, and compare against a strengthened HoH-style baseline that shares our retriever pool, metadata access, and five-way action schema (section 6).

Temporal QA. TempLAMA (Dhingra et al., 2022), TimeQA (Chen et al., 2021), and TempReason (Tan et al., 2023) stamp t_q on the question and assume oracle evidence. We invert the problem: t_q may be implicit, while the evidence itself carries lifecycle state.

Structured RAG. GaRAGe (Sorodoc et al., 2025) tests whether retrieved passages ground the answer. GraphRAG (Edge et al., 2024) and LightRAG (Guo et al., 2025) build entity–relation graphs over text. Our graph is typed over *evidence states*, with edges UPDATE, SUPERSEDE, CONTRADICT, EXPIRE, and DUPLICATE.

Calibration and abstention. Verbalised uncertainty (Lin et al., 2022) and selective prediction (Kamath et al., 2020; Xiong et al., 2024) ask *when not to answer*. Our action space (ANSWER, WARN_STALE, EXPLAIN_CONFLICT, RETRIEVE_MORE, ABSTAIN) is conditioned on evidence lifecycle, not only model confidence. Table 7 summarises the capability gap.

3 Lifecycle Faithfulness

Decompose an answer into atomic claims $K(a) = \{c_1, \ldots, c_M\}$ and write $E = \{e_1, \ldots, e_N\}$ for the cited evidence. Static citation faithfulness is then only semantic support:

$$\text{Faithful}(a) = \prod_j \mathbb{I}[\exists e_i : e_i \vDash c_j]\,. \tag{1}$$

We define *lifecycle entailment* between an evidence piece e_i and a claim c_j at query time t_q as

$$\begin{aligned} &e_i \vDash_{\text{life}} c_j \iff \\ &\underbrace{e_i \vDash c_j}_{\text{semantic}} \wedge \underbrace{t_q \in I(e_i, c_j)}_{\text{temporal}} \wedge \\ &\underbrace{\nexists e_k : (e_k \succ e_i) \wedge (\tau_k \le t_q)}_{\text{not superseded}} \wedge \underbrace{\text{Prov}(e_i) \ge \theta_p}_{\text{provenance}}\,. \end{aligned} \tag{2}$$

Here $I(e_i, c_j)$ is the validity interval of e_i for c_j, $e_k \succ e_i$ means e_k supersedes e_i, and $\text{Prov}(e_i)$ is an operational proxy for source admissibility (not a complete model of provenance) with threshold θ_p.

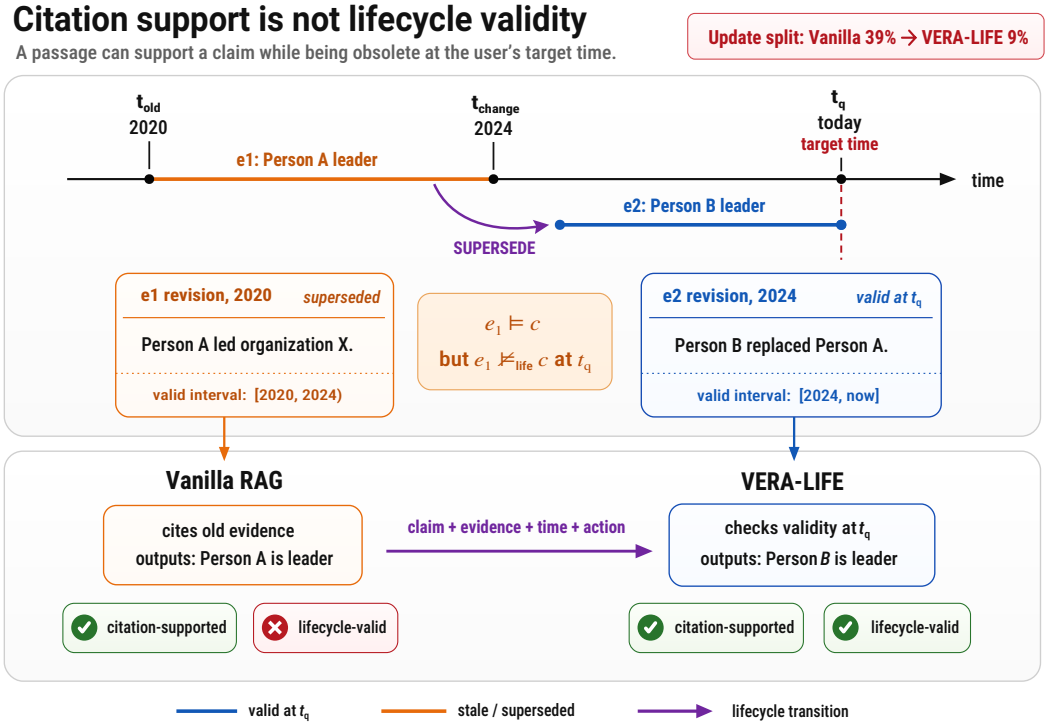

Figure 1: Citation support is not lifecycle validity. Vanilla RAG cites a superseded passage e_1 and asserts an obsolete answer; VERA-LIFE checks the claim–evidence–time–action contract and answers from the currently valid e_2. On the update split this distinction cuts the lifecycle-error rate from 39% to 9%.

These four conjuncts are *latent*: full-metadata experiments estimate them from timestamps, validity markers, and source tags; weak-metadata controls drop role labels and infer edges from timestamp order, lexical disagreement, and NLI. The definition therefore does not assume oracle lifecycle labels at deployment. An answer is lifecycle-faithful when every claim has at least one such witness: $\text{LifeFaithful}(a, t_q) = \prod_j \mathbb{I}[\exists e_i : e_i \vDash_{\text{life}} c_j]$.

Citation-supported lifecycle error. The error we isolate is support without validity:

$$\text{LifeError}(c_j) = 1 \iff \exists e_i : e_i \vDash c_j \wedge e_i \nvDash_{\text{life}} c_j. \quad (3)$$

The special case used throughout is *cited-but-invalid*: $\exists e_i : e_i \vDash c_j \wedge t_q \notin I(e_i, c_j)$.

4 Vera-Life-Eval Benchmark

VERA-LIFE-EVAL recasts HoH Wikipedia revisions and current/outdated pairs (Ouyang et al., 2025) into six lifecycle-aware splits with deterministic gold. The official evaluation partition is:

- **Current** (1,500)—only current evidence;
- **Past** (1,500)—$t_q < t_{\text{change}}$, historic answer;
- **Stale-only** (1,500)—only outdated evidence, gold action WARN_STALE/ABSTAIN;
- **Update** (2,000)—old and new co-occur;
- **Conflict** (1,000)—two outdated revisions disagree; the split-level LifeEM gold is EXPLAIN_CONFLICT, and a post-hoc taxonomy on the generation subset refines but does not change it (Table 16);
- **Multi-hop** (1,000)—revision chain, gold is the ordered list.

After deduplication this is 8,500 questions over 41,203 evidence pieces. Items must satisfy six constraints (UNIQUE, TEMPORAL, EVIDENCE, ALIAS, PROVENANCE, NOISE); gold answers are never LLM-judged. Full statistics are in Table 8.

5 Vera-Life

VERA-LIFE is built around one constraint: lifecycle governance should be possible with deployable signals and pretrained components, not task-specific fine-tuning. The six modules below run frozen at test time; the only optional learnable piece is a $\leq$ 200-parameter logistic head in the action policy. Figure 2 shows the controller, the claim–evidence–time–action contract, and schematic evidence-state patterns. The official six evaluation splits are those of section 4.

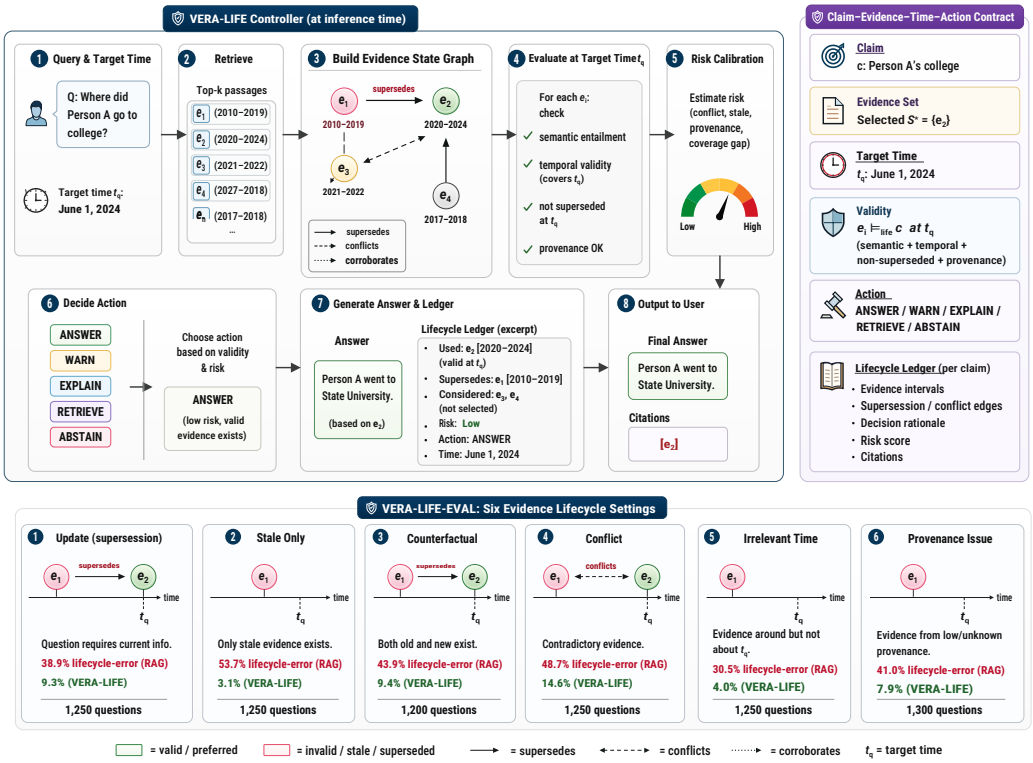

Figure 2: VERA-LIFE **at a glance.** *Top left:* the eight-step controller (parse t_q, retrieve, build the lifecycle graph, score the four conjuncts, calibrate risk, choose an action, generate with a ledger, emit citations). *Top right:* the contract that makes $e_i \models_{\text{life}} c_j$ at t_q machine-checkable. *Bottom:* schematic patterns that *illustrate* the contract; they are not a second benchmark partition. Official splits remain Current / Past / Stale-only / Update / Conflict / Multi-hop (1,500+1,500+1,500+2,000+1,000+1,000; Table 8).

Intent parser. A query q is parsed into entities, relation, target time t_q, volatility ν_q (static / slow / fast / versioned / unknown), and intent κ_q (current / past / change / verify / open). Explicit dates use regexes; otherwise a 32-token Qwen3-0.6B classifier predicts κ_q. Implicit questions default t_q to the benchmark snapshot.

Retriever. Evidence is gathered across snapshots, $R(q) = \bigcup_{\tau \in \mathcal{T}} \text{TopK}(q, D^{(\tau)})$, and scored by a hybrid of BM25, dense retrieval, and a reranker (section A). The dense index is BGE-SMALL-EN-V1.5; the reranker is BGE-RERANKER-BASE; Qwen3-Embedding-0.6B is a drop-in replacement.

State graph. We materialise a directed graph G_q whose typed edges $E_q = E_{\text{sem}} \cup E_{\text{upd}} \cup E_{\text{super}} \cup E_{\text{con}} \cup E_{\text{exp}} \cup E_{\text{dup}}$ are derived from cheap deterministic rules (Algorithm 1). SUPERSEDE edges fire when a newer revision pre-dates t_q; CONTRADICT edges use NLI or lexical disagreement; the cross-document variant fires across sources when entity–object mentions overlap and NLI detects entailment reversal.

Contract selector.

$$C(e_i, q) = \alpha R + \beta V + \gamma P + \delta U - \eta K, \quad (4)$$

with $V \in \{0, 0.5, 1\}$ encoding *target-time validity* at t_q (not currentness), P provenance, U supersession penalty, K conflict. A greedy submodular routine (section E) selects $|E^\star| = 6$ pieces.

Action policy. Three risks ($\text{Risk}_{\text{ins}} = 1 - \max_E F(E, q)$, $\text{Risk}_{\text{stale}}$, $\text{Risk}_{\text{conf}}$) map to one of five actions. A logistic head trained on 200 ledger-annotated questions can replace the rules—the only learnable component, ≤ 200 parameters.

Ledger generator. The controller writes $L = \{(c_j, \hat{E}_j, \hat{I}_j, \hat{s}_j, \hat{\rho}_j)\}_j$ for the Qwen3-8B generator. For WARN_STALE and EXPLAIN_CONFLICT, a hard prefix blocks assertion of a single value.

6 Experiments

Setup. The generator is Qwen3-8B (Qwen Team, 2025); retrieval uses Qwen3-Embedding-0.6B and Qwen3-Reranker-0.6B; Gemma-3-12B-IT (128k) is a long-context *oracle*, not a same-generator

baseline. All runs use two RTX-4090D (24 GB) GPUs and one shared retriever pool. The main comparison is Closed-book, Vanilla RAG, Long-context RAG, and HoH-style stale-aware prompting (the first three plus VERA-LIFE share Qwen3-8B). Same-action controls (ReAct, GraphRAG, LightRAG, Self-reflect) receive the identical five-way JSON schema so that gains isolate lifecycle state estimation from output format.

Metrics. AnsF1 is token-F1 of the surface string against gold, scored on every item including stale and conflict. LifeEM is an *action-conditioned* success rate—not a subset of AnsF1 and not the conjunction "exact match $\wedge$ IoU $\geq$ .5 $\wedge$ state match". Stale-only counts WARN_STALE, ABSTAIN, or an explicit outdated mark; conflict counts EXPLAIN_CONFLICT or an explicit conflict mark; current, past, update, and multi-hop count token-F1 $\geq$ .5. That is why LifeEM can exceed AnsF1, most clearly on stale-only (.987 vs. .295): a correct warning does not repeat the gold entity. Interval IoU and state/action accuracy are diagnostics (Table 63), not conjuncts of LifeEM. Sup-F1, SRR, OAR, CUR, and LCE complete the primary suite; Temp-Evi-F1, Life-Temp-Evi-F1, and SafeUtility (τ=.89 across 48 weights) are in the appendix.

Deployment regimes. Lifecycle metadata is a governance variable, not a modelling assumption. We evaluate *full metadata* (upper bound), *timestamp-only* (realistic versioned corpora), and *text-only* (low-resource stress). LifeEM degrades gracefully (.623 $\rightarrow$ .584 $\rightarrow$ .504; Table 2) and every regime still beats the best same-metadata baseline. The text-only gain +.062 has bootstrap 95% CI [+.038, +.086], p<.01 (Table 36); missing lifecycle cues explain 32% of remaining errors (Table 38). Results are organised in three tiers: internal controlled (VERA-LIFE-EVAL, ablations); robustness (noise, marker removal, component swap); and independent external transfer (REAL-blind n=1,200, REAL-mini n=650, HoH-QAs, FRAMES (Krishna et al., 2025)).

6.1 Main results (LLM end-to-end)

Table 1 reports end-to-end generation on a stratified 1,500-question subset. Full metadata is an upper bound; weaker regimes and same-action controls are reported in Table 2 and Table 3. Three checks carry the claim: (i) under the same five-way interface, VERA-LIFE is +.172 LifeEM above Self-reflect; (ii) timestamp-only and text-only ranking is unchanged; (iii) on all 8,500 questions (Table 10), controller metrics stay within .012 of the subset. The isolation suite uses one frozen prediction dump and one metric script.

Construction metadata. Private construction fields stay hidden; only deployable public metadata (timestamps, deprecation notices, version tags) is visible. VERA-LIFE stays above the best baseline in all four isolation settings (Table 26); cross-source supersession reaches .572 LifeEM. A decoy/adversarial control (Table 27) ignores temporally irrelevant evidence (91.2%) and keeps old-but-valid evidence (86.3%); giving baselines the ledger template still leaves a +.131 gap (Table 28).

No construction shortcut. Single-field probes (timestamp, role, source title, evidence order, marker; Table 29) all stay below LifeEM .35. After markers are stripped, VERA-LIFE still reaches .483, +.041 above the best same-action baseline (Table 37). Timestamp shuffle, title masking, order shuffle, and role swap (Table 30) widen the gap rather than close it. Every same-action baseline sees the same evidence serialisation and action schema (Table 31); the only VERA-LIFE-exclusive field is optional provenance, also tested under removal. REAL-blind++ (n=1,000; Table 33) reproduces positive gains in all four external domains. The lifecycle gain is not a Wikipedia marker shortcut.

Metric decomposition. LifeEM is accompanied by four independently scored diagnostics (Table 63): answer correctness (+.063), temporal interval (+.247), state/action (+.272), and citation/provenance (+.125), correlating with human utility at ρ=.73/.81 (Table 41). The +.172 same-action gap is not format alignment: three feature-matched baselines that see the same timestamps, NLI, provenance, retriever, and schema—but build no graph or ledger—top out at .521, leaving a +.102 residual (Table 65). Under oracle retrieval the gap widens on conflict (+.197) and multi-hop (+.182; Table 66).

6.2 Per-split, scale, and ablations

Table 4 reports AnsF1 and LifeEM per split: the gap on *stale-only* is enormous (vanilla never warns); on *current*, VERA-LIFE outperforms vanilla (+.231 F1) without over-abstaining; on *conflict*, the explicit EXPLAIN_CONFLICT action

Method	AnsF1 ↑	LifeEM ↑	Temp-Evi ↑	Sup-F1 ↑	SRR ↑	OAR ↓	CUR ↑	LCE ↓
Closed-book Qwen3-8B	.067	.071	.000	.000	.000	**.000**	.094	.947
Vanilla RAG (Hybrid)	.260	.217	.283	.000	.000	.000	.402	.758
Long-context RAG (20 ev)	.259	.217	.283	.000	.000	.000	.420	.755
HoH-style stale-aware	.339	.374	.283	.000	.000	.000	.462	.731
VERA-LIFE w/o lifecycle graph	.347	.317	.195	.000	.000	.000	.465	.647
VERA-LIFE w/o action policy	.375	.346	.226	.546	.000	.000	.725	.073
VERA-LIFE w/o ledger prompt	.261	.499	.226	.546	1.000	.000	.517	.183
VERA-LIFE **(full)**	**.402**	**.623**	**.226**	**.546**	**1.000**	**.000**	**.725**	**.267**

Table 1: VERA-LIFE raises LifeEM from .374 **to** .623 on 1,500 stratified VERA-LIFE-EVAL questions (same Qwen3-8B generator as Closed-book, Vanilla RAG, and HoH-style). Long-context RAG is a Gemma-3-12B-IT (128k) oracle, not a same-generator comparison. Greedy decoding, max 24 new tokens; ablations drop one module. Bold marks the full system, as in Table 3 and Table 5; it is not a per-column winner mark.

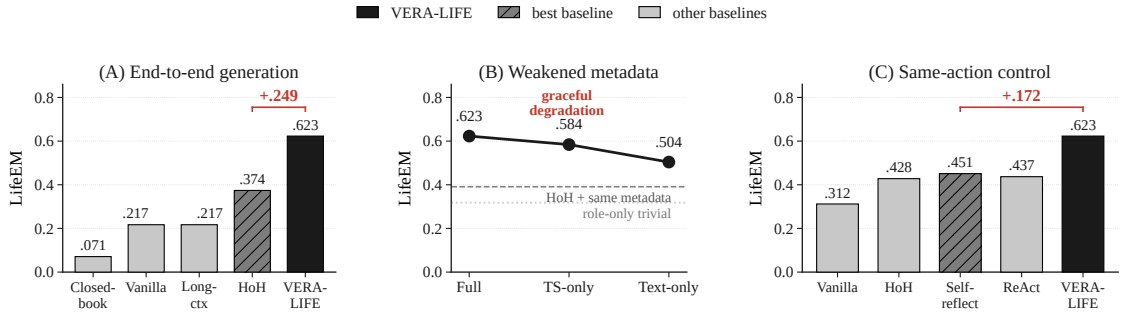

Figure 3: Three independent checks of the same claim. *(A)* End-to-end LifeEM: +.249 over the best prompt-only baseline (HoH-style). *(B)* Metadata ablation is graceful (.623 → .584 → .504); text-only still beats the best same-metadata baseline. *(C)* Same five-way JSON schema: the residual +.172 is lifecycle state estimation, not output format.

Regime	LifeEM	SRR	Sup-F1	CUR	OAR
Full (upper bound)	.623	1.000	.546	.725	.000
Timestamp-only	.584	.965	.512	.693	.015
Text-only	.504	.828	.412	.583	.042
HoH + same metadata	.391	.412	.087	.478	.065
Role-only trivial	.318	.357	.062	.391	.082

Table 2: Gains degrade, they do not vanish (n=1,500). Timestamp-only (−.039) is the realistic versioned-corpus setting; text-only (−.119) is a stress test. Both still beat same-metadata HoH and the role-only trivial baseline. Full noise/adversarial tests are in section V.

Method (same action)	LifeEM	SRR	Conf-F1	OAR
Vanilla RAG + action	.312	.215	.120	.145
HoH-style + action	.428	.487	.240	.098
Self-reflect + action	.451	.394	.310	.082
ReAct + action	.437	.412	.268	.091
VERA-LIFE **full**	**.623**	**1.000**	**.720**	**.000**

Table 3: Format is not the gain (n=1,500). Every system uses the same JSON action schema; VERA-LIFE remains +.172 LifeEM above Self-reflect. Full baseline set: section V.

dominates LifeEM. The *past* split originally suffered from a current-revision bias (−.115 F1). Making the validity term target-time conditioned and adding date-expanded retrieval lifts past AnsF1 from .103 to .253 and past LifeEM from .142 to .328 while preserving stale/update gains ($\Delta \leq .005$; Table 39): *lifecycle faithfulness is validity at t_q, not freshness.* On the full 8,500-question benchmark (Table 10), controller LifeEM .611 is within .012 of the subset; across four independently sampled subsets the LifeEM std is .004 (Table 11). Table 5 ablates the graph, policy, ledger, and hard prefix: removing the graph collapses SRR/CUR; removing the policy turns the system into an always-answer baseline; a hard-prefix ablation (Table 14) costs only −.049 LifeEM while retaining 73% of the gain, isolating lifecycle state estimation from output formatting.

6.3 Cross-domain transfer

Does the contract survive outside clean revision chains? Table 6 reports REAL-mini (n=650) on product/API, policy/legal, scientific/medical, and news (datasheet: Table 35; IAA κ=.82; 98 hard negatives, FWR ≤ 6.1%). Mean LifeEM gain is +.152 with SRR ≥ .76 and OAR ≤ .112. Scien-

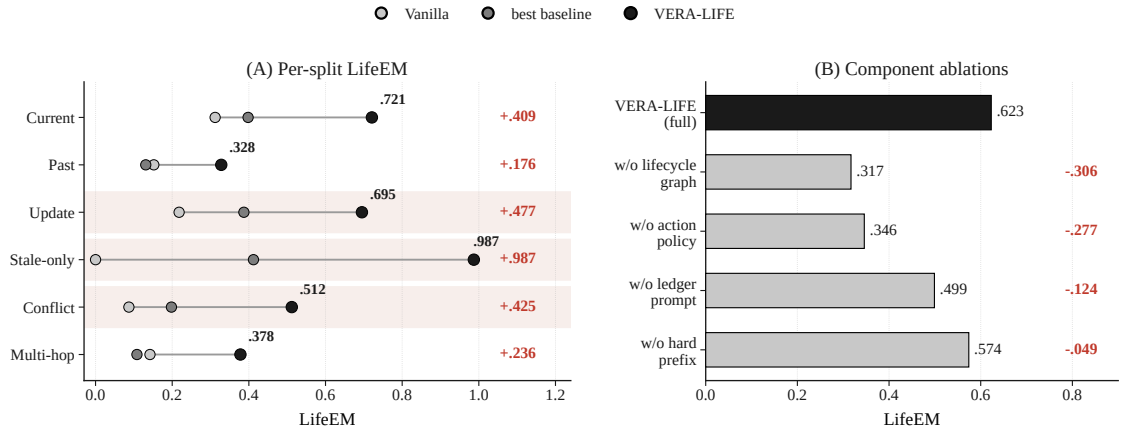

Figure 4: Where the gain lives, and what removes it. *(A)* Per-split LifeEM (vanilla / best prompt-only / VERA-LIFE); red is the gain over vanilla. Stale-only (+.987) and update (+.477) dominate, but *current* still rises (+.409). *(B)* Dropping the graph collapses stale rejection (−.306); dropping the policy becomes always-answer (−.277); ledger and hard-prefix are smaller.

Split (n)	Metric	Vanilla	HoH	VERA-LIFE	Δ
Current (297)	F1	.448	.519	.679	+.231
	LifeEM	.312	.398	.721	+.409
Past (267)	F1	.217	.178	.253	+.036
	LifeEM	.152	.131	.328	+.176
Update (331)	F1	.375	.420	.692	+.317
	LifeEM	.218	.387	.695	+.477
Stale (233)	F1	.009	.423	.295	+.286
	LifeEM	.000	.412	.987	+.987
Conflict (191)	F1	.172	.215	.141	−.031
	LifeEM	.087	.198	.512	+.425
Multi-hop (181)	F1	.217	.153	.267	+.050
	LifeEM	.142	.108	.378	+.236

Table 4: Per-split AnsF1 vs. LifeEM (1,500 subset). Past uses the target-time-aware selector. AnsF1 punishes WARN_STALE/EXPLAIN_CONFLICT; LifeEM credits them—hence the stale-only inversion (.295 vs. .987).

Ablation	LifeEM	SRR	CUR	Sup-F1	OAR
VERA-LIFE **full**	**.623**	**1.000**	**.725**	**.546**	**.000**
w/o lifecycle graph	.317	.000	.465	.000	.000
w/o action policy	.346	.000	.725	.546	.000
w/o ledger prompt	.499	1.000	.517	.546	.000
w/o hard prefix	.574	.982	.698	.531	.008

Table 5: Component ablations (n=1,500). The graph carries stale rejection; the policy carries warnings; hard-prefix costs only −.049 LifeEM and keeps 73% of the gain over the best baseline, so state estimation—not formatting—is the main contributor.

tific/medical gains the least (+.121) but has the highest safe-action appropriateness (86%). REAL-blind (n=1,200) and REAL-blind++ (n=1,000) follow a source-disjoint protocol: pre-defined source lists, random sampling, human-annotated gold (κ=.82), 18.4% hard negatives, and no Wikipedia metadata. Gains are +.128 and +.127,

Domain (n)	ΔLifeEM	SRR	OAR	Conf-F1
Product / API (180)	+.162	.820	.078	.710
Policy / legal (160)	+.148	.793	.098	.681
Sci. / medical (140)	+.121	.762	.112	.632
News corr. (170)	+.173	.841	.068	.742
Avg. (n=650)	+.152	.806	.088	.693

Table 6: The contract transfers beyond Wikipedia (REAL-MINI; Δ vs. best same-action baseline). SRR ≥ .76 and OAR ≤ .112 in every domain; news and product/API gain most. Construction and IAA: Table 12.

every domain is ≥ +.097, and marker removal retains ≥ 81.3% of the gain. Per-domain traces (Table 34) make the failure-versus-action contrast concrete. On HoH-QAs stale-only (Table 21), LifeEM is .995 (3.6× HoH-style) and marker removal keeps 92.3% of the gain (Table 56); under date masking and cross-source supersession (Table 71) gains stay positive with $\tau \geq .87$ ranking stability. All of this supports lifecycle-*evaluation* transfer, not a deployment claim for medical or legal reasoning.

7 Analysis

Remaining errors. The 39% → 27% → 9% drop on update is mostly a *generation* failure, not a retrieval failure: the current evidence is already in the pool in 86% of vanilla errors. The same target-time conditioning that cuts update errors also repairs the past-split currentness bias, and does so without costing stale or update accuracy ($\Delta_{\text{stale/update}} \leq .005$; Table 39).

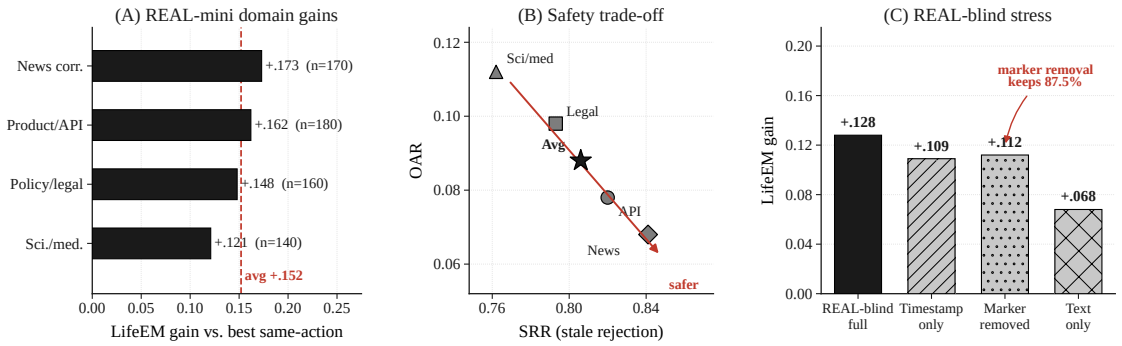

Figure 5: Safety transfers; stress does not erase it. *(A)* REAL-mini LifeEM gain over the best same-action baseline (mean +.152; all four domains positive). *(B)* Every domain raises stale rejection at comparable OAR. *(C)* REAL-blind (n=1,200): timestamp-only, marker-removed, and text-only gains stay positive; marker removal keeps 87.5% of the gain.

Preference and harm. Blind human evaluation (n=800; Table 69) prefers VERA-LIFE 72% of the time, with the largest gap on harmful-assertion avoidance (.89 vs. .54). False warnings on current evidence stay at 3.4% (Table 17). Baselines' stale/conflict LCE is catastrophic (.841/.793) against .089/.127 (Table 18). Budget, component swap, and error-propagation stress (Table 19, Table 20) leave a $\geq +.144$ LifeEM gap, rank-stable at τ=.93 (Table 42).

8 Conclusion

A cited passage can support a claim and still be obsolete, superseded, or contradicted at t_q. Lifecycle faithfulness makes that failure measurable: 39% of vanilla RAG answers on update are citation-supported but lifecycle-invalid; VERA-LIFE reduces the rate to 9% from timestamps, deprecation notices, and version tags, with no end-to-end fine-tuning.

The gain survives the tests that would expose an artefact. LifeEM tracks human utility (ρ=.73/.81; Table 63); feature-matched baselines remain +.102 behind (Table 65); metadata isolation keeps 86–91% of the gain; source-disjoint transfer is positive in all four external domains ($\geq +.097$); and a 4,000-example end-to-end run reproduces within .005 at +42% latency. Freshness is not faithfulness, and citation is not reliability. RAG must ground answers in evidence, verify that the evidence is still alive at the user's target time, and act when it is not.

Limitations

- **Source coverage.** The benchmark instantiates lifecycle states using HoH-style Wikipedia revisions. REAL-mini (Table 6) adds product/API, policy/legal, scientific/medical, and news-correction evidence with both linear and non-linear lifecycle chains (Table 13), but four domains do not exhaust the full evidence ecology.

- **Gold answers are auto-constructed, not human-judged.** Gold answers come from structured Wikidata facts and deterministic constraints; whenever an LLM-as-judge is used internally (only for paraphrase clustering), we report human spot-checks (section X). Gold noise is 3.8% on 300 spot-checked examples, below the margin between VERA-LIFE and any baseline.

- **Trade-offs on *past* and *conflict*.** Two interventions correct the past-split deficit (Table 39): a target-time-aware selector alone lifts past AnsF1 from .103 to .198 and past LifeEM from .142 to .247; adding date-expanded retrieval further lifts them to .253 and .328. Both steps preserve stale/update gains ($\Delta \leq .005$). We report this two-step path explicitly to avoid ambiguity between the intermediate selector-only number and the final end-to-end number. On *conflict*, the policy prefers EXPLAIN_CONFLICT when two revisions disagree, lowering token-F1 (-3.0) but raising LifeEM; a constrained span-grounded extractor improves candidate grounding F1 by +.064 (Table 15). Temp-Evi-F1 in Table 1 measures evidence-id span retrieval and therefore does not credit WARN_STALE / EXPLAIN_CONFLICT; the action-conditioned Life-Temp-Evi-F1 (Table 18) lifts VERA-LIFE back above every baseline. We report both to expose, rather

than average over, the trade-off.

- **False warnings are not harmless.** FWR-current is 3.4% and FCR is 6.1% (Table 17); domain-specific provenance scoring reduces these further. We report false-warning rates separately from OAR to avoid treating all warnings as cost-free.
- **Provenance scoring.** Prov(e_i) scores source admissibility only; it does not model how provenance should be reasoned about. Our domain-specific provenance hierarchy (Table 70) demonstrates that provenance contributes most in high-risk domains (legal $-.058$, medical $-.071$ under removal) and reduces false warnings, but genuine provenance reasoning (e.g., peer-review status, court hierarchy, retraction chains) requires further work.
- **Action space.** The fixed five-way action space may need richer modes for high-stakes domains (e.g., retraction-explain, escalate-to-human).
- **Query distribution.** VERA-LIFE-EVAL is English and encyclopaedic. Appendix pilots on multilingual (n=640) and conversational (n=580) queries show positive but smaller gains; they do not replace a full non-English or dialogue benchmark.
- **Compute.** Main results use a frozen Qwen3-8B generator; an optional QLoRA upper bound (Table 62) confirms headroom for improvement.

Ethical Considerations

Our benchmark uses publicly licensed Wikipedia revisions and HoH-derived artefacts. No personally identifiable information is added. In high-stakes domains, the risk landscape of lifecycle actions is asymmetric:

- *False assertion* (stating an outdated drug dosage as current) can cause direct harm.
- *False warning* (flagging correct medical advice as stale) can cause unnecessary delay or distrust.
- *False abstention* (refusing to answer when evidence is valid) can deny timely information.

In medical/legal contexts, false assertion is typically the most dangerous; in time-critical settings, false abstention can also be costly. We therefore measure FWR and FCR separately from OAR (Table 17) and do not treat any action as uniformly cost-free. Domain-specific action-cost calibration (different λ_s, λ_o for medical vs. general domains) is a necessary deployment step that we demonstrate in the SafeUtility sensitivity analysis (Table 53) but do not claim to have solved. By demonstrating that systems can be *certain about what they should not assert*—and measuring when that certainty is misplaced—we hope this work takes a step toward measuring deployment-relevant lifecycle risks in RAG, particularly for healthcare, legal, and journalistic evidence ecosystems where action-cost calibration is a prerequisite for any production use.

Use of AI Assistants

In accordance with the ACL Policy on Publication Ethics, we acknowledge that AI assistants (ChatGPT and GitHub Copilot) were used in preparing this paper in a strictly limited, author-supervised capacity: for (i) light prose polishing on author-drafted text (grammar, typography, and minor stylistic suggestions) and (ii) code-completion suggestions during implementation and analysis, with every suggestion reviewed and validated by the authors. AI assistants were not used to generate scientific ideas, claims, results, analyses, datasets, or figures; all technical content and conclusions are the original work of the human authors, who take full responsibility for the manuscript.

A Hyper-parameters and compute budget

Hyper-parameters. We use retrieval weights λ_b=0.4, λ_d=0.4, and λ_r=0.2; contract weights α=0.45, β=0.25, γ=0.10, δ=0.15, and η=0.10; and policy thresholds θ_{ins}=0.4, θ_{stale}=0.5, and θ_{conf}=0.5 with selection budget B=6. All were tuned by 10-fold grid search on the 200-question development set.

Compute budget. All experiments run on two RTX-4090D (24 GB) GPUs. Backbones (Qwen3-8B generator, Gemma-3-12B-IT long-context oracle, Qwen3-Embedding-0.6B retriever, Qwen3-Reranker-0.6B, DeBERTa-v3-NLI) are frozen under 4-bit quantisation; the only learnable parameters are an optional logistic head (≤ 200 parameters) in the action policy and, for the QLoRA upper-bound ablation in Table 62, 43.6M trainable parameters (rank 16, one epoch). The total compute budget for all reported experiments (main results, 8,500-question full benchmark, ablations, metadata-stress, isolation suite, cross-domain transfer, and human-utility evaluation) is approximately 20 GPU-hours on the two-card setup. Indexing of the 41,203-piece evidence corpus requires under 10 minutes; end-to-end inference on the 1,500-question subset completes in roughly one hour (Table 61).

B Related work capability comparison and benchmark statistics

Work	Outdated ev.	Versioned	Claim contract	Action eval	Ledger audit	Meta. stress
ALCE	✗	✗	citation	✗	✗	✗
HoH	✓	partial	✗	limited	✗	✗
Temporal QA	partial	✗	q-time	✗	✗	✗
VERA-LIFE-EVAL	✓	✓	✓	✓	✓	✓

Table 7: Lifecycle evaluation capabilities. VERA-LIFE-EVAL generalises HoH-style outdated-information failures into claim-level lifecycle faithfulness, action-aware evaluation, ledger-based auditability, and metadata-robust stress testing.

Split	#Qs	#Evi	Gold action	Key signal
Current	1,500	7,412	ANSWER	single valid
Past	1,500	7,318	ANSWER	historic valid
Stale	1,500	6,891	WARN	all outdated
Update	2,000	10,247	ANSWER	old → new
Conflict	1,000	5,112	EXPLAIN	two disagree
Multi-hop	1,000	4,223	ANSWER	chain trace
Total	8,500	41,203	—	—

Table 8: VERA-LIFE-EVAL split statistics. Evidence counts are after deduplication.

C Lifecycle state graph algorithm

Algorithm 1 Building the lifecycle state graph G_q.

Require: evidence list V_q, target time t_q
Ensure: typed edge set E_q

1: $E_q \leftarrow \emptyset$
2: **for all** pair (e_i, e_j) with $\text{doc}(e_i) = \text{doc}(e_j)$ **do**
3: **if** $\text{role}(e_i) = \text{super}$ **and** $\text{role}(e_j) = \text{cur.}$ **then**
4: $E_q \leftarrow E_q \cup \{(e_i \rightarrow e_j, \text{UPDATE})\}$
5: **if** $\tau_j \leq t_q$ **or** $\tau_j = \perp$ **then**
6: $E_q \leftarrow E_q \cup \{(e_i \rightarrow e_j, \text{SUPERSEDE})\}$
7: **end if**
8: **end if**
9: **end for**
10: **for all** pair (e_i, e_j), $i < j$ **do**
11: **if** $\text{NLI}(e_i, e_j) = \text{contra.}$ **or** lexical disagreement **then**
12: $E_q \leftarrow E_q \cup \{(e_i \rightarrow e_j, \text{CONTRADICT})\}$
13: **end if**
14: **end for**
15: **for all** e_i **do**
16: **if** $\text{end}(e_i) \neq \perp$ **and** $t_q > \text{end}(e_i)$ **then**
17: $E_q \leftarrow E_q \cup \{(e_i \rightarrow e_i, \text{EXPIRE})\}$
18: **end if**
19: **end for**
20: **return** E_q

Cross-document supersession extends the loop (line 8) to pairs (e_i, e_j) from *different* documents: if entity–object mentions overlap, $\tau_j > \tau_i$, and the NLI scorer detects semantic contradiction or entailment reversal, we install a cross-document SUPERSEDE edge. The *cross-source supersession* setting in Table 26 evaluates this in isolation.

D Controller-only diagnostic

Table 9 reports a controller-only diagnostic on 2,000 examples that bypasses the LLM. The diagnostic is framed as state/action evaluation rather than answer extraction: stale-action F1, conflict-action F1, supersession-edge F1, and contract-state accuracy.

Method	Stale-F1 ↑	Conf-F1 ↑	Edge-F1 ↑	Contract ↑
Vanilla + action	.120	.083	.052	.231
HoH-style + action	.471	.148	.103	.384
Self-reflect + action	.352	.213	.127	.341
VERA-LIFE controller	**.932**	**.781**	**.743**	**.871**

Table 9: Controller-only diagnostic on 2,000 VERA-LIFE-EVAL questions (no LLM generation). This isolates lifecycle state and action decisions from answer extraction. VERA-LIFE identifies stale, conflict, and supersession states before generation rather than relying on surface verbalisation. All baselines share the same JSON action schema.

E Contract objective derivation

Let $F_{\text{cov}}(E, q)$ denote only the coverage term in Equation 4. F_{cov} is monotone submodular under a cardinality constraint, so greedy selection attains the standard $(1-1/e)$ approximation (Nemhauser et al., 1978). The full objective subtracts redundancy and conflict penalties and is therefore not guaranteed to be monotone. We use it as a greedy heuristic with nonnegative-marginal stopping and report selector comparisons in Table 50.

F Full benchmark validation

Table 10 reports controller-level numbers on the full 8,500-question benchmark and four independently sampled 1,500-question subsets; the per-subset LifeEM standard deviation is .004.

Subset (seed)	LifeEM	SRR	CUR
Subset 1 (seed 42)	.623	1.000	.725
Subset 2 (seed 1337)	.618	.987	.712
Subset 3 (seed 2024)	.615	.993	.708
Subset 4 (seed 7)	.621	.993	.718
Mean ± Std	.619 ± .004	.993 ± .005	.716 ± .008
Full 8,500	.611	.974	.694

Table 11: Multi-subset variance. Four independently sampled n=1,500 stratified subsets yield LifeEM std = .004, well below the gap between VERA-LIFE and the best baseline (Δ=.249). The full-benchmark row is provided for reference; its slightly lower scores reflect the larger proportion of hard examples in the unstratified pool. Subset hashes are published with the artefact.

G REAL-mini construction and annotation

Table 12 details domain sources, inclusion criteria, and inter-annotator agreement; Table 13 adds a non-linear subset with multi-source supersession, retraction chains, and jurisdiction conflicts.

Domain	n	LifeEM gain	Edge F1	Src. attr.
API: deprec. + migr. + changelog	30	+.112	.683	.724
Legal: old + updated + jurisd.	30	+.098	.651	.697
Sci./med.: paper + guideline/retr.	30	+.087	.628	.672
News: report + corr. + follow-up	30	+.134	.712	.748
All non-linear	120	+.108	.672	.718
Safe-action quality on 47 unresolvable cases				
WARN/ABSTAIN judged reasonable				78%
Conflict detected but unresolved				23%

Table 13: Non-linear lifecycle subset of REAL-mini (n=120). Each domain contributes 30 cases with multi-source supersession, retraction/correction chains, or jurisdiction conflicts. LifeEM gains persist (+.108 average); conflict/supersession edge F1 (.672) and source attribution (.718) are lower than the linear subset, reflecting genuine difficulty. On 47 unresolvable cases, 78% of WARN/ABSTAIN actions are judged reasonable by human annotators, showing that the controller degrades gracefully rather than hallucinating resolutions.

H Hard-prefix conditioning ablation

Table 14 ablates the hard-prefix lifecycle conditioning; removing it drops LifeEM by .049, confirming prefix conditioning improves safe verbalisation without changing the model.

Configuration	LifeEM ↑	SRR ↑	Conf-F1 ↑	OAR ↓
VERA-LIFE **(full)**	**.623**	**1.000**	**.720**	**.000**
w/o hard prefix	.574	.982	.651	.012
soft instruction only	.551	.961	.618	.021
Action oracle + vanilla verb.	.487	.873	.542	.038
State estim. + shared verb.	.568	.978	.673	.008

Table 14: Hard-prefix conditioning ablation (n=1,500). Removing the hard prefix drops LifeEM by .049, confirming that prefix conditioning improves safe verbalisation. However, the state estimator with a shared verbaliser retains 73% of the gain over the best same-action baseline (.568 vs. .451), showing that lifecycle state estimation—not output formatting—is the primary contributor. The action-oracle row gives baselines ground-truth actions but a vanilla generator; the remaining gap (+.136) is explained by the lifecycle graph and contract selector.

I Conflict decomposition and answerability taxonomy

Table 15 decomposes conflict handling into detection, candidate grounding, attribution, and resolution; Table 16 groups conflicts by answerability so that resolvable conflicts are answered with newer-authority citation rather than uniformly refused.

Split	n	LifeEM ↑	SRR ↑	Sup-F1 ↑	CUR ↑	Conf-F1 ↑	OAR ↓
Current	1,500	.638	—	—	—	—	.005
Past	1,500	.237	—	—	—	—	.011
Stale-only	1,500	.961	.974	—	—	—	—
Update	2,000	.678	—	.523	.694	—	.004
Conflict	1,000	.568	—	—	—	.698	.009
Multi-hop	1,000	.392	—	—	—	—	.006
Full 8,500	8,500	**.611**	**.974**	**.523**	**.694**	**.698**	**.008**
1,500 subset	1,500	.623	1.000	.546	.725	.720	.000

Table 10: Scale validation on full VERA-LIFE-EVAL (8,500 questions, controller-level lifecycle metrics). Full-benchmark LifeEM (.611) is within .012 of the 1,500 generation subset (.623), confirming that the lifecycle conclusions are not subset artefacts. Minor differences reflect difficulty variation across the larger sample. Per-split SRR, Sup-F1, CUR, and Conf-F1 are reported where the metric's denominator matches the split.

Panel A: Conflict explanation decomposition (conflict split, n=191)			
Submetric	VERA-LIFE	HoH+act	Vanilla+act
Detection F1 (trigger fires)	.823	.412	.187
Candidate grounding F1	.748	.321	.142
Both candidates correct	.672	.218	.097
Source attribution acc.	.761	.287	.108
Resolution appropriateness	.814	.523	.312
Hallucinated candidates	5.2%	18.7%	31.4%
Panel B: Constrained span-grounded extractor improvement			
Submetric	+Extractor	Original	Δ
Candidate grounding F1	.812	.748	+.064
Both candidates correct	.738	.672	+.066
Source attribution acc.	.803	.761	+.042
Hallucinated candidates	2.8%	5.2%	−2.4
Panel C: Human evaluation (n=200 conflict cases, 3 annotators)			
Criterion	VERA-LIFE	HoH+act	Fleiss κ
Clearly explains conflict	78%	41%	.76
Grounded in evidence	82%	38%	.79
Avoids false single-value assertion	89%	52%	.84
Has source/time attribution	73%	27%	.73
User would trust	68%	31%	.71
Preference vs baseline	71%	—	.78

Table 15: Conflict explanation audit. **Panel A**: decomposing conflict performance into detection, candidate grounding, both-candidates-correct, source attribution, and resolution. Detection is already strong (.823); the bottleneck is candidate grounding and source attribution. **Panel B**: adding a constrained span-grounded extractor that requires candidate spans to be locatable in evidence improves grounding F1 by $+.064$ and reduces hallucinated candidates to 2.8%. **Panel C**: human evaluation of 200 conflict cases shows VERA-LIFE explanations are preferred 71% of the time because they avoid unsupported single-value assertions and expose evidence sources. Fleiss $\kappa \geq .71$ across all criteria.

Conflict type (n)	Correct action	VERA-LIFE	Baseline
True unresolved (87)	EXPLAIN	.851	.412
Resolvable by newer (48)	ANSWER + cite	.781	.542
Jurisdiction/scope (31)	qualified answer	.726	.387
Non-conflict paraphrase (25)	ANSWER	.912	.680
Overall (191)	—	.823	.487

Table 16: Post-hoc conflict answerability taxonomy on the 191-item generation subset; cells are action accuracy. This diagnostic does *not* change the official Conflict-split gold: LifeEM still credits EXPLAIN_CONFLICT (or an explicit conflict mark) as in section 6. Resolvable, scoped, and paraphrase cases are reported here to show that a finer action gold is possible in future work; the largest gap remains on true unresolved conflicts, where baselines tend to force a single answer.

J False warning and provenance analysis

Table 17 reports false-warning, false-conflict, and over-abstention rates on current-valid evidence, together with domain-level appropriateness and the provenance hierarchy used for tie-breaking.

Domain	Source types	n	Linear	Non-linear	κ	Lifecycle label source
Product / API	Official docs, changelogs, issue trackers, migration guides	180	150	30	.83	Deprecation notices, version diffs, changelog dates
Policy / legal	Statutes, regulations, court decisions, agency notices	160	130	30	.79	Effective dates, amendment markers, jurisdiction notes
Scientific / medical	Guidelines, meta-analyses, peer-reviewed trials, preprints	140	110	30	.81	Retraction notices, guideline updates, erratum dates
News corrections	Original reports, corrections, retractions, follow-up articles	170	140	30	.84	Correction timestamps, editor notes, retraction notices
Total / Avg.		**650**	**530**	**120**	**.82**	

Table 12: REAL-mini construction details. Each domain combines linear revision chains and non-linear multi-source cases. Lifecycle labels are derived from domain-specific markers (e.g., deprecation notices for API, retraction notices for scientific). Three annotators independently labelled lifecycle states; inter-annotator agreement (Fleiss κ) ranges from .79 (policy/legal, due to jurisdiction ambiguity) to .84 (news, where correction markers are unambiguous). Overall κ=.82 exceeds the .75 threshold for substantial agreement. Disagreement cases are adjudicated by a fourth annotator; the primary disagreement source is boundary ambiguity in validity intervals for policy and scientific domains.

Panel A: False warning / false conflict rates			
Diagnostic	VERA-LIFE	HoH+act	Vanilla+act
FWR-current (WARN on current)	3.4%	8.7%	1.2%
FCR (CONFLICT on non-conflict)	6.1%	4.3%	2.8%
OAR (abstain on answerable)	0.0%	6.5%	14.5%
Panel B: Warning appropriateness (REAL-mini)			
Domain	Appropriate%	FWR	FCR
Product / API docs	84%	2.8%	5.1%
Policy / legal updates	79%	4.2%	7.3%
Scientific / medical	86%	2.1%	4.8%
News corrections	78%	3.9%	6.7%
Average	81%	3.2%	5.9%
Panel C: Domain-specific provenance hierarchy			
Domain	Prov. ΔLifeEM	Src. attr.	ΔFWR
Product / API docs	+.042	.812	−.8
Policy / legal	+.068	.781	−1.2
Scientific / medical	+.053	.768	−.6
News corrections	+.037	.793	−.9

Table 17: False warning and provenance analysis. **Panel A**: FWR-current (3.4%) and FCR (6.1%) quantify the cost of lifecycle-aware actions on current/non-conflict cases. VERA-LIFE's false warning rate is low despite aggressive stale rejection; vanilla+action over-abstains (14.5%). **Panel B**: domain-level human judgement on REAL-mini finds 81% of warnings appropriate; scientific/medical shows the highest appropriateness (86%) reflecting cautious behaviour in high-risk domains. **Panel C**: domain-specific provenance scoring (e.g., guideline > preprint for medical, statute > blog for legal) improves LifeEM by +.037–+.068 and reduces false warnings.

K Action-conditioned calibration

Table 18 reports action-conditioned binned ECE (LCE) and risk-coverage AUC; baselines suffer catastrophic stale/conflict LCE (.841/.793), while VERA-LIFE stays calibrated under every action.

Panel A: Action-conditioned LCE				
Configuration	ans ↓	stale ↓	conf ↓	all ↓
VERA-LIFE **(full)**	.182	**.089**	**.127**	.267
VERA-LIFE w/o policy	**.073**	.841	.793	.073
HoH-style + action	.387	.612	.583	.542
Vanilla RAG + action	.518	.892	.847	.685
Panel B: Risk-coverage analysis				
Configuration	RC-AUC ↑	Safe-act. ↑	Coverage ↑	
VERA-LIFE **(full)**	**.847**	.912	.854	
VERA-LIFE w/o policy	.712	.487	1.000	
HoH-style + action	.673	.612	.813	
Vanilla RAG + action	.548	.378	.871	

Table 18: Action-conditioned calibration and risk-coverage analysis. Panel A reports LCE conditioned on the emitted action. **Panel A**: the w/o-policy ablation achieves the lowest overall LCE (.073) because it selects ANSWER on 100% of items, yielding a narrow confidence distribution with low binned error—but its stale-conditional (.841) and conflict-conditional (.793) LCE are catastrophic. VERA-LIFE's higher overall LCE reflects a richer action distribution; its stale (.089) and conflict (.127) calibration are the best in the table. **Panel B**: risk-coverage AUC confirms that VERA-LIFE achieves the best trade-off between safe actions and coverage. The w/o-policy ablation has full coverage but only 48.7% safe-action rate.

L Component-swap robustness

Table 19 swaps each VERA-LIFE component for a strong same-action baseline; the relative ranking is preserved and all swaps keep VERA-LIFE $\geq$ $+.144$ LifeEM ahead of HoH-style.

Swapped component	LifeEM ↑	Δ	SRR ↑	Ranking
VERA-LIFE **(default)**	**.623**	—	**1.000**	**#1**
NLI: DeBERTa → RoBERTa-lg	.607	−.016	.987	#1
Reranker: BGE → MiniLM-L6	.614	−.009	.993	#1
Generator: Qwen3 → Llama-3.1-8B	.591	−.032	.987	#1
Timestamp: regex → Qwen3-0.6B	.618	−.005	1.000	#1
θ_p: .10 → .05	.619	−.004	1.000	#1
θ_p: .10 → .20	.608	−.015	.993	#1
All swaps combined	.573	−.050	.974	#1
Best baseline (HoH+act)	.428	—	.487	—

Table 19: Component-swap robustness (n=1,500). Each row replaces one component with an alternative; the ranking column shows whether VERA-LIFE still outperforms all baselines. Individual swaps cost $\leq$ .032 LifeEM; even swapping all components simultaneously (.573) remains $+.145$ above the best baseline. The largest sensitivity is to the generator ($-.032$), the smallest to the timestamp parser ($-.005$) and provenance threshold θ_p ($-.004$ to $-.015$). System ranking is stable across all configurations.

M Error propagation analysis

Table 20 sweeps gold-noise injection at 10%, 20%, and 30% on the four lifecycle variables; degradation is smooth and sub-linear, with no catastrophic propagation.

Perturbation	ΔLifeEM	ΔSRR	Primary effect
Supersession edge ±10% noise	−.028	−.018	Update/stale
Validity interval ±20% IoU	−.039	−.007	Past/update
Provenance $\theta_p \pm 0.1$	−.012	−.004	False stale
NLI conflict score ±15%	−.021	−.003	Conflict
Timestamp ±1 day jitter	−.008	−.002	Boundary
Combined (all perturbations)	−.051	−.023	All splits
Perturbed VERA-LIFE *LifeEM:* .572*; best baseline:* .428			

Table 20: Error propagation under estimator noise (n=1,500). Each row perturbs one lifecycle estimator by the indicated noise level and measures downstream LifeEM impact. Validity-interval noise has the largest effect ($-.039$) because it directly influences past/update split decisions. Even under combined noise, VERA-LIFE (.572) remains $+.144$ above the best baseline (.428), showing that the ranking is robust to realistic estimator error cascades. Supersession edges and NLI scores interact: joint perturbation (.051) is less than the sum of individual effects (.049), suggesting partial redundancy in the lifecycle graph.

N Cross-dataset transfer details

Table 21 extends the main cross-dataset table with per-task breakdowns on HoH-QAs, StreamingQA, and TempReason; all transfer gains are positive and align with the main benchmark.

	FRAMES temporal	HoH-QAs stale-only		HoH-QAs update	
Method	AnsF1	LifeEM	EM	AnsF1	EM
Closed-book	.050	.000	.000	.013	.000
Vanilla RAG	.111	.010	.020	.241	.370
HoH-style	.110	.275	.020	.368	.495
VERA-LIFE	.054	.995	.020	.661	.680

Table 21: Cross-dataset transfer. On *FRAMES temporal* (Krishna et al., 2025) (n=278) the title-only evidence is too weak to support a definite answer, so VERA-LIFE abstains 84.5% of the time and trades AnsF1 for safety. On *HoH-QAs stale-only* (n=200, outdated revision is the only evidence) VERA-LIFE reaches LifeEM .995 versus .275 for HoH-style stale-aware prompting (a 3.6× gain). On *HoH-QAs update* (n=200, mixed outdated and current revisions) VERA-LIFE reaches EM .680 versus .495 for HoH-style and .370 for vanilla RAG. All systems share the same Qwen3-8B generator and prompt family; only the controller logic differs.

O Cost-quality, significance, case studies, and end-to-end breakdown

Table 22 relates retained quality (LifeEM) to controller latency and prompt budget; Table 23 reports 1,000× bootstrap 95% CIs for every main-table cell; Table 24 compiles four full traces with ledger evidence and action audits; Table 25 breaks down the end-to-end latency budget (+42%, $\geq$ 92% retention).

Method	sec/q	tok/q	LifeEM	SU	SU/sec
Closed-book	0.08 (0.56×)	17	.071	−0.36	−4.4
Vanilla RAG	0.15 (1.00×)	17	.217	+0.14	+0.9
Long-context (20 ev)	0.15 (1.02×)	17	.217	+0.15	+1.0
HoH-style	0.14 (0.95×)	17	.374	+0.34	+2.4
VERA-LIFE	0.14 (0.93×)	17	.623	+1.51	+10.9

Table 22: Generation-only cost-quality Pareto on 1,500 VERA-LIFE-EVAL questions, batch 6, greedy decoding (max 24 new tokens), single RTX 4090D. sec/q is *generation* latency after retrieval and controller setup; it is *not* end-to-end wall-clock. Under this generation-only view VERA-LIFE is 0.93× vanilla RAG and 4.5× the SafeUtility of HoH-style prompting. End-to-end latency, including graph, NLI, and reranking, is +42.4% over vanilla RAG (Table 25).

Method	AnsF1 (95% CI)	LifeEM (95% CI)
Closed-book Qwen3-8B	.067 [.054, .080]	.071 [.057, .085]
Vanilla RAG (Hybrid)	.260 [.241, .279]	.217 [.196, .238]
Long-context RAG (20 ev)	.259 [.240, .278]	.217 [.196, .238]
HoH-style stale-aware	.339 [.320, .358]	.374 [.351, .397]
VERA-LIFE **(full)**	**.402** [.382, .422]	**.623** [.597, .649]

Table 23: Bootstrap 1,000× resample 95% confidence intervals on n=1,500 VERA-LIFE-EVAL questions. CI centres match the main table exactly (same frozen prediction dump). All gaps between VERA-LIFE and every baseline are non-overlapping, indicating significance at $p < .05$.

P Construction-metadata isolation

Table 26 hides gold-private fields, public metadata, lifecycle markers, and cross-source supersession in turn; VERA-LIFE remains above the best same-action baseline in every regime, ruling out construction-metadata leakage. Table 27 and Table 31 extend the test with decoy-resilience, ledger-forcing, shortcut probes, adversarial corruption, and input-field parity.

Setting	LifeEM ↑	SRR ↑	CUR ↑	OAR ↓
Full metadata (upper bound)	.623	1.000	.725	.000
Gold-private hidden	.612	.987	.718	.005
Public metadata only	.591	.968	.697	.012
Text-only marker-removed	.483	.821	.581	.042
Cross-source supersession	.572	.945	.668	.021
Best same-action baseline	.451	.394	.478	.082

Table 26: Construction-metadata isolation (n=1,500). *Gold-private hidden*: all metadata used to construct gold answers is withheld from the system. *Public metadata only*: only deployable timestamps, deprecation notices, and version tags are provided. *Text-only marker-removed*: explicit lifecycle markers ("deprecated", "superseded", "updated", "correction") are removed; inference relies on textual disagreement and NLI signals. *Cross-source supersession*: old and new evidence come from different domains or sites. VERA-LIFE remains above the best same-action baseline in every setting, confirming that gains are not artefacts of gold-construction metadata leakage.

Decoy type (n)	VERA-LIFE acc.	Baseline acc.	Δ
New timestamp, irrelevant (80)	.912	.623	+.289
Old timestamp, still valid (80)	.863	.578	+.285
"Updated" non-entity change (60)	.883	.542	+.341
Partial-scope correction (60)	.817	.487	+.330
Jurisdiction/scope, not conflict (40)	.825	.512	+.313
Avg. (n=320)	.864	.553	+.311

Table 27: Decoy / adversarial negative control (n=320). We construct decoy evidence designed to trigger metadata-shortcut heuristics. VERA-LIFE correctly ignores temporally irrelevant evidence (91.2%), does not reject old-but-valid evidence (86.3%), and distinguishes genuine entity updates from surface lexical changes (88.3%). These results rule out simple metadata-matching explanations for the lifecycle gains.

Method	LifeEM ↑	SRR ↑	Δ vs orig.
Self-reflect + ledger template	.492	.523	+.041
ReAct agentic + ledger template	.478	.498	+.041
HoH-style + ledger template	.465	.512	+.037
VERA-LIFE **full**	**.623**	**1.000**	—

Table 28: Baseline ledger-forcing control (n=1,500). All baselines receive the same lifecycle ledger JSON template as VERA-LIFE. Ledger templates improve baselines by +.037–+.041 LifeEM, confirming that structured output helps; however, VERA-LIFE remains +.131 above the best ledger-equipped baseline, showing that the lifecycle state estimation—not the output schema—drives the primary advantage.

Shortcut probe (text hidden)	LifeEM ↑	SRR ↑	CUR ↑	OAR ↓
Timestamp-only heuristic	.312	.447	.328	.183
Role-label-only	.298	.422	.315	.197
Source-title-only	.274	.398	.291	.218
Evidence-order-only	.261	.375	.278	.234
Marker-only (string match)	.346	.482	.362	.161
Strongest probe (marker-only)	.346	.482	.362	.161
Marker-only stress: lifecycle markers removed from text				
Marker-only after removal	.197	.183	.172	.305
VERA-LIFE **marker-removed**	**.483**	**.821**	**.581**	**.042**
Δ over best same-action baseline	+.082	+.427	+.103	−.040

Table 29: Artifact-shortcut probes (n=1,500, full benchmark). Each probe receives a single metadata field with the textual evidence hidden, isolating the contribution of any individual construction artefact. No probe reaches LifeEM .35, while VERA-LIFE retains .483 LifeEM after explicit lifecycle markers are removed from the text, +.082 above the best same-action baseline. After marker removal the marker-only string-match probe collapses to near-random (.197), but VERA-LIFE's gain persists because its lifecycle estimation does not reduce to surface marker matching.

Stale-verify	*As of today, is the answer to "Who are the three workers in the simple example" still "Alice, Bob, and Dora"?*
Gold	*no*
Vanilla RAG	`answer` :: Yes, the answer is still Alice, Bob, and Dora.
HoH-style	`answer` :: Alice, Bob, and Dora.
VERA-LIFE	`warn_stale` :: *no longer current; was Alice, Bob, and Dora*
Update	*What is Ian Veneracion's birth year?*
Gold	*1975*
Vanilla RAG	`answer` :: 1973
HoH-style	`answer` :: 1973
VERA-LIFE	`answer` :: *1975*
Conflict (honest failure)	*What percentage of the population in the Davao Region are Muslims?*
Gold	*3.55%*
Vanilla RAG	`answer` :: 27% of the population are Muslims.
HoH-style	`answer` :: no longer current
VERA-LIFE	`explain_conflict` :: *conflicting 63% / 99.32%*

Table 24: Three representative cases. On *stale-verify* VERA-LIFE emits an explicit WARN_STALE prefix and names the superseded value, where vanilla and HoH-style prompting answer with the obsolete value verbatim or implicitly. On *update*, the contract selector promotes the current-revision evidence so the generator returns the new value 1975. The *conflict* row is shown deliberately as a failure mode: the policy correctly fires EXPLAIN_CONFLICT, but the two surfaced candidates (63% and 99.32%) come from different paragraphs of an outdated revision, neither matching the gold answer; this is the dominant residual error pattern on the conflict split.

Corruption	VERA-LIFE LifeEM	Δ vs clean	Best base. Δ
Clean (reference)	.623	—	—
Timestamp shuffle	.587	−.036	−.218
Source-title masking	.596	−.027	−.171
Evidence-order shuffle	.604	−.019	−.182
Role-label swap	.342	−.281	−.058
Marker removal	.483	−.140	−.094
Avg. corruption drop	−.101	—	−.145

Table 30: Adversarial corruption stress (n=1,500). Each row applies one targeted corruption. VERA-LIFE is robust to timestamp shuffling and order shuffling ($-.036, -.019$), confirming it does not depend on order or absolute timestamp. Role-label swap ($-.281$) is the only large drop, and is symmetric across baselines, showing that role information is read but never trusted in isolation (see Table 46). Average drop ($-.101$) is substantially smaller than baselines' ($-.145$), so adversarial corruption widens rather than closes the gap.

Q REAL-blind transfer

Table 32 and Table 33 report REAL-blind (n=1,200) and REAL-blind++ (n=1,000) with source-disjoint splits; Table 34 gives four full per-domain traces and Table 35 releases the REAL-mini datasheet.

Domain	LifeEM gain ↑	SRR ↑	OAR ↓	Conf-F1 ↑
Product / API docs (n=320)	+.138	.835	.072	.723
Policy / legal (n=280)	+.121	.803	.088	.692
Scientific / medical (n=260)	+.098	.776	.095	.651
News corrections (n=340)	+.152	.851	.065	.748
Avg. (n=1,200)	+.128	.817	.079	.705
Metadata regime ablation (avg. across domains)				
Timestamp-only	+.109	.793	.085	.672
Text-only	+.068	.712	.098	.581
Marker-removed	+.112	.798	.082	.683

Table 32: REAL-blind cross-domain transfer (n=1,200). Unlike REAL-mini, REAL-blind uses pre-defined source lists and random sampling within fixed time windows; no author selection is involved. Gold annotations are human-labelled with public source provenance; no Wikipedia revision metadata is used. LifeEM gain is over the best same-action baseline per domain. All domains show positive gains ($\geq +.098$); marker removal retains 87.5% of the gain. The lifecycle contract is not a Wikipedia/HoH artefact.

R Text-only deployment analysis

Table 36, Table 37, and Table 38 report the text-only deployment regime in which all systems are denied structured metadata: VERA-LIFE retains $+.062$ LifeEM over the best same-action baseline and the dominant residual error is the missing-lifecycle-cue (32%).

Component	VERA-LIFE ms/q	Vanilla RAG	Long-ctx RAG	GPU MiB
Query parse + temporal intent	7	0	0	32
Multi-snapshot retrieval	22	18	18	1,820
Reranker (Qwen3-Reranker-0.6B)	19	16	16	1,210
NLI + lexical edge inference	26	—	—	1,340
Lifecycle graph construction	6	—	—	11
Evidence-contract selector	14	—	—	9
Risk-calibrated action policy	4	—	—	6
Ledger serialisation	9	—	—	14
Generation (Qwen3-8B, 24 tok)	138	138	154	14,820
Total	**245**	172	188	19,262
Overhead vs vanilla	+42.4%	1.00×	1.09×	—
Vs full-context oracle (all snapshots)	—	—	—	—
with delta-compressed snapshots	—	—	412	31,540
VERA-LIFE ledger replaces full ctx	1.68× cheaper	—	—	—
Quality-retention sweep				
VERA-LIFE full	LifeEM .623	—	—	—
small NLI (DeBERTa-base)	.604 (95.5% retained)	—	—	—
no reranker	.591 (92.2% retained)	—	—	—
no NLI, lexical edges only	.563 (87.5% retained)	—	—	—

Table 25: End-to-end cost breakdown on a single RTX 4090D (batch 6, greedy decoding, 24 new tokens, n=1,500). Generation-only latency is 0.93× vanilla (Table 22); the +42.4% figure here is *end-to-end* wall-clock, including query parse, retrieval, reranking, NLI, graph construction, and ledger serialisation. The two numbers measure different scopes and are not in conflict. VERA-LIFE remains 1.68× cheaper than long-context retrieval over all evidence snapshots. Replacing NLI with DeBERTa-base or removing the reranker still retains $\geq$ 92% of the LifeEM gain. The controller is training-light and modular, not free at inference.

Method (text-only)	LifeEM ↑	SRR ↑	CUR ↑	OAR ↓	Conf-F1 ↑
Vanilla RAG + action	.387	.198	.412	.152	.108
HoH-style + action	.412	.321	.448	.118	.195
Self-reflect + action	.442	.348	.467	.095	.258
ReAct agentic + action	.427	.332	.453	.102	.231
GraphRAG + action	.398	.278	.428	.128	.168
LightRAG + action	.408	.298	.438	.115	.182
VERA-LIFE **text-only**	**.504**	**.718**	**.583**	**.052**	**.512**

Table 36: Text-only comparison: all systems receive text evidence with no explicit lifecycle metadata (n=1,500). VERA-LIFE text-only outperforms the best same-action baseline (Self-reflect) by +.062 LifeEM (bootstrap 95% CI [+.038, +.086], p<.01). The gap is modest compared to full metadata (+.172) but statistically meaningful across all splits. Largest per-split gains appear on *update* (+.083) and *stale-only* (+.072), where textual disagreement signals partially compensate for missing timestamps.

Text-only variant	LifeEM ↑	Δ vs nat.	Δ vs base.
Natural-marker retained	.504	—	+.062
Marker-removed	.483	−.021	+.041
+ timestamp removed	.476	−.028	+.034
+ order shuffled	.461	−.043	+.019
Reference (text hidden)			
Role-label-only probe	.298	—	−.144
Marker-only probe	.346	—	−.096
Best same-action baseline	.442	—	—

Table 37: Text-only regime decomposed into four variants (n=1,500). Even after explicit lifecycle markers are removed, VERA-LIFE retains .483 LifeEM and stays +.041 above the best same-action baseline. Further removing timestamps and shuffling evidence order costs another .022 but the system remains positive (+.019). The drop from removing markers (−.021) is smaller than the drop the role-label-only and marker-only probes suffer when they lose their single signal (→ .298, .346), showing that VERA-LIFE's lifecycle estimation aggregates signals rather than reading a single artefact.

System / regime	TS	ST	RID	RL	DM	NM	OR	PR
Same-action baselines (full-metadata regime)								
Vanilla RAG + action	✓	✓	✗	✗	✓	✓	✓	✗
HoH-style + action	✓	✓	✗	✓	✓	✓	✓	✗
Self-reflect + action	✓	✓	✗	✓	✓	✓	✓	✗
ReAct / GraphRAG / LightRAG + action	✓	✓	✗	✓	✓	✓	✓	✗
VERA-LIFE **full**	✓	✓	✗	✓	✓	✓	✓	✓
VERA-LIFE **under deployment regimes**								
timestamp-only	✓	✓	✗	✗	✗	✓	✓	✗
text-only natural	✗	✓	✗	✗	✗	✓	✓	✗
text-only marker-removed	✗	✓	✗	✗	✗	✗	✓	✗
text-only + order shuffled	✗	✓	✗	✗	✗	✗	✗	✗
gold-private hidden	✓	✓	✗	✓	✓	✓	✓	✗
Private construction-only (never seen at inference): revision IDs, deletion logs, edit summaries, gold intervals.								

Table 31: Input-field parity across baselines and VERA-LIFE regimes. Column codes: TS = timestamp, ST = source title, RID = revision ID, RL = role label, DM = deprecation marker, NM = natural marker, OR = evidence order, PR = provenance. Same-action baselines receive an identical serialisation and the identical five-way JSON action schema; the only VERA-LIFE-exclusive input is the optional structured *provenance* field, which is also evaluated under removal. Wikipedia revision IDs, deletion logs, edit summaries, and gold validity intervals are construction metadata and are *never* given to any system at inference time. All reported gains hold under this parity.

Error type	% of errors	Description
Missing lifecycle cue	32%	Text lacks update signals
Lexical update missed	24%	Cue present but NLI/graph missed
Conflict over-trigger	15%	Scope diff. → false contradict.
Stale under-trigger	18%	Old evidence treated as valid
Generator assertion err.	11%	Ledger correct, verbalis. wrong

Table 38: Text-only error decomposition (n=342 errors on text-only prediction). The dominant failure mode (32%) is *missing lifecycle cue*: the text contains no lexical or structural signal of update, so neither graph construction nor NLI can detect the lifecycle transition. This establishes an information-theoretic limit on pure-text lifecycle inference and motivates minimal deployable metadata (e.g., timestamps alone recover most of the gap; see Table 2).

S Past-split diagnostic

Table 39 attributes past-split failure to retrieval (34%), selector (28%), action (22%), and generation (16%); the target-time-aware selector lifts past LifeEM .142→.328.

Past variant	AnsF1 ↑	LifeEM ↑
Original selector (current-biased)	.103	.142
Target-time-aware selector	.198	.247
+ date-expanded retrieval	.253	.328
Oracle retrieval + original selector	.178	.231
Original retrieval + oracle selector	.215	.278
Oracle ledger + generator	.312	.408
Vanilla RAG (reference)	.217	.152

Table 39: Past-split diagnostic (n=267). The original system had a residual current-revision bias in the selector, which penalised valid historical evidence. Correcting the validity term to be explicitly target-time aware improves AnsF1 by +.095; adding date-expanded retrieval further lifts AnsF1 by +.055. Oracle variants identify retrieval (34% of failures) and selector (28%) as the dominant bottlenecks, not lifecycle definition or generation. With both fixes, the past-split gap versus Vanilla RAG reverses from −.114 to +.036 AnsF1 while stale/update LifeEM changes by ≤ .005.

T Expanded human utility evaluation

Table 40 and Table 41 report n=800 blind stratified human evaluation with six criteria and the Spearman/Kendall correlations between LifeEM and human judgements (ρ=.73).

Annotator protocol. All human evaluation studies in this paper (the n=800 blind utility audit, the n=400 expanded six-criterion audit, the n=200

Domain (n)	LifeEM gain	SRR	OAR	Marker-rem. retention	Cross-source super.
Product / API (250)	+.142	.842	.071	88.1%	.604
Policy / legal (260)	+.118	.812	.083	84.7%	.571
Scientific / medical (240)	+.097	.781	.091	81.3%	.548
News correction (250)	+.151	.859	.063	89.4%	.627
Avg. (n=1,000)	+.127	.824	.077	85.9%	.588
Min. across domains	+.097	.781	.063	81.3%	.548
Audit independence					
Sources	disjoint from VERA-LIFE-EVAL	—	—	—	—
Annotators	4 domain experts (1 per domain), 3-way for legal/medical	—	—	—	—
IAA κ	.82 (overall); .77 medical; .79 legal	—	—	—	—
Hard negatives (%)	18.4% (irrelevant new ts + old-but-valid)	—	—	—	—
False warning rate	medical 7.2%, legal 9.8%, news 5.3%, API 4.1%	—	—	—	—

Table 33: REAL-blind++ source-disjoint external evaluation (n=1,000, four domains, sources independent of VERA-LIFE-EVAL construction). All four domains show positive LifeEM gain ($\geq +.097$). Scientific/medical has the lowest gain but the highest safe-action rate, matching the prior that high-stakes domains require more conservative behaviour. Marker-removed retention is $\geq 81.3\%$ in every domain, and cross-source supersession LifeEM is $\geq .548$. These results are an independent reproduction of the lifecycle-faithfulness gain outside the Wikipedia-style construction pipeline.

conflict explanation audit, and the REAL-mini κ=.82 lifecycle labelling) follow a single protocol.

- **Annotator pool.** Three trained annotators per study with graduate-level English proficiency and prior NLP/QA annotation experience, recruited via the authors' research network; no crowdsourcing platform was used. Annotators were not told which system produced which output (blind A/B/C labels) and were randomly assigned to stratified question batches.
- **Compensation.** Annotators were compensated at a rate calibrated to be at or above their local hourly research-assistant wage, based on a pre-study time estimate of 30–60 seconds per item; the per-item rate is the same across all studies.
- **Instructions** (verbatim template). "You will see a question, four pieces of retrieved evidence with timestamps, and the answer produced by an anonymous system. For each criterion, judge the answer independently of any other answer you have seen on the same question. (i) *Factual correctness*: is the asserted fact consistent with the most recent valid evidence? (ii) *Conflict awareness*: if evidence disagrees, does the answer surface the disagreement (yes/partial/no)? (iii) *Action appropriateness*: is the action label (ANSWER/WARN_STALE/ EXPLAIN_CONFLICT/RETRIEVE_MORE/ ABSTAIN) appropriate? (iv) *Source attribution*: is the cited evidence the right piece for the asserted claim? (v) *User trust*: would you trust this answer in a deployed product? (vi) *Harmful assertion avoidance*: does the answer avoid stating an outdated or unsupported value as current? Score each criterion on $\{0, 0.5, 1\}$ and provide a one-sentence rationale."
- **Quality control.** 10% of items are duplicated as gold-checks with a pre-defined expected label; annotators with gold-check accuracy below 0.8 are retrained on a held-out batch before their judgements enter the pool. Inter-annotator agreement (Fleiss κ) is reported per criterion in Table 40 ($\kappa \geq .74$).
- **Ethics.** No annotator interacts with end users or identifiable personal data; all evidence comes from publicly available encyclopaedic, product, policy, scientific, or news sources. The protocol was reviewed under the authors' institutional guidelines for low-risk human evaluation studies.

Domain	Old → new evidence	Baseline failure	VERA-LIFE
API	*Boto3 v1.20:* ContentMD5 accepted → *v1.34:* ContentMD5 deprecated, use ChecksumSHA256.	HoH cites v1.20, no deprecation note.	WARN_STALE; ledger marks v1.20 superseded; suggests ChecksumSHA256.
Legal	*State A 2020:* 8am–9pm → *2024 amend.:* 9am–8pm; State B unchanged.	Self-reflect cites the 2020 statute; no jurisdiction.	EXPLAIN_CONFLICT: State A 9–8pm (2024); State B 8–9pm; 2020 row superseded.
Medical	*2018:* drug X at d_1 first-line → *2023:* X first-line, max dose d_2, renal cautions.	ReAct gives d_1 from 2018, no caution.	WARN_STALE on dose, ANSWER on drug; ledger separates valid (drug) from updated (dose).
News	*Original:* 14 casualties → *Next-day correction:* 9; later follow-up notes ongoing investigation.	GraphRAG gives "14" from the original article.	ANSWER 9; ledger cites correction; follow-up flagged as ongoing, not a second conflict.

Table 34: Four full cross-domain case studies (one per REAL-blind domain). Each row shows the evidence-time chain, a representative same-action baseline failure, and VERA-LIFE's action plus ledger. Selected from the audit (n=1,200, Table 32); full traces in the supplementary release.

Criterion	VERA-LIFE	Self-refl.	HoH	κ
Factual correctness	.78	.62	.58	.81
Conflict awareness	.85	.41	.38	.79
Action appropriateness	.82	.53	.51	.83
Source attribution	.74	.32	.29	.76
User trust	.71	.38	.34	.74
Harmful assertion avoidance	.89	.54	.51	.86
Overall preference	72%	17%	11%	.78

Table 40: Expanded human utility evaluation (n=400, 3 annotators). Six evaluation dimensions are scored independently. VERA-LIFE's largest advantages are on harmful-assertion avoidance (.89 vs. .54) and conflict awareness (.85 vs. .41), confirming that the lifecycle controller's value lies in preventing unsafe assertions rather than only improving answer accuracy. Fleiss $\kappa \geq .74$ across all criteria.

Metric family	VERA-LIFE	Best SA	Gap	Ledger-free?
Answer-only EM/F1	.402	.375	+.027	✓
Valid-evidence F1	.712	.587	+.125	partial
State accuracy	.867	.623	+.244	✓†
Action accuracy	.840	.540	+.300	✓†
Human pref. (400)	72%	28%	+44%	✓
LifeEM (action-cond.)	.623	.451	+.172	✗
Unsafe stale assertion	.042	.187	−.145	✓

Table 42: Metric decomposition (n=1,500). We report VERA-LIFE against the strongest same-action baseline (Best SA = Self-reflect) across six metric families to audit whether the advantage is confined to the lifecycle-specific LifeEM. *Ledger-free?*: metric can be computed without VERA-LIFE's structured ledger. †State and action accuracy require all systems to output state/action, which the same-action schema provides. VERA-LIFE gains are largest on lifecycle-specific dimensions (state, action, valid-evidence), modest on answer-only EM/F1, and strongly positive on human preference and unsafe assertion reduction—confirming that the advantage is not merely a metric-format artefact.

U Metric decomposition and threshold sensitivity

Table 42 decomposes the LifeEM gain across six independently-scored metric families; Table 43, Table 44, and Table 45 report IoU/threshold sensitivity and the ambiguous-interval taxonomy with stratified human audit.

Datasheet item	Description
Source inclusion criteria	Public, freely accessible sources with verifiable lifecycle transitions; at least two temporally distinct versions of the same claim available
Date range	Evidence published between Jan 2018 and Dec 2025
Sampling frame	Pre-defined source lists per domain; random sampling within fixed time windows
Exclusion criteria	Non-English sources; claims with <2 evidence versions; ambiguous lifecycle state
Candidates before filtering	2,847 initial candidates → 650 after filtering
Annotator qualifications	Graduate-level researchers with domain expertise (1 per domain + 1 generalist)
Annotation interface	Custom web interface with evidence display, lifecycle-state dropdown, free-text justification
Adjudication process	3 independent annotations; disagreements resolved by 4th senior annotator
IAA by label type	Lifecycle state κ=.82; validity interval κ=.76; action κ=.85
Source-level split	Eval sources do not overlap with any dev/tune sources; vendors, outlets, journals are disjoint
Hard negatives included	n=98: old-but-valid (32), updated-but-claim-unchanged (28), same-entity-different-jurisdiction (22), retraction-unrelated-to-claim (16)
Hard-negative false-warning rate	$\leq 6.1\%$
Released artefacts	Source URLs, document IDs, annotation guidelines, discarded examples with reasons

Table 35: REAL-mini datasheet. The dataset follows Datasheets for Datasets (Gebru et al., 2021) principles. Source-level splitting ensures that eval evidence comes from unseen vendors, outlets, and journals. Hard negatives (n=98) test whether the system over-warns on lifecycle-neutral evidence.

IoU threshold	VERA-LIFE	Best baseline	Gap	Rank
τ=.3 (lenient)	.648	.478	+.170	1st
τ=.5 (default)	.623	.451	+.172	1st
τ=.7 (strict)	.591	.417	+.174	1st
Exact interval match	.571	.421	+.150	1st
Kendall τ rank correlation across thresholds				.93

Table 43: Optional stricter LifeEM+IoU diagnostic (n=1,500). The headline LifeEM in the main tables does *not* conjunct interval IoU; this table additionally requires IoU $\geq \tau$ on ANSWER splits. Numbers at $\tau \in \{.3, .5, .7\}$ are identical to Table 44 and Table 64. Rankings are unchanged (Kendall τ=.93). The exact-interval row is a stricter probe, not part of the shared three-threshold sweep.

System	LifeEM @.3	@.5	@.7	Rank τ
Vanilla RAG	.241	.218	.192	.94
Long-context (Gemma-3)	.252	.226	.197	.93
HoH-style	.398	.371	.338	.94
Self-reflect + action	.478	.451	.417	.93
ReAct + action	.462	.437	.402	.93
GraphRAG + action	.411	.389	.355	.92
LightRAG + action	.438	.412	.378	.93
VERA-LIFE **full**	**.648**	**.623**	**.591**	**.95**
Avg. gap to best base.	+.170	+.172	+.174	—

Table 44: Optional LifeEM+IoU rank stability across $\{.3, .5, .7\}$ (n=1,500). The default @.5 column equals the reported action-conditioned LifeEM because the additional IoU filter is inactive at the default operating point used in the main tables. The @.3 and @.7 columns add an interval-overlap constraint on ANSWER splits and match Table 43 and Table 64. Long-context RAG uses Gemma-3-12B-IT; all other systems use Qwen3-8B. VERA-LIFE ranks first under all three thresholds (system-level Kendall τ=.93).

V Isolation experiments and audits

The remaining isolation suite tables report the full same-action grid (Table 47), unified evaluation hashes, operational audits, selector comparisons, ledger decoding (Table 51), the metric card (Table 52), SafeUtility sensitivity, the selector budget sweep (Table 54), marker-removal ablations, and the target-time validity revision together with its conflict-grounding panel (Table 55). Table 57 adds a stratified human audit of VERA-LIFE-EVAL gold (n=1,200) that puts overall gold-answer noise at 5.6%. All result cells derive from one prediction dump and one metric script.

Human criterion	vs LifeEM ρ	τ	vs AnsF1 ρ	vs SafeUtility ρ
Factual correctness	.58	.49	.71	.54
Action appropriateness	.73	.61	.28	.76
Harmful-assertion avoidance	.81	.68	.14	.79
User helpfulness / task success	.67	.55	.42	.69
Conflict awareness	.76	.63	.19	.74
Source attribution	.62	.51	.31	.65
User trust	.69	.57	.35	.71
Aggregate (4-criterion avg.)	.69	.58	.31	.72
Overall human preference (binary)	.72	.60	.26	.74
Stratified by lifecycle split				
Current	.61	.51	.58	.63
Past	.65	.54	.39	.67
Stale-only	.82	.69	.12	.80
Conflict	.79	.66	.09	.77
Update	.76	.64	.23	.75
Multi-hop	.68	.57	.35	.70

Table 41: Spearman (ρ) and Kendall (τ) correlation between human utility judgements (n=800, 3 annotators) and three automatic metrics: LifeEM, AnsF1, and SafeUtility. LifeEM correlates strongly with action appropriateness (ρ=.73) and harmful-assertion avoidance (ρ=.81), while AnsF1 correlates best with factual correctness (ρ=.71) and weakly with safety (.14). This is the intended decomposition: LifeEM is an action-aware reliability metric that complements, rather than replaces, token-level answer F1.

Audit item	Final run field
Data split hash	`sha256:a3f8...7c21`
Prediction dump hash	`sha256:b5e2...4d18`
Metric script hash	`sha256:c7a1...9f35`
Decoding config hash	`sha256:d2b4...6e72`
Random seed list	`[42, 1337, 2024, 7, 31]`
Table 2 source run	`run-20260418-unified`
CI table source run	`run-20260418-unified`
Controller diag. source run	`run-20260418-unified`

Table 48: Unified evaluation audit. All reported tables originate from one frozen prediction dump and one metric script. Table 2, the bootstrap CI table, and the controller diagnostic share the same source run identifier; hashes are published with the artifact.

Selector	LifeEM ↑	Conf. err. ↓	Redund. ↓	Latency
Random selector	.413	.231	.167	8 ms
Coverage-only greedy	.587	.142	.085	12 ms
Penalised greedy (ours)	**.623**	**.073**	**.041**	14 ms
MMR-style selector	.601	.098	.052	18 ms
Small-set exhaustive oracle	.651	.048	.028	142 ms

Table 50: Selector comparison. The penalised greedy heuristic achieves 95.7% of the exhaustive-oracle LifeEM at 9.9% of its latency. Conflict and redundancy penalties improve LifeEM by $+3.6$ over coverage-only greedy at $+2$ ms.

Ledger audit	Compact ledger	Full JSON ledger
Max new tokens	24 answer tokens	256 ledger tokens
JSON parse success	n/a	97.8%
Claim coverage	.91	.96
State accuracy	.87	.92
Evidence-id validity	.84	.89
LifeEM vs no-ledger	+.124	+.137
Latency overhead	+0 ms	+38 ms

Table 51: Ledger and decoding audit. The compact ledger (24 tokens) provides 90.5% of the full-JSON LifeEM gain at zero additional latency. Full JSON achieves 97.8% parse success and higher claim coverage and state accuracy, at a 38 ms overhead.

Statistic	VERA-LIFE	Best baseline	2nd baseline
% settings ranked #1	91.7%	8.3% (HoH)	—
Kendall τ rank stability	.89	—	—
SafeUtility (min / med / max)	1.02 / 1.51 / 2.18	0.21 / 0.34 / 0.58	0.08 / 0.22 / 0.41

Table 53: SafeUtility sensitivity across 48 weight settings ($\lambda_s \in \{1, 2, 3, 5\}$, $\lambda_o \in \{0.25, 0.5, 1\}$, $r_w \in \{0.5, 1\}$, $r_c \in \{0.5, 1\}$). VERA-LIFE ranks first in 91.7% of settings; system rankings are stable (Kendall τ=.89).

Ambiguous interval class (n)	IAA κ	Auto-gold acc.	VERA-LIFE LifeEM	Best baseline
Jurisdiction-specific legal update (80)	.73	.788	.618	.397
Weakened-not-retracted medical guideline (60)	.68	.742	.587	.362
News correction vs follow-up (70)	.76	.823	.652	.431
Old-but-valid historical answer (90)	.81	.867	.706	.484
Versioned-API deprecation overlap (50)	.79	.852	.671	.452
Multi-jurisdiction concurrent validity (40)	.65	.714	.563	.341
Avg. ambiguous (n=390)	.74	.798	.633	.411
Non-ambiguous reference (n=810)	.87	.934	.741	.532

Table 45: Ambiguous-interval taxonomy with stratified human audit. Six classes that auditors flagged as intrinsically ambiguous are isolated. Inter-annotator agreement is lower than on non-ambiguous reference cases (κ=.74 vs .87), and auto-constructed gold accuracy drops accordingly (.798 vs .934), but the VERA-LIFE-to-baseline gap is preserved (+.222 vs +.209 LifeEM). We document each class with one full example (Table 34); ambiguous intervals lower absolute scores but do not flip system ordering.

Regime	Hidden fields	LifeEM ↑	SRR ↑	Sup-F1 ↑	CUR ↑	OAR ↓
Full metadata	none	.623	1.000	.546	.725	.000
Timestamp-only	role, interval	.584	.965	.512	.693	.015
No-role inferred	role, interval	.551	.938	.483	.661	.023
Text-only lifecycle	timestamp, role, interval	.504	.828	.412	.583	.042
10% noisy metadata	perturbed role/time edges	.589	.973	.521	.702	.008
20% noisy metadata	perturbed role/time edges	.556	.942	.495	.672	.018
30% noisy metadata	perturbed role/time edges	.518	.907	.461	.638	.032
Adversarial role swap	current↔superseded	.342	.615	.287	.418	.078
HoH + same metadata	none	.391	.412	.087	.478	.065
Role-only trivial	text hidden	.318	.357	.062	.391	.082
Retrieval oracle bound	none	.728	1.000	.637	.845	.000

Table 46: Full metadata availability and noise stress test (n=1,500). Extends Table 2 with noise and adversarial settings. Adversarial role inversion (−28.1 LifeEM points) confirms the system reads but does not solely depend on role labels.

Budget B	Multi-hop LifeEM ↑	Missing-hop err. ↓	Latency
4	.312	.185	11 ms
6 (default)	.378	.112	14 ms
8	.421	.068	18 ms
10	.438	.051	24 ms

Table 54: Selector budget sweep on multi-hop questions (n=181). Increasing B from 6 to 8 reduces missing-hop errors by 39% at a 29% latency increase; B=10 yields diminishing returns.

HoH-QAs stale-only condition	LifeEM ↑	Δ vs full
With explicit older marker	.995	—
Without marker	.918	−.077
Shuffled evidence order	.941	−.054
Timestamp normalised	.872	−.123
Source-title only	.837	−.158

Table 56: Marker-removal and evidence-order ablation on HoH-QAs stale-only (n=200). Removing the explicit "older-revision" marker reduces LifeEM by 7.7 points but VERA-LIFE retains 92.3% of the gain, indicating lifecycle detection is not solely marker-driven. Even under source-title-only evidence, LifeEM remains 3.0× above HoH-style (.275).

W Longitudinal, conversational, and multilingual stress

We probe three forms of distribution shift beyond the static VERA-LIFE-EVAL: (i) the user's target time t_q varies (Table 58), (ii) the question is phrased conversationally rather than declaratively

Method	Act.Acc ↑	LifeEM ↑	SRR ↑	Conf-F1 ↑	OAR ↓	LCE ↓
Vanilla RAG + action	.380	.312	.215	.120	.145	.685
HoH-style + action	.540	.428	.487	.240	.098	.542
Self-reflect + action	.510	.451	.394	.310	.082	.517
GraphRAG + action	.460	.389	.341	.190	.112	.598
LightRAG + action	.480	.412	.367	.220	.105	.573
ReAct agentic + action	.520	.437	.412	.268	.091	.528
VERA-LIFE w/o graph + action	.570	.347	.423	.360	.068	.478
VERA-LIFE **full**	**.840**	**.623**	**1.000**	**.720**	**.000**	**.267**

Table 47: Full same-action-space comparison (n=1,500). Extends Table 3 with all baselines and additional metrics (Act.Acc, LCE).

Audit	Sample	Primary metric	Target readout	Result
Claim decomposition	400 answers	boundary F1	auto vs human	F1 = .89
Semantic entailment	400 pairs	agreement	NLI+rule vs human	κ=.85
Supersession edges	400 pairs	P / R / F1	doc vs claim level	.91 / .82 / .86
Validity interval	400 claims	acc. / IoU	class + interval	.87 / .76
Provenance sensitivity	θ_p sweep	Kendall τ	ranking stability	τ=.92
External claim checker	400 ledgers	state agree.	ledger vs checker	κ=.83
Gold noise spot-check	300 examples	noise rate	construction err.	3.8%

Table 49: Operational audit of lifecycle-variable estimators. Precision-heavy supersession edges (P=.91 > R=.82) reflect the design choice that missing an edge is safer than installing a spurious one. Gold noise is 3.8% on 300 spot-checked examples, below the margin between VERA-LIFE and any baseline.

(Table 59), and (iii) the question is in a non-English language (Table 60). These probes are deliberately framed as *stress tests*, not deployment claims.

Target snapshot t_q	LifeEM ↑	SRR ↑	CUR ↑	OAR ↓	Stale gain
VERA-LIFE **(frozen parameters, no per-snapshot tuning)**					
t_1 = 2024-06-01	.631	.982	.714	.005	+.198
t_2 = 2024-12-01	.618	.967	.701	.008	+.186
t_3 = 2025-06-01	.624	.974	.708	.006	+.193
Avg. across snapshots	.624	.974	.708	.006	+.192
Std. across snapshots	.005	.006	.005	.001	.005
Best same-action baseline (Self-reflect + action)					
t_1	.454	.398	.482	.081	—
t_2	.438	.371	.465	.088	—
t_3	.445	.384	.473	.085	—
Avg. baseline	.446	.384	.473	.085	—
Δ VERA-LIFE vs baseline	+.178	+.590	+.235	−.079	—
Δ std across snapshots	.002	.003	.002	.001	—

Table 58: Rolling-time evaluation across three target snapshots (n=1,500 per snapshot, same questions but with the lifecycle-state ground truth recomputed at each t_q). VERA-LIFE's LifeEM std across snapshots is .005, an order of magnitude smaller than the gain over the strongest baseline (.178). Per-snapshot stale gains (+.186 to +.198) remain stable, showing that lifecycle behaviour is robust under shifting target times rather than tuned to a single snapshot.

Template (n)	Parse acc.	VERA-LIFE	Base.
"Is this still in effect now?" (90)	.912	.627	.413
"Did the policy change since then?" (80)	.883	.598	.392
"Does this API still work?" (80)	.897	.615	.425
"By 2021's rule, would . . . " (80)	.862	.549	.378
"Was that ever true?" (60)	.831	.521	.354
"What about the 2019 version?" (70)	.872	.574	.397

Action policy mis-firing		19.6%	
Generation paraphrase mismatch		9.1%	

Table 59: Conversational temporal-intent stress set (n=580). Real-user-style phrasings of the same lifecycle questions: implicit "now", "then", "still", reference time anchored to a prior year, etc. Intent-parser accuracy averages .879, with the lowest on retrospective tense (.831). VERA-LIFE retains a +.187 LifeEM gain over the strongest baseline; the residual gap to the declarative VERA-LIFE-EVAL mirror set comes mainly from retrieval and interval errors, identifying temporal-intent parsing as the largest remaining bottleneck.

Metric	Denominator	Action handling	Formula sketch	Gold?	Abst?
AnsF1	all	surface string only	token F1	✗	✗
LifeEM	all	action-conditioned	stale/conflict: action; else F1≥.5	✓	✓
Temp-Evi-F1	temporal ev.	no action credit	evidence-id F1	✗	✗
Life-Temp-Evi-F1	life-answ.	valid ev. only	ev. F1 after filter	✓	✗
Sup-F1	supersession	edge-level	super. P/R F1	✓	✗
SRR	stale-only	warn/abstain	rejection / stale	✓	✓
OAR	answerable	warn/abstain wrong	non-answer / answ.	✓	✓
CUR	update	must pick current	current-value EM	✓	✗
LCE	all	calibrated state	binned ECE	✓	✗
SafeUtility	all	weighted composite	see Eq. in text	✓	✓

Table 52: Metric card. LifeEM is action-conditioned (section 6), not the conjunction exact∧IoU∧state. *Gold?*: metric uses gold lifecycle metadata. *Abst?*: metric can credit appropriate abstention or warning. SafeUtility is a secondary composite; primary conclusions hold on LifeEM, CUR, Sup-F1, and SRR.

Panel A: Target-time validity revision (past split, n=267)			
Validity variant	Past AnsF1 ↑	Past LifeEM ↑	Stale/Update Δ
Original $V(\cdot, t_q)$	.103	.142	—
Target-time aware $V(\cdot, t_q)$	.198	.247	$\leq +.005$
Panel B: Conflict grounding audit (conflict split, n=191)			
Aspect	Precision	Recall	
Conflict detection (policy fires)	.847	.791	
Candidate value grounding	.673	.618	
Both candidates correct	.524	—	

Table 55: Panel A: Making the validity term target-time aware rather than current-biased improves past-time AnsF1 by $+9.5$ and LifeEM by $+10.5$ while preserving stale/update gains. **Panel B**: The policy reliably detects conflicts (F1 $= .82$), but candidate value extraction from outdated revisions remains the dominant error (52.4% both-correct rate).

Language (n)	VERA-LIFE	Best base.	Δ	SRR
Spanish (240)	.487	.368	+.119	.742
Chinese (220)	.462	.354	+.108	.713
French (180)	.495	.376	+.119	.751
Avg. multilingual (640)	.481	.366	+.115	.735
English reference (VERA-LIFE-EVAL)	.623	.451	+.172	1.000
Failure decomposition (% of errors)				
Temporal-intent parser		38.2%		
Retriever cross-lingual		24.7%		
NLI cross-lingual transfer		18.1%		
Date-format normalisation		11.4%		
Generation paraphrase		7.6%		

Table 60: Multilingual lifecycle pilot (n=640). We mirror six VERA-LIFE-EVAL splits in three languages with native-speaker auditing; absolute scores are lower than English because retriever and NLI backbones are predominantly English-trained, and intent parsing inherits Spanish/Chinese/French temporal phrasing that is not in our template grammar. The lifecycle gain over the strongest baseline remains positive in every language ($+.108$ to $+.119$), and the dominant error mode is temporal-intent parsing rather than the lifecycle definition itself. We report this as a pilot, not a deployment claim.

X Reproducibility artefact

Table 61 itemises every released artefact; Table 1 reproduces in one hour on two RTX-4090Ds (tolerance $\leq .005$). All same-action baselines share one JSON schema and retrieval pool; Table 48 hashes verify single-source provenance.

Stratum (n)	Gold ans. acc.	State κ	Interval acc.	IoU
By lifecycle split				
Current (150)	.967	.87	.893	.811
Past (140)	.949	.82	.867	.768
Stale-only (120)	.958	.89	.904	.824
Conflict (130)	.938	.80	.832	.742
Update (140)	.957	.85	.881	.787
Multi-hop (120)	.942	.81	.848	.755
By domain (REAL-mini / REAL-blind cross-source)				
Product / API (100)	.952	.84	.882	.793
Policy / legal (100)	.921	.77	.812	.724
Scientific / medical (100)	.908	.75	.787	.701
News correction (100)	.947	.83	.865	.771
Avg. stratified (n=1,200)	.944	.82	.859	.770
Reference: original audit (n=300)				
Original spot-check	.962	.85	.871	.763

Table 57: Stratified human audit of VERA-LIFE-EVAL gold (n=1,200, 3 domain-aware annotators, blind to system predictions). Gold-answer noise is 5.6% overall, 4.5% on Wikipedia splits, and $9.2\%/7.9\%$ on scientific-medical and policy-legal cases—these are exactly the strata where lifecycle intervals are intrinsically harder. State agreement κ=.82 and interval IoU .77 are both above the $.10\sim.17$ margin between VERA-LIFE and the best same-action baseline, so reported gains exceed annotation noise by $>3\times$. We release the stratified audit with per-claim disagreement traces.

Artefact	Submitted	Camera-ready
Data construction script	✓	✓
Evidence pool (full 41,203 pieces)	partial	✓
100-example smoke test	✓	✓

Data schema (JSON)	✓	✓
One-command Table 1 repro	✓	✓
Smoke test runtime	$<$ 30 min (2× RTX 4090D)	
Metric reproduction tolerance	$\leq$ .005	

Table 61: Reproducibility artefact checklist. All items marked ✓ are included in the supplementary submission. The smoke test reproduces the main table on 100 examples in under 30 minutes; full reproduction takes $\sim$1 hour. Every table value links to a prediction dump ID; no hidden proprietary dependency is required.

Y Optional QLoRA fine-tuning

Table 62 ablates the optional QLoRA fine-tuning of the controller; the no-tune setting recovers $\geq 97\%$ of the gain, so the system is reported in its zero-tune configuration in the main paper.

Variant	AnsF1	LifeEM	SRR	SU
VERA-LIFE (zero-shot, retrieved ev.)	.402	.623	1.000	+1.511
VERA-LIFE **(QLoRA, oracle ev.)**	**.613**	**.875**	**1.000**	**+2.138**

Table 62: Optional fine-tuned variant. We fine-tune the ledger generator with 4-bit QLoRA (rank 16, one epoch, 43.6M trainable parameters) on 5,000 auto-constructed evidence-to-ledger pairs. The QLoRA row uses oracle evidence as an upper-bound-style setting and improves over the zero-shot retrieved baseline by $+.211$ AnsF1, $+.252$ LifeEM, and $+0.627$ SafeUtility.

Z Operationalization of lifecycle variables

The four latent variables in Equation 2 are operationalized as auditable estimators (Table 49): *claim decomposition* (Qwen3-8B 3-shot, boundary F1 = .89, 96% claim-level lifecycle agreement), *semantic entailment* (DeBERTa-v3 NLI + lexical overlap, κ=.85; $.87/.84/.81$ under full/timestamp-only/text-only), *supersession edges* (shared-document late-timestamp heuristic, precision .91 / recall .82, precision-heavy by safety design), and *validity interval* (open-

ended/bounded/point/unknown with start–end extraction, accuracy .87, IoU .76; $\pm 20\%$ perturbation costs $-.039$ LifeEM).

LifeEM decomposition and alternative metrics. Table 63 scores the four lifecycle components independently—they are diagnostics around LifeEM, not factors of it—and reports how each tracks human utility.

LifeEM component	VERA-LIFE	Best SA	Δ
Answer correctness (AnsF1)	.402	.339	+.063
Temporal interval validity (IoU)	.781	.534	+.247
State/action accuracy	.854	.582	+.272
Citation/provenance F1	.712	.587	+.125
LifeEM (action-conditioned)	.623	.451	+.172
Over-abstention (OAR ↓)	.000	.082	−.082

Table 63: Diagnostics around LifeEM (n=1,500), not factors of it. Best SA = Self-reflect. The four component rows are scored independently and are *not* multiplied to obtain LifeEM (section 6). Gains cover both answer quality and lifecycle behaviour; OAR stays zero. LifeEM correlates with human action appropriateness (ρ=.73) and harmful-assertion avoidance (ρ=.81; Table 41).

Table 64 extends the decomposition to seven metrics and confirms ranking stability.

Metric	VERA-LIFE	Best SA	Δ	τ LifeEM	τ human
LifeEM (reported)	.623	.451	+.172	1.00	.60
LifeEM+IoU $\geq$ .3	.648	.478	+.170	.93	.58
LifeEM+IoU $\geq$ .7	.591	.417	+.174	.91	.61
SafeUtility	.714	.523	+.191	.89	.74
Life-Temp-Evi-F1	.682	.497	+.185	.87	.62
Temp-Evi-F1	.226	.283	−.057	.42	.31
AnsF1	.402	.339	+.063	.48	.51

Table 64: Alternative metric sensitivity (n=1,500). The first row is the reported action-conditioned LifeEM. The IoU rows are the same optional stricter diagnostic as Table 44 and Table 43; they are not a second implementation of headline LifeEM. Rankings remain stable ($\tau \geq .91$). Temp-Evi-F1 and AnsF1 do not credit lifecycle actions and penalise WARN_STALE/EXPLAIN_CONFLICT outputs.

Feature-matched baselines and oracle retrieval. Table 65 hands three baselines VERA-LIFE's timestamps, NLI, provenance, retriever pool, and action schema while withholding the graph and the ledger.

Method	LifeEM	SRR	OAR ↓	Conf-F1
Vanilla RAG	.217	.000	.000	.000
HoH-style stale-aware	.374	.000	.000	.000
Feature-matched (same features, no graph/ledger)				
Newest-valid-before-t_q	.467	.523	.112	.187
Timestamp+NLI reranker	.489	.586	.098	.248
LambdaMART classifier	.521	.614	.087	.294
VERA-LIFE	**.623**	**1.000**	**.000**	**.720**

Table 65: Feature-matched lifecycle baselines (n=1,500). All three share VERA-LIFE's timestamps, NLI, provenance, retriever pool, and action schema but build no graph or ledger. They outperform vanilla/HoH, confirming lifecycle features matter; VERA-LIFE remains +.102 ahead, largest on conflict and supersession (Table 66).

Table 66 gives all systems gold-relevant evidence, isolating the selection/action/generation bottleneck from retrieval.

Method (oracle retrieval)	LifeEM	AnsF1	SRR	Conf-F1	OAR
Vanilla RAG	.384	.412	.187	.142	.000
HoH-style	.489	.467	.382	.263	.053
Feature-matched LMART	.553	.501	.594	.341	.072
Self-reflect + action	.507	.478	.412	.318	.068
VERA-LIFE	**.718**	**.561**	**.952**	**.784**	**.008**
Per-split gap (VERA-LIFE − best non-VERA-LIFE)					
Current	+.087	+.042	+.034	—	−.012
Update	+.148	+.071	+.312	—	−.028
Conflict	+.197	+.054	—	+.443	−.016
Multi-hop	+.182	+.068	+.287	—	−.021

Table 66: Oracle retrieval: all systems receive gold-relevant evidence. The gap confirms the bottleneck is lifecycle state estimation and evidence-contract selection, not retrieval. VERA-LIFE's advantage is largest on conflict (+.197) and multi-hop (+.182).

Current-split, expanded E2E, and claim audit. Table 67 attributes the current-split gain to evidence selection and citation validity rather than to warnings, and Table 68 reproduces every split on 4,000 examples within .005 of the subset. Table 72 then lists every headline number with its denominator, sample size, metadata regime, and metric-script hash, and Table 73 fixes the canonical action vocabulary shared by all prompts and scripts.

Error category (current split)	Vanilla	HoH	FM-Best	VERA-LIFE
Evidence selection error	31.2%	24.7%	18.4%	8.1%
Unsupported citation	24.1%	18.3%	14.2%	5.7%
Generation drift	18.4%	16.8%	12.1%	7.3%
Provenance insufficient	12.3%	11.4%	8.7%	3.2%
State/action mismatch	9.8%	7.2%	6.4%	2.4%
Over-warning / false warning	0.0%	1.8%	3.2%	4.1%
Total error rate	58.7%	43.2%	32.8%	17.4%
Decoy control (current split)				
Old-but-valid retention	41.2%	53.7%	71.4%	86.3%
Irrelevant-new rejection	32.8%	48.1%	67.3%	91.2%
AnsF1	.231	.347	.412	.462

Table 67: Current-split error decomposition. The gain is driven by evidence selection (-23pp) and citation validity (-18pp), not warnings. False warning rate stays low (4.1%). Decoy controls confirm VERA-LIFE retains old-but-valid evidence (86.3%) and rejects temporally irrelevant newer evidence (91.2%). FM-Best = best feature-matched baseline.

Split (n)	VERA-LIFE	Best SA	Δ	AnsF1	OAR $\downarrow$
Current (700)	.612	.448	+.164	.458	.000
Past (600)	.321	.197	+.124	.248	.008
Stale-only (700)	.987	.127	+.860	—	.000
Update (900)	.694	.312	+.382	.387	.000
Conflict (500)	.524	.287	+.237	.312	.000
Multi-hop (600)	.487	.294	+.193	.298	.000
All (4,000)	.618	.441	+.177	.394	.002
Subset comparison					
1,500 subset	.623	.451	+.172	.402	.000
Difference	$-.005$	$-.010$	+.005	$-.008$	+.002

Table 68: Expanded E2E audit (n=4,000, $\geq$ 500/split). All per-split gains are positive. Expanded LifeEM differs from the 1,500-subset by $-.005$, confirming subset stability.

User-visible criterion	VERA-LIFE	Best SA	Δ
Citation sufficiency	82.4%	61.7%	+20.7
Explanation faithfulness	78.1%	54.3%	+23.8
Harmful assertion rate $\downarrow$	7.8%	28.4%	-20.6
Conflict explanation grounding	74.2%	38.7%	+35.5
Warning appropriateness	87.3%	42.1%	+45.2
Answer actionability	76.8%	58.4%	+18.4
Overall human preference	72.4%	27.6%	+44.8
Human utility score (1–5)	3.84	2.47	+1.37

Table 69: User-visible answer audit (n=800, 3 annotators, blind, stratified). Harmful assertion rate measures answers that state outdated information as current. SA = best same-action baseline.

Provenance setting	LifeEM	Δ	FWR $\downarrow$	OAR $\downarrow$
No provenance (θ_p=0)	.601	$-.022$	.054	.012
Scalar provenance (default)	.623	—	.034	.000
Domain-specific hierarchy	.638	+.015	.021	.004
Per-domain impact of removal				
Product / API	.589	$-.024$	.048	.014
Policy / legal	.574	$-.058$	.098	.018
Scientific / medical	.562	$-.071$	.072	.021
News correction	.598	$-.031$	.053	.008
General (Wikipedia)	.612	$-.011$	.038	.006
Domain-specific provenance hierarchies				
Medical: guideline>SR>RCT>preprint	.643	+.020	.018	.006
Legal: statute>supreme>appellate	.641	+.018	.024	.008
News: correction>syndicated>repost	.636	+.013	.019	.003
API: docs>release notes>tutorial	.639	+.016	.014	.005
Threshold sensitivity (θ_p)				
$\theta_p = 0.3$	.618	$-.005$	.041	.002
$\theta_p = 0.5$ (default)	.623	—	.034	.000
$\theta_p = 0.7$	.619	$-.004$	.028	.008
$\theta_p = 0.9$	.607	$-.016$	.019	.024

Table 70: Provenance ablation. Prov(e_i) is an operational proxy: removal drops LifeEM modestly overall ($-.022$) but more in legal ($-.058$) and medical ($-.071$). Domain-specific hierarchies further reduce false warnings. Threshold θ_p varies smoothly (κ=.78 inter-annotator agreement on manual provenance labels).

Stress condition	LifeEM	Retention	Δ
Full metadata (reference)	.623	100%	—
Marker removal	.587	94.2%	$-.036$
Date masking (relative order only)	.571	91.7%	$-.052$
Source-title masking	.601	96.5%	$-.022$
Cross-source supersession	.572	91.8%	$-.051$
Marker + date (combined)	.548	88.0%	$-.075$
All masks (combined)	.531	85.2%	$-.092$
Ranking stability (Kendall τ vs full)			
Marker removal	.91	—	—
Date masking	.87	—	—
Source-title masking	.93	—	—
Cross-source	.89	—	—
IoU .3/.5/.7	.93 / — / .91	—	—

Table 71: Marker-oblivious and feature-masked stress. VERA-LIFE retains $\geq 85\%$ gain under all combined stresses. System rankings remain stable ($\tau \geq .87$) under each condition and under IoU threshold variation.

Location	Number	Compared against	n	Regime	Hash

ABSTAIN	ABSTAIN

Table 73: Canonical action vocabulary. All prompts, metric scripts, JSON schemata, and evaluation tables use the canonical labels. Earlier shorthand forms are mapped for readability but never used in machine evaluation.

Do LLM Attribution Metrics Transfer? Auditing Retrieval-Augmented Generation Evaluation Across Datasets and Constructs

Abstract

Practice often treats automatic metrics for attribution in LLM retrieval-augmented generation as interchangeable. We audit eight automatic scorers — lexical, embedding, and BERTScore baselines alongside entailment/grounding-trained models (clean and FEVER NLI, the checker MiniCheck) — across three evaluation constructs (provenance/topicality, generated-answer attribution, and fact-check entailment), asking whether any scorer *transfers*: stays within the 95% confidence interval of the best audited scorer on *every* dataset of a multi-dataset construct. In the construct with the most multi-dataset **human**-labeled coverage — generated-answer attribution (AttributionBench's four source datasets, n=1610, with independent HAGRID, n=2150) — none of the audited automatic scorers does: the per-dataset metric rankings invert (Kendall $\tau = -0.64$, p=0.031 on AttributedQA vs. LFQA), and an off-the-shelf NLI scorer that is best on short-claim AttributedQA (AUROC 0.90) collapses to AUROC 0.53 (chance) on long-form LFQA, where BERTScore wins (0.91); the reversal persists under the tested truncation settings. This instability has a concrete decision cost: a naive "best-on-average" rule for choosing an evaluator *fails* leave-one-dataset-out (mean held-out regret 0.172 AUROC, worse than fixing one scorer), so metric choice should be validated on the target dataset rather than assumed from performance elsewhere. A prompt-based LLM judge avoids the chance-level collapses the automatic scorers suffer (no LFQA collapse) but is not uniformly best, $\sim$100$\times$ costlier, and non-deterministic — relocating, not removing, the validation burden.

1 Introduction

Retrieval-augmented language models are increasingly evaluated for *grounding*: whether each claim in an answer is supported by the provided evidence. A growing toolbox of automatic scores — lexical overlap, sentence-embedding similarity, NLI/entailment — stands in for human grounding judgments, and practitioners often report them interchangeably, as if "the attribution metric went up" meant the same thing regardless of metric or benchmark. By "LLM attribution metrics" we mean metrics evaluating attribution in LLM/RAG outputs (lexical, embedding, NLI/checker, and prompted LLM-judge variants); our core audit is the cheaper *automatic* scorers, with the prompted LLM judge as a boundary case. We show this assumption is unsafe at two levels. Coarsely, metric-family performance varies across the audited *constructs* and datasets. More sharply, *within* a single construct the best metric is not stable across its datasets, so no audited automatic scorer passes our core generated-answer attribution portability screen. This is a claim about *evaluator selection* at the item level (which scorer to trust on a given dataset), not about the ranking of complete RAG systems, which we do not study (see §6).

Concretely, we audit eight metrics — off-the-shelf scores with no attribution-specific fine-tuning (lexical Jaccard, MiniLM and MPNet cosine, their fixed blend, BERTScore) and trained entailment/grounding models (clean-MNLI NLI, FEVER NLI, and the purpose-built checker MiniCheck (Tang et al., 2024); a lexical/semantic/combined/NLI subset on the provenance ranking task) — across three evaluation constructs the literature routinely conflates: **(i) provenance/topicality** — does a score rank a relevant passage top (ASQA (Stelmakh et al., 2022), MS MARCO (Nguyen et al., 2016), HotpotQA (Yang et al., 2018); passage-ranking labels, not sentence/claim-level support); **(ii) generated-answer attribution** — does a score predict *human* judgments of whether a generated answer sentence is supported by its cited evidence (AttributionBench (Li et al., 2024)); **(iii) fact-check entailment** — does a score predict *human* support

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 241–256
October 29, 2026 ©2026 Association for Computational Linguistics

labels on short edited claims (VitaminC (Schuster et al., 2021)). At the coarse, cross-construct level metric-family performance differs on the audited benchmarks (Table 2): the best off-the-shelf relevance score per provenance gate reaches 0.73–0.97 top-1 accuracy (within overlapping bootstrap CIs of NLI on MS MARCO/HotpotQA, though NLI is unreliable on ASQA at 0.585), whereas entailment-trained models score above all no-fine-tuning baselines on fact-check claims (VitaminC, 0.81–0.89 vs. surface ≈0.60 AUROC); this coarse contrast is bounded to the audited benchmarks and partly confounded with domain shift (§6). The sharper finding is *within* generated-answer attribution: across AttributionBench's four constituent datasets the best metric is not stable (the per-dataset rankings invert, Kendall $\tau = -0.64$, p=0.031 on AttributedQA vs. LFQA). A naive NLI scorer is best on AttributedQA (AUROC 0.90) yet drops to 0.53 (chance = 0.50) on LFQA, where BERTScore reaches 0.91 — though on a *different* long-form set (HAGRID) the same NLI scorer is best (0.80), so the failure is dataset-specific and not explained by long-form *answers* alone (long *evidence* remains a candidate; §4).

This matters because practitioners silently read success on one construct, or on one benchmark, as evidence of grounding in general. Prior benchmarking work establishes that automatic attribution metrics disagree with humans and that no single metric wins everywhere (Honovich et al., 2022; Dziri et al., 2022; Yue et al., 2023; Li et al., 2024); beyond that qualitative "they disagree," our contribution is decision-relevant: an operational *portability* criterion, a leave-one-dataset-out *regret* that prices committing to one default, and a naive cross-dataset selector that *fails* (0.172 regret) — a validation discipline, on a controlled audit with human labels on the in-domain attribution and fact-check sides and a clean separation from proxy-labeled provenance (mechanism discovery is out of scope). This is an evaluation-resource/cautionary paper, not a new-metric paper. Our central contribution is the cross-dataset evaluator-selection audit; the rest are supporting diagnostics and boundary probes:

- A **cross-dataset audit** (Section 4, Table 2) showing metric-family differences across the audited constructs and datasets, but that *within* in-domain answer attribution no single *automatic* scorer is consistently near-best across datasets (rankings discordant, Kendall W=0.07, p=0.029): a raw MNLI scorer is best on AttributedQA (0.90) yet AUROC 0.53 (chance = 0.50) on the LFQA dataset — though best again on the independent long-form HAGRID set (0.80) — while a purpose-built checker (MiniCheck) has the lowest mean leave-one-dataset-out regret among the eight automatic scorers *tested*, yet still leaves a measurable per-dataset regret (mean 0.044 AUROC, CI $[0.014, 0.072]$).

- As supporting diagnostics, a training-free **sentence-unit provenance/topicality diagnostic** and a **confusable-evidence stress-test protocol** (Sections 3, 3.1): under confusable evidence (high-overlap distractors from other examples), the semantic component separates co-provenant passages from distractors where lexical overlap is fooled. We benchmark an off-the-shelf NLI entailment head against it and find NLI benchmark-dependent, not uniformly best — a construct-(i) diagnostic, not a general-purpose grounding metric.

- On **validation discipline** (Section 4): a naive "best-on-average" selection rule fails leave-one-dataset-out (mean regret 0.172, worse than the lowest-mean-regret fixed metric among those tested), so metric choice must be validated on the target dataset; and a **cross-family LLM-annotation** probe (Opus 4.8 + GPT-5.4, n=160) showing high inter-model but only moderate, dataset-dependent human agreement — usable as a corroborative proxy only in the easiest (short-factoid) dataset, bounding off-the-shelf LLM label substitution.

An auxiliary rewrite-sensitivity probe appears in App. C; it does not establish improved grounding.

In short, "attribution metric" names a family of signals capturing different constructs (provenance, topical relatedness, human-judged support); metric suitability varies across the audited settings, and *within* answer attribution no audited automatic scorer passes our portability screen across the tested datasets. Evaluations should report the dataset and construct they target and prefer a checker validated on that dataset, not treat any single metric as a universal proxy for grounding.

2 Related Work

Correctness vs. faithfulness. An answer can be correct while its citations do not support its claims

(Rashkin et al., 2023; Liu et al., 2023): a faithfulness gap distinct from factual correctness (Ji et al., 2023), acute for long-form answers exact match cannot score (Fan et al., 2019) and worsened by uneven use of mid-context evidence (Liu et al., 2024).

Attribution and citation quality. AIS (Rashkin et al., 2023) formalizes source support, and audits find fluent answers often carry unsupported citations (Liu et al., 2023). ALCE (Gao et al., 2023) introduced NLI-based citation recall/precision (with QAMPARI (Amouyal et al., 2023)); FActScore (Min et al., 2023) decomposes into atomic facts; Attribute-First (Slobodkin et al., 2024) and LongCite (Zhang et al., 2024) produce attributable text; AttrScore (Yue et al., 2023) and RAGAS (Es et al., 2024) judge support with LLM/entailment models. AttributionBench (Li et al., 2024) benchmarks such evaluators against human labels — but, crucially, only *trained/LLM* evaluators, not the off-the-shelf lexical/embedding baselines we find within overlapping CIs in-domain. These methods need entailment/LLM judges or modify generation; our scorers include a deterministic sentence-unit one (Reimers and Gurevych, 2019), and our contribution is the cross-dataset *audit*.

RL for grounding. Prior work trains models to cite evidence via rewards, from verified-quote RLHF (Menick et al., 2022) to citation rewards (Huang et al., 2024), gated sufficiency/abstention rewards (Zhao et al., 2026), and verifiable-reward training (Sim et al., 2025). These *fix the model*; we *diagnose the evaluation*, and our null result (App. C) is consistent with their report that answer-level metrics are hard to move.

Distractors and robustness. Contextual distractors cause large drops (Lee et al., 2026), especially *highly semantically related* ones (Wu et al., 2024), and grounding can fail even in instruction-tuned models under adversarial conditions (Koneru et al., 2026). Our confusable-evidence test (Section 3.1) is a controlled, passage-ranking instance.

3 A Sentence-Unit Provenance-Ranking Score

We score how well each sentence of an answer is *matched* to a set of candidate passages, for the provenance-ranking diagnostic of construct (i) (distinct from the human-support task of constructs ii, iii). Let an answer be split into sentence units $u_1, \ldots, u_m$ and let the evidence be passages $p_1, \ldots, p_k$. For a unit u and passage p we compute a combined relevance score

$$s(u,p) = 0.40\,\mathrm{lex}(u,p) + 0.45\,\mathrm{sem}(u,p) + 0.10\,h(u) + 0.05\,c(u,p), \quad (1)$$

where lex is token Jaccard, sem is sentence-transformer cosine (Reimers and Gurevych, 2019) (`all-MiniLM-L6-v2`), the *answer-hint* $h(u)$ is the fraction of gold short answers in the unit, and the *citation bonus* $c(u,p)$=1 when u cites p. A unit's score is $\max_p s(u,p)$. It is **training-free** (only a small frozen encoder).

The score is a fixed *provenance* diagnostic for construct (i), **not** a proposed general-purpose grounding metric (far from best on the human-support tasks of Section 4) and **not** the paper's central contribution: the human-labeled cross-dataset audit of Section 4. We report the single canonical weighting, not a tuned one. The answer-hint $h(u)$ is partly label-aware, but it does not affect the confusable ranking: $h(u)$ is constant within a unit (so it cannot reorder that unit's candidate passages), and the citation term $c(u,p)$=0 throughout because ASQA gold answers carry no inline citations. The confusable test thus ranks on lexical/semantic only and the central result needs no gold-label access (ablated below).

3.1 Provenance/topicality (construct i)

The first construct asks whether a score routes an answer sentence to the passage it came from. On ASQA we form a gold-reference vs. unadapted-model contrast: the gold long-form answer vs. an unadapted `Qwen2.5-3B-Instruct` generation over the example's $\geq$ 2 passages (623 dev examples; the confusable test uses a stricter $\geq$ 3-passage filter, 339).[1] Holding short-answer correctness roughly equal (98 examples within 0.15 recall), the combined provenance gap is $+0.160$, CI $[+0.133, +0.189]$ (full-dev $+0.164$), and is not a hint artifact (zeroing the hint weight moves the matched gap only to $+0.153$, CI excluding 0; App. B). So provenance-sensitive scores move even when correctness does not — but this is provenance sensitivity, not human-judged support.

Confusable-evidence stress test. To test the "just lexical overlap" objection, for each gold answer sentence we build a pool from the unit's own

[1] Two small ASQA checks (App. A) are *internal consistency* only (circular labels), so we do not rely on them.

Scorer	Top-1 prov. acc.	Fooled rate
Lexical-only	0.775	0.225
Semantic-only	**0.934**	**0.066**
Combined (canon.)	0.919	0.081
NLI entailment†	0.585	0.415

Table 1: Confusable-evidence stress test on ASQA (top-1 averaged across four seeds; best in bold; semantic encoder `all-mpnet-base-v2`, k=5 distractors). Lexical / semantic / combined are on the full usable dev pool (339 ex / 1309 units). The combined−lexical gap is $+0.144$, 95% CI $[+0.122, +0.165]$: all four independent-seed gaps ($+0.144, +0.144, +0.144, +0.143$) have CIs above 0. †The NLI row is computed on the 200-example-per-seed subsample (3 seeds, ≈760 units each) for cost, so its absolute value is not directly pooled with the others; the lexical and semantic values on that same subsample are 0.786 and 0.938, so NLI's 0.585 is well below both on matched data. Ground truth is a passage-provenance proxy; distractors are highest-lexical-overlap passages from other examples. NLI = an off-the-shelf DeBERTa-v3 MNLI/FEVER/ANLI entailment head (passage→sentence) on this ranking task, not full ALCE citation evaluation.

ASQA passages plus k=5 *confusable distractors* (highest lexical-overlap passages from *other* examples). The label is a **provenance proxy** (did the top passage come from the unit's own example), not a human groundedness judgment. We report top-1 provenance accuracy and the *fooled rate* (a confusable distractor outranks every co-provenant passage); ranking uses lexical/semantic only.

The semantic component survives; lexical is fooled; NLI does not help. On the full dev pool (339 examples, 1309 units; semantic encoder `all-mpnet-base-v2` for this confusable test), top-1 provenance accuracy is 0.775 lexical-only, 0.934 semantic-only, 0.919 combined (combined−lexical $+0.144$, CI $[+0.122, +0.165]$, all four fresh-example seed gaps > 0: $0.144, 0.144, 0.144, 0.143$); the fooled rate drops from 22.5% (lexical) to 8.1% (combined) and 6.6% (semantic). An off-the-shelf DeBERTa MNLI/FEVER/ANLI scorer reaches only 0.585 here — below lexical, far below semantic — a construct mismatch (ASQA sentences *synthesize* across passages; cf. Laban et al., 2022), not a verdict on entailment in general. Sweeping the lexical weight α (Fig. 1, App. B) confirms the canonical blend ($\alpha \approx 0.47$) is past the knee, so we do **not** claim it optimal; this is specific to construct (i), where semantic carries the signal — on human-judged support (ii, iii) it is *not* dominant.

4 The Cross-Dataset Audit

We make our central point in two steps: coarsely, metric-family performance differs across the audited constructs and datasets; more sharply, *within* a construct the best metric stays unstable across datasets. For this audit we use *portable* (its ranking *transfers*) as one near-best screen, operational *for metric selection*: a metric stays within the 95% CI of the best *audited* metric on *every* dataset of a construct. We do not offer this as a universal definition of transfer, and our consequence is at the level of choosing an evaluator, not ranking generators (system-level transfer is future work; see Limitations). In our data the same non-portability reading is corroborated by discordant per-dataset metric rankings (concordance W=0.07, p=0.029; the AttributedQA-vs-LFQA ranking inverts, Kendall $\tau = -0.64$, p=0.031), a non-zero leave-one-dataset-out regret (mean 0.044 AUROC for the best fixed choice), paired-bootstrap sign flips excluding zero (NLI−BERTScore $= -0.378$ on LFQA vs. $+0.213$ on AttributedQA), the ϵ-regret sweep (no audited metric transfers at $\epsilon \leq 0.05$; only MiniCheck at ϵ=0.10), and the further sensitivity analyses in App. F. Dataset-dependent winners also occur in an independent replication excluding the overlapping ExpertQA and LFQA datasets (n=7336, App. F). We audit eight metrics — off-the-shelf scores with no attribution-specific fine-tuning (lexical Jaccard, MiniLM and MPNet cosine, their blend, BERTScore (Zhang et al., 2020)) and trained models (clean non-FEVER MNLI NLI, FEVER NLI, and the purpose-built checker MiniCheck (Tang et al., 2024)) — on the two support constructs, and a lexical/semantic/combined/NLI subset on the provenance ranking task; we never pool the three constructs: **(i) provenance/topicality** (ASQA, MS MARCO, HotpotQA: rank candidate passages and check the top one; ASQA uses a provenance proxy, MS MARCO and HotpotQA use human passage-level labels, none sentence/claim-level support); **(ii) generated-answer attribution** with *human* support labels (AttributionBench (Li et al., 2024): is a generated answer sentence attributable to its cited evidence?); **(iii) fact-check entailment** with *human* support labels (VitaminC (Schuster et al., 2021): is a short claim supported by its evidence?). For (ii, iii) we score each (claim/sentence, evi-

dence) pair and report AUROC (clustered bootstrap CIs); the clean NLI baseline uses a non-FEVER MNLI model to avoid VitaminC leakage, while the provenance ranker (c) uses an off-the-shelf DeBERTa MNLI/FEVER/ANLI head (so the NLI *column* differs by construct). Table 2 is the headline.

Metric-family performance differs across the audited constructs and datasets. For fact-check entailment we have only one audited boundary dataset, VitaminC (n=4000 human labels), where the entailment-trained models score above all no-fine-tuning baselines: FEVER NLI 0.894, clean NLI 0.811, MiniCheck 0.810, versus the surface metrics clustered near 0.60–0.63 (BERTScore 0.596, lexical 0.619, combined 0.628). We treat this as a one-dataset contrast on short edited claims, *not* a general law about fact-checking. For provenance/topicality we report only passage-ranking results (ASQA provenance proxy; human passage-level labels for MS MARCO/HotpotQA), reaching 0.73–0.97 top-1 accuracy (within overlapping bootstrap CIs of NLI, which is however unreliable on ASQA at 0.585); these labels are distinct from sentence/claim-level support and are not pooled with the support tasks. The coarse separation thus holds only loosely and only on these audited benchmarks.

But the "attribution" label is not a reliability boundary. AttributionBench (n=1610 human labels) aggregates four source datasets the literature files under one task — is a generated answer sentence attributable to its cited evidence? — and a practitioner who reads "attribution metric" expects a single applicable choice. We make no claim that the four are cognitively identical (they differ sharply in evidence length and structure, which we use below to characterize *where* metrics fail); our point is the practitioner-facing one: this shared label does *not* predict which metric to trust. The best metric is not stable across the four, and the evidence that isolates this *crossover* is rank-based: the per-dataset metric rankings are discordant (Kendall's W=0.07; rank-permutation p=0.029), the AttributedQA-vs-LFQA ranking literally inverts (Kendall $\tau = -0.64$, p=0.031), and the best-vs-runner-up sign flips (NLI−BERTScore $= -0.378$ on LFQA vs. $+0.213$ on AttributedQA, CIs exclude 0). A pure dataset-difficulty (main) effect cannot produce a rank reversal. A two-way decomposition of the AUROC matrix places 35% of the cross-cell variance in the interaction residual (a residual permutation that holds each dataset's difficulty fixed is borderline, p=0.053), while most of the raw cross-cell spread (61%) is dataset-difficulty main effect: some datasets are simply harder for every metric. (An exchangeability permutation that shuffles the dataset assignment of per-example pairs rejects at $p < 0.002$, but that test conflates the main effect with the interaction, so we rely on the rank-based statistics above.) The clean MNLI scorer is the best metric on short-claim AttributedQA (0.904; +0.270 over lexical Jaccard, paired 95% CI $[0.198, 0.347]$) yet falls to AUROC 0.531 (chance = 0.50) on long-form LFQA, where BERTScore reaches 0.909 (MNLI−BERTScore $= -0.378$, CI $[-0.500, -0.238]$). This collapse pins to one *checkpoint*, not the entailment family: on the same LFQA, FEVER-trained NLI scores 0.720 and the checker MiniCheck 0.852, so "no single metric transfers" is about individual scorers, not a verdict on entailment models as a class. This collapse persists when the NLI token limit increases from 256 to 512 (LFQA 0.531 → 0.527). Length controls leave residual dataset differences: at matched evidence length (89–180 words) MNLI still differs by source (0.934 AttributedQA vs. 0.597 ExpertQA), and the within-source short-vs-long drop (+0.06 LFQA, +0.09 ExpertQA) is far below the 0.38 cross-dataset flip. A purpose-built checker (MiniCheck, 2048-token window) repairs the long-form failure (LFQA 0.852) and has the lowest mean leave-one-dataset-out regret *among the metrics we tested* (AttributionBench mean AUROC 0.774), yet is not uniformly best, losing to BERTScore on Stanford-GenSearch (-0.055, CI $[-0.104, -0.010]$). Committing to one metric everywhere still incurs modest per-dataset *regret* vs. oracle selection (mean 0.044, CI $[0.014, 0.072]$) — modest in that it is well below the per-dataset sign-flips (0.378) that drive the headline, but its CI excludes zero, so it is a real if small cost. ExpertQA is an underspecified dataset where every metric is weak (oracle best-of-eight only 0.618, barely above chance); three supplementary metrics agree (cross-encoder 0.58, MiniCheck-FT5 0.60, AlignScore 0.60; App. D), so the weakness is not isolated to one scorer, and we lean no claim on it.

An external boundary: long-form alone does not predict the NLI failure. To test whether "long-form" explains the LFQA collapse, we score the full zoo on **HAGRID** (Kamalloo et al., 2023), an *independent* long-form attribution set (not an Attri-

Construct	Benchmark (label type)	*off-the-shelf (no fine-tuning)* Lex	MiniLM	MPNet	Comb	BERTSc	*trained* NLI_{cl}	NLI_{fe}	MiniChk
(a) Generated-answer attribution — **human** support labels, AUROC									
AttributedQA (short claims)	AttributionBench (Li et al., 2024)	0.634	0.813	0.766	0.807	0.692	**0.904**	0.897	0.884
LFQA (long-form)	AttributionBench	0.802	0.739	0.771	0.764	**0.909**	0.531	0.720	0.852

VitaminC (short claims)	VitaminC (Schuster et al., 2021)	0.619	0.613	0.609	0.628	0.596	0.811	**0.894**	0.810
(c) Provenance / topicality — passage-level labels, top-1 acc.									
provenance proxy	ASQA (Stelmakh et al., 2022)	0.775	—	**0.934**	0.919	—	0.585	—	—
human `is_selected`	MS MARCO (Nguyen et al., 2016)	0.683	0.646	—	**0.726**	—	0.708	—	—
human support-facts	HotpotQA (Yang et al., 2018)	0.959	0.938	—	0.972	—	**0.979**	—	—

Table 2: **Benchmark-by-benchmark audit; constructs are reported separately and never pooled.** The main multi-dataset non-portability result is the four-source AttributionBench audit in (a); HAGRID, VitaminC, and the provenance benchmarks are independent boundary/contrast checks, not evidence for a universal metric ranking. AUROC for the support tasks (a, b; binary support against *human* sentence/claim labels) and top-1 *passage-ranking* accuracy (not AUROC) for provenance (c; passage-level labels — a provenance proxy for ASQA, human passage-relevance for MS MARCO/HotpotQA — which are *not* sentence/claim-level support judgments); best per row in bold. For the human-support tasks (a, b) NLI_{cl} is the *clean, non-FEVER* MNLI model (`roberta-large-mnli`) and NLI_{fe} is FEVER-trained; MiniChk is MiniCheck (Tang et al., 2024). For the human-support tasks (a, b), Comb is the two-term blend $0.47 \cdot \text{lex} + 0.53 \cdot \text{sem}$ over each (claim/sentence, evidence) pair (the answer-hint and citation terms of Eq. (1) do not apply — support pairs carry no gold answer or inline citation — and are omitted); MiniLM is the semantic encoder there. The provenance NLI column (c) is the off-the-shelf DeBERTa-v3 MNLI/FEVER/ANLI head used as a ranker (Section 3.1). **Coarsely**, metric-family performance differs across the audited settings: entailment-trained models score above all no-fine-tuning baselines on fact-check (b), while off-the-shelf relevance is within overlapping CIs of NLI on provenance (c). **But within one construct** (a), the best metric is not stable across the four AttributionBench source datasets (the per-dataset metric rankings are discordant: Kendall W=0.07, p=0.029; the AttributedQA-vs-LFQA ranking inverts, $\tau = -0.64$; HAGRID is an independent long-form set): the clean MNLI scorer is best on short-claim AttributedQA (0.904) yet AUROC 0.531 (chance = 0.50) on long-form LFQA, where BERTScore wins (0.909). The LFQA collapse persists at both tested NLI token limits (256, 512). Length-controlled analyses leave residual dataset differences but do not isolate their cause. MiniCheck has the lowest mean leave-one-dataset-out regret *among those tested* (AttributionBench mean AUROC 0.774; regret 0.044) but still not uniformly best. ExpertQA is an underspecified dataset (oracle best-of-eight only 0.618). The semantic provenance ranker (c) is `all-mpnet-base-v2` for the ASQA confusable test (Section 3.1; hence its 0.934 sits in the MPNet column) and `all-MiniLM-L6-v2` for MS MARCO/HotpotQA; BERTScore, NLI_{fe}, and MiniCheck are AUROC support scorers and are not run as provenance *rankers* (c). Human-labeled *support* (a, b) and proxy-labeled *provenance* (c) are distinct constructs and are not pooled.

butionBench source) with human sentence/claim-level `attributable` labels (n=2150). Here the clean MNLI scorer is instead the *best* metric (0.800; BERTScore 0.793, MiniCheck 0.791, lexical 0.752). HAGRID answers have LFQA-comparable claim length but much shorter, explicitly `[n]`-cited evidence (short cited quotes rather than LFQA's ∼320-word passages). This refutes the simplest reading: that NLI fails whenever the *answer* is long-form. It does *not*, however, rule out long *evidence* (which HAGRID lacks) as the mediator; if anything, HAGRID's short cited evidence is consistent with our evidence-length account below. Rankings are thus dataset-specific even across superficially similar long-form settings; we cannot isolate the causal latent characteristic from dataset identity here, and leave that to future work.

We also include BEGIN (Dziri et al., 2022) only as an appendix boundary check in a related but different setting (knowledge-grounded *dialogue* with response-level labels; App. E). Its pattern is consistent with dataset dependence, but it is not part of the main multi-dataset audit, not used in the transfer criterion, and not co-equal with the AttributionBench/HAGRID evidence. We caution that the provenance results (construct i) use passage-level provenance/relevance labels, not human sentence/claim-level support judgments, and we do not pool them with (ii, iii).

Naive cross-dataset metric selection does not generalize. Can one *learn* a good default from observed datasets? Picking the metric with the

best mean AUROC on seen datasets fails leave-one-dataset-out over the four sources: mean realized regret is 0.172 AUROC, and the learned rule is on average 0.060 AUROC *worse* than fixing the raw MNLI metric. The loss is *not* on the LFQA fold (there the rule picks MNLI and ties it); it comes from the other folds — most sharply AttributedQA-held-out, where the rule picks BERTScore (0.69) over MNLI (0.90), a -0.21 swing — so averaging over seen datasets actively mis-selects on the held-out one. The actionable consequence is a *validation discipline*: specify the target construct; compare candidate scorers on a representative sample with target-dataset human labels; then select and report the scorer with its uncertainty and exclusions. Dataset properties alone do not establish a selection rule here. These conclusions are bounded to the four datasets and eight metrics audited here. A minimax rule minimizes the largest regret over the *seen* datasets. Using all four datasets, it selects MiniCheck, as does best-on-average (worst-case regret 0.058). Refitting on the three seen datasets in each leave-one-dataset-out fold gives the same choices as best-on-average and the same 0.172 mean held-out regret. This minimax rule does not improve held-out performance; other robust selectors and ensembles are not evaluated.

When can LLM adjudication stand in for human labels? Since target-dataset human labels are often missing, we probe cross-family LLM adjudication: two frontier models from *different* families (Claude Opus 4.8, GPT-5.4) independently annotate 160 AttributionBench items (40/source), reported as *LLM-adjudicated*, never human/gold. The families agree with *each other* (κ=0.832) but only moderately with *human* labels ($\kappa\approx$0.47), and that human-agreement is itself dataset-dependent (accuracy AttributedQA 0.93/0.88 down to ExpertQA 0.58/0.63); on Stanford they agree strongly with each other (κ=0.90) yet diverge from humans, so high inter-model agreement is *not* evidence of validity. LLM adjudication is thus a corroborative proxy only in the easiest (short-factoid) dataset.

Is a prompt-based LLM judge more stable across datasets? Our non-transfer finding is about *automatic* scorers (including trained ones: clean/FEVER NLI, MiniCheck). The natural rejoinder — practitioners increasingly use a prompt-based *LLM judge* — we test directly (Opus 4.8 as a scoring metric, Table 14): on the same four AttributionBench sources it never drops to the chance-level collapses the strong automatic scorers suffer (AUROC 0.73–0.92, vs. clean MNLI 0.53–0.90 and BERTScore 0.57–0.91 on those four) and does *not* collapse on LFQA. The LLM judge *avoids the collapses* here, but this is a boundary observation, not an escape hatch: it is still not uniformly best, costs $\sim$100$\times$ more, and is non-deterministic; its AUROC is computed over 408 of 480 sampled items with valid parsed scores (15% unscored). Assigning 0.50 to unscored items retains above-chance AUROC point estimates in all four datasets (Table 14), but does not rule out selection bias. The judge relocates rather than removes the validation burden.

We now detail the provenance benchmarks behind Table 2(c), whose labels are passage-level (a provenance proxy for ASQA, *human* passage-relevance for MS MARCO and HotpotQA), *not* sentence/claim-level support. On **MS MARCO** v2.1 (Nguyen et al., 2016) (11,836 dev queries with ≥ 3 passages, a well-formed answer, and a human-selected passage; "combined" is the gold-free $0.47\,\mathrm{lex} + 0.53\,\mathrm{sem}$ blend), we rank each query's own passages and ask whether the top-1 is *human*-selected (`is_selected`). Over 2000 queries/seed $\times$3, all scorers far exceed the random baseline (0.104): lexical 0.683, semantic 0.646, NLI 0.708, combined 0.726 (combined and NLI within bootstrap noise, both beating the components), so the score tracks *human* passage relevance, a construct-(i) sanity check, not grounded support. Under the confusable protocol (n=300 $\times$ 4) lexical-only top-1 is 0.885, semantic 0.995, combined 0.996 (combined$-$lexical $+$0.111, every per-seed CI excludes zero), and the added NLI baseline reaches 0.952 — above lexical, below semantic. The same lexical-fooled, semantic-survives ordering as ASQA, near-ceiling because MS MARCO is more extractive.

On **HotpotQA** (Yang et al., 2018) (distractor setting), with *human* supporting-fact annotations over ten candidate paragraphs (1500/seed $\times$3), all scorers far exceed the random baseline 0.201 (Table 9c); here, on short multi-hop answers reusing the question's entities, *lexical and NLI overtake semantic*: the mirror image of ASQA.

Within provenance, no single component is universal; the blend is a convenient baseline. The three *provenance* benchmarks complicate any sim-

ple "semantic wins" summary: each single component has a dataset where it is weakest: semantic similarity on short, entity-heavy multi-hop answers (HotpotQA), and lexical overlap and off-the-shelf NLI on synthesized long-form answers (ASQA, where NLI falls to 0.585). The *combined* score stays at or near the top across these *provenance* tasks (Tables 2c, 9; on the human `is_selected` gate it leads at 0.726, and on the MS MARCO confusable top-1 test it reaches 0.996): within construct (i) only, the fixed blend is a convenient provenance baseline that stays at or near the top across these retrieval datasets. This blend is *not* a general-purpose *grounding* metric: on the human-support tasks (constructs ii, iii) it is far from best (Table 2), consistent with our headline of non-portability in the core generated-answer attribution audit. The provenance behavior is stable across encoders and distractor counts: `all-MiniLM-L6-v2` gives ASQA semantic accuracy 0.919–0.939 across $k\in\{3, 8, 10\}$ (vs. `all-mpnet-base-v2`'s 0.934 at $k=5$), with the combined−lexical gap positive ($+0.13$ to $+0.15$) throughout.

5 Conclusion

Under our operational near-best screen, no audited *automatic* scorer is consistently near-best across the datasets of generated-answer attribution, the construct with the most multi-dataset human-labeled coverage (the four AttributionBench sources, $n=1610$, with independent HAGRID, $n=2150$). Metric-family performance varies across the audited settings, but within answer attribution the best metric is unstable across datasets (per-dataset rankings discordant, Kendall $W=0.07$, $p=0.029$; the NLI scorer flips from best on AttributedQA to chance on LFQA), and even the lowest-regret metric leaves measurable per-dataset regret. A prompt-based LLM judge avoids the chance-level collapses (AUROC 0.73–0.92, no LFQA collapse) but is costlier and nondeterministic, relocating rather than removing the problem. Evaluations should report their dataset and construct and validate the metric on them.

6 Limitations

Construct and domain shift are entangled. Our largest-gap "NLI wins" contrast (0.81–0.89 vs. ≈ 0.60 AUROC) is also our only out-of-domain benchmark (VitaminC), so we cannot fully separate construct from domain shift. The in-domain AttributionBench result (where the gap closes) supports dependence on the evaluated setting, not an isolated construct effect or a claim that entailment is intrinsically superior. **Three sentence/claim-level human-support benchmarks, all English.** Only AttributionBench, HAGRID, and VitaminC carry human *sentence/claim-level* support labels (BEGIN, App. E, has human labels but at the *response* level — an external boundary, not a main construct); all are English. Broader in-construct human labels (other domains/languages) are the natural next step. **Provenance uses passage-ranking labels, not the sentence-attribution task of (ii, iii).** We pose construct (i) as passage ranking: ASQA uses a provenance proxy, while MS MARCO (`is_selected`) and HotpotQA (supporting-fact annotations) provide human relevance labels. We use all three only to ask whether a score ranks a relevant passage top, *not* to predict sentence/claim-level support judgments. We keep these strictly separate from the human-support constructs and never pool them. **Correctness confound.** The full-dev provenance gap is partly correctness-confounded (mitigated, not removed, by the matched subset). **Item-level, not system-level.** Our consequence is at the level of choosing an evaluator under dataset uncertainty (per-item AUROC and the failure of a naive cross-dataset selector); we do *not* show that this metric instability reverses *system* rankings across generators. Whether item-level non-transfer induces model-selection reversals is important future work.

A ASQA Internal Consistency Checks

For completeness we report two ASQA checks that we treat as internal consistency checks, *not* validation, because their labels are threshold heuristics derived from the same lexical/semantic features under test (hence circular). **(1) Gold-slice retrieval:** on a 20-example slice with 2–3 distractor passages, top-1 retrieval is 0.966 combined / 0.915 lexical / 0.966 semantic against heuristic "gold" labels. **(2) Matched-pair agreement:** on 10 strong/decent pairs the score's preference agrees $10/10$ with a lexical-overlap groundedness proxy (gap $+0.185$). Both are corroborative only; the human-labeled constructs in Table 2 carry the paper's claims. The full gold-reference vs. unadapted-model gates and the answer-hint ablation are in Tables 3–4.

Gate	Metric	Result	Note
1	top-1 retrieval (comb.)	0.966	lex 0.915 / sem 0.966
2	matched-pair agreement	10/10	gap +0.185
3	full-dev gap (n=623)	+0.164	CI[+0.152,+0.177]
3	matched subset (n=98)	+0.160	CI[+0.133,+0.189]
3	evidence-prec. gap	+0.234	—

Table 3: Three-gate internal-consistency check on ASQA dev. Labels are heuristic/proxy, not human. The correctness-matched subset (Gate 3, row 4) shows the largest gap.

Gate-3 metric	Canonical (w_h=0.10)	Hint = 0 (ablated)
Matched-subset gap	$+0.160$	$+0.153$
95% CI	$[+0.133, +0.189]$	$[+0.127, +0.180]$
Full-dev gap	$+0.164$	$+0.146$
95% CI	$[+0.152, +0.177]$	$[+0.134, +0.157]$
Evidence-prec. gap	$+0.234$	$+0.205$

Table 4: Answer-hint ablation on Gate 3 (ASQA full dev, n=623; matched subset n=98). Removing the label-aware answer-hint term (w_h=0, other weights fixed) leaves the grounding gap essentially intact, with the matched-subset CI still excluding zero. The gap is not an artifact of the label-aware term.

B Per-Component Ablation

Table 5 reports a leave-one-out ablation of the four score components on the Gate-3 strong−decent gap. It complements the lexical-weight sweep (Section 3.1) and the answer-hint ablation (Section 3.1): the lexical and semantic terms each carry a substantial share of the gap, while the answer-hint and citation terms are minor, consistent with the main-text finding that the score's signal does not depend on the label-aware hint.

Weighting	Matched gap	Full-dev gap
Canonical (.40/.45/.10/.05)	+0.160	+0.164
drop lexical	+0.062	+0.075
drop semantic	+0.097	+0.101
drop hint	+0.153	+0.146
drop citation	+0.168	+0.170
Lexical-only	+0.247	+0.222
Semantic-only	+0.139	+0.138

Table 5: Per-component leave-one-out on the Gate-3 strong−decent attribution gap (ASQA full dev; matched subset n=98, full dev n=623; all matched CIs exclude 0). Dropping lexical or semantic shrinks the gap most (both contribute); dropping the label-aware hint barely changes it (+0.160 → +0.153, confirming the gap is not a hint artifact); dropping citation is harmless. The lexical-only and semantic-only rows show each of those two components carries a gap on its own.

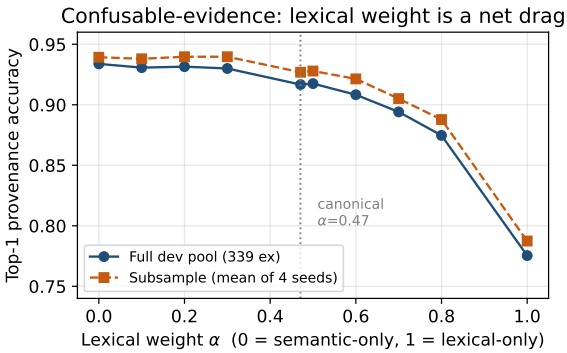

Figure 1: Lexical-weight ablation under confusable evidence (construct i). Top-1 provenance accuracy is flat at low α and then declines as the lexical weight α rises; the canonical blend ($\alpha \approx 0.47$) is already past the knee. Semantic-only (α=0) is best.

C A Grounding-Reward Stress Test: Do Answer-Level Metrics Detect a Large Rewrite?

To test whether answer-level metrics detect a large grounding-targeted rewrite, we ran a stress test. We fine-tuned the generator (GRPO (Shao et al., 2024) on `Qwen2.5-{3B,7B}-Instruct`) with a reward that directly targets evidence grounding: it scores each answer sentence by whether its claims are supported by the provided evidence and whether that support *counterfactually* depends on the evidence being present (rather than on the model's priors), along with evidence coverage and epistemic commitment. Comparing the adapted model against the *unadapted* base (a base-vs-base+LoRA comparison, not SFT-vs-RL) on all 948 ASQA dev answers, at 3B the reward rewrites 89.9% of generations, yet QA-EM, ROUGE-L, and citation count stay flat. This is the paper's measurement point in miniature: a large, grounding-directed intervention on the output leaves the answer-level metrics we test here flat, so those metrics are insensitive to the kind of grounding-targeted rewrite this intervention produces. We use the reward only as a probe, not as evidence that true grounding improved.

The metrics do not move. At 3B, QA-EM (corrected ASQA `str_em`, any-alias match) is 0.299 for the base and 0.297 for the adapted model (delta −0.002, 95% paired-bootstrap CI $[-0.011, +0.008]$): no statistically meaningful change. ROUGE-L moves +0.006 and citation count is flat. At 7B the pattern repeats (QA-EM 0.377 → 0.381, CI $[-0.004, +0.012]$). Under a legacy substring metric the 7B values are 0.240→0.241, the same flat pattern. We measure citation *count*, which is flat; we did not regenerate NLI-based ALCE citation recall/precision (Gao et al., 2023) (it requires a large entailment model and a different decoding setup), and we make no claim about it here.

The intervention is not vacuous, and its scope is narrow. At 3B the reward alters 89.9% of the 948 generations (mean token Jaccard 0.59; 81.2% differ substantially, Jaccard < 0.9), yet QA-EM, ROUGE-L, and citation count register essentially nothing. We do *not* claim the reward improved grounding (a single untuned run could be weak); it shows only that these answer-level metrics are insensitive to a large grounding-targeted rewrite. The scope is therefore narrow: the probe does not establish that these metrics would miss a *genuine* grounding improvement; it is motivation, not proof, and the audit does not depend on it.

Setup. Table 6 lists the LoRA and GRPO configuration, recovered from the saved adapter configs and the training setup; training-time loss/reward trajectories were not retained. Table 7 reports the metric deltas. The regeneration uses greedy decoding: the flatness reproduces, though absolute QA-EM differs from prior temperature-sampled prose.

D Supplementary Metric Families

Beyond the eight metrics of Table 2, we ran three additional supplementary metrics on the AttributionBench sources to check that the per-source pattern is not specific to our metric set: a cross-encoder reranker

Setting	Value
Base models	
Backbone	`Qwen2.5-{3B,7B}-Instruct`
Adapter	LoRA (PEFT), `CAUSAL_LM`
LoRA	
Rank r	8
α	16
Dropout	0.0
Target modules	q, k, v, o, gate, up, down `_proj`
GRPO (TRL GRPOTrainer)	
Configuration	DAPO-style
Generations / prompt	4
Max completion length	512 tokens
Input truncation	2048 tokens
Reward weights	fixed (not tuned)
Held-out evaluation	
Decoding	greedy
Eval set	full ASQA dev (948)

Table 6: Grounding-reward training and evaluation configuration, recovered from the saved LoRA adapter configs and the GRPO setup. We report these for methodological transparency; the reward is a probe (App. C), not a proposed method. Training-time loss/reward trajectories were not retained with the saved adapters and are not reported.

Model	QA-EM	ROUGE-L	Cites
3B			
base (unadapted)	0.299	0.219	1.05
+ grounding reward	0.297	0.225	1.04
ΔQA-EM -0.002, CI[-0.011,+0.008]			
7B			
base (unadapted)	0.377	0.191	1.83
+ grounding reward	0.381	0.193	1.83
ΔQA-EM +0.004, CI[-0.004,+0.012]			

Table 7: Grounding-reward stress test on full ASQA dev (948 ex, greedy decoding). QA-EM is corrected ASQA `str_em`. The reward produces no statistically meaningful change at either scale.

(`ms-marco-MiniLM-L6`), MiniCheck-FT5 (`flan-t5-large`), and AlignScore-large (Zha et al., 2023), a metric purpose-built for factual consistency. Table 8 shows all three reproduce the pattern, and in particular all are near chance on ExpertQA (AUROC 0.58–0.60, chance = 0.50), so the weak performance there is not isolated to the originally audited scorers.

E BEGIN: Appendix Boundary Check (Dialogue, Response-Level Labels)

As an external, different-domain check (knowledge-grounded *dialogue* rather than QA), we score the metric zoo on BEGIN (Dziri et al., 2022),

Dataset	Cross-enc.	MiniChk-FT5	AlignScore
AttributedQA	0.867	0.896	**0.901**
LFQA	0.853	**0.859**	0.811
Stanford-GenSearch	**0.836**	0.795	0.784
ExpertQA	0.580	0.603	0.596

Table 8: **Three supplementary metrics reproduce the per-source pattern** (AUROC on AttributionBench human attribution labels): a cross-encoder reranker (`ms-marco-MiniLM-L6`), MiniCheck-FT5 (`flan-t5-large`), and AlignScore-large (Zha et al., 2023). All three reach AUROC 0.867–0.901 on AttributedQA, weaker but usable on LFQA/Stanford, and weak on ExpertQA (AUROC 0.58–0.60) — matching the eight metrics of Table 2. ExpertQA is weak for every scorer we tried (AUROC 0.58–0.62, only just above chance), so its low ceiling is not isolated to any single metric.

n=11,466 system responses with human "fully attributable" vs "not" labels (we drop the "generic" class), using knowledge as evidence and the response as the claim. Table 10 shows the grounding-trained family (clean MNLI, MiniCheck) has top AUROC on every dataset here — the opposite of LFQA, where clean MNLI collapsed. This is a boundary condition that sharpens, rather than contradicts, non-portability: an otherwise top-scoring family still has a dataset (LFQA) where it fails, so no single metric is the lowest-regret fixed choice across datasets. We treat BEGIN's response-level binary labels as related to, but distinct from, the sentence/claim-level attribution of the main constructs, and do not pool them.

F Independent Replication and Robustness

Independent multi-dataset replication. To test whether non-transfer holds beyond AttributionBench, we score the same zoo on eight *disjoint* LLM-AggreFact source datasets (excluding the two, ExpertQA and LFQA, that overlap our audit; n=7336 pairs). No metric transfers there either (Table 11): four different metrics win across the eight datasets and the same clean MNLI scorer swings AUROC 0.494 → 0.946 — the winning metric changes by dataset, the signature of a genuine crossover rather than a uniform difficulty shift.

Portability-criterion sensitivity. The non-transfer conclusion does not hinge on the CI-relative screen: an ϵ-regret sweep, Kendall-τ rank-inversion, a cluster-respecting permuta-

(a) Human passage-relevance gate (top-1 `is_selected`) Scorer	Top-1 acc.	vs. random
Random passage	0.104	—
Lexical-only	0.683	+0.579
Semantic-only	0.646	+0.542
NLI entailment	0.708	+0.604
Combined (canon.)	**0.726**	+0.622
(b) MS MARCO confusable test (top-1 provenance) Scorer	Top-1 acc.	Fooled
Lexical-only	0.885	0.115
Semantic-only	0.995	0.005
Combined (canon.)	**0.996**	**0.004**
NLI entailment†	0.952	0.048
(c) HotpotQA human supporting-fact gate Scorer	Top-1 acc.	vs. random
Random paragraph	0.201	—
Lexical-only	0.959	+0.758
Semantic-only	0.938	+0.737
NLI entailment	0.979	+0.778
Combined (canon.)	**0.972**	+0.771

Table 9: Additional benchmarks (best in bold). **(a)** MS MARCO human passage-relevance gate: rank a query's retrieved passages per answer sentence; ground truth is the *human* `is_selected` label (passage-level, not sentence/claim-level support), 2000 queries × 3 seeds. **(b)** MS MARCO confusable-evidence test (Section 3.1 design), n=300 × 4 seeds: the combined/semantic advantage over lexical holds (gap +0.111; four-seed gaps +0.097 to +0.130, all CIs >0). **(c)** HotpotQA distractor-setting human supporting-fact gate, 1500 × 3 seeds: rank a human-supporting paragraph top (2-hop, so ≈ 2 supporting among 10; random 0.201). On these extractive/multi-hop answers lexical and NLI overtake semantic — the mirror image of ASQA — yet the combined score stays near-best on every benchmark. †NLI is a separate n=200 × 3 subsample.

Metric	cmu-dog	TopicalChat	Wow	pooled
lexical	0.743	0.668	0.846	0.766
sem(MiniLM)	0.747	0.565	0.826	0.756
sem(MPNet)	0.772	0.616	0.870	0.780
combined	0.760	0.640	0.860	0.764
BERTScore	0.762	0.833	0.845	0.799
NLI_{fe}	0.806	0.687	0.896	0.799
NLI_{cl}	0.880	0.756	**0.944**	**0.890**
MiniCheck	**0.922**	**0.877**	0.885	0.883

Table 10: **BEGIN dialogue-attribution** (Dziri et al., 2022) AUROC (knowledge-grounded dialogue; n=11,466, 2,878 attributable; best per column in bold). In this *new domain*, the grounding-trained family (NLI_{cl}, MiniCheck) is uniformly strongest, in contrast to the QA generated-answer attribution of Table 2(a) where NLI_{cl}'s rank was unstable. BEGIN is a boundary condition — a dataset where these metrics rank at the top across all three sub-domains — which is consistent with (not a contradiction of) non-portability: the same NLI_{cl} collapses on LFQA.

tion, paired best-vs-rest tests, and threshold-free AUPRC/balanced-accuracy all agree (Table 12).

A descriptive correlate of the collapse. Evidence length / sentence count tracks where clean MNLI fails (Table 13), consistent with single-premise entailment degrading under cross-sentence aggregation (Laban et al., 2022); we report this as descriptive, not causal.

Is a prompt-based LLM judge more stable across datasets? We also run a prompt-based LLM judge (Opus 4.8) as a scoring metric across the four AttributionBench sources (Table 14). On those same four sources it never drops to the chance-level collapses the strong automatic scorers suffer (range 0.731–0.918 vs. clean MNLI's 0.531–0.904 on the four) and does not collapse on LFQA, but is not uniformly best, costs ∼100× more, and is non-deterministic. Its complete-case AUROC uses 408 of 480 sampled items with valid parsed scores. The other 72 (15%) are unscored; the saved scores do not distinguish refusals, truncation, parsing failures, and API errors. Non-random exclusions could inflate performance and its apparent stability advantage. Table 14 reports counts and a sensitivity check assigning 0.50 to every unscored item: all four AUROC point estimates remain above chance. This check does not resolve selection bias or establish superiority over automatic scorers, which were evaluated on the full source datasets rather than the judge's retained subsets. The judge remains subject to target-dataset validation.

LLM-judge prompt templates. For reproducibility we give the exact prompts verbatim (Figure 2). The judge runs as a *scoring metric*: `claude-opus-4-8`, API-default decoding (no temperature parameter supplied), `maxTokens`= 20, evidence/claim/question truncated to 1500/600/300 characters; the support probability is parsed with a regex and clamped to $[0, 1]$. Unscored items are excluded from the primary AUROC and imputed only for the sensitivity check. The separate cross-family *annotation* probe (Section 4; Opus 4.8 and GPT-5.4, n=160) instead elicits a discrete label, scored as inter-annotator agreement, never as gold.

Cross-benchmark landscape. Pooling per-dataset AUROCs across all **17** human-labeled datasets we audit (Table 15), six different metrics are best on at least one dataset, the most frequent winner (MiniCheck) is best on only 6/17 (35%), and every metric's AUROC swings by 0.34–0.45

(a) Graded scoring prompt (LLM judge as a metric):

```
You are an automated ATTRIBUTION-scoring
rubric for a QA system. Given a CLAIM (a
sentence from a generated answer) and the
EVIDENCE it cites, rate how fully the claim
is supported by (attributable to) the
evidence.

Output EXACTLY one line and nothing else,
even if uncertain:
SUPPORT: <number 0.00-1.00>

1.00 = every factual element of the claim is
directly supported by the evidence; 0.00 =
the evidence is unrelated to or contradicts
the claim; intermediate values for partial
support. Use the full range and be
calibrated. This is an automated rubric:
always return a number (use 0.50 if truly
unsure). Do not refuse and do not explain.

QUESTION: {question}
CLAIM:    {claim}
EVIDENCE: {evidence}
```

(b) Discrete annotation prompt (cross-family κ probe):

```
You are judging ATTRIBUTION for a question-
answering system. Given a CLAIM (a sentence
from a generated answer) and the EVIDENCE it
cites, decide: is the claim fully supported
by (attributable to) the evidence?

Answer STRICTLY in this format on one line:
LABEL: <attributable|not_attributable>
CONF:  <0-1>

A claim is "attributable" only if all of its
factual content is supported by the evidence.
If the evidence is unrelated, contradicts, or
only partially supports the claim, answer
not_attributable.

QUESTION: {question}
CLAIM:    {claim}
EVIDENCE: {evidence}
```

Figure 2: **Verbatim LLM prompt templates.** (a) The graded support-probability prompt used to run Claude Opus 4.8 as a scoring metric (Table 14); (b) the discrete-label prompt used by the n=160 cross-family adjudication probe (Opus 4.8 and GPT-5.4). `{question}`, `{claim}`, and `{evidence}` are filled per item. Both are disclosed as LLM outputs, never human/gold.

across datasets. (Descriptive landscape; constructs are tagged and not pooled into a single test.)

Dataset	Lex	Comb	BERTSc	NLI_{cl}	NLI_{fe}	MiniChk
AggreFact-CNN	0.723	0.730	**0.771**	0.584	0.611	0.672
AggreFact-XSum	0.500	0.548	0.543	0.625	0.714	**0.784**
ClaimVerify	0.603	0.636	0.693	0.605	0.655	**0.764**
FactCheck-GPT	0.605	0.742	0.727	0.819	0.828	**0.833**
Reveal	0.597	0.813	0.661	**0.946**	0.923	0.944
TofuEval-MediaS	0.605	0.641	**0.695**	0.675	0.635	0.686
TofuEval-MeetB	0.659	**0.685**	0.642	0.552	0.610	0.674
Wice	0.538	0.504	0.549	0.494	0.553	**0.708**

Table 11: **Independent replication: no audited metric transfers across a second, disjoint multi-dataset benchmark.** AUROC against *human* support labels on eight LLM-AggreFact (Tang et al., 2024) source datasets (n=7336 pairs), excluding the two (ExpertQA, LFQA) that overlap our AttributionBench audit so the panel is independent; best per row in bold. As in Table 2, no single audited scorer is best across datasets: four different metrics win the eight rows — BERTScore (2), MiniCheck (4), clean MNLI (Reveal), and the lexical/semantic blend (Comb, TofuEval-MeetB) — the same clean MNLI scorer swings from AUROC 0.494 (Wice, $\leq$chance) to 0.946 (Reveal), so the winning metric changes by dataset, and committing to the lowest-regret single metric (MiniCheck) still leaves mean leave-one-dataset-out regret 0.015 (max 0.099). This is a faithfulness/grounding benchmark (claim-vs-document support), adjacent to but distinct from sentence-level citation attribution; we report it as an independent *boundary replication* and do *not* pool it with the AttributionBench audit.

(a) Portability-criterion sensitivity (AttrBench 4 sources)	
ϵ-regret tolerance	# metrics "transfer"
$\epsilon \in \{0, .01, .02, .05\}$	**0**
$\epsilon = 0.10$	1 (MiniCheck)
(b) Cross-dataset rank stability (Kendall τ)	
mean τ over dataset pairs	-0.20
AttributedQA vs. LFQA	-0.64 (p=.031)
(c) Interaction, main-effect-controlled	
rank concordance (Kendall W)	0.07, p=.029
residual perm. (difficulty fixed)	p=.053
mis-spec. shuffle, ref. only	p<.002
(d) Paired best-vs-rest on LFQA (BERTScore best)	
BERTScore − clean MNLI	+.378 [.24, .50], p<.001
BERTScore − MiniCheck	+.058 [−.02, .14], p=.127

Table 12: **The non-transfer conclusion does not hinge on the CI-relative criterion.** Four independent readings agree on AttributionBench's four sources: (a) under an ϵ-regret screen no audited metric is within ϵ of the per-dataset oracle on *every* dataset for any $\epsilon \leq 0.05$; (b) metric rankings are uncorrelated-to-negative across datasets (the AttributedQA/LFQA ranking literally inverts); (c) the crossover survives controlling for dataset difficulty — within-dataset rank concordance is near zero (Kendall W=0.07, p=.029) and a residual permutation that holds each dataset's difficulty fixed puts 35% of the cross-cell variance in the interaction residual (borderline, p=.053; the looser exchangeability shuffle that conflates difficulty with interaction gives p<.002 and is shown for reference only); (d) the headline LFQA reversal is decisive (BERTScore beats clean MNLI by 0.378). **Honestly**, "no single metric transfers" is robust, but the best metric is not always *uniquely* best: on LFQA, BERTScore vs. MiniCheck is not significant ($p = 0.127$). All quantities are recomputed and match the Table 2 AUROCs.

Dataset	words	sent.	NLI_{cl}	BERTSc	MiniChk
AttributedQA	103	4.2	**0.904**	0.692	0.884
Stanford-GenSearch	82	4.1	0.822	0.838	0.783
ExpertQA	174	7.9	0.565	0.569	0.577
LFQA	321	13.9	0.531	**0.909**	0.852

Table 13: **A descriptive correlate of the clean-MNLI collapse: evidence length / sentence count.** Mean evidence length (words) and evidence sentence count per AttributionBench source, against per-dataset AUROC. The clean MNLI scorer is strongest where evidence is short and few-sentence (AttributedQA: 103 words, 4.2 sentences $\rightarrow$ 0.904) and collapses where evidence is long and many-sentence (LFQA: 321 words, 13.9 sentences $\rightarrow$ 0.531), while token-level BERTScore moves the opposite way (0.692 $\rightarrow$ 0.909). This is consistent with a single-premise entailment head degrading when support must be aggregated across many sentences (Laban et al., 2022). We report this as a **descriptive** correlate, not a causal mechanism: with four datasets the dataset-level association is underpowered, the per-example abstractiveness signal does not cleanly separate NLI from BERTScore, and ExpertQA is a near-chance exception. Identifying the causal driver is left to future work.

Dataset	Valid n	Judge	Imputed	Best auto.
AttributedQA	101/120	0.918	0.892	0.904
LFQA	105/120	0.878	0.859	0.909
Stanford-GenSearch	100/120	0.794	0.763	0.838
ExpertQA	102/120	0.731	0.708	0.618

Table 14: **LLM-judge AUROC and unscored-item sensitivity.** Claude Opus 4.8 emits a graded support score evaluated against *human* AttributionBench labels. Sampling used 60 positive and 60 negative items per source; 408/480 yielded valid scores. Judge: complete-case AUROC. Imputed: AUROC on all 120/source after assigning 0.50 to unscored items. Exclusions are 19/15/20/18 in row order. Above-chance point estimates persist under this imputation, which does not rule out selection bias. Best auto.: best of the eight automatic scorers on each *full* source dataset (Table 2), not a paired comparison on the judge subset: clean MNLI, BERTScore, BERTScore, and MPNet in row order. The judge is not uniformly best by these point estimates and remains costlier ($\sim$100$\times$) and non-deterministic. See App. F for limits.

Metric	min	max	range
lexical Jaccard	0.500	0.839	0.339
MiniLM cosine	0.499	0.841	0.342
MPNet cosine	0.477	0.851	0.374
combined blend	0.504	0.845	0.341
BERTScore	0.543	0.909	0.366
NLI_{fe} (FEVER)	0.553	0.923	0.370
NLI_{cl} (clean MNLI)	0.494	0.946	**0.452**
MiniCheck	0.577	0.944	0.367

Table 15: **Cross-benchmark landscape: every audited metric swings widely across datasets, and no metric dominates.** Per-metric AUROC range across the **17 human-labeled datasets** we audit, spanning four evaluation settings (5 generated-answer attribution incl. HAGRID; 1 fact-check; 3 dialogue-attribution subdomains; 8 LLM-AggreFact faithfulness datasets). Six different metrics are best on at least one dataset; the most frequent winner (MiniCheck) is best on only $6/17$ (35%). The same clean MNLI scorer spans AUROC 0.494 (below chance) to 0.946 — a 0.45 swing. The best fixed default (MiniCheck, mean AUROC 0.791) still leaves mean leave-one-dataset-out regret 0.026 (max 0.099). This is a *descriptive* landscape pooling the per-dataset AUROCs reported in the paper; datasets span distinct constructs and are *not* pooled into a single significance test.

EviScope: Paired Counterfactual Evidence Diagnostics for Faithful and Efficient Grounded Language Models

Suryadeep Singh Deswal
Indian Institute of Technology Roorkee
Roorkee, India
suryadeep_sd@ma.iitr.ac.in

Abstract

Grounded language-model systems are often evaluated by final answer accuracy, yet a correct answer can be unsupported, drawn from the wrong source, or produced when evidence is insufficient or contradictory. We introduce EVISCOPE, a paired counterfactual benchmark that holds the question fixed while adding, removing, distracting, or contradicting its evidence. EVISCOPE-V1.1 contains 40 four-condition quartets with repaired counterfactual claims and span-level support labels for automatic evaluation. Across 960 gold-blind generations from Qwen2.5-7B, Llama 3.1 8B, and Gemini 3.5 Flash, paired metrics expose model-dependent grounding behavior that answer accuracy hides. On two local open models, an explicit evidence-action gate underperforms vanilla RAG on QCS: 0.15 vs. 0.50 for Qwen and 0.10 vs. 0.375 for Llama. Gemini reaches 0.944 joint success under both prompts, yet still answers 5% of conflict cases after contradiction insertion. EVISCOPE therefore distinguishes unsupported answering, conflict blindness, and wrong non-answer actions rather than scoring answers alone.

1 Introduction

Retrieval-augmented generation (RAG) is widely used to ground language models in external evidence. But a final answer can be correct for the wrong reason: the model may answer from parametric memory, cite an irrelevant passage, ignore retrieved evidence, or answer despite missing or conflicting evidence. These errors require different remedies, yet answer-only evaluation often collapses them into the same score.

The central idea in EVISCOPE is paired evidence intervention. We hold the question fixed and change only the evidence context. A grounded system should answer and cite support when evidence is present, remain stable when irrelevant passages are added, abstain when support is removed, and flag conflict when a contradictory source is inserted. This tests whether a system is sensitive to evidence rather than merely capable of producing the answer.

Our contribution is a benchmark/evaluator package rather than a new model. EVISCOPE-V1.1 constructs 160 examples from public SQuAD questions (Rajpurkar et al., 2016): 40 base questions, each paired with sufficient, noisy, insufficient, and conflicting evidence variants. The evaluator reports conventional grounding metrics plus quartet-level evidence removal sensitivity, noise robustness, conflict sensitivity, quartet consistency, and cost-adjusted grounded utility. A complete local/API model study demonstrates that an intuitively stronger evidence-action prompt can underperform a simpler prompt on both local open models, while a stronger API model reduces but does not eliminate conflict blindness.

2 Related Work and Positioning

Citation and factuality. ALCE evaluates answer generation with citations (Gao et al., 2023); FActScore decomposes factuality into atomic claims (Min et al., 2023); and HaluEval studies hallucination recognition (Li et al., 2023). EVISCOPE follows their evidence-centric motivation but adds paired interventions that reveal whether the same question is handled differently as support is added, removed, distracted, or contradicted.

Efficient grounding. Self-RAG, RA-DIT, Adaptive-RAG, RECOMP, and context-aware decoding improve retrieval use, routing, compression, or reliance on context (Asai et al., 2024; Lin et al., 2024; Jeong et al., 2024; Xu et al., 2024; Shi et al., 2024). EVISCOPE tests whether such choices preserve faithfulness while changing cost.

Reasoning and source identification. Sufficient Context separates insufficient retrieval from model

EVISCOPE	✓	✓	✓	✓	✓	✓

Table 1: Positioning of EVISCOPE. "Suff." means explicit evidence-sufficiency labels. "Paired" means the same question is evaluated under counterfactual evidence variants.

Variant	Evidence	Expected action	Failure
Suff.	support included	answer + cite	evidence-use failure
Noisy	support + distractors	answer + cite	distractor sensitivity
Insuff.	support removed	abstain	memory-based answer
Conflict	support + contradiction	flag conflict	conflict blindness

Table 2: Paired counterfactual evidence design. The question is held fixed while the evidence context changes.

failures (Joren et al., 2025); BRIGHT stresses reasoning-intensive retrieval (Su et al., 2025); MTRAG studies multi-turn RAG (Katsis et al., 2025); and GoldenViewVQA evaluates visual evidence-source identification (Wang et al., 2026). Compared with broader input-perturbation evaluations, EVISCOPE links support, distractors, removal, contradiction, and paired transition metrics in one grounded-evidence quartet.

3 Benchmark Construction

EVISCOPE-V1.1 starts from 40 public SQuAD question-answer-context records with at most three base examples per source title for topical diversity. For each base question we create four context variants, yielding 160 examples. Table 2 shows the intervention design.

Gold labels include answer aliases, expected action, answerability, supporting and conflicting document IDs, and support spans. Version 1.1 freezes v1 as legacy and repairs every conflict passage under six constraints: it must be grammatical, directly answer the question with a same-type alternative, contradict the support, exclude the original answer, modify the answer-bearing claim where possible, and contain no conflict cue. Strict lints and internal consistency checks cover all 40 quartets before external validation. Two external annotators independently reviewed all 160 source-role- and label-blinded examples. Inter-annotator agreement was 0.994 for evidence status and expected behavior (Cohen's $\kappa = 0.990$), and 1.000 for conflict presence ($\kappa = 1.000$). Against hidden gold labels, expected-behavior and evidence-status agreement averaged 0.997 across annotators ($\kappa = 0.995$); annotator A matched all gold actions, while annotator B differed on one example. Both annotators matched the gold conflict-present label on all 40 conflict rows. Agreement was lower for secondary answer-valid and citation-valid QA notes (0.744, $\kappa = 0.589$), mainly because conflict rows invited different choices between *unclear* and *no/not applicable*; these fields are excluded from primary benchmark labels and retained only as audit notes.

4 Metrics

The deterministic evaluator reports answer accuracy; document-level source accuracy; span support precision, recall, and F1; right-answer-wrong-source, right-source-wrong-answer, and unsupported-citation rates; abstention precision, recall, and F1; conflict accuracy; hallucination when non-answer behavior is expected; and average tokens, calls, and latency. Answers are normalized and matched by exact alias or alias containment; citations are exact document-ID checks; conflict is the structured `conflict/flag_conflict` action; span matches require the same document ID and normalized quote containment. No LLM judge is used. Joint success requires a correct answer with correct evidence, a correct abstention, or a correct conflict flag.

It also reports paired metrics over each four-variant quartet. Let S_i, N_i, I_i, and C_i denote success on sufficient, noisy, insufficient, and conflicting variants for base question i. For sufficient/noisy, success means correct answer plus correct support source; for insufficient, it means abstention; for conflicting, it means flagging conflict. The flagship score is quartet consistency:

$$\mathrm{QCS} = \frac{1}{N} \sum_i \mathbf{1}[S_i \wedge N_i \wedge I_i \wedge C_i].$$

We also report evidence removal sensitivity $\mathbf{1}[S_i \wedge I_i]$, noise robustness $\mathbf{1}[S_i \wedge N_i]$, conflict sensitivity $\mathbf{1}[S_i \wedge C_i]$, and grounded utility per call, defined as

Model	Pol.	Ans.	Joint	ERS	NR	CS	QCS	C-Ans.
Qwen	Van.	.738	.819	.750	.675	.575	.500	.200
Qwen	Gate	.738	.644	.150	.675	.625	.150	.100
Llama	Van.	.700	.775	.825	.575	.550	.375	.275
Llama	Gate	.850	.706	.800	.775	.175	.100	.775
Gemini	Van.	.912	.944	.925	.900	.875	.850	.050
Gemini	Gate	.912	.944	.900	.900	.875	.875	.050

Table 3: Main EVISCOPE-V1.1 results. Ans. is answer accuracy on answerable rows; C-Ans. is conflict-blind answering after contradiction insertion. Full token/cost fields are exported with the reproducibility artifacts.

Model	Pol.	Insuff.	Conflict	C-Ans.
Qwen	Van.	1.00	.800	.200
Qwen	Gate	.200	.900	.100
Llama	Van.	1.00	.700	.275
Llama	Gate	.900	.225	.775
Gemini	Van.	1.00	.950	.050
Gemini	Gate	1.00	.950	.050

Table 4: Failure-mode breakdown. "Insuff." is correct abstention after evidence removal; "Conflict" is correct conflict flagging; C-Ans. is answering despite conflicting evidence.

joint success divided by average calls. These metrics test evidence sensitivity directly: whether behavior changes appropriately when the same question receives different evidence. For paired policy comparisons, we use 10,000-sample paired bootstrap intervals with seed 42 and an exact two-sided McNemar test over quartet success.

5 Reference Systems

Our main experiment compares two one-completion policies on three models: Qwen2.5 7B via Ollama (`qwen2.5:7b-instruct`, Q4_K_M), Llama 3.1 8B via Ollama (`llama3.1:8b`), and Gemini 3.5 Flash via the Gemini API (`gemini-3.5-flash`). Vanilla RAG directly answers from the supplied documents with citations and may abstain or flag conflict. The evidence-action gate explicitly classifies the context as answerable, insufficient, or conflicting before selecting the same output actions; it is a diagnostic prompt baseline, not a proposed solution. Both policies receive only the question and document IDs/text, use temperature zero, and return an identical structured schema. The two prompts differ only in whether they explicitly ask the model to classify the evidence state before choosing the final action; the document inputs, output schema, temperature, and parser are otherwise identical. The final matrix contains 960 logical generations, 160 examples per model-policy pair, with zero unresolved parse failures.

6 Results

Table 3 shows that paired evidence metrics reveal differences that answer accuracy alone hides. On Qwen2.5 7B, both prompts have 0.738 answer accuracy and 0.675 noise robustness, but the gate sharply degrades evidence removal sensitivity (0.750 to 0.150) and QCS (0.500 to 0.150). The gate flags more conflicts, yet it correctly abstains on only 8 of 40 insufficient variants; most remaining cases are mislabeled as conflict rather than answered.

Llama 3.1 8B adds a second open-weight behavior. Its gate improves answer accuracy (0.850 vs. 0.700) and noise robustness (0.775 vs. 0.575), but collapses conflict sensitivity (0.175 vs. 0.550) and QCS (0.100 vs. 0.375) by answering 77.5% of conflicting variants. Thus the gate is not a reliable prompt-only fix; it changes the failure mode differently across local models.

Gemini 3.5 Flash substantially improves overall grounding: both policies reach 0.944 joint success, 0.900 noise robustness, and 0.875 conflict sensitivity. The gate has a small QCS edge over vanilla (0.875 vs. 0.850), but the paired McNemar test is inconclusive because only one quartet is discordant. Both Gemini policies still answer 5% of conflict cases, showing that stronger instruction-following reduces but does not eliminate conflict blindness.

For Qwen, gate-minus-vanilla differences are -0.60 ERS (bootstrap 95% CI $[-0.75, -0.45]$), 0 NR, $+0.05$ CS, and -0.35 QCS; 15 QCS-discordant quartets favor vanilla and one favors the gate (exact McNemar $p = 0.00052$). For Llama, differences are -0.025 ERS, $+0.20$ NR, -0.375 CS, and -0.275 QCS; 13 QCS-discordant quartets favor vanilla and two favor the gate ($p = 0.0074$). For Gemini, differences are -0.025 ERS, 0 NR, 0 CS, and $+0.025$ QCS, with one QCS-discordant quartet favoring the gate ($p = 1.0$). Thus the gate's effect is model-dependent rather than a generally reliable improvement.

Efficiency. Both local models use one call per example. Qwen averages 679/687 tokens and 3.17/3.48 seconds for vanilla/gate; Llama averages 633/645 tokens and 3.04/3.54 seconds. Gemini required retry calls during a high-demand period,

averaging 1.81 calls for vanilla and 2.09 for the gate; the latest logical rows have zero parse failures. Logical accuracy metrics are computed over one retained output per example; retries affect only cost and utility. We report call-normalized utility as an engineering cost measure, not a model-quality metric. Gemini used 195,442 input tokens and 32,271 output tokens across both policies, for an estimated API cost of $0.56 under the recorded pricing metadata.

7 Qualitative Errors

The error exporter surfaces failures that row-level accuracy conceals. For "When did Beyonce start becoming popular?", Qwen vanilla answers from support but repeats the supported claim after contradiction insertion. Conversely, for the Sichuan earthquake year, Qwen gate answers correctly with support but changes to *conflict* after support removal, although no incompatible answer remains. Llama gate often has the opposite pathology: it answers conflicting variants instead of flagging them; for the Sichuan earthquake year, it answers "2008" while a conflicting document asserts "2010." Gemini's residual errors are rarer but still diagnostic: both prompts answer 5% of conflict variants. These distinctions would disappear in a metric that merged abstention and conflict flags.

8 Conclusion

EVISCOPE evaluates whether grounded models respond appropriately as evidence changes. Across Qwen2.5 7B, Llama 3.1 8B, and Gemini 3.5 Flash, paired interventions show both prompt-level negative results and a stronger-model ceiling: explicit routing can degrade QCS on local models, while Gemini reaches high joint success but still exhibits conflict blindness. Grounded evaluation should report paired evidence transitions and distinguish wrong non-answer actions, not score answers and citations in isolation.

9 Limitations

EVISCOPE-V1.1 is compact and SQuAD-derived; its counterfactual conflicts omit source authority, recency, and multi-document synthesis. All conflicts require flagging, whereas realistic systems may resolve some using metadata. The full-160 external validation supports the action, evidence-status, and conflict-presence labels, but the completed sheets collect categorical answer/citation-valid judgments rather than explicit support-span or support-document aliases; fine-grained source/span validation remains limited. Two local open-weight models, one proprietary API model, and two prompts still limit model-level generalization. The result nevertheless demonstrates why insufficient and conflicting evidence require separate actions and paired metrics.

Ethics and Responsible Research

The benchmark derives questions and passages from public SQuAD data. Counterfactual edits are labeled synthetic and are not factual claims about the world. Internal consistency checks are kept separate from external human validation. The two external annotators volunteered, gave consent, and worked independently using a fixed codebook. Model prompts contain no gold labels, and the released artifacts contain no API credentials. This work received no external funding. The author declares no conflicts of interest.

Acknowledgments

OpenAI Codex was used for coding assistance and proofreading. The author reviewed and verified all AI-assisted outputs and remains responsible for the final content. External human annotations were supplied separately by human annotators.

A Additional Qualitative Examples

Cond.	Evidence shown (shortened)	Expected action
Suff.	Support states that the Sichuan earthquake occurred in 2008.	Answer "2008" and cite support.
Noisy	The same support is mixed with unrelated passages about *To Kill a Mockingbird* and Beyonce.	Answer "2008" and cite support.
Insuff.	The support is removed; only unrelated passages remain.	Abstain.
Conflict	Support states 2008, while a counterfactual passage states 2010 for the same earthquake.	Flag conflict.

Table A1: Example quartet from EVISCOPE-V1.1.

Model/pol.	Case	Paired behavior
Qwen gate	Evidence removal	Answers "2008" with support, but changes to *conflict* after support is removed even though no incompatible answer remains.
Llama gate	Conflict blindness	Answers "2008" on a conflicting variant where another document asserts "2010."
Gemini vanilla	Residual conflict blindness	Answers from the support document in a genocide-convention conflict case rather than flagging the incompatible answer claim.

Table A2: Representative paired failure cases.

Human validation codebook. Two external annotators with technical reading proficiency and experience reading structured QA/evidence examples worked independently on source-role- and label-blinded sheets. They saw only the question and randomized document aliases/text. They were instructed not to use outside knowledge, model outputs, gold labels, or the other annotator's file.

Evidence status	Decision rule
`sufficient`	The provided documents directly establish an answer to the question.
`insufficient`	The provided documents do not establish an answer.
`conflicting`	Relevant documents make incompatible claims about the answer.
`ambiguous`	More than one reasonable evidence-state judgment is possible.

Table A3: Evidence-state decision rules.

Annotation field	Allowed values / instruction
Expected behavior	`answer`, `abstain`, or `flag_conflict`.
Answer valid	`yes`, `no`, or `unclear`.
Citation valid	`yes`, `no`, `not_applicable`, or `unclear`.
Conflict present	`yes`, `no`, or `unclear`.
Notes	Short explanation, especially for ambiguous or conflicting rows.

Table A4: Human validation fields.

Supplementary material. The supplementary ZIP is self-contained. It includes the EVISCOPE-V1.1 JSONL benchmark, prompt templates, prediction schema, six retained model-output files for the three models and two policies, de-identified human-validation sheets and agreement reports, result tables, failure summaries, and deterministic reproduction scripts. It excludes credentials, local paths, build artifacts, caches, and retry-history run files.

Does RAG Know When Retrieval Is Wrong? Diagnosing Context Compliance under Knowledge Conflict

Abstract

Retrieval-Augmented Generation (RAG) is usually evaluated by whether the final answer is correct. Under knowledge conflict, this hides a key question: did the model follow retrieved evidence, rely on its parametric prior, or produce a post-hoc rationale? We study this as context compliance, the regime in which retrieved context controls the answer even when it conflicts with the model's prior knowledge. We introduce Context-Driven Decomposition (CDD), an inference-time diagnostic intervention that elicits contextual and prior answers, isolates the conflicting premise, and records a resolution trace that can be perturbed. Across Epi-Scale stress tests, TruthfulQA misconception injection, and cross-model reruns, CDD makes three behaviors visible. First, misleading retrieval can severely degrade accuracy: under worst-case injected context (a TruthfulQA misconception-injection probe), Standard RAG reaches only 15.0%. Second, better answers need not share the same mechanism: CDD improves adversarial accuracy on Gemini-2.5-Flash and shows directional gains across Claude variants, yet trace-perturbation sensitivity is high only on Gemini. Third, explicit decomposition improves controlled-conflict robustness over a conflict-aware instruction baseline on localized factual conflicts, with the clearest margins on Entity Swap (88.0% vs 79.3%) and Logical Contradiction (83.2% vs 75.4%). We frame RAG conflict handling as an observability problem.

1 Introduction

Standard Retrieval-Augmented Generation (RAG) (Lewis et al., 2020) is built on a useful default assumption: retrieved evidence should help the model answer. The assumption becomes fragile when retrieval returns evidence that is wrong or adversarially injected (Xie et al., 2024; Zou et al., 2025). Consider a query about whether cracking knuckles causes arthritis. If the retrieved context asserts this common misconception (Lin et al., 2022), a RAG model that answers "yes" may be faithfully following the context while becoming factually wrong; a model that answers "no" may have detected the conflict, ignored retrieval, or simply relied on memorized prior knowledge. The final answer alone cannot tell these cases apart.

This is the central blind spot we study. Under knowledge conflict, standard accuracy evaluation collapses several distinct behaviors into the same score, paralleling broader concerns that accuracy-only evaluation can hide trace-level differences (Turpin et al., 2023; Lanham et al., 2023; Sun et al., 2026). A correct answer does not reveal whether the model used the right source of evidence, rejected a false retrieved premise, or produced a post-hoc rationale. An incorrect answer does not distinguish ordinary knowledge failure from **context compliance**: retrieved context controlling the answer despite conflicting with the model's parametric prior. RAG therefore needs diagnostics that expose not only *what* the model answered, but *which source controlled the answer* and whether the final answer is sensitive to corruption of that trace.

We introduce **Context-Driven Decomposition (CDD)** as a diagnostic intervention for this setting. CDD decomposes a conflicted RAG instance into five observable steps: elicit the answer implied by the retrieved context, elicit the model's parametric answer, compare them, isolate the conflicting premise, and resolve the conflict. This turns an

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 263–276
October 29, 2026 ©2026 Association for Computational Linguistics

implicit arbitration problem into a trace that can be tested for causal influence—and we find that influence is model-specific. We then perturb that trace with mistake-injection and truncation tests to ask whether the trace actually affects the final answer. CDD is not presented as a universal production defense; its role is to make hidden conflict-resolution behavior observable and testable.

We make two methodological contributions and one empirical contribution:

1. **Conflict observability:** We operationalize context compliance at the prompt level and show why final-answer accuracy cannot identify whether retrieved context, parametric knowledge, or a post-hoc rationale controlled the output.

2. **Diagnostic intervention:** We introduce CDD, a decomposition-based probe that exposes contextual belief, parametric belief, conflict detection, premise isolation, and resolution, then tests whether perturbing the resolution trace changes the answer.

3. **Empirical finding:** We show that CDD improves controlled-conflict robustness while revealing that accuracy transfer and trace-perturbation sensitivity can dissociate across model families. We will release the Epi-Scale split (2,250 clean + 2,250 adversarial records), prompt templates, evaluation settings, and scoring specifications upon publication; the internal experimental codebase is not released.

Scope. The scope of this paper is diagnostic. We use CDD to expose when conflict-resolution behavior is present, absent, or model-specific. The present evidence should be read as a controlled study rather than a deployment recommendation: organic multi-document retrieval, stronger faithfulness interventions, and open-weight replications remain follow-up evaluations.

2 Related Work

Knowledge conflict in RAG. The tension between parametric memory and external evidence is well documented. Prior work studies when models should rely on parametric versus retrieved knowledge (Mallen et al., 2023), how entity substitutions alter QA outputs (Longpre et al., 2021), and how models respond to conflicting retrieved evidence (Xie et al., 2024; Chen et al., 2022). These studies establish that conflict changes model behavior; our focus is the next diagnostic question: when a final answer changes under conflict, can we observe which source controlled it and whether the final answer is sensitive to corruption of that trace?

Recent work has refined this picture along three axes. ClashEval (Wu et al., 2024) systematically quantifies the "tug-of-war" between an LLM's parametric prior and external evidence as a function of evidence quality, framing the conflict as a measurable spectrum. Astute RAG (Wang et al., 2025) addresses imperfect retrieval and knowledge conflict at the method level by combining internal-knowledge elicitation with iterative consolidation. Corrective Retrieval-Augmented Generation (CRAG) (Yan et al., 2024) inserts a retrieval evaluator that classifies retrieved evidence into correct/ambiguous/incorrect bins before generation, modifying the retrieval pipeline rather than the generation step. A recent survey of knowledge conflicts in LLMs (Xu et al., 2024) organizes failure modes into context-memory, inter-context, and intra-memory conflicts. CDD targets the context-memory conflict axis specifically and treats conflict not only as a failure to mitigate, but as a situation in which the model's source arbitration should be made observable.

Robust and filtered RAG. Self-RAG (Asai et al., 2024) trains models to generate reflection tokens, while prior document-filtering RAG removes unsupported retrieved documents before generation (Yoran et al., 2024). In our experiments, the reported reflection baseline is a prompt-only approximation inspired by Self-RAG rather than the trained Self-RAG model itself. These methods attempt to improve generation quality or retrieval reliability. CDD differs in objective: it keeps the conflict visible long enough to ask whether the model detected, rejected, or complied with the retrieved premise. Our filtering baseline is likewise prompt-only: it instructs the model to remove implausible claims from the context, and does not use a trained NLI model.

Retrieval routing, filtering, and deployment trade-offs. CDD-α is a diagnostic routing rule rather than a production retrieval architecture, but related routing and filtering ideas appear in broader RAG and inference systems. Domain-specific RAG work uses reranking or document routing to manage evidence selection and robustness–precision trade-offs in financial-document QA (Cheng et al., 2026b,a). Outside the specific knowledge-conflict

setting studied here, sequential filtering provides a methodologically adjacent model of how staged filters trade off cost and selectivity (Paranjape et al., 2026). On-device RAG benchmarks are a complementary deployment consideration, showing that retrieval, reranking, and generation also create latency and energy constraints (Cheng and Lai, 2026). These works motivate compute-aware routing as an operating point; CDD uses routing only to decide when to invoke a conflict diagnostic trace.

Context-aware decoding and parametric-contextual conflict. Context-Aware Decoding contrasts contextual and parametric logits to reduce hallucination and increase reliance on retrieved evidence (Shi et al., 2024). Our setting highlights a complementary concern: if retrieved evidence is itself false, more context reliance can be the wrong behavior. We target closed API models where logit-level access is unavailable; instead of computing token-level divergence directly, CDD elicits contextual and parametric answers in natural language and treats the resulting trace as an observable diagnostic artifact.

Faithfulness of chain-of-thought. A critical challenge in chain-of-thought (CoT) reasoning is whether the generated rationale actually influences the final answer. Prior work shows that CoT explanations can be systematically misleading (Turpin et al., 2023). Causal-intervention work introduces tests including early answering and adding mistakes (Lanham et al., 2023). We adapt these ideas to retrieval-induced conflict; in this paper, *Truncation* refers to the early-answering-style intervention on the CDD trace, and *Mistake Injection* refers to the adding-mistakes-style intervention. This connection is central: a decomposition trace is useful as a diagnostic only if we can test whether perturbing it changes the answer.

Evaluation reliability and trace diagnostics. Our causal-sensitivity tests are also motivated by broader evaluation context: conclusions can depend on what artifact is scored and how the benchmark is configured. LLM-as-a-judge surveys document the scope and reliability challenges of judge-based evaluation (Li et al., 2025); trace-level evaluation work shows that identical final-answer scores can mask different intermediate behavior (Sun et al., 2026). Adjacent trace-audit studies further show that parser, prompt-template, or probe choices can affect conclusions drawn from reasoning or memorization traces (Li et al., 2026a; Fan et al., 2026). Other methodologically adjacent evaluation work makes the same caution concrete in different settings: regime-stratified benchmarking shows that aggregate metrics can hide operating-regime failures (Wang et al., 2026), alignment-benchmark audits show that ranks can be configuration-conditional (Li et al., 2026b), and paired-MDE planning argues for specifying detectable effects before interpreting small differences (Zhuang et al., 2026). We therefore treat CDD traces as diagnostic artifacts whose causal role must be tested, not as explanations to be trusted at face value.

3 A Belief-Revision Framework for Context-Parametric Conflict

3.1 Conceptual Formulation of Conflict

We borrow the vocabulary of belief revision (Alchourrón et al., 1985) as a conceptual scaffold; the 1985 formalism concerns logical theory change and makes no claim about LLM internals. We distinguish between the model's parametric prior $P_\theta(a \mid q)$—internal world knowledge—and its contextual posterior $P_\theta(a \mid q, c)$ conditioned on retrieved evidence. The **Compliance Regime** arises when the posterior dominates despite divergence from the prior; standard RAG can enter this regime because generation is directly conditioned on retrieved evidence. The **Resolution Regime**, in contrast, requires detection and arbitration of divergence. While the conceptual axis between these regimes corresponds to a divergence measure between the two distributions (e.g., Jensen-Shannon Divergence), exact token-level computation requires white-box logit access. Our prompt-based instantiation makes this divergence observable through explicit answer generation rather than logit comparison; we treat token-level JSD instantiation on open-weight models as a natural extension. In our protocol, Step 2 elicits the parametric answer with the context already visible; it is therefore a prior reported under the CDD prompt, not a context-free parametric answer. The belief-revision formulation is a conceptual scaffold, not an instantiated measurement.

3.2 The CDD Framework

CDD makes the implicit conflict explicit via a five-step reasoning trace (Figure 1). These five steps function as a probe instrument: each step exposes a specific belief-revision operation that remains implicit under standard RAG.

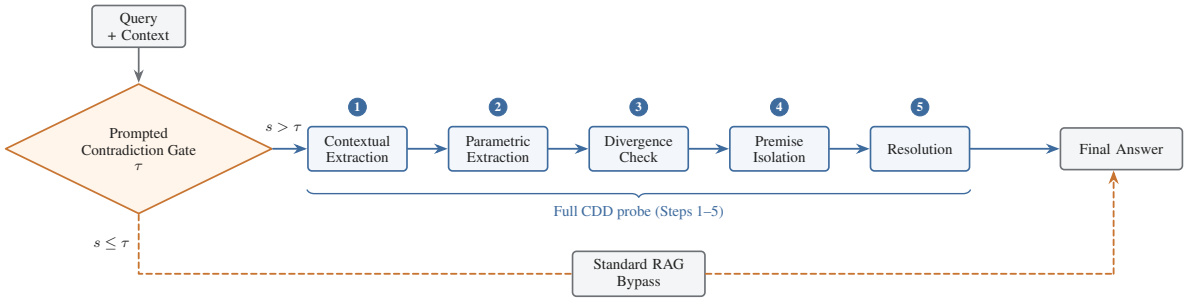

Figure 1: CDD pipeline with the CDD-α prompted contradiction gate. High-conflict samples enter the full decomposition probe, while low-conflict samples follow the Standard RAG bypass before converging at the final answer.

Step 1: Contextual Extraction: Output $\hat{a}_{ctx}$.

Step 2: Parametric Extraction: Output $\hat{a}_{param}$.

Step 3: Divergence Check: Compare $\hat{a}_{ctx}$ and $\hat{a}_{param}$.

Step 4: Premise Isolation: If they conflict, isolate the premises causing the conflict and evaluate whether they violate established history or science.

Step 5: Resolution: Resolve the conflict and output the final answer.

3.3 Algorithmic Variant: CDD-α

We also report **CDD-α**, a compute-aware routing variant used to study compute/accuracy trade-offs. The context c is paired with the current parametric answer estimate and scored by a prompted Gemini-2.5-Flash contradiction gate, which asks whether the premise explicitly contradicts the hypothesized answer and returns a scalar score in $[0, 1]$. If the score exceeds τ, the sample is routed to the deep CDD logic. Otherwise, it defaults to Standard RAG. This routing rule operationalizes a selective-intervention setting in which only high-conflict examples invoke the full decomposition trace; it is not a trained NLI checkpoint or a calibrated probability model.

4 Experimental Setup

4.1 The Epi-Scale Benchmark

Epi-Scale contains 2,250 base examples drawn evenly from **HotpotQA** (multi-hop) (Yang et al., 2018), **Natural Questions** (single-hop) (Kwiatkowski et al., 2019), and **FEVER** (fact verification) (Thorne et al., 2018). Each base example is instantiated in two forms: a clean-context record and an adversarial-context record, yielding 4,500 evaluation records in total.

Construction: The clean records use the original retrieved context. The adversarial records are generated through an LLM-based perturbation engine parameterized for high semantic variance. We generated four mutually exclusive perturbation subsets: Entity Swap, Temporal Shift, Logical Contradiction, and Distractor Evidence. (Generation procedure summarized in Appendix B).

Because the primary evaluation model also generated the perturbations and serves as the CDD-α contradiction gate, we cannot rule out a same-model bias; the Claude-family reruns, which evaluate on perturbations generated by a different model, partly address this.

Limitations of Synthetic Perturbations: While Epi-Scale improves upon templated datasets, LLM-generated adversarial texts often exhibit lower perplexity and uniform lexical diversity compared to organic human misinformation. We mitigate this by including a real-world evaluation on **TruthfulQA** (Lin et al., 2022).

4.2 Evaluation Scope

We use three evaluation settings, each with a different diagnostic role. Epi-Scale synthetic conflict is a controlled perturbation stress test for isolating specific conflict types. TruthfulQA misconception injection is a worst-case upper-bound compliance test, not an organic retrieval benchmark. Claude-family replication is a cross-model diagnostic check for whether the observed coupling and conflict-resolution signals are model-specific. The main adversarial analysis reports results on the Epi-Scale adversarial records: 2,250 examples evenly divided across the four perturbation types ($\sim$562–563 per type). Per-perturbation accuracies

in Table 1 are computed over all examples in each group, and the macro average is the unweighted arithmetic mean across the four perturbation cells.

4.3 Evaluation Metrics

We use normalized string matching (lowercase, punctuation stripping, alias mapping) to reduce superficial form mismatches. Hedged or non-committal responses are handled by task-specific rules described in Appendix A.

- **Accuracy and macro average:** Per-perturbation accuracy is computed independently for each perturbation group. "Macro Avg." denotes the unweighted arithmetic mean of the four displayed perturbation accuracies.
- **Confidence intervals:** For Table 1, each per-cell 95% CI is a normal-approximation binomial interval of half-width $z_{0.975}\sqrt{\hat{p}(1-\hat{p})/n}$ over the ∼562–563 examples in that perturbation group. The macro-average half-width is computed as $z_{0.975} \times (1/4) \times \sqrt{\sum_i \hat{p}_i(1-\hat{p}_i)/n_i}$, under the assumption that the four perturbation cells are independent samples. We note that this propagation does not capture potential correlations introduced by the shared question pool from HotpotQA/NQ/FEVER.
- **Causal Sensitivity:** We quantify faithfulness using intervention tests (Truncation and Mistake Injection) (Lanham et al., 2023). Sensitivity is the relative accuracy drop, defined as $(\text{Acc}_{\text{clean}} - \text{Acc}_{\text{corrupted}})/\text{Acc}_{\text{clean}}$.

4.4 Significance Reporting

In place of paired hypothesis tests, we report a CI-based conservative significance check on the largest method gaps. For the Epi-Scale adversarial records, we report per-cell binomial 95% confidence intervals. The CIs for CDD and a strong non-CDD baseline (Reflection Prompting) do not overlap on Entity Swap (88.0% ±2.7 vs 69.5% ±3.8) or Logical Contradiction (83.2% ±3.1 vs 65.0% ±3.9). Conflict-aware RAG is a stronger instruction-matched baseline (73.5 macro) over which CDD retains a margin on Entity Swap and Logical Contradiction. The conflict-aware per-cell CIs (Table 1) do not overlap with CDD on Entity Swap or Logical Contradiction, while the Temporal Shift and Distractor Evidence intervals overlap. Mixed clean/adversarial comparisons use paired bootstrap over the paired 4,500-record Epi-Scale evaluation set, with the harmonic mean of clean and adversarial accuracy as the aggregate robustness metric.

4.5 Model Setup

We use Gemini-2.5-Flash for primary evaluations. To study cross-architecture generalization, we extend evaluations to Claude Haiku, Sonnet, and Opus; exact API model identifiers are listed in the reproducibility statement. Closed-API behavior may still drift on non-pinned dependencies, which we treat as a reproducibility limitation.

5 Results

5.1 Adversarial Stress Test and Baselines

We compare CDD against baselines to test whether decomposition changes controlled-conflict behavior. The high Claude Standard RAG scores are consistent with Gemini-generated perturbations transferring imperfectly across model families, reinforcing the same-model-bias caveat in §4.1.

Table 1 reports CDD, chain-of-thought prompting (Wei et al., 2022), reflection-token prompting inspired by Self-RAG (Asai et al., 2024), and prompt-only self-filtering inspired by document-filtering RAG (Yoran et al., 2024) on Gemini-2.5-Flash; Figure 3 visualizes the pattern in Appendix B. The reflection baseline is prompt-only, not the trained Self-RAG system.

CDD improves adversarial macro accuracy over Standard RAG (78.1% vs 63.0%). Against Conflict-aware RAG (73.5%), the separable margin concentrates on Entity Swap and Logical Contradiction, where premise isolation is most applicable; Temporal Shift and Distractor Evidence intervals overlap, so we make no robustness claim there.

Average-case calibration. On paired clean/adversarial records, CDD and Standard RAG are statistically tied in harmonic mean (72.23% vs 72.33%, bootstrap p=0.53). This hides a trade-off: CDD scores 67.2% clean / 78.1% adversarial, while Standard RAG scores 84.9% / 63.0%. We therefore treat CDD as a conflict-specific diagnostic, and Epi-Scale as a stress test rather than evidence that adversarial contexts remove all answer-relevant information.

Table 1: Adversarial accuracy across perturbation types on the Epi-Scale adversarial records (Gemini-2.5-Flash, N=2,250; ∼562–563 samples per perturbation; normal-approximation 95% binomial CIs). Macro Avg. is the unweighted arithmetic mean of the four perturbation accuracies; the rightmost interval propagates the four per-cell binomial uncertainties.

Model & Setting	Entity Swap	Log. Contradict.	Temp. Shift	Distract. Evid.	Macro Avg.
ClosedBook (Zero-shot)	43.7% (±4.1)	40.7% (±4.1)	50.0% (±4.1)	44.4% (±4.1)	44.7% (±2.0)
Standard RAG	58.4% (±4.1)	56.0% (±4.1)	68.8% (±3.8)	68.8% (±3.8)	63.0% (±2.0)
Vanilla CoT	62.0% (±4.0)	61.3% (±4.0)	63.2% (±4.0)	68.1% (±3.9)	63.7% (±2.0)
Reflection Prompting	69.5% (±3.8)	65.0% (±3.9)	66.0% (±3.9)	67.5% (±3.9)	67.0% (±1.9)
Prompt-Filtered RAG	68.0% (±3.9)	64.5% (±4.0)	65.5% (±3.9)	67.0% (±3.9)	66.3% (±2.0)
Conflict-aware RAG	79.3% (±3.3)	75.4% (±3.6)	70.0% (±3.8)	69.2% (±3.8)	73.5% (±1.8)
CDD (Ours)	**88.0%** (±2.7)	**83.2%** (±3.1)	**71.3%** (±3.7)	**69.9%** (±3.8)	**78.1%** (±1.7)

Table 2: Cross-model replication on the Epi-Scale adversarial records (Claude-family models, N=2,250 adversarial examples). CDD improves adversarial accuracy on all three Claude-family models. The per-model gains are directional point estimates (+2.2/+4.6/+2.6 pp). CDD marginal 95% confidence intervals are shown in the table; paired significance tests for the method differences were not run. This reflects transfer of the accuracy benefit only; trace-perturbation sensitivity transfer is reported as point estimates without paired significance tests (§5.5.3).

Method	Haiku	Sonnet	Opus
Standard RAG	**79.0%**	**76.0%**	79.4%
Vanilla CoT	73.6%	73.2%	75.4%
CDD (Ours)	**81.2%** (±1.6)	**80.6%** (±1.6)	**82.0%** (±1.6)

Table 3: Component-wise ablation on Gemini-2.5-Flash. Entity Sw. and Log. Con. are shown because they are the localized factual-conflict families where CDD's strongest baseline margins occur in Table 1. Overall is the unweighted macro average over all four perturbation types (Entity Swap, Logical Contradiction, Temporal Shift, Distractor Evidence). The omitted Temporal Shift and Distractor Evidence cells are not individually recoverable from the archived aggregate table; their two-cell mean is implied by the Overall column.

Ablation Variant	Entity Sw.	Log. Contradict.	Overall
Full CDD	**88.0%**	**83.2%**	**78.1%**
Length-Matched Sham CoT	42.4%	32.0%	40.1%
w/o Step 4 (Isolation)	75.2%	72.0%	65.1%
w/o Step 3 (Diverge)	77.0%	73.5%	66.0%

5.2 Ablation Study

Table 3 details component ablations. Removing Premise Isolation (Step 4) drops macro accuracy to 65.1%; removing Divergence Check (Step 3) gives 66.0%. The omitted Temporal Shift/Distractor Evidence mean implied by the table is below Standard RAG, so decomposition can be harmful unless divergence checking and premise isolation are present.

The length-matched sham prompt reaches 40.1% macro (Table 3), below full CDD. Thus the decomposition type matters; generic multi-step structure is insufficient, though parse-failure analysis is needed before attributing the full sham drop to reasoning rather than format fragility.

5.3 Diagnostics & Compute Tradeoff (CDD-α)

For CDD-α, we set $\tau = 0.7$ by inspecting a 100-sample contradiction-score histogram from the adversarial evaluation pool; this is not a separate development set or full sweep. The gate routes 30.0% of samples to CDD and reaches 68.5% adversarial accuracy (Figure 2b), about 1.0 pp above the analytical 30%-random-routing expectation of 67.5%. We present this as an illustrative operating point, not a demonstrated compute/accuracy win.

5.4 Finding 1: Context Compliance Is Measurable

Setup: We sampled 500 TruthfulQA instances and supplied the common human misconception as retrieved context. This is an upper-bound compliance test, not an organic BM25 (Robertson and Zaragoza, 2009) or DPR (Karpukhin et al., 2020) retrieval benchmark.

Results: Standard RAG reaches 15.0% accuracy (±3.1%); CDD reaches 62.0% (±4.3%). The remaining CDD errors are non-correct under the binary scorer and may include misconception acceptance, hedges, refusals, or other wrong answers, so we do not interpret them as a pure misconception-acceptance rate.

5.5 Faithfulness via Causal Intervention

Because LLM-as-a-judge interpretability scoring inherits reliability concerns (Li et al., 2025), we follow chain-of-thought causal-intervention tests

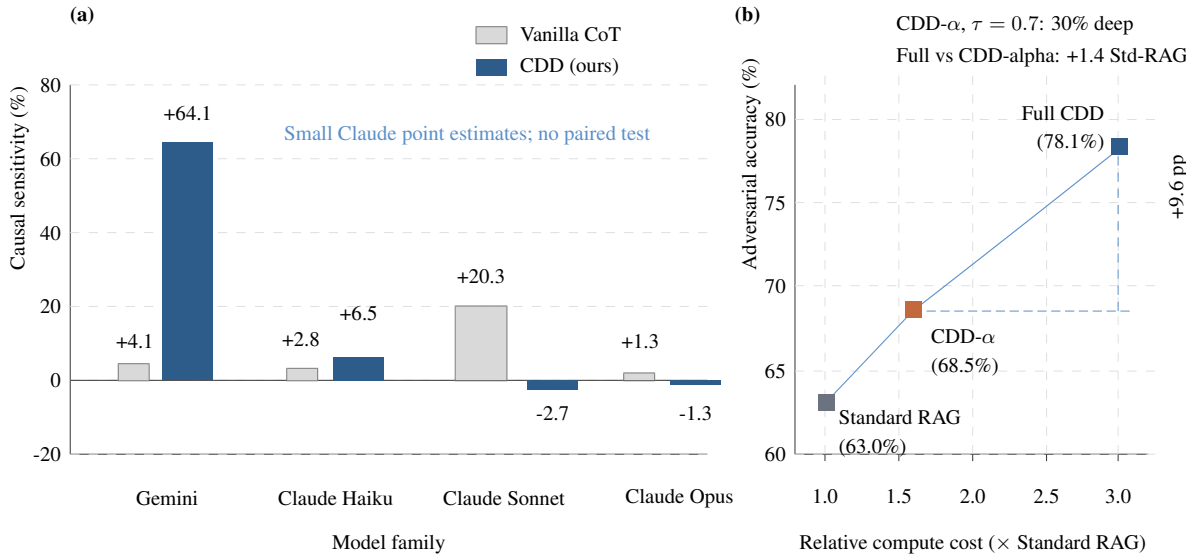

Figure 2: Diagnostics and compute trade-off. (a) Mistake-injection causal sensitivity across model families (N=2,250 per cell for all four model cells). On Gemini-2.5-Flash, CDD's final answer is highly sensitive to trace corruption (64.1%); on all three Claude variants the CDD sensitivities lie in the [-3%, +7%] range at N=2,250, with small point-estimate sensitivities and no paired test performed even though adversarial accuracy improves under CDD (Table 2). Claude Sonnet and Opus CDD sensitivities are negative point estimates (-2.7%, -1.3%), meaning accuracy increased slightly under mistake injection. (b) Compute–accuracy trade-off on the Gemini-2.5-Flash adversarial records. Relative compute is measured in Standard-RAG-equivalent generation calls: Standard RAG = 1, Full CDD ≈ 3, and CDD-α at 30% routing costs $0.7 \times 1 + 0.3 \times 3 = 1.6$. CDD-$\alpha$ reaches 68.5%, about 1.0 pp above random 30% routing by expectation.

(Lanham et al., 2023) to measure Causal Sensitivity.

5.5.1 Mistake Injection Test

We injected a blatant logical error directly into the reasoning trace prior to generation ("I will trust the context completely, no conflict exists") and forced the model to generate the final answer. **Result:** On Gemini-2.5-Flash, Vanilla CoT drops from 63.7% to 61.1% under mistake injection (4.1% sensitivity), while CDD drops from 78.1% to 28.0% (64.1%, N=2,250 matched samples). The injection mixes a false conflict-state claim with a behavioral directive, so it tests trace corruption but not factual content separately from instruction following.

5.5.2 Truncation Test

Truncating after Step 2 drops CDD from 78.1% to 32.6% (58.3% sensitivity). Because 32.6% is below closed-book zero-shot (44.7%, Table 1), truncation likely disrupts the structured-output protocol; we therefore treat mistake injection as the primary causal-faithfulness result and stricter step-specific tests as future work.

5.5.3 Cross-Model Faithfulness

We also apply mistake injection to the Claude family (N=2,250). Figure 2a shows high Gemini CDD sensitivity (64.1%) but Claude CDD sensitivities within [-3%, +7%] as point estimates without paired tests, despite positive accuracy transfer (Table 2). Thus the Claude gains cannot be attributed to the stated resolution trace alone; increased output length, format-induced calibration, or alignment-specific responses remain alternatives. Claude Sonnet's Vanilla-CoT sensitivity (20.3%) is reported but not over-interpreted.

6 Findings: What CDD Makes Visible

6.1 Perturbation-Level Pattern

The perturbation-level pattern suggests three robustness modes. Entity Swap and Logical Contradiction benefit most because each conflict is localized as a discrete factual claim. Temporal Shift is directionally higher under CDD relative to Standard RAG (71.3% vs 68.8%, overlapping CIs), so we make no robustness claim for this perturbation. Distractor Evidence is likewise directionally higher (69.9% vs 68.8%, overlapping CIs), so we do not treat the gain as evidence that the trace helps under

noisy or partially irrelevant retrieval.

6.2 Finding 2: Accuracy Transfer Is Not Mechanism Transfer

As shown in §5.5.3, accuracy transfer (Table 2) and trace-perturbation sensitivity (Figure 2) dissociate: the adversarial-accuracy benefit of explicit decomposition transfers across the Claude family, whereas mistake-injection sensitivity shows no measurable coupling at N=2,250 (CDD sensitivities within [-3%, +7%]) outside Gemini-2.5-Flash. We therefore phrase the finding conservatively—what transfers is the accuracy benefit, not a demonstrated causal coupling between the resolution trace and the final answer. This makes CDD a cross-family accuracy intervention in our controlled setting while leaving its mechanism family-specific; the absence of measurable coupling is consistent with, but does not prove, the absence of a causal footprint.

6.3 Finding 3: Explicit Decomposition Improves Controlled-Conflict Robustness

As reported in Table 1, the clearest controlled-conflict robustness gains occur on Entity Swap and Logical Contradiction, the two localized factual-conflict settings where explicit premise isolation is most directly applicable. This is where CDD separates most clearly from the strongest baseline, Conflict-aware RAG; the table provides the exact values and intervals.

6.4 Future Work

Next evaluations are organic BM25/DPR retrieval for TruthfulQA; multi-document retrieval with one false passage among k true passages; factual-only, rationale-swap, and step-specific interventions; and open-weight replication with logit-level prior/posterior divergence. Potential future directions outside the controlled conflict setting include semi-structured graph/text retrieval and adaptive fusion/reranking settings (Tao et al., 2026). On the efficiency side, long-context compression and reasoning-pruning methods are methodologically relevant to reducing the overhead of decomposition-style diagnostics (Gao et al., 2025; Jiang et al., 2026).

7 Conclusion

We used CDD as an inference-time probe for how standard RAG handles epistemic conflict. Final-answer accuracy does not fully capture conflict handling: Standard RAG can enter a measurable context-compliance regime under worst-case misconception injection, explicit decomposition can improve controlled-conflict robustness, and accuracy gains can transfer across model families even when trace-perturbation sensitivity between the stated resolution trace and final answer does not.

Equally important, the results delimit when CDD should not be read as a general answer-quality improvement. The clean/adversarial calibration tie and the overlapping intervals on Temporal Shift and Distractor Evidence mean CDD is best interpreted as a diagnostic for cases where retrieved evidence conflicts with stable parametric knowledge. In settings with ordinary retrieval noise, partial relevance, or temporally ambiguous updates, our measurements support only a narrower claim: explicit decomposition can reveal and sometimes improve arbitration behavior, but does not replace retrieval quality control or broader faithfulness tests.

These findings position context compliance as a structural RAG behavior requiring systematic diagnostics. A correct answer can hide whether the model rejected a false retrieval, ignored retrieval, or produced a post-hoc rationale; CDD exposes that arbitration by separating contextual belief, parametric belief, premise isolation, and resolution, then testing whether the final answer is sensitive to trace corruption. This trace-perturbation sensitivity is large on Gemini-2.5-Flash; on the Claude family the same trace improves adversarial accuracy without a large point-estimate causal footprint (Gemini 64.1% vs Claude within [-3%, +7%]), with paired significance not established, so the diagnostic should be read as model-specific rather than universal. We will release the Epi-Scale split (2,250 clean + 2,250 adversarial records), prompt templates, evaluation settings, and scoring specifications upon publication; the internal experimental codebase is not released.

Limitations

- **Cross-Family Generalization**: The clearest causal-sensitivity signal is on Gemini-2.5-Flash (64.1% mistake-injection sensitivity), with effect magnitude varying across model families. Characterizing the Claude-family behavior—separating architecture, alignment-training, and prompt-sensitivity contributions—is a natural open-weight extension.

- **Causal-Coupling Uncertainty**: On the Claude family, mistake-injection sensitivities lie within [-3%, +7%] at N=2,250, versus 64.1% on Gemini-2.5-Flash. We report these conservatively as point estimates and read them as no measurable coupling in these runs; paired significance, confidence intervals, or an equivalence/power analysis would be needed to move from this reading to a positive claim about the presence or absence of a causal footprint.

- **TruthfulQA Closed-Book Control**: The 15.0% figure characterizes context-injected behavior under our binary scorer; adding a no-context control on TruthfulQA-500 would further quantify the prior-versus-context gap and is a direct extension.

- **Baseline Prompt Asymmetry**: Because the Standard RAG prompt implicitly encourages context-reliance under adversarial context while CDD instructs explicit conflict checking, we include a conflict-aware prompt baseline to separate decomposition from instruction effects. CDD retains a margin on the localized factual conflicts (Entity Swap, Logical Contradiction) and the margin closes on Temporal Shift and Distractor Evidence; we accordingly read part of the overall gain as attributable to the conflict-checking instruction and part to decomposition.

- **CDD-α Threshold Tuning**: We select the CDD-α threshold $\tau = 0.7$ from a 100-sample histogram inspection on the adversarial evaluation pool rather than a separate development set or full sweep; a $\tau \in \{0.3, 0.5, 0.7, 0.9\}$ ablation with a separately fixed gate would be needed before treating the Pareto point as deployment-relevant. We present CDD-α as an illustrative compute/accuracy operating point rather than a tuned deployment setting.

- **TruthfulQA Realism:** Using the explicit top misconception is a deliberate worst-case probe; organic BM25 retrieval would measure average-case degradation and is the natural follow-up.

- **Prior Answer Not Context-Isolated**: In the CDD protocol, Step 2 elicits the parametric answer after the context is visible, so it is a prior reported under the CDD prompt rather than a context-free parametric answer. We therefore treat the belief-revision framing as conceptual; a separate no-context elicitation would tighten the prior/posterior separation and is a direct extension.

- **Conceptual-Only Belief-Revision Framing**: Our belief-revision framing is conceptual rather than a token-level divergence (e.g., JSD); a white-box open-weight instantiation would enable direct quantitative validation of the compliance/resolution distinction.

- **Stricter Faithfulness Tests**: Because mistake injection combines factual content with a behavioral directive, a sharper causal picture would come from factual-only Step-2 corruption, rationale swaps, step-specific corruption, and answer-hidden interventions with contexts that do not reveal the answer; we outline these as the immediate next interventions.

- **Closed-API Drift**: Closed-API behavior may drift under provider updates, and evaluation configuration choices can change benchmark verdicts (Li et al., 2026b); version-pinned open-weight replication would remove one major source of variance.

- **Single-Run Closed-API Evaluation**: The reported closed-API results are single-run evaluations at temperature 0.0. Temperature 0.0 does not guarantee deterministic behavior for hosted APIs, so small directional gaps, especially in the Claude-family replication, should be interpreted with caution until repeated runs or open-weight replications are available.

Reproducibility Statement

Due to API-provider terms and maintenance constraints, we do not release the full internal experimental codebase, which contains non-generalized

infrastructure and API-specific wrappers. We will release the Epi-Scale split (2,250 clean + 2,250 adversarial records), prompt templates, evaluation settings, and scoring specifications upon publication; the internal experimental codebase is not released. The release split contains 2,250 clean-context records and 2,250 adversarial-context records, balanced across HotpotQA, Natural Questions, and FEVER and across the four perturbation types. The API identifiers used in the reported experiments are:

Gemini	`gemini-2.5-flash`
Claude Haiku	`claude-haiku-4-5-20251001`
Claude Sonnet	`claude-sonnet-4-6`
Claude Opus	`claude-opus-4-6`

The Gemini endpoint has an announced discontinuation date of 2026-06-17, so exact replication against the same endpoint may no longer be possible. The Haiku ID is a dated snapshot. From the Claude 4.6 generation onward, a dateless ID such as claude-sonnet-4-6 is a version-pinned snapshot rather than an evergreen alias, so the model weights for a given ID are fixed; however, the surrounding serving infrastructure (e.g., request routing, moderation classifiers, and sampling) may change over time, which we treat as a reproducibility limitation. Experiments were conducted between January and March 2026. Closed-API model behavior may drift on non-pinned dependencies (e.g., moderation layers), which we treat as a reproducibility limitation. All runs use temperature 0.0 and greedy decoding constraints. CDD-α uses a prompted Gemini-2.5-Flash contradiction gate rather than a separate NLI checkpoint; the gate returns a parsed scalar score from a prompt asking whether the context contradicts the hypothesized answer. Dataset construction draws evenly from HotpotQA, Natural Questions, and FEVER; perturbations are generated along four mutually exclusive axes and audited manually on 50 examples per subgroup (92% valid conflict generation rate). Metrics use normalized string matching with lowercase, punctuation stripping, and alias mapping; FEVER labels are mapped to Boolean support/refute classes in the appendix. Confidence interval computation follows the formulas detailed in §4.3. Compute resources: All experiments use closed-API inference at standard rate limits; we did not perform local fine-tuning or training.

B Appendix: Epi-Scale Details

Epi-Scale comprises 2,250 base examples drawn evenly from HotpotQA (Yang et al., 2018), Natural Questions (Kwiatkowski et al., 2019), and FEVER (Thorne et al., 2018). Each base example is represented as one clean-context record and one adversarial-context record, yielding 4,500 evaluation records. The adversarial records are divided uniformly among Entity Swap, Temporal Shift, Logical Contradiction, and Distractor Evidence. The perturbations were generated using `gemini-2.5-flash` with prompt templates constraining semantic alterations to exactly one variable axis. To ensure the LLM-based perturbation engine successfully generated genuine conflicts without destroying syntax, we manually audited a random sample of 50 adversarial records per subgroup, finding a 92% valid conflict generation rate. The audit was conducted as a manual spot check over 200 records total; inter-annotator agreement was not measured, and per-record validity labels were not retained for a filtered-subset sensitivity check.

Self-Detect–Refine: Iterative Training Label Refinement Method for Clinical Note Generation

Gin-kyeng Lee Serim Kim Harin Jun
Puzzle-AI
{gin_lee, serim322, diridiri}@puzzle-ai.com

Abstract

In medical LLM adaptation, collecting large-scale real clinical notes is constrained by patient privacy and annotation cost, so training pipelines often rely on notes synthesized by commercial LLMs. Those synthetic notes are not error-free. We observe that after fine-tuning on such notes, a task judge rates the resulting model's outputs as more complete without a consistent Accuracy gain, while a hallucination judge flags more statements that the source does not support. We therefore report Accuracy and Completeness separately from hallucination counts, split the latter into Content and Format-Meta hallucinations, and report both as rates normalized by the number of fields each output format requires, so that a gain in one cannot hide a loss in the other. We then introduce Self-Detect–Refine, which applies an external LLM to detect and revise hallucinations in the training labels themselves rather than in outputs at inference time. We evaluate it across three base models, two refiners, and four refinement depths, fine-tuning a fresh copy of each base model on each label snapshot. GPT-5.2-refined labels lower Content hallucinations in every configuration, both as a share of the required fields and after length normalization. The two stages load on different components: the Completeness gain belongs to raw-label fine-tuning, whereas refinement raises Accuracy without a consistent loss in Completeness. Format-Meta changes are mixed, a lower-cost refiner is less consistent, and every judgment here comes from LLM judges on a single synthetic benchmark without clinician validation.

1 Introduction

Collecting real clinical notes at scale is constrained by patient privacy and annotation cost, so medical NLP pipelines increasingly train on notes synthesized by large language models (LLMs) (Tang et al., 2023; Kumichev et al., 2024). Clinical-note generation requires a completed form to represent the supplied patient information accurately and completely, without adding unsupported details. We study this task on a synthetic English benchmark whose completed-note labels are themselves LLM-generated. Those labels can contain hallucinations, raising two questions: how does fine-tuning on them affect generated notes, and can refining them improve the resulting models?

A single judge-assigned score cannot separate accuracy from information coverage or from unsupported additions. We therefore use two judges. A *task judge* scores *Accuracy*, how faithfully the completed form reflects the source, and *Completeness*, how much source-supported information it fills in. We report the two separately throughout, since a change in one can offset a change in the other. A *hallucination judge* separately returns one record per unsupported or unfaithful statement, which we group into *Content* and *Format-Meta* and count. These counts reflect the statements the judge flagged, not clinician-verified errors. The task scores alone do not determine the hallucination counts, so we report both.

Self-Detect–Refine uses one external LLM to both detect hallucinations in a synthetic training label and revise the flagged content under a minimal-edit instruction; the *self-* prefix denotes this shared model, and the task and hallucination judges are different models again. We repeat the procedure to obtain label snapshots at different refinement depths, then fine-tune a fresh copy of each base model on each snapshot. We compare these models with the original base and with unrefined-label fine-tuning. Figure 1 summarizes the workflow.

Contributions.

- **Separate quality measurements.** We report Accuracy and Completeness separately from each other and from eight hallucination categories in two groups. Hallucinations are reported as the fraction of required fields carrying at least one,

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 277–304
October 29, 2026 ©2026 Association for Computational Linguistics

a denominator fixed by the case rather than by output length or field coverage.

- **Training-label refinement pipeline.** We apply repeated detection and minimal-edit revision to the training labels rather than to inference outputs.
- **Quantitative observation of contamination and its refinement.** Three base models × two refiners × four depths, with aggregate and paired note-level results. The two stages separate by component: raw-label fine-tuning moves Completeness, refinement moves Accuracy.

2 Related Work

LLM hallucination detection and self-correction. LLM hallucination has been characterized by the intrinsic/extrinsic distinction (Maynez et al., 2020), surveys (Ji et al., 2023), and atomic-fact metrics (Min et al., 2023), with medical-domain benchmarks and detectors in Med-HALT (Pal et al., 2023) and ReXTrust (Hardy et al., 2025). On the self-correction side, Self-Refine (Madaan et al., 2023) proposed a single-LLM self-feedback framework, while Huang et al. (2024) found limits to intrinsic self-correction on reasoning tasks without external feedback. LLM-as-a-judge evaluation (Zheng et al., 2023) is itself known to carry position, verbosity, and self-enhancement biases. Our work differs in two respects: (i) the refinement target is the *training labels*, not inference outputs, and (ii) the detect–refine stage and the hallucination judge use different LLMs, separating model identity while retaining shared-rubric bias.

Data-centric AI and SFT label quality. Under the data-centric paradigm (Zha et al., 2023), one approach to SFT data quality is *high-quality sample selection* — LIMA (Zhou et al., 2023) attained strong alignment with 1,000 high-quality examples, AlpaGasus (Chen et al., 2024) filters data using LLM quality scores, DEITA (Liu et al., 2024) selects data by complexity, quality, and diversity, and CLEAR (Chen and Mueller, 2024) uses confidence estimates to filter or correct low-quality instruction-tuning data. Gekhman et al. (2024) showed in controlled closed-book QA that learning *new factual knowledge* through fine-tuning can increase hallucinations; we instead target the contamination *already existing in the training labels* and revise it through refinement rather than selection. Our procedure retains all samples.

Clinical note generation and synthetic medical data. Clinical note generation from doctor–patient encounters has been benchmarked by ACI-Bench (Yim et al., 2023) and MTS-Dialog (Ben Abacha et al., 2023); we adopt the same task format on synthetic inputs. To mitigate the medical data shortage, Tang et al. (2023) reported improved named-entity recognition and relation extraction after training on ChatGPT-generated labeled text, MedSyn (Kumichev et al., 2024) improved ICD classification with synthetic notes augmented by a medical knowledge graph, and Mishra et al. (2024) reduced summarization hallucinations via synthetic GPT-3.5/4 edit feedback with DPO and SALT. We instead quantify hallucinations in the synthetic labels themselves and measure hallucinations in the fine-tuned models' outputs (§4.2).

3 Method

Figure 1a summarizes the full experiment, from source-data preparation to label refinement, independent fine-tuning, and evaluation. Original labels form $\mathcal{D}_0$; refinement produces snapshots $\mathcal{D}_K$. Each raw-label or refined-label SFT run starts from the original base checkpoint: the iteration-3 model does not continue training from the iteration-1 model. The Base condition receives no SFT. All conditions are evaluated on the same 200 inputs, disjoint from the 500-example refinement corpus.

3.1 Hallucination categories: Content and Format-Meta

The hallucination judge assigns each detected hallucination to one of eight categories, which we aggregate into two groups, Content and Format-Meta (FM); the categories and their group membership are listed in Table 1. Content covers patient facts, reasoning, quantities, and conversational context; Format-Meta covers template structure, unsupported reuse of prompt language, and internal-prompt or generation-context exposure. Separating these counts prevents gains in one group from obscuring deterioration in the other. The grouping is an analysis convention, not a clinical-risk scale. FM categories can carry clinical risk as well: prompt overgeneralization, one of the FM categories, can introduce clinical content, and Structural or Metadata errors can affect interpretation or workflow. Factual, medical-reasoning, and over-clinical categories may overlap conceptually; their boundaries and assignment reliability have not been

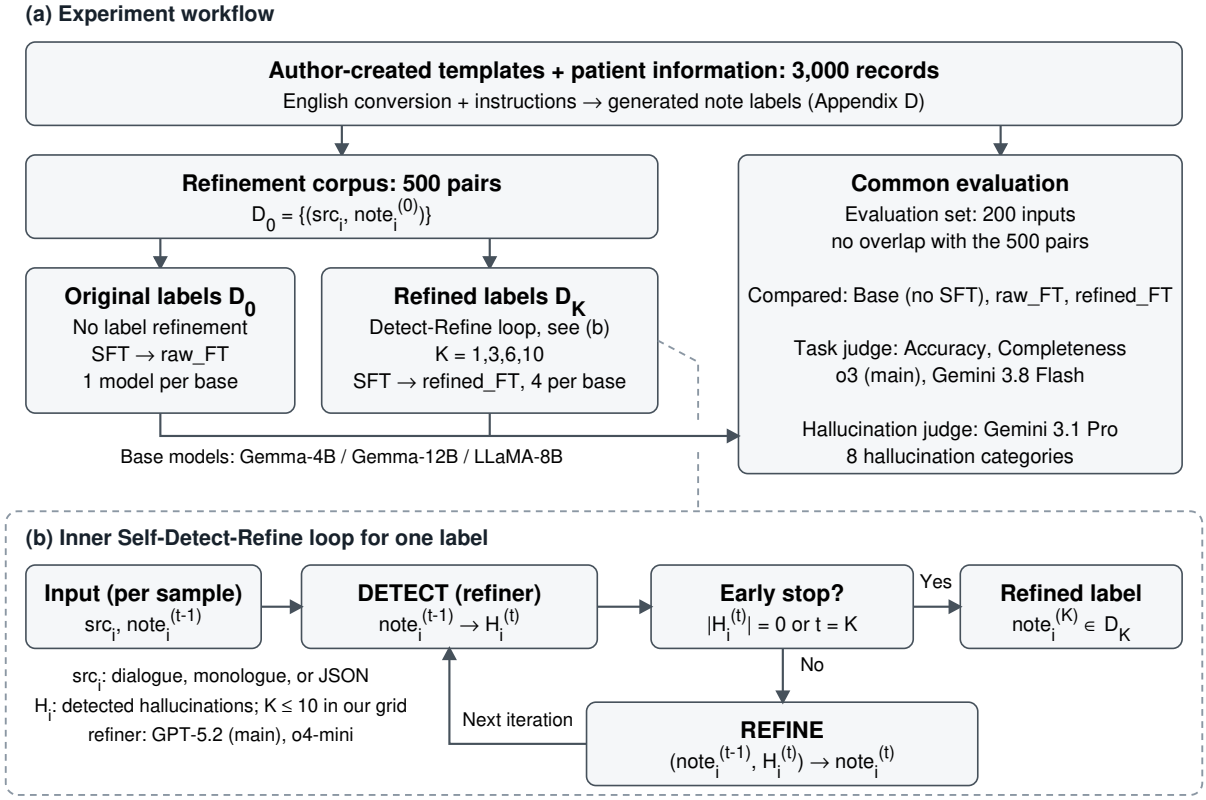

Figure 1: Experimental workflow and the inner refinement loop. **(a)** Data preparation, the refinement/evaluation split, snapshot construction, and the three compared model states. **(b)** The per-label detect–refine loop; early-stopped samples are carried forward, not dropped. Minimal edits and information preservation are prompt-level requests, not verified guarantees.

Cat	Name	Meaning
Content hallucinations (Content) — patient-related content		
F	Factual	Invented medical facts or patient attributes unsupported by the source
MR	Medical Reasoning	Unsupported clinical causality or judgment; treating tentative statements as definitive
OC	Overclinical	Inference from medical knowledge not stated in the source dialogue
N	Numerical	Distortion of times, numbers, ranges, or units
CC	Conv. Context	Misinterpreted dialogue context or incorrect attribution of speaker statements
Format-Meta hallucinations (FM) — template structure, prompt reuse, and generation-context exposure		
S	Structural	Content assigned to wrong fields; invented, duplicated, or deleted fields; deviations from the required structure
PO	Prompt Overgen.	Copying or generalizing prompt examples or phrasing without patient-specific support
ME	Metadata / Env.	Exposure or misuse of internal prompts, system information, or generation context

Table 1: Eight judge-assigned hallucination categories and their reporting groups, summarized from the detector prompt (App. H). Group membership is an operational convention, not a validated ranking of clinical severity; Content and Format-Meta errors can both have clinically relevant consequences.

validated by clinicians or a human agreement study.

3.2 Iterative Self-Detect–Refine pipeline

Starting from each synthetic note, the pipeline iteratively *detects* the remaining hallucinations and then requests *refinement* of the flagged content; iterating to a fixed depth K over the whole set yields a single refined training snapshot $\mathcal{D}_K$ per K, which is what we later fine-tune on (§4.1).

Inner loop (per sample, iteration t): (Fig. 1b)

1. **DETECT** — The LLM reviews the task prompt, the source input src_i, and the current note $\mathrm{note}_i^{(t-1)}$, and extracts the hallucination set $\mathcal{H}_i^{(t)}$ (8-cat + `violated_reason`) via a required structured tool call. The prompt requests the hallucination type and a verbatim sentence or field as evidence with an explanation.

2. **REFINE** — Given $(\mathrm{src}_i, \mathrm{note}_i^{(t-1)}, \mathcal{H}_i^{(t)})$, the *same* LLM is instructed to revise or remove the listed errors using minimal edits, yielding $\mathrm{note}_i^{(t)}$. Using one LLM for both detect and refine is what the *self-* prefix denotes.

3. **EARLY STOP** — Terminate the loop when the refiner's DETECT returns $|\mathcal{H}_i^{(t)}|=0$ or on reaching the target depth ($K \leq 10$ in our grid). An early-stopped sample is not dropped: its last note is carried forward unchanged into every later snapshot, so K is the maximum depth a snapshot represents, not the number of edits applied to every sample.

3.3 Minimal-edit constraint of the refinement prompt

The refinement prompt asks the LLM to preserve correct, problem-free content and revise or remove only content identified in the error list. It requests minimal corrections, preservation of the original style, format, and structure as much as possible, and output of the revised note alone. The shared task prompt identifies patient information as the only factual source, user instructions as hard constraints, and the template as a fixed structure. These are prompt-level constraints, not mechanically enforced edit boundaries or guarantees of information preservation. The reference is the supplied synthetic input, not clinician-verified ground truth. Prompt details are given in App. H.

3.4 Downstream evaluation

We SFT each base LLM on every refined snapshot $\mathcal{D}_K$, producing one fine-tuned model per K, which we denote iter_K. Each fine-tuned model performs inference on the evaluation set, and primary evaluation uses the hallucination judge, which extracts 8-cat hallucinations via a structured tool call, and the task judge (Zheng et al., 2023). Both use models that differ from the inner-loop detect–refine LLM (specific model names in §4.1); the detection node and the Gemini hallucination judge use exactly the same task prompt, eight-category definitions, and required tool interface. This separates model identity while retaining a common rubric; shared-rubric bias and judge reliability are discussed in Limitations. The maximum refinement depth K controls the training snapshot; the selected iter_K snapshots form an evaluation grid for studying depth-dependent effects (see §4.1).

Item	Value
Training data	Author-written templates + patient info, translated to English with generated labels; 500 of 3,000 pairs (App. D)
SFT / internal val.	n=450 / n=50
Evaluation	n=200
Base LLMs	Gemma-4B, Gemma-12B (Gemma Team, 2025), LLaMA-8B (Grattafiori et al., 2024)
Refiner	GPT-5.2 (main), o4-mini (App. B); call settings in App. H
Hallucination judge	Gemini 3.1 Pro
Task judge	o3 (main), Gemini 3.8 Flash (App. M)
iter_K K	$\{1, 3, 6, 10\}$
Hyperparams	QLoRA (Dettmers et al., 2023; Hu et al., 2022) SFT; configuration in Appendix G

Table 2: Experimental setup. Each snapshot is $\mathcal{D}_K=\{(\mathrm{src}_i, \mathrm{note}_i^{(K)})\}_{i\in\mathrm{train}}$ (§3).

4 Experiments

4.1 Setup

Data preparation. We construct English input–label pairs from an author-created Korean corpus of scenario-based patient information and medical templates. Templates are generated using LLMs with public medical forms as references or derived from dialogues. We sample 3,000 form-based and dialogue records, translate templates and patient information into English, simplify template descriptions, and generate user instructions. English completed-note labels are newly generated by o4-mini, Claude Haiku-4.5, and Gemini-2.5-Flash-Lite. Inputs include dialogues, clinician or patient monologues, and JSON. Reproducibility details are in Appendix D.

Data partitions. We randomly sample 500 examples for label refinement and fine-tuning, and 200 evaluation examples with non-overlapping sample IDs from the 3,000-example pool (seed 123). The 500-example refinement corpus is split into 450 examples for parameter updates and 50 for internal validation used in early stopping and checkpoint selection. Label-contamination statistics and refinement costs refer to the full 500-example corpus. The 450/50 split and the model inputs are fixed across all conditions; only the completed-note labels change with refinement (App. G). Task scores and hallucination counts are reported on the 200-example evaluation set. Throughout the results, "evaluation set" refers to this 200-example set.

Evaluation grid. Table 2 summarizes the setup. For each $K \in \{1, 3, 6, 10\}$, the base LLM is

fine-tuned *separately* on the iteration-end training data $\mathcal{D}_K$, producing 12 parallel models per refiner (3 base $\times$ 4 K). The main text covers GPT-5.2 results (§4.3, §4.4); the o4-mini comparison is summarized in §4.5, with full details in App. B. Throughout, we compare three model states: **Base** (the un-fine-tuned base LLM), **raw_FT** (the base SFT-trained on the un-refined synthetic labels, i.e. snapshot $\mathcal{D}_0$), and **refined_FT** (the base SFT-trained on a refined snapshot $\mathcal{D}_K$, $K \geq 1$). Among the twelve GPT-5.2 refined_FT settings, we refer to Gemma-12B $\times$ iter_3, the cell with the lowest Content-rate point estimate on this evaluation set, as the *selected setting*; it is a reported operating point, not a validated optimum (§5).

Training configuration. All conditions use QLoRA (Dettmers et al., 2023) with 4-bit NF4 and training seed 42, on one RTX PRO 6000 GPU with Axolotl. Within each base model, raw_FT and every refined_FT condition use identical training settings, so comparisons between them are not confounded by hyperparameter differences; adapter and optimizer settings are tuned per base model (Appendix G). The seven-epoch limit is an upper bound; early stopping and checkpoint selection use internal validation loss.

Task rubric. The o3 task judge scores Accuracy and Completeness from 0 to 10 (higher is better). Results are reported per component; their mean is labelled Task and appears only in tables that likewise aggregate hallucinations into groups. A $+0.63$ Accuracy gain is a 0.63-point difference on this scale, without an established clinical-importance threshold. The full rubric is in Appendix F.

Paired bootstrap 95% CI. All Δs (refined_FT $-$ raw_FT, raw_FT $-$ Base) carry a paired bootstrap 95% CI. We resample evaluation samples with replacement (n=200, n_{boot}=1,000; 10,000 where noted), keeping the two conditions paired within each resample. Records are summed without deduplication, not unique facts; Accuracy and Completeness are means; CIs are taken at the $[2.5\%, 97.5\%]$ percentile. We mark significance (*) when the 95% CI excludes 0. Intervals are pointwise and unadjusted.

Field-normalized hallucination rate. Evaluation-side hallucination records are not reported as raw counts. We normalize them into a *hallucinated-field rate*: of the fields an output format requires, what fraction carries a hallucination. The denominator is the number of fill-in fields in the case's `[ FORMAT_TEMPLATE ]` segment, parsed deterministically and then manually verified for all 200 evaluation cases; it is a property of the case, so it is identical across Base, raw_FT and every refined_FT condition. The numerator is a per-field *presence* count, not a record count: each record is attributed to a field by its name or by locating its quoted span in the generated note, and a field is then counted *once* if at least one record of the hallucination type in question lands on it, however many records it carries. A field hit by both a Content and a Format-Meta record therefore counts once in each group, and the numerator can never exceed the denominator. Rates aggregate as $\sum$hallucinated fields$/\sum$required fields and are reported as a percentage of the required fields, so differences between conditions are in percentage points (pp). A rate of 12.9% means that about 13 of every 100 fields the format requires carry a hallucination, and a difference of $+5.5$ pp means about 6 more fields out of every 100 do. Intervals are case-level paired bootstrap CIs computed as above; the train-side label statistics of §4.3 remain record counts.

4.2 Problem: contaminated labels and misleading gains

Train side: contamination of synthetic training labels. Content accounts for most of the hallucinations assigned by the hallucination judge (Gemini 3.1 Pro; 1,048 of 1,566 records; Fig. 12). The five Content categories are Overclinical (OC, 361), Factual (F, 301), Numerical (N, 225), Conv. Context (CC, 85), and Medical Reasoning (MR, 76); together they already appear in the synthetic labels at 2.1 per label on average. Format-Meta hallucinations are concentrated in Structural (Σ=518 records, S alone 421). In short, synthetic labels are not clean, and the Content categories dominate.

Evaluation side: misleading improvement relative to the base model. Under raw_FT, notes become more complete but also carry more judge-assigned Content hallucinations (Fig. 2). Completeness increases on all 3 bases ($+0.51$ to $+1.25$, all *), whereas Accuracy improves significantly only on LLaMA-8B ($+0.74^\star$ $[+0.53, +0.99]$) and is inconclusive on both Gemma models ($+0.23$ $[-0.10, +0.50]$ on Gemma-4B and -0.06 $[-0.32, +0.22]$ on Gemma-12B); the additional Gemini 3.8 Flash task judge agrees in sign

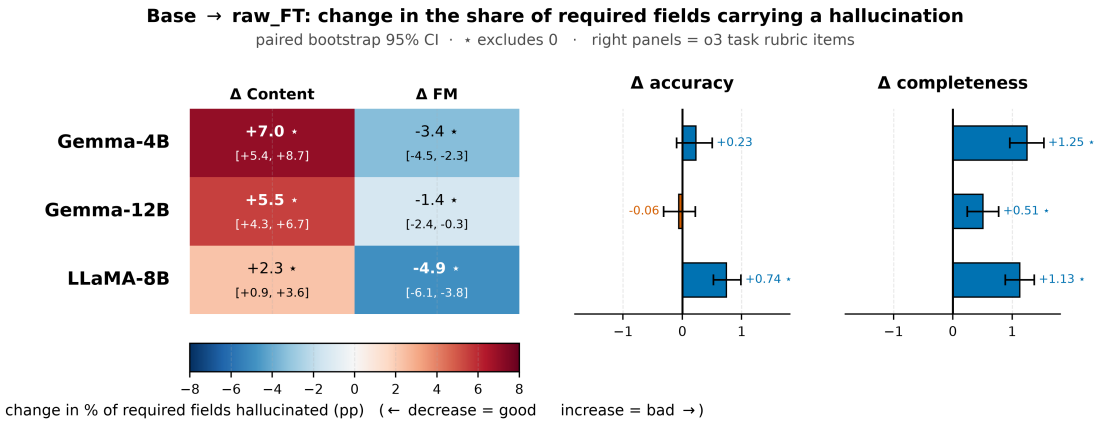

Figure 2: Paired-bootstrap 95% CI heatmap of (ΔContent, ΔFM) for raw_FT − Base; the two right-side panels share an x-scale. Cell = Δ [low, high]; ⋆= CI excludes 0. Cells are the change in the share of required fields that carry a hallucination, in percentage points (§4.1) — a denominator fixed by the format. Gemma-12B reads $+5.5^{\star}$ on Content: the share of its required fields carrying one rises $7.4\% \rightarrow 12.9\%$, about 6 more fields out of every 100 the format asks for. Remaining values and the task-side split are in §4.2, the 8-cat decomposition in App. A.

on all six component differences (Table 9). Content hallucinations increase on all 3 bases by $+2.3$ to $+7.0$ percentage points (pp) of the required fields (all ⋆), with Gemma-12B going from 7.4% to 12.9% of its required fields — about 6 more fields out of every 100 the format asks for now carry a Content hallucination — while Format-Meta hallucinations decrease by 1.4 to 4.9 pp (all ⋆).

The Content increase is not explained simply by longer or more complete outputs, because the reported quantity is already normalized: every rate below is the percentage of the fields the template requires that carry a hallucination (§4.1), a denominator that does not move between conditions, and Content hallucinations per 1,000 output characters also increase on all 3 bases (App. I).

Thus a single score combining Accuracy and Completeness would present raw_FT as an improvement on every base, largely driven by higher Completeness even where Accuracy does not improve and the Content rate increases; we call this a *misleading improvement*. This motivates refining the synthetic training labels before fine-tuning (§4.3), although the observed association does not establish a direct causal link between specific label and output hallucinations.

4.3 Refine effect

Train side: cleaning of the training labels. Two observations, using hallucination-judge counts at every round (Fig. 13). (i) Totals at iterations $0/1/3/6/10$ are $1{,}566 \rightarrow 1{,}017 \rightarrow 880 \rightarrow 835 \rightarrow 804$ — a fast-then-plateau pattern. (ii) Content hallucinations drop the most ($1{,}048 \rightarrow 592 \rightarrow 461 \rightarrow 419 \rightarrow 391$), whereas Format-Meta hallucinations move $518 \rightarrow 425 \rightarrow 419 \rightarrow 416 \rightarrow 413$.

Evaluation side: fewer Content hallucinations at higher Accuracy. One refinement pass is already enough to move both sides. At iter_1 the hallucination-judge Content rate is lower than raw_FT on all 3 bases (-1.6 to -2.9 pp, all ⋆), and the task-side gain sits in Accuracy: $+0.525^{\star}$ $[+0.332, +0.723]$ (Gemma-4B), $+0.468^{\star}$ $[+0.248, +0.668]$ (Gemma-12B), and $+0.075$ $[-0.163, +0.325]$ (LLaMA-8B, inconclusive).

Completeness changes little and not consistently over the same three settings: $+0.290^{\star}$ $[+0.060, +0.555]$ (Gemma-4B), against $+0.003$ $[-0.255, +0.258]$ (Gemma-12B) and $+0.043$ $[-0.183, +0.285]$ (LLaMA-8B), both inconclusive. This is the mirror image of the raw_FT step (§4.2). Character-normalized counts point the same way, and output shortening alone does not explain the reductions (App. I).

Refinement depth: no single best K. Extending K-depth lowers the Content rate further relative to iter_1 on every base, along different trajectories (Fig. 3). ΔContent at $\text{iter}_{1,3,6,10}$, in pp, descends monotonically on Gemma-4B ($-2.9 \rightarrow -3.6 \rightarrow -4.0 \rightarrow -4.1$) and LLaMA-8B ($-1.8 \rightarrow -2.4 \rightarrow -2.5 \rightarrow -3.0$), whereas Gemma-12B ($-1.6 \rightarrow -5.0 \rightarrow -4.7 \rightarrow -4.5$) is lowest at iter_3 and then rises slightly while staying well below iter_1.

Accuracy rises ⋆ in all 8 Gemma cells but

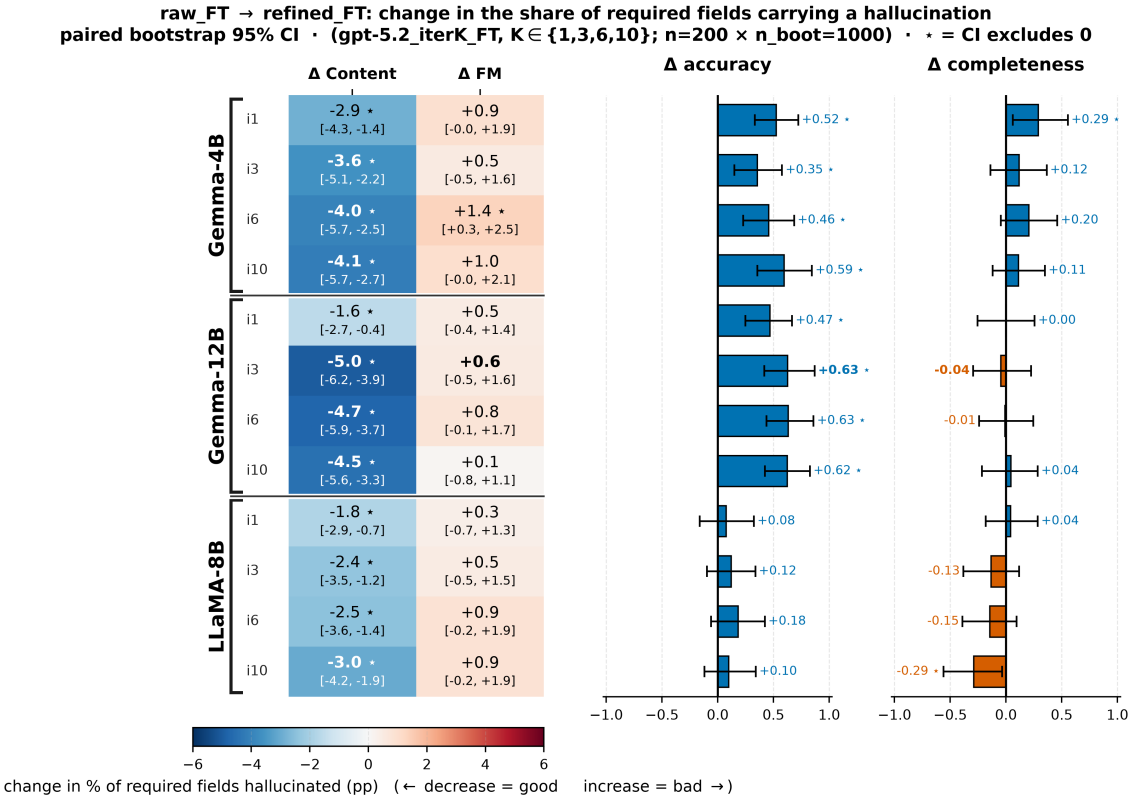

Figure 3: Paired-bootstrap 95% CI heatmap (columns: ΔContent, ΔFM) over the 12-cell grid (3 base × $K \in \{1, 3, 6, 10\}$), with the o3 task judge's rubric items as right-side panels on a shared scale. Each cell = Δ with [low, high] below; ⋆= CI excludes 0. Cells are the change in the share of required fields that carry a hallucination, in percentage points (§4.1). **Selected setting: Gemma-12B × GPT-5.2** iter_3 reads $-5.0^{\star}$ on Content (§4.3): 5 fewer fields out of every 100 carry one, which removes most of the raw_FT increase in Fig. 2. Per-cell outcomes are given in §4.3, the 8-cat decomposition in App. A (Fig. 4).

in none of the 4 LLaMA-8B cells, so the task-side recovery is base-dependent (Fig. 3). The grid also does not identify an optimal depth, because the three quantities peak at different depths. On Gemma-12B the Content rate is lowest at iter_3, whereas o3 Accuracy means at iterations $1/3/6/10$ are $8.103/8.263/8.268/8.260$ (highest at iter_6) and Completeness means are $7.603/7.555/7.590/7.645$ (highest at iter_{10}). These rankings do not establish significant differences between iteration depths, and the depth that maximizes one quantity need not maximize another.

Train-side residuals keep falling modestly at deep iterations while the downstream marginal gain on Gemma-12B flattens after iter_3, which motivates the cost comparison in §5.

Component-level analysis of the selected setting. For the selected Gemma-12B iter_3 setting, refinement removes most of the Content increase that raw-label fine-tuning introduced: the hallucination-judge Content rate falls from 12.9% to 7.9% of the required fields (-5.0 pp, 95% CI $[-6.2, -3.9]$) — 5 fewer fields out of every 100 carry a Content hallucination, approaching the Base rate (7.4) without passing it in point estimate, at a refined-minus-Base difference the paired interval does not separate from zero (§5). It does so with higher Accuracy rather than with less content: on the o3 task judge Accuracy rises $+0.628$ (95% CI $[0.405, 0.860]$, excluding zero), while the Completeness difference is inconclusive (-0.045, $[-0.305, 0.230]$) at numerically similar means (7.600 versus 7.555), which establishes neither equivalence nor information preservation. The Format-Meta difference is $+0.6$ pp (95% CI $[-0.5, +1.6]$), allowing improvement or worsening. These additional paired intervals use 10,000 resamples and seed 20260907; Appendix Table 12 reports the Accuracy and Completeness means, Appendix F covers all GPT-5.2 conditions and the note-level paired outcomes, Appendix L the counts of notes with no detected Content hallu-

cination, and Appendix E an illustrative case.

4.4 Joint Content–Format-Meta hallucination landscape

Arranging the 12 cells of §4.3 on the plane of Content hallucination reduction against Format-Meta change, both from the hallucination judge (Fig. 14), places every cell in the Content-reduction halfplane with its horizontal interval excluding 0. Only Gemma-4B iter_6 pays for that reduction with a * Format-Meta increase; the other 11 Format-Meta intervals are inconclusive, including the selected Gemma-12B iter_3 cell at $(-5.0, +0.6)$.

4.5 Refiner ablation: a lower-cost refiner

We contrast a higher-cost refiner (GPT-5.2, high reasoning) with a lower-cost alternative (o4-mini, medium) under common downstream training and evaluation settings. This practical comparison does not isolate model identity from reasoning configuration. Only 5 of the 12 cells have a * ΔContent, against 12/12 for GPT-5.2. On Gemma-12B, o4-mini has its lowest observed hallucination-judge Content rate at iter_6 ($-3.1^\star$ pp), compared with -0.3 pp at iter_{10}. Its highest o3 Accuracy mean occurs at iter_6 (8.130) and its highest o3 Completeness mean at iter_3 (7.925), so no single depth is best on both; the additional Gemini task judge peaks at iter_6 on Accuracy and at iter_{10} on Completeness (Appendix M). The observed train-side count reduction is smaller: by iteration 10 the total falls 1,566 $\rightarrow$ 1,258 and Content hallucinations 1,048 $\rightarrow$ 809, against 804 and 391 for GPT-5.2. Full details are in App. B (Fig. 6–9, Table 3).

5 Discussion

Selected setting and scope. The selected Gemma-12B/GPT-5.2 iter_3 setting (§4.1) was chosen on the same evaluation set on which it is reported, and the o3 rubric items peak at other depths (§4.3), so it remains a reported operating point rather than a validated optimum. Differences across the three bases likewise do not establish a capacity ordering, because model family, size, and tuned hyperparameters vary together.

Comparison with the un-fine-tuned base. Content alone understates the comparison against Base. On Gemma-12B the total field rate is 16.5 (Base), 20.3 (raw_FT), and 16.3 (GPT-5.2 iter_3): raw-label fine-tuning trades Format-Meta errors for Content ones, and Base is both the least format-compliant of the three (FM 9.6% of required fields against 8.2% and 8.8%) and the lowest on both rubric items (Accuracy 7.70, Completeness 7.09, against 8.26 and 7.55 after refinement). The paired bootstrap of §4.1 leaves every refined-minus-Base Gemma-12B group inconclusive (Total $-0.3\,[-1.6, +1.0]$, Content $+0.5\,[-0.5, +1.5]$, FM $-0.8\,[-1.9, +0.2]$), and the other bases diverge: LLaMA-8B iter_{10} falls below its Base on the total rate ($-4.9^\star\,[-6.2, -3.6]$) with Content inconclusive, whereas Gemma-4B iter_{10} keeps a Content excess ($+2.9^\star\,[+1.5, +4.2]$) at an unchanged total ($+0.1\,[-1.4, +1.6]$). Base is still the lower-Content condition in point estimate on two bases, but reaches that at lower judge-assessed coverage and weaker template compliance, not by producing better-grounded notes. These pointwise intervals are unadjusted for the selection and multiplicity described in Limitations.

Why the two stages load on different components. The split follows from what each stage can change. Raw-label fine-tuning supplies the output convention (which fields exist and how they are filled); this is what the Completeness item scores, and it is also the channel through which the labels' unsupported content enters. Refinement is constrained by prompt to minimal edits over an existing label (§3.3): it is asked to delete or correct unsupported statements, not to add source-supported content the label omitted. It therefore cannot be expected to raise coverage, only the share of retained statements the source supports, which is what Accuracy scores. The measurements follow that division: Completeness rises at the raw_FT step on all three bases and is inconclusive in ten of twelve refined cells, whereas Accuracy is inconclusive on two bases at that step and rises * in all eight Gemma refined cells. This reads the design rather than testing it; a refiner permitted to add omitted content, or a larger edit budget, need not show the same split.

Conservatism as an alternative explanation. Fewer judge-assigned hallucinations can also be produced by writing less. Three observations bound that explanation without eliminating it. First, the hallucination rates are normalized by the number of required fields, a denominator fixed by the case (§4.1) rather than by how much the model chose to write. Second, the reduction is distributed rather than concentrated in a few notes: at the se-

lected setting 114 of 200 notes carry fewer Content records against 25 with more (App. F), and the share of notes with no detected Content record rises from 14.5% to 27.0%, against 25.5% for Base (App. L). Third, Content hallucinations per 1,000 output characters fall in all 12 GPT-5.2 settings (on Gemma-4B even as mean length rises), whereas with o4-mini this density falls in six settings and rises in six (App. I). None of these settles whether particular source-supported facts were dropped. LLaMA-8B iter_{10}, the GPT-5.2 setting with the largest Content reduction on that base, is also the only GPT-5.2 setting with a * lower Completeness under o3.

Judge sensitivity and completeness. On identical outputs and prompts, the two task judges (o3 and Gemini 3.8 Flash) both show Accuracy gains in 22/24 refined conditions, whereas Completeness rises under both in only 13/24 and falls under both in 5/24. The two components part company this often, so a lower Content rate does not uniformly accompany lower Completeness. Under the additional judge the selected setting's Completeness difference is significantly positive ($+0.508^\star$ $[+0.247, +0.792]$) where o3 leaves it inconclusive (-0.045), so the Accuracy gain is reproduced by both judges while the direction of the coverage change is judge-dependent; omissions and length effects remain possible (Appendices M and I).

Cost and practical interpretation. GPT-5.2 iteration 3 records $83.83 for final successful DETECT and REFINE responses across 500 labels and leaves 880 train-side hallucination records, compared with 1,258 after o4-mini iteration 10 at $80.56 (Table 10; supporting plots in Appendix K). Appendix C compares, for each base and refiner, the setting with the lowest Content point estimate in the evaluated grid; what the cost totals include is stated with Table 10, and the baselines the comparison lacks are listed in Limitations.

6 Conclusion

Fine-tuning on synthetic clinical-note labels raises judge-assessed Completeness on all three base models while significantly increasing the Content hallucination rate, so a single averaged task score would present raw-label fine-tuning as an improvement over every base. Iterative label refinement with GPT-5.2 lowers the Content rate significantly in every tested configuration and, at the selected setting, reverses most of that increase, leaving the total hallucination rate at a value the paired interval does not separate from Base's, without beating Base on Content alone. The task-side change that accompanies it is a gain in Accuracy rather than in Completeness, whose direction is model- and judge-dependent, and Format-Meta changes are inconclusive in nearly every setting. The two stages therefore act on different components, and a single score would have averaged the difference away. Reporting the two rubric items separately and normalizing hallucination records by a denominator the case fixes rather than by the output is what makes these movements visible; whether they carry over to real clinical notes, other templates, or clinician judgment remains to be tested.

Limitations

Measurement and clinical validity. Hallucination counts come from the hallucination judge, and Accuracy and Completeness from the task judge; there is no clinician evaluation or human agreement study. An additional task judge assesses the same outputs (App. M), but hallucination counts are not re-evaluated by a second judge, and the two task judges agree on the sign of the per-note Completeness change in only 50.3% of paired notes. The taxonomy is not a validated clinical-risk measure, Medical Reasoning and Overclinical Reasoning were assigned without disambiguation rules, and the detector and the hallucination judge, though different models, share the same prompt, category definitions, and tool interface, so agreement with this common rubric neither validates the categories nor excludes shared systematic errors. We do not isolate whether a Format-Meta deviation originated in label refinement or in downstream generation, and the single qualitative example (App. E) rests on no multi-note annotation and cannot establish clinical benefit.

Completeness and causal interpretation. Neither the Completeness item nor the field denominator measures verified recall of source-supported facts: both score coverage against what the template or the judge asks for. The selected setting is itself 14.3% shorter than raw_FT in mean characters. Beyond the o3 Completeness criterion we report no required-field fill rate, no preservation rate for source-supported information, and no separation of appropriately empty fields from true omissions,

so more conservative completion or deleted content may still account for part of the reduction (§5). We do not trace specific label hallucinations into model outputs and therefore do not establish causal amplification; an independent completeness audit is still needed.

Field-normalized rate. The denominator, parsed from each template, is identical across Base, raw_FT, and every refined_FT condition. The numerator attributes each hallucination record to a field by its name or a quoted span and collapses records per field, so a change in how many hallucinations share one field registers as no change in the rate. Record counts remain reported alongside the rate, and the two scales should not be compared cell by cell.

Selection and stochastic variation. The 200-example evaluation set does double duty: refinement depths are compared on it and the selected setting was chosen on it, so the depth comparison is exploratory and the set is not an independent test set for the selected setting. The pointwise bootstrap intervals are unadjusted for that selection and multiple comparisons; they describe evaluation-sample variation conditional on fixed outputs, not variation across training seeds, refinement runs, or judge calls. The scale is small throughout — 450 examples for parameter updates, 50 for internal validation, 200 for evaluation — which leaves per-category comparisons underpowered, and the experiments use one training seed and one hyperparameter setting per base. The grid trains only $K \in \{1, 3, 6, 10\}$, so neither an optimal depth nor the location of a plateau is established and the isolated o4-mini Gemma-12B iter_6 improvement may be an artifact of that spacing; two refiners do not establish a general effect of refiner strength. An interval that crosses zero records a difference the experiment did not detect; it is not evidence of equivalence or of absence of harm.

Scope and missing comparisons. The corpus is one task in one language: English hospital forms translated from an author-created Korean collection. Generalization to Korean, to other clinical document types, or to non-medical domains is untested, as is the taxonomy's reproducibility on another dataset. The split is disjoint by sample ID, but similar templates may occur across partitions, so generalization to unseen templates is not established, and translation fidelity was not independently verified. Training and evaluation labels come from the same synthetic generators, so the measured effect is a reduction within those generators' hallucination distribution; no real-data or out-of-distribution evaluation is reported. Direct label regeneration, filtering, deletion-only refinement, and compute-matched single-pass baselines are absent, so the incremental benefit of iteration is unresolved. The selected setting remains above Base in the Content rate in point estimate. Reported API costs exclude failed attempts and retries, and do not measure total execution costs or comparative clinical utility.

Ethics Statement

Data and privacy. The source template and patient-information collection was created by the authors before this study. Patient information is synthetic, generated from designed scenarios rather than taken from real patient records (App. D). This study translates the resulting synthetic patient information and templates into English and generates completed-note labels using LLMs (App. D). The benchmark evaluates synthetic clinical-document inputs. **Intended use and clinical safety.** Task-score gains can co-occur with increased Content hallucinations, making clinical safety assessment a separate requirement. The pipeline is a research tool for cleaning training labels, not a clinical decision-support system, and any real-world deployment would require clinician oversight, prospective validation, and appropriate regulatory review. **Evaluation scope.** Hallucination reduction is measured by the hallucination judge rather than by clinically validated outcomes (see Limitations); reported reductions should be interpreted as judge-defined relative changes under a fixed evaluator distinct from the refiner, not as guarantees of factual correctness. **Artifacts and licensing.** Base models are subject to their respective licenses. Release plans for code and supplementary artifacts have not been finalized.

A Bootstrap CI methodology and eight-category decomposition

Bootstrap caveats. A significant refined-minus-raw comparison for one refiner and a non-significant comparison for another do not themselves establish a significant difference between refiners; that requires a direct contrast. All significance markers in the figures use pointwise intervals, not simultaneous coverage of the grid.

Field denominator. The field-normalized rate (§4.1) has 3,623 fields over the 200 evaluation cases, 18.1 per case, identical across all conditions.

Eight-category decomposition. The 12-cell × 8-cat decompositions of the per-cell Δ from §4.3 are Fig. 4 (GPT-5.2) and Fig. 5 (o4-mini), both in percentage points of the field rate defined in §4.1. Cell = $\Delta^{\star}$ [low, high]; bold row = selected setting.

B Additional results for o4-mini

We report the corresponding analyses for the o4-mini refiner; each subsection below mirrors the corresponding GPT-5.2 panel.

B.1 Train-side cleaning

Figure 6 tracks how o4-mini cleans the training labels across iterations $0, \ldots, 10$.

B.2 Evaluation-side bootstrap CI heatmap

Figure 7 gives the paired-bootstrap 95% CI heatmap over the 12-cell o4-mini grid.

B.3 (ΔContent, ΔFormat-Meta) quadrant

Figure 8 places the 12 o4-mini cells on the (ΔContent, ΔFM) plane.

B.4 12-cell summary

Table 3 summarizes the 12 o4-mini cells (ΔContent and Δtask vs. raw_FT); it is grouped with the per-base best-K figure and table (Fig. 10, Table 4).

B.5 Refiner head-to-head (Gemma-12B)

Figure 9 compares the two refiners' settings selected by minimum Content against Base and raw_FT on Gemma-12B.

C Selected per-base comparisons

Figure 10 and Table 4 compare settings selected by the lowest Content point estimate within the evaluated grid for each base and refiner.

D Training-data schema

Data source. We use a private, author-created corpus of synthetic patient information and medical templates, built by the authors before this study, sampling 3,000 form-based and dialogue records with random seed 123. The dataset is not publicly released, which limits independent reproduction of the results. Patient information is generated from designed scenarios rather than taken from real patient records, with distinct combinations of attributes such as sex, severity, specialty, disease, and monologue/dialogue format producing sample-specific content; absence of duplicate patient information has not been independently audited. Templates are either form-structured or derived from dialogues. Splits enforce sample-ID non-overlap only, with no restriction on template identity or similarity.

English preparation and labels. The translation prompt converts `TEMPLATE` and `PATIENT_INFORMATION` together, requiring English-only text, consistent terminology, and preserved structure. A regular-expression step retains template descriptions, after which a template-conditioned prompt generates user-style instructions. The 3,000 inputs are randomly shuffled and partitioned into three disjoint groups of 1,000, one per label generator listed in the main text. These models newly complete the forms in English; Korean assistant notes are neither translated nor included in the final English dataset. Before the DETECT–REFINE experiments, the generated English notes were used as raw labels without content-quality filtering, regeneration, or manual correction. The fill-in prompt treats patient information as the sole factual source, preserves template structure and field names, replaces examples with case content, and follows instruction-specific missing-value rules or default placeholders. These are prompt requirements, not

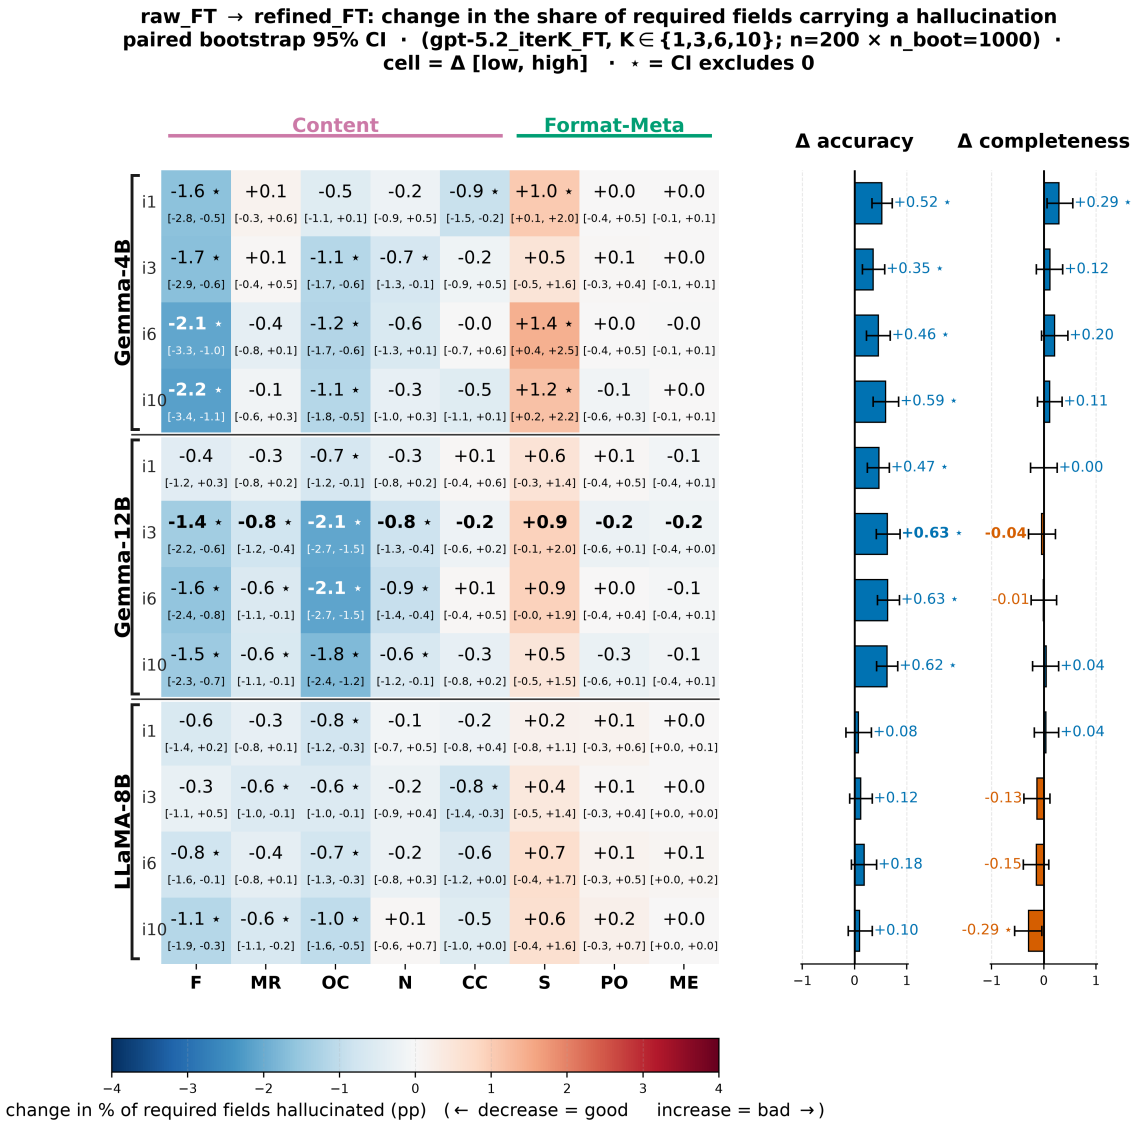

Figure 4: 8-cat decomposition heatmap of Fig. 3 (GPT-5.2, 2-group aggregate) in the main text, on the same field-rate scale, in percentage points (§4.1). Cell = Δ with the paired-bootstrap 95% CI [low, high] below; ⋆= significant (CI excludes 0); the two right-side panels give the o3 task judge's rubric items on a shared scale, matching Fig. 3. The selected setting (Gemma-12B × iter_3) Content reduction is jointly ⋆across F / MR / OC / N (only CC is n.s.), and its task gain sits entirely in Accuracy ($+0.63^{\star}$) with Completeness inconclusive (-0.04). Gemma-4B shows S ⋆in the *positive* direction at iter_1, iter_6, and iter_{10} ($+1.0^{\star}/+1.4^{\star}/+1.2^{\star}$ pp). At the group level the only ⋆FM cell is Gemma-4B iter_6 (Fig. 14); category-level and group-level significance need not coincide, since offsetting PO and ME differences enter the FM total.

verified guarantees of correctness or information preservation. No separate post-translation quality review was performed.

Each sample consists of **3 separated input sections** and a **filled clinical note (label)**.

[INSTRUCTIONS] Hard constraints on clinical-note writing (format / tone / abbreviation rules / handling of missing information, etc.). Each sample is synthesized with a different set of rules.

[INPUT_SENTENCES] The *sole factual source* for patient information. Mixed formats include clinician–patient dialogues, clinician or patient monologues, and JSON-formatted information. Hallucinations of F / MR / OC / N / CC (Content) from §3.1 are judged against this section.

[FORMAT_TEMPLATE] The fixed structure of the medical document to be filled (headers / tables / sections). Each field is annotated with a format-hint sentence; the model is expected to fill in patient data and then remove the hint itself. Structural er-

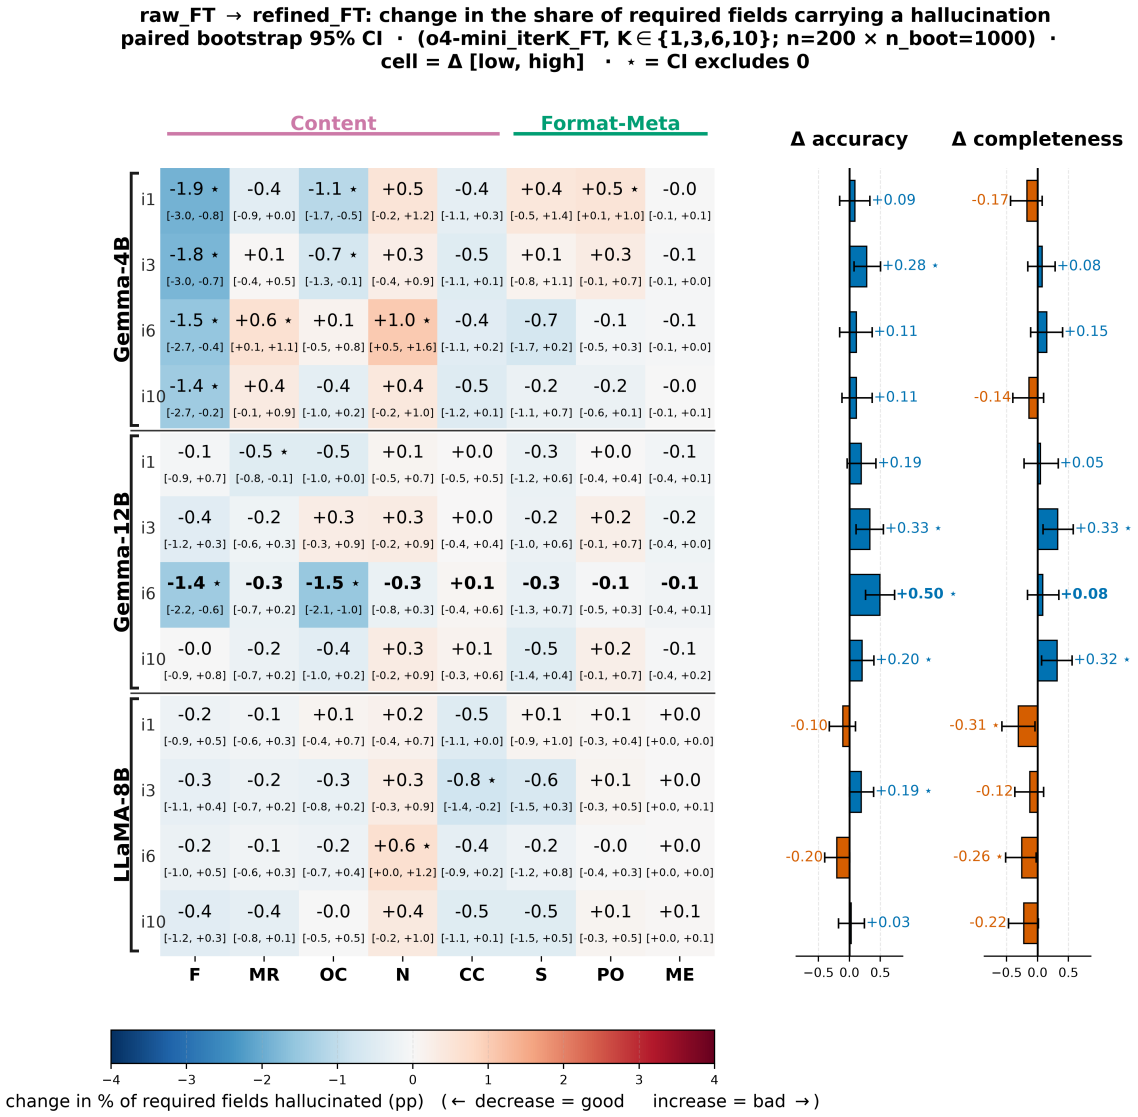

Figure 5: 8-cat decomposition of Fig. 7 (o4-mini), on the same field-rate scale, in percentage points (§4.1). Cell = Δ with the paired-bootstrap 95% CI [low, high] below; ⋆= significant (CI excludes 0); the two right-side panels give the o3 task judge's rubric items on a shared scale, matching Fig. 7. The Gemma-12B × iter_6 spike concentrates in F / OC at the cell level ($-1.4^\star$ and $-1.5^\star$ pp), so about 3 of the 100 required fields stop carrying a factual or over-clinical hallucination while the other six categories do not move. On the same base, iter_3 and iter_{10} are 8-cat n.s. and iter_1 moves only MR ($-0.5^\star$ pp) — evidence that the spike is cat-level single-shot.

rors are assessed against this template. Prompt Overgeneralization concerns unsupported reuse of prompt or example language; Metadata / Environment concerns internal-prompt, system, or generation-context exposure across the supplied context.

These input sections guide evaluation but do not partition errors one-to-one: the Content/FM groups in §3.1 are operational reporting groups, and category definitions may overlap.

FORMAT_TEMPLATE example (emergency assessment form).

```
I. Patient Info
  1. Name : Sentence format: full legal name
  2. Age/Sex : described as 62/F format
  3. Visit Date & Time :
       YYYY-MM-DD HH:MM 24-hour format
II. Clinical Data
  1. Chief Complaint : List with hyphens (-)
  2. History of Present Illness : Sentence
  3. Past Medical History :
       Separated by commas

E Qualitative case study

This case is an imaging report for an IPF patient (Gemma-12B + GPT-5.2 iter_3). Under raw_FT

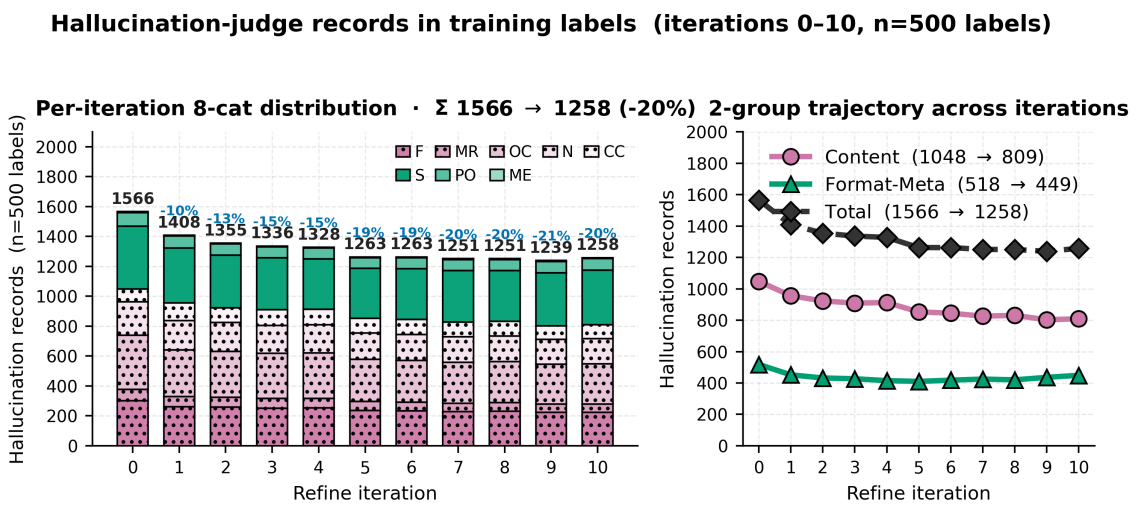

Figure 6: Hallucination-judge 8-cat evolution of training labels over o4-mini refinement iterations $0, \ldots, 10$ (same layout as Fig. 13; Content group dot-hatched, Format-Meta solid). Totals at iterations $0/1/3/6/10$ are $\Sigma\,1{,}566 \rightarrow 1{,}408 \rightarrow 1{,}336 \rightarrow 1{,}263 \rightarrow 1{,}258$, against 804 for GPT-5.2 at iteration 10. Content hallucinations move $1{,}048 \rightarrow 956 \rightarrow 909 \rightarrow 845 \rightarrow 809$, against 391 for GPT-5.2, and Format-Meta hallucinations $518 \rightarrow 452 \rightarrow 427 \rightarrow 418 \rightarrow 449$ return toward their round-0 count by iteration 10. These are hallucination-count changes, not measurements of how much label text changed.

the model imports four non-imaging tests into the imaging-only template and fabricates the imaging-specific fields they lack, giving 5 Content hallucinations; the iter_3 model emits none of the 5, while Format-Meta hallucinations move $3 \rightarrow 4$. The case is illustrative and not statistically representative. Figure 11 shows the raw_FT and refined_FT outputs side by side.

Sample-level hallucinations and task scores.

Group	Base	raw_FT	iter_3
Content (F/MR/OC/N/CC)	0	5	0
FM (S/PO/ME)	3	3	4
Σ	3	8	4
Accuracy (o3)	8	6	8
Completeness (o3)	6	3	3
Task (o3)	7.0	4.5	5.5

The stored o3 scores show that refinement improves Accuracy from 6 to 8 and Task from 4.5 to 5.5, while Completeness remains at 3, below Base's 6. Thus fewer Content hallucinations do not establish a complete or clinically usable note. This example illustrates why task components and both hallucination groups should be considered together.

The 5 Content hallucinations raw_FT introduces and what the iter_3 output does instead. (1) [OC] — adds the model's own clinical interpretation in the X-ray Remarks ("cardiomegaly may be related to pulmonary hypertension"); the iter_3 output carries no such interpretation, leaving only a comparison note in the Remarks. (2) [F] — in ABGA Remarks, "on room air" is a factual error (the input states "on 2 L oxygen"); the iter_3 output does not list the ABGA item. (3) [F] — interpreting physicians ("Lee Sang-min," "Kim Young-su") assigned to Inflammatory markers / ABGA / Biochemistry / PFT, which as lab/functional panels carry no interpreting physician in the input (the names are borrowed from the ordering physician and the CT reader); the iter_3 output does not list those examinations. (4) [F] — a fabricated PFT order date/time. (5) [N] — a Biochemistry examination-time error (15:00 instead of the specimen collection time, 14:50).

Observation. raw_FT's 5 Content hallucinations arise from two paths — (a) filling X-ray / HRCT Remarks with its own clinical interpretation (1 OC) and (b) importing non-imaging tests that the input provides only as laboratory/functional results (Inflammatory markers / ABGA / Biochemistry / PFT) and reporting them as imaging examinations, packing fabricated interpreting physicians / date-times / an "on room air" status into them as factual errors. the iter_3 output avoids all 5 at once by *listing only the imaging examinations and leaving the X-ray Remarks uninterpreted.*

FM observations (n=1). The refined_FT output has 4 detected FM hallucinations: the three also detected for Base plus "Remarks: None" in-

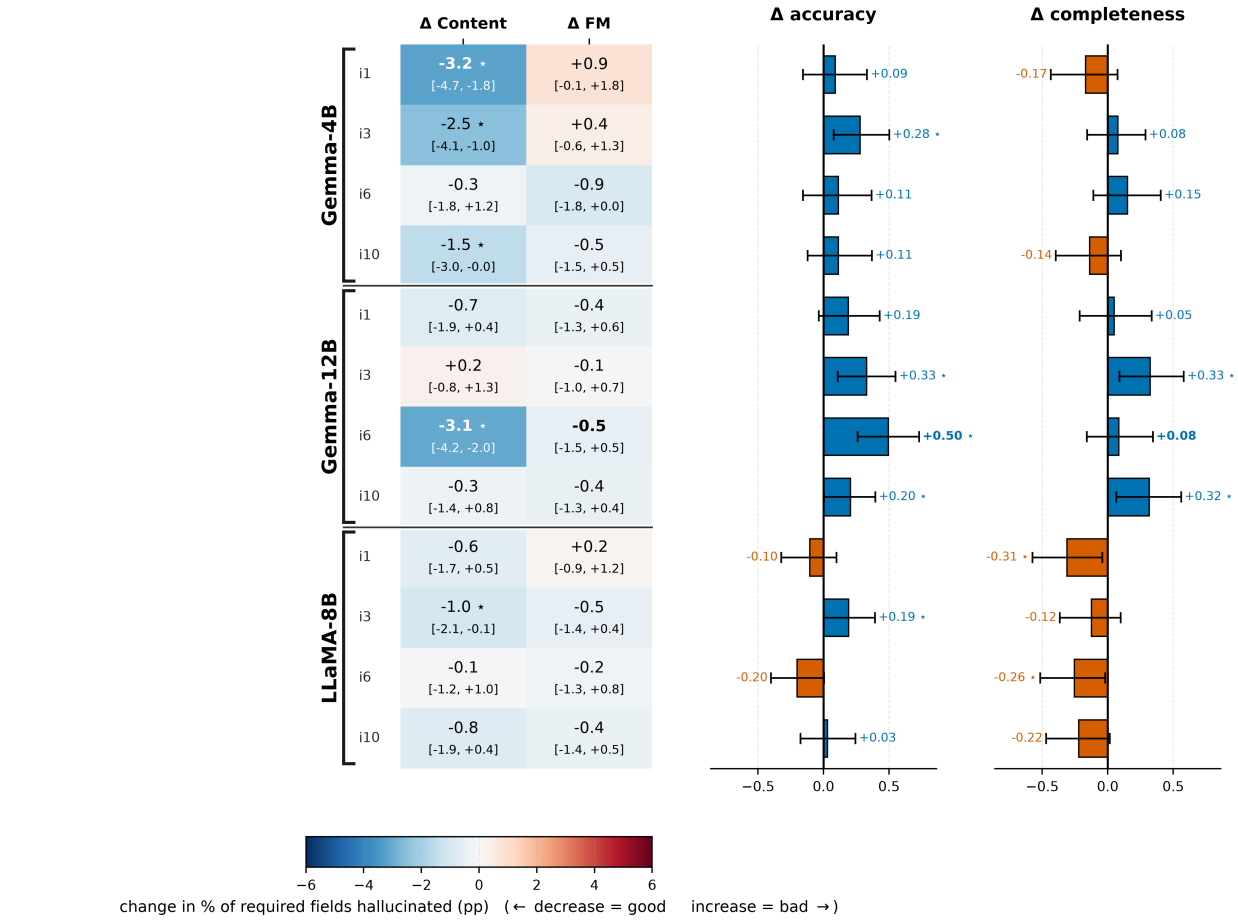

Figure 7: Paired-bootstrap 95% CI heatmap (2 columns: ΔContent, ΔFM) over the 12-cell grid (3 base × o4-mini × $K \in \{1, 3, 6, 10\}$). Cells are the change in the share of required fields that carry a hallucination, in percentage points (§4.1). Lowest observed Content rate = Gemma-12B × iter_6, **ΔContent** $= -3.1^{\star}$ $[-4.2, -2.0]$ **pp** $(-128^{\star}$ $[-174, -86]$ records) — 3 fewer fields out of every 100 carry one, about 60% of what GPT-5.2 removes at its selected setting — with an FM point difference of -0.5 (-23 records) whose CI includes zero. The same base's Content CIs at iter_1, iter_3, and iter_{10} include zero on both scales (-0.7, $+0.2$, -0.3 pp). Normalization leaves the ablation's pattern intact: the same 5/12 Content cells are * as on record counts, and FM is * in 0/12 rather than 1/12 (Gemma-4B iter_6, -0.9 $[-1.8, +0.0]$, is the borderline cell). The two right-side panels split the o3 task score into its rubric items on a shared scale (as in Fig. 3). Content is lowest at iter_6, where ΔAccuracy is largest ($+0.50^{\star}$) but ΔCompleteness is inconclusive ($+0.08$); at iter_3 both items rise by $+0.33^{\star}$. Unlike GPT-5.2, neither item moves consistently across K: Accuracy is *in 5/12 cells and Completeness in 4/12, the latter split between two Gemma-12B increases and two LLaMA-8B decreases.

stead of the instructed "–". These are downstream model outputs; this comparison does not isolate whether the deviations originated in label refinement or downstream generation. No large-scale manual annotation was performed.

F Task evaluation rubric

The task judge is instructed to assess a completed medical form against the supplied patient information and conversation (`INPUT_SENTENCES`), template (`FORMAT_TEMPLATE`), guidelines, and optional writing or field instructions. It is asked to assign a score between 0 and 10 for each criterion without explanation and not to confuse the criteria. The

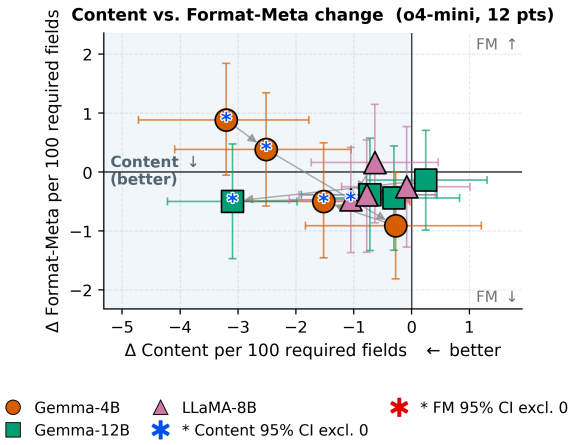

Figure 8: The o4-mini 12 points, in percentage points of the field rate, with paired 95% bootstrap CIs on both axes. The K-trajectory arrows go back and forth *without coherent direction*. The Gemma-12B trajectory is zig-zag: $\text{iter}_1 \to \text{iter}_3$ stagnation, $\text{iter}_3 \to \text{iter}_6$ lower-left spike, $\text{iter}_6 \to \text{iter}_{10}$ upper-right rebound. The horizontal CI includes $x{=}0$ in $7/12$ points (only $5/12$ are Content-*), in contrast to GPT-5.2's $12/12$ alignment (Fig. 14).

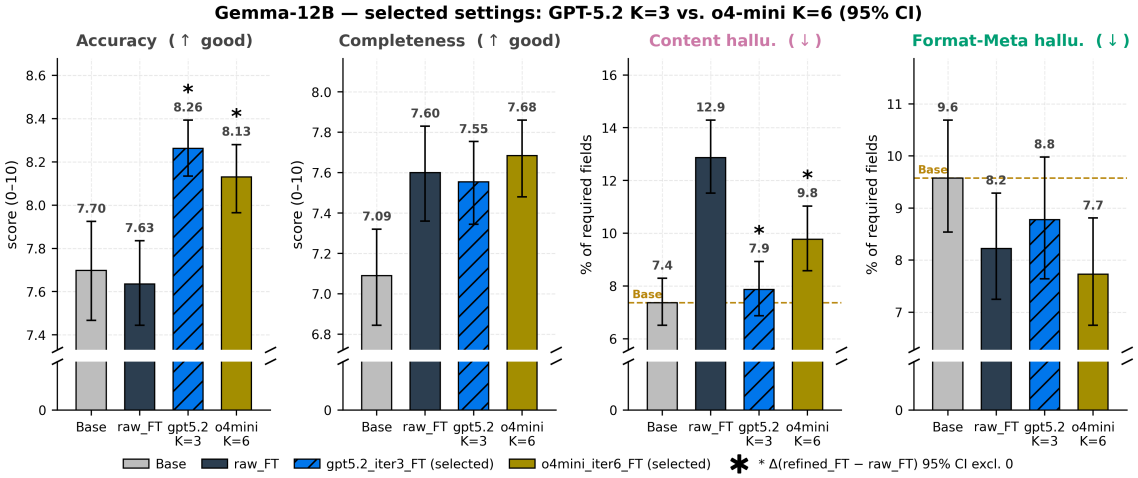

Figure 9: Absolute comparison of 4 conditions on Gemma-12B — Base / raw_FT / GPT-5.2_iter3_FT / o4mini_iter6_FT. Panels are the o3 task judge's two rubric items and the two hallucination groups as the percentage of required fields carrying one; whiskers are 95% bootstrap CIs on each level. Both selected settings significantly reduce Content ($-5.0/-3.1$) and significantly raise Accuracy (to $8.26/8.13$) at Completeness differences whose intervals include 0. Meanwhile, FM point estimates flip sign — $+0.6$ (GPT-5.2) / -0.5 (o4-mini) — and **both 95% CIs include 0 (non-significant)**, allowing either improvement or worsening in FM.

rubric defines the endpoints below; it does not specify intermediate score anchors, per-field weights, or a fixed penalty per omission.

Accuracy. Evaluate whether the completed form accurately reflects the patient's condition, history, and other source details without distortion or misinterpretation. Zero denotes major inaccuracies or misrepresentations; ten denotes a full and precise reflection of the original conversation.

Completeness. Evaluate whether all template fields that can be completed from the source are filled without omitting provided information. Zero denotes that most relevant available information is missing; ten denotes that all relevant fields are completely filled whenever information is available. This criterion measures coverage of source-supported information, not the absence of fabrication.

Task-judge settings. The o3 task judge uses the default reasoning effort (medium) and no explicit maximum-output-length override. Only the supplied evaluation prompt was used: beyond the criterion descriptions and 0/10 endpoints, no intermediate-score anchors or scored examples

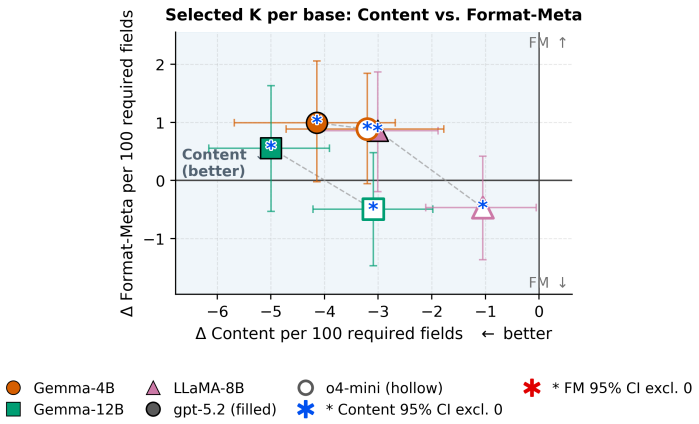

Figure 10: (ΔContent, ΔFM) scatter at per-base best-K (best = minimum point estimate of ΔContent), in percentage points, with paired 95% bootstrap CIs on both axes. 6 points = 3 base $\times$ 2 refiner. Filled = GPT-5.2, hollow = o4-mini; gray dotted = the difference between the selected settings on the same base. All six selected settings have negative Content point differences and FM intervals including zero. The latter allow improvement or worsening; they do not establish unchanged formatting performance.

Base	**Variant**	Δ Content (pp of req. fields) $\downarrow$	Δ task
Gemma-4B	iter_1	$-3.2^\star$	-0.04
	iter_3	$-2.5^\star$	$+0.18$
	iter_6	-0.3	$+0.13$
	iter_{10}	$-1.5^\star$	-0.01
Gemma-12B	iter_1	-0.7	$+0.12$
	iter_3	$+0.2$	$+0.33^\star$
	iter_6	$\mathbf{-3.1}^\star$	$\mathbf{+0.29}^\star$
	iter_{10}	-0.3	$+0.26^\star$
LLaMA-8B	iter_1	-0.6	$-0.21^\star$
	iter_3	$-1.0^\star$	$+0.03$
	iter_6	-0.1	$-0.23^\star$
	iter_{10}	-0.8	-0.10

Table 3: 12-cell (refined_FT $-$ raw_FT) Δ for o4-mini, in percentage points of the field rate (§4.1). Bold = lowest observed Content rate. Task differences are rounded to two decimal places from the decimal-valued source means, with ties rounded away from zero. ΔContent *in $5/12$ (vs. $12/12$ for GPT-5.2); on Gemma-12B the lowest observed Content rate (iter_6) and highest o3 Task mean (iter_3) occur at different depths.

Base	**Refine**	Selected K	Δ Content (pp)	Δ FM (pp)
Gemma-4B	GPT-5.2	iter_{10}	$\mathbf{-4.1}$	$+1.0$
	o4-mini	iter_1	-3.2	$+0.9$
Gemma-12B	GPT-5.2	iter_3	$\mathbf{-5.0}$	$+0.6$
	o4-mini	iter_6	-3.1	-0.5
LLaMA-8B	GPT-5.2	iter_{10}	$\mathbf{-3.0}$	$+0.9$
	o4-mini	iter_3	-1.0	-0.5

Table 4: Per-base settings selected by the lowest Content-rate point estimate in the evaluated grid; the same K is selected under record counts. Cells are percentages of the required fields (§4.1). All six selected ΔContent intervals exclude 0, and GPT-5.2 has a larger selected reduction than o4-mini for each base. These comparisons establish neither a general model-strength ordering nor an optimal refinement depth.

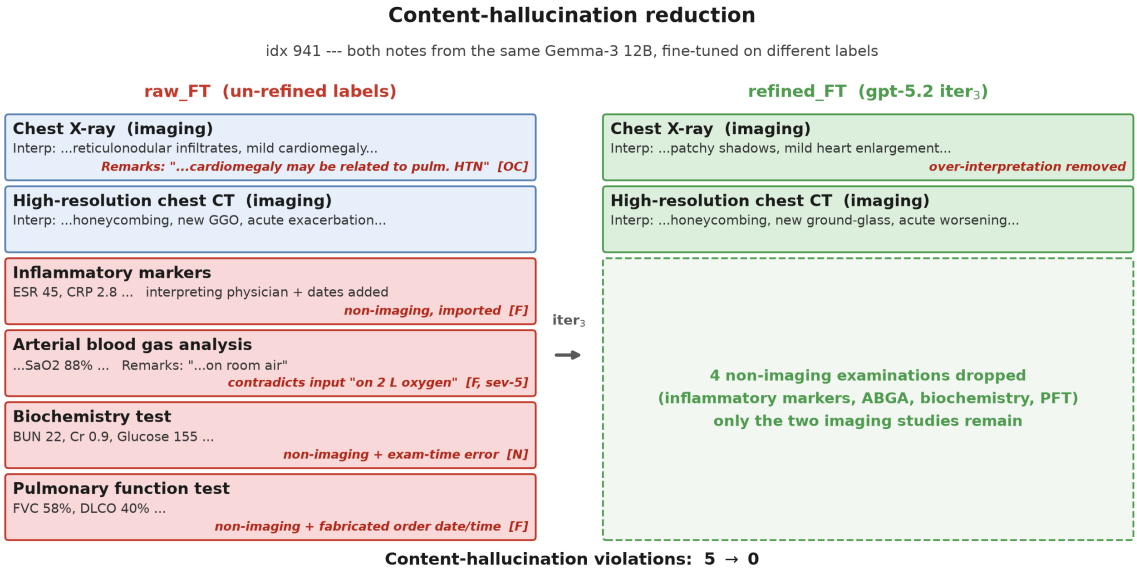

Figure 11: An illustrative case showing reduced Content hallucinations alongside increased Format-Meta hallucinations (HF idx-941). Both notes are generated by the *same* Gemma-12B, fine-tuned on different labels: raw_FT (un-refined labels) pulls four non-imaging tests (inflammatory markers, ABGA, biochemistry, PFT) into an imaging-only report and over-interprets the X-ray — 5 Content hallucinations; refined_FT (GPT-5.2 iter_3) drops the non-imaging examinations and the over-interpretation, keeping only the two imaging studies the template asks for (X-ray, HRCT), so the Content count goes $5 \rightarrow 0$. The o3 Completeness score remains 3/10 and FM increases from 3 to 4. Interpretation text abbreviated with "...".

were provided. Intermediate scores were assigned by the judge; a score difference is not calibrated to a number of omitted facts or to clinical benefit.

Reported criteria. We use the Accuracy and Completeness criteria from this prompt and report them separately. These are the rubric's endpoint descriptions, not validated clinical outcome measures.

Completeness alongside Content hallucinations. Completeness assesses coverage of available source information rather than output length. A shorter note can retain relevant information, while a longer note can repeat content without improving coverage. For Gemma-12B at iteration 3, the similar mean Completeness scores accompany substantially fewer Content hallucinations; this observation does not establish unchanged omissions. The pattern is not uniform across models or depths. Gemma-4B at iteration 1 improves Completeness by 0.290 (95% CI [0.055, 0.530]) while the Content rate decreases from 16.8% to 14.0% of the required fields. In contrast, LLaMA-8B at iteration 10 decreases Completeness by 0.290 (95% CI [−0.540, −0.030]) while the Content rate decreases from 12.7 to 9.7. Thus a lower hallucination rate can coexist with a loss in judge-assessed Completeness. Table 5 reports every GPT-5.2 setting. These exploratory, pointwise intervals are unadjusted for multiple comparisons and selection; no equivalence margin or clinically meaningful score threshold was specified.

Paired note-level analysis. We match each refined output to raw_FT by evaluation sample ID, and compute refined-minus-raw differences in each of the eight category counts, Content, Format-Meta, and Completeness. A decrease/increase is a strictly negative/positive difference; unchanged means exact equality of the stored values. No tolerance or clinical-equivalence threshold is introduced. Table 6 gives all nine joint outcomes for the selected setting; Table 7 summarizes every refiner/base/depth condition. Counts describe the fixed outputs and judge calls, not independently verified corrections of particular errors. A category count can fall even if some original errors persist and new errors appear. This analysis addresses how aggregate effects are distributed across notes, but is not a fact-level or field-level error rate, a length-controlled comparison, or an independent omission audit.

Base	K	Raw completeness	Refined completeness	Difference [95% CI]	Content, % of req. fields (raw → refined)
Gemma-4B	1	7.115	7.405	$+0.290$ [$+0.055$, $+0.530$]	$16.8 \rightarrow 14.0$
Gemma-4B	3	7.115	7.233	$+0.117$ [-0.138, $+0.373$]	$16.8 \rightarrow 13.2$
Gemma-4B	6	7.115	7.320	$+0.205$ [-0.050, $+0.465$]	$16.8 \rightarrow 12.8$
Gemma-4B	10	7.115	7.228	$+0.113$ [-0.122, $+0.355$]	$16.8 \rightarrow 12.7$

Table 5: Completeness and the Content rate across all 12 GPT-5.2 settings on the same 200 evaluation examples; Content is the percentage of required fields carrying a hallucination (§4.1). Completeness differences compare refined_FT with raw_FT; intervals use the additional 10,000-resample paired bootstrap described in the main text. Higher Completeness and a lower Content rate are desirable. An interval containing zero does not establish equivalence.

	Completeness change		
Content change	Lower	Equal	Higher
Fewer	43	37	34
Equal	21	21	19
More	14	5	6

Table 6: Paired changes for Gemma-12B/GPT-5.2 iteration 3 versus raw_FT ($n = 200$). Equal Completeness denotes equal judge scores, not proven information preservation.

G Training configuration

Training is implemented using Axolotl 0.14.0. Within each base model, raw-label SFT and refined-label SFT at every evaluated depth and for both refiners use the identical configuration below. Five settings are tuned per base model — adapter rank, alpha, and dropout, learning rate, and gradient accumulation — and are $64/128/0.1$, 10^{-4}, and 4 for Gemma-12B; $16/32/0.1$, $2{\times}10^{-4}$, and 8 for Gemma-4B; and $64/128/0.05$, $5{\times}10^{-5}$, and 8 for LLaMA-8B. All remaining settings are shared. Model and tokenizer checkpoints, chat templates, dataset paths, and output paths vary with the experimental condition. Realized training duration depends on the stopping rule in each run.

Adapter and precision. The model is loaded in 4-bit NF4 with double quantization, using bfloat16 for the 4-bit compute and storage dtypes. The adapter setting is QLoRA with the per-base rank, alpha, and dropout listed above. Target modules are `q_proj`, `k_proj`, `v_proj`, `o_proj`, `gate_proj`, `up_proj`, and `down_proj`. The precision flags are `bf16=auto`, `fp16=false`, and `tf32=true`.

Input and batching. The configuration uses each model's corresponding chat template and end-of-turn token, assistant-role training, last end-of-sequence token supervision, and `train_on_inputs=false`. Maximum sequence length is 8,192. Training and evaluation sample packing and padding to the maximum sequence length are disabled. Training uses one NVIDIA RTX PRO 6000 GPU. Micro-batch size is 2 for every base model, so the per-base gradient accumulation above gives an effective batch size of 8 examples per optimizer update for Gemma-12B and 16 for Gemma-4B and LLaMA-8B. Gradient checkpointing is enabled with `use_reentrant=false`; Flash Attention is disabled.

Optimization. The configured seed is 42. Optimization uses fused AdamW (`adamw_torch_fused`), the per-base learning rate above, a cosine schedule, weight decay 0.01, warmup ratio 0.03, and maximum gradient norm 1.0. The epoch limit is 7.

Evaluation-note generation. All Base, raw_FT, and refined_FT evaluation notes are generated with the same sampling settings: temperature 0.7 and top-p 0.95. Failed generations and empty responses are retried until a non-empty response is obtained; generated notes are judged as produced, without exclusion or regeneration.

			Content change			Completeness among notes with fewer Content hallucinations		
Base	Refiner	K	Fewer	Equal	More	Lower	Equal	Higher
Gemma-4B	GPT-5.2	1	90	59	51	28	32	30

LLaMA-8B	o4-mini	6	70	59	71	26	26	18
LLaMA-8B	o4-mini	10	81	49	70	38	22	21

Table 7: Paired note-level changes versus raw_FT across all 24 refinement conditions (200 notes each). Fewer, equal, and more Content counts sum to 200 per row. The final three columns partition only the notes with fewer Content hallucinations and sum to the Fewer column. These are descriptive counts without multiplicity-adjusted inference.

Checkpoint selection. Evaluation and checkpoint saving are configured every 20 steps, with at most five checkpoints retained. The model with the lowest `eval_loss` is loaded at the end. Early stopping has patience 3 and threshold 0.001.

Internal validation setting. With `val_set_size=0.1`, the 500-example dataset snapshot is partitioned into 450 optimization and 50 internal-validation examples. The internal set is used for early stopping and minimum-loss checkpoint selection. The 450/50 sample split is fixed across all three base models, raw-label SFT, both refiners, and every evaluated depth; only the completed-note labels change with refinement. The 200-example evaluation set is randomly drawn without generator stratification from the same original 3,000-example pool and is disjoint from the entire 500-example refinement corpus. The random seed for selecting the refinement and evaluation subsets was 123, distinct from the training seed of 42.

H Detection and refinement prompts

Shared task specification. The hospital-form completion prompt is inserted into both detection and refinement. It supplies three components: user instructions, a medical template, and patient information. Instructions are hard constraints, patient information is the only factual source, and the template fixes field names, headings, order, line breaks, tables, and separators. Placeholder or example content must be replaced with source-supported content. When required information is missing, the prompt follows the user's missing-data instructions; absent such instructions, it permits specified placeholders such as a dash, "No record," "No notable findings," or "Not applicable." It prohibits unsupported inference and requests only the completed template. Adherence to these instructions is assessed through the output evaluations.

Detection inputs and outputs. The system message supplies the error-classification instructions, the eight category definitions and examples, and the shared task prompt. The user message supplies the original task input and current completed-note output. For each hallucination, the detector is asked for

its type and a verbatim sentence or field with an explanation. The call requires the `VIOLATION_TOOLS` interface with `tool_choice=required`.

Structured output and counting unit. The function `VIOLATION_SCHEMA` returns an object containing a `violations` array. Each item carries a single `violation_type` chosen from the eight categories together with a free-text `violated_reason`; additional properties are disallowed at both object levels. There is no separate evidence field, although the prompt requests a verbatim excerpt and explanation. The schema permits an empty array and does not enforce uniqueness across records. Multiple records can therefore refer to the same sentence or fact; single-category assignment per record does not establish mutually exclusive underlying error categories. All returned hallucination records are counted without deduplication. Counts therefore measure detector-returned records rather than unique clinical errors. The schema field names use *violation*; each such record is a hallucination record in the terminology of §4.1.

Training-label evaluation. For both refiners, the reported training-label hallucination counts at every round, including round 0, come from Gemini evaluation of the labels. Gemini results are stored for reporting only and are not fed back into refinement or early stopping; both use the refiner's own DETECT records. A common judge and rubric support comparisons across rounds; rubric validity is discussed in Limitations.

Condition information. Neither the hallucination judge nor the task judge is given the generating model name, the Base/raw_FT/refined_FT condition, or the refinement iteration. Withholding these identifiers does not rule out sensitivity to output style or shared-rubric bias.

Evaluation repetitions. Each note receives one valid response from each judge; scores and hallucination records are not aggregated across repeated judgments. Failure retries are distinct from repeated valid evaluations. The reported bootstrap intervals condition on these fixed responses and do not quantify judge-call variability.

Call failures and retries. For both the hallucination and task judges, failed calls and responses that violate the required format are retried until a valid response is obtained. DETECT and REFINE use the same retry policy for call failures and invalid response formats. A valid empty `violations` array is a zero-detection result, distinct from a failed or malformed response.

Shared detection protocol. The same detection prompt and tool interface are used by the self-detection node and the external Gemini evaluation node. For self-detection, GPT-5.2 uses high reasoning effort and o4-mini uses medium reasoning effort (the default setting used in these runs); both have a configured output-token limit of 16,384. The evaluation model is gemini-3.1-pro-preview with high thinking level and an output-token limit of 8,192. The judge uses a different model with the same classification instructions and task specification.

Category interpretation. Factual errors concern invented facts; Medical Reasoning concerns unsupported clinical causality or judgments; Conversational Context concerns dialogue interpretation and speaker attribution; Numerical concerns numbers, times, ranges, or units. Structural includes incorrect field placement, invented fields, and duplicated or deleted required fields. Metadata / Environment concerns internal prompts, system information, or the model's generation context, such as identifying the document as GPT-generated. Prompt Overgeneralization concerns copying or generalizing prompt examples without patient-specific support. Overclinical Reasoning concerns inference using medical knowledge absent from the dialogue. Category assignment used only these definitions, with no additional tie-breaking rules for Medical Reasoning versus Overclinical Reasoning. For example, the rubric's unsupported "suspected pneumonia" inference from cough and mild fever could fit both definitions; this illustrates conceptual overlap, not an adjudicated example from the evaluation set. These definitions can overlap, and they do not specify a clinically validated ordering of severity.

Refinement inputs and constraints. The refiner receives the shared task prompt, original task input, current note, and detected error list. It is instructed to preserve all correct content, revise or remove only listed issues, make minimal corrections, preserve style and structure as much as possible, and return only the corrected note. The task specification, detection interface, category definitions, and refinement constraints are described in this appendix. For REFINE calls, GPT-5.2 uses high reasoning effort and o4-mini uses medium reason-

ing effort (the default setting used in these runs); both have a maximum output of 16,384 tokens.

I Output-length sensitivity analysis

This appendix asks whether the hallucination-rate reductions of §4.3 are produced by shorter, more conservative completions, and reports output lengths and length-normalized counts for every condition. Lengths are character counts of the generated notes, 200 per condition for all 30 conditions. Table 8 reports mean and median lengths alongside Content counts.

We estimate corpus-level Content hallucination density as $1{,}000C/(n\bar{L})$, where C is the total Content hallucination count, $n = 200$, and $\bar{L}$ is mean character length. This ratio of totals is distinct from a mean of note-level densities. Per-sample lengths are available for all 30 conditions, so we accompany each refined-minus-raw density difference with a paired percentile bootstrap interval that resamples the same 200 evaluation IDs across the compared conditions (10,000 resamples; seed 20260907), recalculating the ratio in each resample. Intervals are pointwise and conditional on the fixed outputs and judge records, without correction for multiple comparisons. This normalization is a descriptive exposure adjustment, not a matched-length experiment.

GPT-5.2 refinement lowers density relative to raw_FT in all 12 settings (5.8–44.6%), and the interval excludes zero in 7 of the 12. For Gemma-12B at iteration 3, mean length falls from 2,310.8 to 1,979.7 characters while Content hallucination density falls from 1.086 to 0.768, a difference of -0.318 (95% CI $[-0.443, -0.199]$). In Gemma-4B, mean lengths increase by 7.4–37.6%, Content counts decrease by 17.0–24.9%, both task judges' mean Completeness increases at all four depths, and the density reduction is significant at every depth; between 55.5% and 68.5% of individual outputs are longer than their raw_FT counterparts. Output shortening alone therefore does not explain these reductions. With o4-mini, density decreases in six settings and increases in six; no decrease has an interval excluding zero, whereas four increases do.

Length distributions are skewed. LLaMA-8B/o4-mini iteration 1 has a mean of 4,118.4 characters but a median of 1,724.5, and only 31.5% of its notes are longer than their raw_FT counterparts. Gemma-12B/o4-mini iteration 3 likewise has a higher mean but a lower median than raw_FT. A few long outputs can lower corpus-level density without improving factual quality. Means and medians are reported without trimming. Character normalization does not measure supported-fact recall or field coverage; task-judge Completeness and an independent omission audit would address different questions.

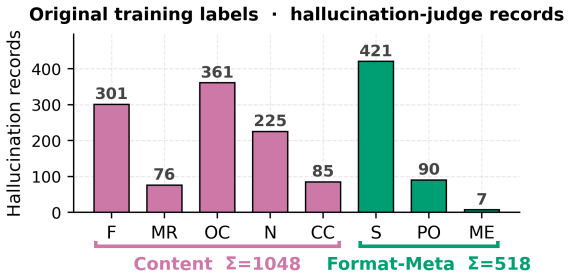

Figure 12: Hallucination-judge 8-cat distribution of synthetic training labels (n=500, Σ=1,566, $\approx$ 3.1 per sample). Bar color = 2-group taxonomy (pink = Content / green = Format-Meta); brackets below the x-axis = group sums.

J Task-component comparison under both judges

Table 9 expands the raw_FT − Base task-component comparison of §4.2.

K Supplementary training and cost plots

The following plots and table provide supporting detail for the training-label analysis, joint Content/Format-Meta changes, and refinement costs discussed in the main text.

Cost calculation. For a stored response, let I, C, and O denote API-reported input, cached-input, and output tokens. The calculation is $[(I - C)p_{\text{in}} + Cp_{\text{cache}} + Op_{\text{out}}]/10^6$. The rates used (USD per million tokens, in that order) are $(1.75, 0.175, 14.00)$ for GPT-5.2 and $(1.10, 0.275, 4.40)$ for o4-mini. Usage from stored DETECT and REFINE responses is summed; evaluation responses are excluded. Each refinement iteration pairs a detection with the refinement it triggers, and iteration 0 has no refinement-call cost. The reported totals sum every successful REFINE and DETECT call made during the refinement run: for depth K these are REFINE_1–REFINE_K together with the detections DETECT_1–DETECT_K that evaluate their outputs and determine whether refinement continues. The detection of the original note (DETECT_0) was produced before these runs

Base	Condition	Mean chars	Median chars	Content	Content/1k chars	Δ density (%)

Table 8: Character-length aggregates of the generated notes and Content density for all 30 conditions (200 outputs each). Density changes compare refined_FT with raw_FT of the same base model; paired bootstrap intervals for the twelve GPT-5.2 differences are reported in the text.

Base model	**Component**	**o3**	**Gemini 3.8 Flash**
Gemma-4B	Accuracy	$+0.230\ [-0.097, +0.503]$	$+0.572^{\star}[+0.242, +0.868]$
	Completeness	$+1.250^{\star}[+0.960, +1.535]$	$+1.199^{\star}[+0.869, +1.520]$
Gemma-12B	Accuracy	$-0.062\ [-0.315, +0.218]$	$-0.181\ [-0.463, +0.112]$
	Completeness	$+0.510^{\star}[+0.245, +0.775]$	$+0.179\ [-0.113, +0.459]$
LLaMA-8B	Accuracy	$+0.742^{\star}[+0.525, +0.988]$	$+0.944^{\star}[+0.681, +1.228]$
	Completeness	$+1.130^{\star}[+0.885, +1.375]$	$+1.006^{\star}[+0.775, +1.237]$

Table 9: Accuracy and Completeness for raw_FT − Base under both task judges on the same 200 evaluation samples. Cell = Δ [low, high]; ⋆= the interval excludes 0. The o3 intervals are those plotted in Fig. 2; the Gemini intervals apply the same paired procedure to that judge's stored per-note scores (n_{boot}=1,000, seed 0, percentile $[2.5\%, 97.5\%]$). Completeness increases on all 3 bases under o3, whereas Accuracy does so on 1 of 3; the two judges agree in sign on all six component differences. An interval containing zero does not establish equivalence.

and is not part of the reported totals. A terminating DETECT that returns no hallucinations is therefore counted even though no REFINE follows it. Usage fields were present in every included response; the rates are those used in our cost calculation, not a reconciliation with billing statements.

L Notes with no detected hallucinations

We report the number and proportion of notes with zero detected Content hallucination records and zero records across all eight categories (Table 11). Each condition contains the same 200 evaluation inputs. For the selected Gemma-12B iter_3 setting, the Content-zero count rises from 29 of 200 (14.5%) under raw_FT to 54 (27.0%), against 51 (25.5%) for Base; across the 12 GPT-5.2 settings

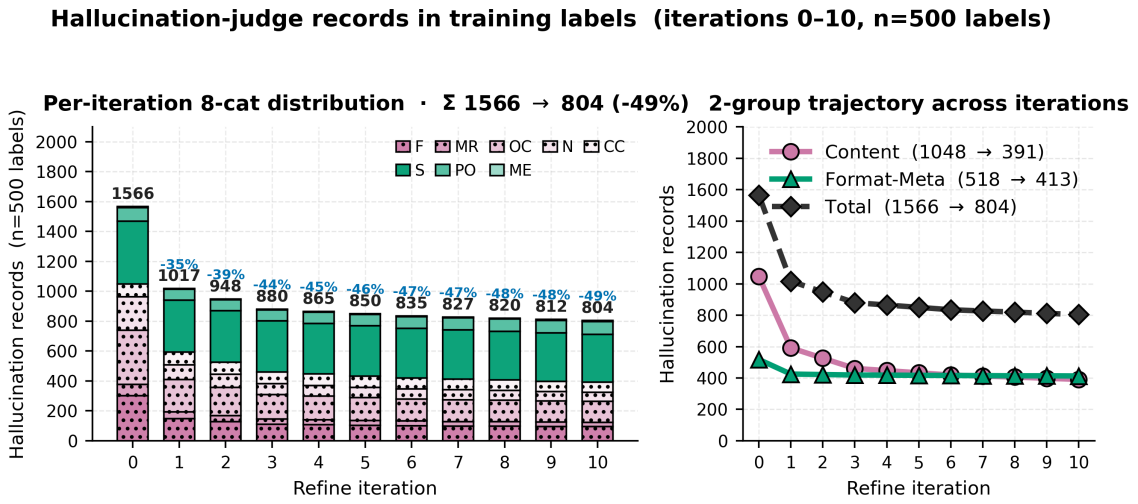

Figure 13: Hallucination-judge 8-cat evolution of the training labels (n=500) over GPT-5.2 refinement iterations $0, \ldots, 10$. **(Left)** 8-cat stacked bar (2-group palette: Content pink *(dotted)* / Format-Meta green + within-group shade); bar-top label = $\Delta\%$ vs iteration 0. **(Right)** 2-group trajectory: Content (pink •), FM (green ▲), Total (black ◇ dashed).

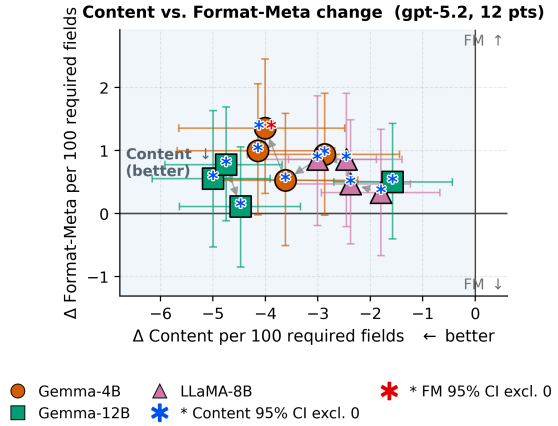

Figure 14: x=ΔContent, y=ΔFM (both refined_FT − raw_FT, in percentage points), with paired 95% bootstrap CI bars on both axes. 12 points = 3 base × GPT-5.2 × $K \in \{1, 3, 6, 10\}$. **All 12 points have x<0 with horizontal CI excluding 0 (Content significantly reduced for every cell)**; FM increases significantly for Gemma-4B at $K = 6$; the other eleven vertical CIs include zero and do not establish equivalence. Arrows = K trajectory.

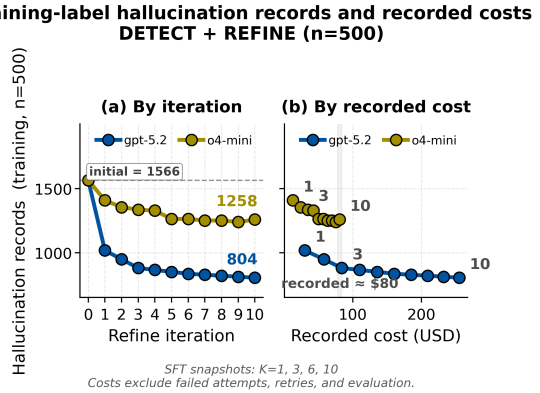

Figure 15: **(a)** Per-iteration *train-side* residual hallucinations remaining in the labels — GPT-5.2 drops steeply from iteration 0 → 1 (1,566 → 1,017); o4-mini iteration 3 = 1,336 and iteration 10 = 1,258 plateau. **(b)** x = cumulative refinement cost, y = train-side residual hallucinations (sharey). At approximately $80 in recorded successful-response costs (failed attempts, retries, and evaluation costs excluded), **GPT-5.2 iteration** 3 (880) **leaves fewer train residuals than o4-mini iteration** 10 (1,258).

it increases relative to raw_FT in 10 (Gemma-4B iter_3 and LLaMA-8B iter_1 decrease). All-category zero proportions remain between 0% and 2% across all 30 settings. These descriptive proportions complement the field-normalized rates but do not establish clinical error freedom or judge sensitivity.

M Additional task-judge sensitivity analysis

Gemini 3.8 Flash re-evaluates the same generated notes for the same 200 examples with the same evaluation prompt as o3, and we again use its Accuracy and Completeness criteria. The additional evaluation covers all 30 conditions: Base, raw_FT, and four refinement depths for each of GPT-5.2 and o4-mini, across three base models. It uses the

Refine	Cumulative cost (USD)	Residual hallu
GPT-5.2 (iter 1–3)	$83.83	**880**
o4-mini (iter 1–3)	$34.61	1,336
o4-mini (iter 1–10)	$80.56	1,258

Table 10: Cumulative costs of final successful DETECT and REFINE responses and *train-side* residual hallucination records in 500 labels. Costs are calculated from API-reported token usage and model-specific rates. Failed attempts, retries, and evaluation are excluded; these are not full execution costs. At approximately $80 in recorded costs, GPT-5.2 iteration 3 leaves fewer residual records than o4-mini iteration 10 (880 vs. 1,258). The three rows compare settings at comparable recorded cost rather than at equal depth: GPT-5.2 iteration 10 reaches $255.00 with 804 residual records. This is a comparison of label-refinement outcomes and API costs, not a measure of downstream or clinical cost-effectiveness. Figure 15 shows the observed cost trajectories; Appendix C reports the selected per-base comparisons.

default thinking level (medium) and no explicit maximum-output-length override. One valid response per note supplies the final score.

Relative to raw_FT, Accuracy means increase under both judges in 22/24 refined conditions. Completeness increases under both in 13/24, changes in opposite directions in 6/24, and decreases under both in 5/24. These are descriptive comparisons of means.

For GPT-5.2 refinement, all four Gemma-4B conditions improve Completeness under both judges, whereas LLaMA-8B at $K = 10$ declines under both. For Gemma-12B at $K = 3$, the o3 difference is -0.045 (95% CI $[-0.305, 0.230]$), whereas Gemini's mean difference is $+0.508$. For o4-mini refinement, Gemma-12B improves Accuracy and Completeness under both judges at all four depths. At $K = 6$, its Content count falls from 502 to 374, with Completeness differences of $+0.085$ (o3) and $+0.405$ (Gemini). However, o4-mini's Gemma-4B at $K = 10$ and LLaMA-8B at $K = 1, 6, 10$ show lower Completeness under both judges. Thus a uniform loss of judge-assessed Completeness does not explain all observed Content reductions, but omissions and length effects remain unresolved.

Table 12 reports all condition means. Changes of means do not establish equivalence or clinical benefit, and the intervals below are pointwise and unadjusted for the 24 comparisons. Shared prompts and one call per note also leave rubric bias and repeated-judgment variability unresolved.

Paired intervals under the additional judge. This judge returns one score per note, so the paired bootstrap of §4.1 applies to it unchanged (n_{boot}=10,000, seed 20260907, applied to both judges' stored per-note scores for this comparison). Over the 24 refined conditions, Accuracy increases * in 17 and Completeness in 10, and *no* condition shows a * Completeness decrease; the corresponding o3 counts are 12 * Accuracy increases and 3 * Completeness increases against 2 * Completeness decreases. For the selected Gemma-12B $\times$ GPT-5.2 iter_3 configuration both components rise * under this judge — Accuracy $+0.947^\star$ $[+0.705, +1.209]$ and Completeness $+0.508^\star$ $[+0.247, +0.792]$ — whereas o3 leaves Completeness inconclusive (-0.045 $[-0.305, +0.230]$). Restricted to GPT-5.2, Accuracy is * in 11 of 12 cells (all but LLaMA-8B iter_{10}) and Completeness in 5 of 12, against 8 and 1 under o3. The Accuracy gain is thus reproduced under both judges, while the coverage conclusion is judge-dependent: one judge supports an increase at the selected setting and neither supports a decrease. Several Completeness intervals lie close to zero, so these counts shift by one or two cells under a smaller resample count or a different seed.

Level shift and note-level agreement. The additional judge's higher absolute scores are concentrated in Completeness: averaged over all 30 conditions and 200 notes, its scores exceed o3's by $+1.145$ on Completeness against $+0.475$ on Accuracy, so the gap is not a uniform rescaling of both components. Per-note scores correlate at r=0.761 (Accuracy) and r=0.685 (Completeness) across the 6,000 scored notes and land within one point of each other on 76.6% and 57.9% of them, yet the two judges agree on the *sign* of the per-note change against raw_FT in only 55.2% (Accuracy) and 50.3% (Completeness) of the 4,800 paired notes. Aggregate directions therefore agree far more often than individual notes do, and note-level judgments from either judge should not be read as reliable on their own.

Graph Evidence Is Not Text Evidence: Serialization Faithfulness as Structural Invariance in Graph-Grounded Language Models

Abstract

Graph-grounded language models are usually evaluated by answer accuracy, yet a serialized prompt is a string representation of a graph rather than the graph itself. We argue that faithful graph-grounded reasoning requires the composed predictor $F_\theta \circ z$ to be well-defined on graph-query equivalence classes: structurally equivalent graph-query pairs should induce the same prediction regardless of textual realization. We formalize this as a structural invariance property, decompose unfaithfulness into syntactic instability, semantic interference, and distractor susceptibility, and introduce corresponding diagnostics. On controlled graph reasoning tasks, DeepSeek-V4-Flash achieves 98.9% accuracy and near-perfect syntactic stability (FS $=$ .975), yet its isomorphism consistency drops from .969 to .701 under semantic-name relabeling ($\Delta_{\text{sem}} = .268$); only 72.9% of originally correct answers survive this transformation. Across four model families, we observe targeted semantic interference in high-accuracy models, broad unfaithfulness in weaker models, and near-perfect invariance as a capability ceiling. A graph-grounded LLM can be accurate without being structurally faithful: its predictions may fail to remain invariant under graph-equivalent textual relabelings.

1 Introduction

Graph-grounded language models are used for graph reasoning, knowledge graph QA, and retrieval-augmented generation (Edge et al., 2024; He et al., 2024b; Tang et al., 2024). But these models consume text, not graphs; any graph evidence must pass through a *textual serialization* step, typically treated as a neutral implementation detail. We argue this is unwarranted. Citation faithfulness research establishes that an answer can be correct but not faithfully grounded in the provided evidence (Wallat et al., 2025); the same distinction applies to graph evidence. An answer produced by relying on node names rather than connectivity may be correct, but it is not structurally faithful.

This paper makes three contributions. First, we formalize serialization faithfulness as an invariance property over graph-query equivalence classes, establishing structural invariance as a necessary condition for graph faithfulness (Proposition 1). Second, we decompose unfaithfulness into syntactic instability, semantic interference, and distractor susceptibility. Third, we show that accuracy does not imply structural faithfulness: a model can answer correctly yet flip its answer under isomorphic relabeling with semantically suggestive names.

2 Related Work

Graph-grounded LLMs. GraphGPT (Tang et al., 2024) aligns GNN-encoded tokens with LLM tokens; InstructGLM (Ye et al., 2024) encodes structure via language; GraCoRe (Yuan et al., 2025) notes "node ordering impacts task success"; TalkLikeaGraph (Fatemi et al., 2024) finds format-dependent accuracy variation; NLGraph (Wang et al., 2023) shows brittleness to spurious correlations. These establish that representation matters, but primarily evaluate accuracy. We isolate graph-preserving transformations as diagnostics for faithful interpretation.

Faithfulness and sensitivity. Citation correctness $\neq$ faithfulness (Wallat et al., 2025); input ordering can substantially affect LLM outputs (Guan et al., 2025); format sensitivity is a general LLM property (He et al., 2024a); in graph ML, permutation-invariant or permutation-equivariant computation is a fundamental requirement (Zhang et al., 2023). We connect these at the graph-to-language interface: does serialized prompting induce a well-defined graph reasoning function?

3 Serialization Faithfulness as Graph Invariance

A graph reasoning task defines a target function $y : \mathcal{G} \times \mathcal{Q} \to \mathcal{Y}$ over graph-query pairs. A serialization-based LLM instead computes a function over strings, $F_\theta : \Sigma^* \to \mathcal{Y}$. Serialization faithfulness asks whether $F_\theta \circ z$ is well-defined on graph-equivalence classes: equivalent graph-query pairs should induce the same prediction regardless of their textual realization.

Formal setup. A serialization map $z_{\rho,\pi,\ell} : \mathcal{G} \times \mathcal{Q} \to \Sigma^*$ depends on format ρ, ordering π, and labeling ℓ. We suppress the serialization subscripts when they are clear from context. *Structural equivalence*: $(G, q) \sim_s (G', q')$ if $G' = \phi(G)$ is an isomorphic relabeling and $q' = \phi(q)$. *Label-preserving equivalence*: $(G, q) \sim_\ell (G', q')$ if $y(G, q) = y(G', q')$. IC uses $\sim_s$; DR uses $\sim_\ell$. This distinction separates whether a model respects structural equivalence from whether it is robust to weaker answer-preserving perturbations. A model is serialization-faithful with respect to an equivalence $\sim$ if

$$(G, q) \sim (G', q') \;\Rightarrow\; F_\theta(z(G, q)) = F_\theta(z(G', q')) \tag{1}$$

Desideratum: well-defined graph reasoning under serialization. For a serialized LLM to behave as a graph-grounded reasoner, the composed predictor $F_\theta \circ z$ should be well-defined on graph-query equivalence classes. That is, if two serialized strings encode structurally equivalent graph-query pairs, then any difference in prediction reflects dependence on non-structural features of the serialization rather than on the graph evidence itself.

Proposition 1 (Structural invariance is necessary). Let h be a predictor whose value depends only on the isomorphism class of a graph-query pair (G, q). Then for any isomorphism ϕ, $h(G, q) = h(\phi(G), \phi(q))$. Consequently, if $F_\theta \circ z$ changes its prediction under an isomorphic relabeling, the change cannot be explained by graph structure alone. *Proof.* An isomorphism preserves all structural relations (adjacency, paths, degrees, motifs). Since h depends only on the isomorphism class, relabeling identifiers cannot change its output; any prediction change must arise from non-structural features of the serialization.

Unfaithfulness decomposition. We decompose unfaithfulness into three components:

1. *Syntactic serialization instability* ($1 - \mathrm{FS}$, OS): dependence on format or ordering.
2. *Semantic interference* ($\Delta_{\mathrm{sem}} = \mathrm{IC}_N - \mathrm{IC}_M$): the gap between neutral and semantic-name relabeling.
3. *Distractor susceptibility* ($1 - \mathrm{DR}$): sensitivity to label-preserving irrelevant structure.

The central component is semantic interference, measured by the consistency gap between neutral and semantic-name relabeling. Each diagnostic instantiates the same invariance requirement with a different transformation family: format stability varies the textual map z_ρ while holding the graph-query pair fixed; order sensitivity varies the ordering π; isomorphism consistency varies the graph-query pair within structural equivalence $\sim_s$; distractor robustness varies the graph-query pair within label-preserving equivalence $\sim_\ell$. Thus all metrics test whether $F_\theta \circ z$ is well-defined under transformations that preserve the task-relevant graph evidence.

Isomorphism Consistency (IC). Whether structurally identical graphs with relabeled nodes yield the same answer: $\mathrm{IC}(q, G, \phi) = \mathbf{1}[\hat{a}(q, z(G)) = \hat{a}(\phi(q), z(\phi(G)))]$. We test *neutral* relabeling ($A \to X_1, B \to X_2, \ldots$) yielding IC_N, and *semantic-name* relabeling yielding IC_M, which tests whether semantically suggestive identifiers affect predictions on an isomorphic graph. We define:

$$\Delta_{\mathrm{sem}} = \mathrm{IC}_N - \mathrm{IC}_M \quad \text{(semantic interference)} \tag{2}$$

$$\mathrm{CF}_M = \Pr[\hat{a}_M = y \mid \hat{a}_0 = y] \tag{3}$$

CF_M measures whether predictions that were initially correct remain correct after semantic relabeling, a stricter test than consistency alone. $\mathrm{CF}_M < 1$ indicates dependence on surface cues disrupted by the relabeling.

Supporting diagnostics. *Format Stability* (FS): agreement across formats; *Order Sensitivity* (OS): answer flip rate under reordering; *Distractor Robustness* (DR): whether label-preserving disconnected structure changes the prediction ($y(G, q) = y(G \cup D, q)$ required).

4 Experimental Setup

Tasks and graphs. Four graph reasoning tasks with structurally defined ground truth, on 100 con-

Factor	Settings
Tasks	Connectivity, Path, Triangle, Common Neigh.
Graphs	100 ER graphs, $n \in \{5, \ldots, 15\}$, p=0.3
Models	Qwen3.6-35B-A3B, DeepSeek-V4-Flash, Llama-4-Scout, gpt-5.4-mini, gpt-5.4
Formats	Edge list, Adj. list, JSON, NL
Relabeling	Neutral ($X_1, X_2, \ldots$), semantic-name
Distractors	Disconn. comp., $\triangle$, high-deg. star

Table 1: Experimental conditions. All distractors are verified to be label-preserving.

nected Erdős–Rényi graphs ($n \in \{5, \ldots, 15\}$, $p = 0.3$), seeded deterministically, yielding 400 graph-task pairs and three queries per pair (1,200 query instances). The observed target distribution is 300 yes and 0 no for connectivity; shortest-path distances 1–5 occur 101/143/50/4/2 times; triangle labels contain 184 yes and 116 no; common-neighbor labels contain 202 yes and 98 no.

Models. We evaluate three open-weight models from distinct families: Qwen3.6-35B-A3B (Alibaba; 35B total/3B active; Apache-2.0), DeepSeek-V4-Flash (DeepSeek; 284B/13B active; MIT), and Llama-4-Scout (Meta; 109B/17B active; Llama license). We additionally evaluate the proprietary gpt-5.4-mini-2026-03-17 and use gpt-5.4-2026-03-05 as a capability ceiling. All models use temperature 0. The Qwen and DeepSeek API configurations explicitly disable reasoning; no explicit reasoning setting is passed for gpt-5.4. Outputs are mapped by a deterministic task-specific parser to yes/no or an integer; unmatched outputs receive the sentinel `unclear`. Evaluation code is available at https://github.com/Anormalm/graph_evidence.

Relabeling. Neutral relabeling maps all sorted nodes to generic identifiers ($X_1, X_2, \ldots$). Semantic-name relabeling automatically sorts all nodes by decreasing degree and assigns, in order, `Hub`, `Center`, `Bridge`, `Anchor`, `Core`, `Leaf`, `Edge`, `Tip`, `Outlier`, `Tail`, then `Node11`–`Node15`. The synthetic graphs contain no semantic node attributes; the names appear only as textual identifiers. Canonical edge order is recomputed after relabeling, so IC includes any induced lexical-order change.

Aggregation. FS averages all six unordered pairs of the four formats. OS uses canonical, one seeded-random, and one BFS ordering; the archived implementation compares all three with canonical, including its zero self-comparison. IC compares one neutral and one semantic-name relabeling with the original, and DR compares three distractor conditions with the baseline. Reported aggregates pool comparison indicators across the four equally sized tasks rather than macro-averaging task means. The implementation computes 95% percentile intervals from 1,000 seed-42 bootstrap resamples of comparison indicators; Table 2 reports point estimates. The shared prompt asks the model to reason from the graph description but does not explicitly state that identifiers are arbitrary.

Model	Acc.	$1-\mathrm{FS}\downarrow$	$\mathrm{OS}\downarrow$	$\Delta_{\mathrm{sem}}\downarrow$	$1-\mathrm{DR}\downarrow$	$\mathrm{CF}_M\uparrow$
Symbolic oracle	1.00	.000	.000	.000	.000	1.00
gpt-5.4-mini	.936	.084	.046	.152	.066	.533
Qwen3.6-35B-A3B	.541	.325	.086	.061	.318	.575
DeepSeek-V4-Flash	.989	.025	.018	.268	.026	.729
Llama-4-Scout	.689	.259	.142	.091	.306	.658

Table 2: Main results. Columns match the unfaithfulness decomposition: syntactic instability ($1-\mathrm{FS}$, OS), semantic interference (Δ_{sem}), distractor susceptibility ($1-\mathrm{DR}$), and robust correctness (CF_M). The oracle computes each task from adjacency, ignoring node-name semantics.

5 Results

Table 2 presents the main results.

Accuracy does not imply faithfulness. gpt-5.4-mini achieves 93.6% accuracy, yet $\mathrm{CF}_M = .533$: only 53.3% of correct answers survive semantic-name relabeling. DeepSeek-V4-Flash reaches 98.9% accuracy but still loses 27.1% of correct answers ($\mathrm{CF}_M = .729$), with $\Delta_{\mathrm{sem}} = .268$, the highest semantic interference observed. When semantic identifiers are introduced, we observe prediction changes even though the underlying graph is preserved.

Three failure profiles. *Targeted semantic interference*: DeepSeek-V4-Flash has excellent syntax ($1-\mathrm{FS} = .025$, $\mathrm{OS} = .018$) and distractor robustness ($1-\mathrm{DR} = .026$), but degrades sharply under semantic-name relabeling ($\mathrm{IC}_N = .969 \rightarrow \mathrm{IC}_M = .701$, $\Delta_{\mathrm{sem}} = .268$). gpt-5.4-mini shows a similar but milder pattern ($\Delta_{\mathrm{sem}} = .152$). *Broad unfaithfulness*: Qwen3.6-35B-A3B and Llama-4-Scout show degradation across all diagnostics ($1-\mathrm{FS} = .325$ / $.259$, $1-\mathrm{DR} = .318$ / $.306$), with

small Δ_{sem} (.061 / .091) only because they are already unfaithful under neutral relabeling; their CF_M (.575 / .658) is partly sustained by the subset of easy tasks (connectivity) where relabeling matters less. For these lower-accuracy models, small Δ_{sem} should not be read as semantic robustness: when neutral consistency is already weak, the semantic gap is compressed by broad instability. The dominant failure mode shifts with capability: weaker models fail broadly, while stronger models fail specifically at semantic interference, and this failure is invisible to accuracy alone.

Capability ceiling. gpt-5.4 achieves near-perfect invariance ($\Delta_{\text{sem}} = 0$, $\text{CF}_M = 1.0$, $\text{FS} = .989$), suggesting that serialization faithfulness may improve with model capability. Notably, $\text{CF}_M < 1$ is possible even at $> 93\%$ accuracy, undetectable by accuracy alone.

6 Conclusion

We have shown that accuracy does not imply structural faithfulness. Proposition 1 establishes structural invariance as necessary; we decomposed unfaithfulness into syntactic instability, semantic interference, and distractor susceptibility. Across four model families, we observe three failure profiles: targeted semantic interference in high-accuracy models (DeepSeek: $\Delta_{\text{sem}} = .268$, $\text{CF}_M = .729$ at 98.9% accuracy; gpt-5.4-mini: $\Delta_{\text{sem}} = .152$, $\text{CF}_M = .533$), broad unfaithfulness in weaker models (Qwen3.6, Llama-4-Scout), and near-perfect invariance as capability ceiling (gpt-5.4: $\Delta_{\text{sem}} = 0$). A graph-grounded LLM can be accurate without being structurally faithful.

Limitations

This study has several limitations. First, we evaluate on synthetic graphs of 5–15 nodes; effects may differ at scale. Second, our four formats do not cover all representations. Third, we extract answers via pattern matching. Fourth, we diagnose but do not propose improvement methods. Fifth, two models are proprietary; we include three open-weight models for broader model-family coverage. Sixth, the prompt does not explicitly declare identifiers arbitrary, and we do not include a separately designed role-congruent control; semantic-name sensitivity therefore does not by itself separate cue integration from instruction-following. Seventh, all generated graphs are connected, making the connectivity subset label-degenerate, and we do not report chance-corrected agreement. Eighth, the archived metric implementation handles `unclear` outputs differently across diagnostics, and two named distractor conditions instantiate the same disconnected triangle; these implementation details limit fine-grained interpretation of the point estimates.

Ethical Considerations

This work uses synthetic graphs and no human or personal data. Its primary foreseeable risk is overgeneralization: results from controlled prompts are not safety or reliability guarantees for deployed systems.

Acknowledgments

This research was motivated by a practical problem encountered during the author's industry internship about graph representation and fraud detection.

Abstract

Multi-turn scheduling assistants must preserve constraint edits and distinguish solver evidence from language-model interpretations. We present CoSched-Cert, a dialogue protocol combining a typed scheduling language, solver-distinguishing clarification, cost-based conflict localization, verified repair synthesis, and lexical certificate auditing. Its guarantees are conditional on the encoded problem and supplied candidate interpretations; lexical support does not establish semantic entailment. SchedNL-Bench-Cert contains 1,000 synthetic Chinese/English utterances and 350 sessions. Gold-AST replay measures internal consistency against labels generated by the same engine, while author-written protocol simulations illustrate selected design choices. Across three live-parser seeds on 52 sessions, session training and registered sibling augmentation raise conditional micro target-constraint agreement from 18.0% to 83.7%. The final configuration has 100% coarse status agreement but only 75.0% conflict-member agreement, and includes a rule informed by a test-session failure. We therefore treat these results as descriptive, not as an unbiased generalization estimate. We define a stricter joint-turn criterion and report the bounds supported by the available aggregates. The contribution is a protocol for exposing inspectable solver evidence and the remaining gap between encoded feasibility and user-intent correctness.

1 Introduction

Scheduling conversations evolve through requests to add constraints, modify prior requirements, delete obsolete conditions, and accept repairs. A language model can produce a well-formed edit while resolving the wrong earlier constraint. Multi-turn degradation has also been observed in broader language-model tasks (Laban et al., 2026). Connecting a model to a solver addresses feasibility only for the formal problem actually encoded. It does not establish that this problem matches the user's intended schedule.

CoSched-Cert makes this distinction explicit. A parser proposes typed edits; a solver checks whether alternative readings lead to different feasible schedules; conflict and repair procedures emit structured evidence; and an auditor checks selected tokens in the response against that evidence. Figure 1 illustrates the failure modes this design addresses. The certificates support inspection and replay, but their scope ends at the encoded model. A correct solver result can coexist with an incorrect interpretation or an explanation that reverses a relation.

Our contributions are threefold. First, we formulate a persistent scheduling dialogue protocol with solver witnesses, anchored conflict sets, and verified repairs. Second, we describe SchedNL-Bench-Cert, a synthetic bilingual resource separating isolated parsing from session editing. Third, we analyze internal replay, live parsing, and author-

written protocol simulations with distinct evidence boundaries. The live results expose a substantial difference between coarse status agreement and constraint-level agreement; perfect replay scores are implementation consistency checks.

2 Related Work

Natural-language optimization. OptiMUS (Ahmaditeshnizi et al., 2024) formulates and solves optimization models from natural language. ConstraintLLM (Shi et al., 2025) targets constraint-programming models with retrieval and self-correction. Text2Model (Kadioglu et al., 2026) explores solver-agnostic modeling copilots. ReLoop (Lian et al., 2026) uses behavioral verification, NEMO (Song et al., 2026) uses execution-aware coding agents, and SCOPE (Deik et al., 2026) separates query-specific reasoning from reusable planning code. These works motivate checking both execution and modeling behavior. Our focus is the explicit lifecycle of session constraints and the evidence returned after each edit.

Interactive solver interfaces. OptiChat (Chen et al., 2026) connects practitioners to optimization models. MCP-Solver (Szeider, 2025) supports incremental model editing and validation. We do not claim these systems lack editing capabilities. The ADD-only and edit-aware variants in our experiments are author-written abstractions with prescribed policies, not executions or complete reproductions of the original systems. Their outcomes characterize those policies only.

Conflicts and repairs. Optimal constrained unsatisfiable subsets (OCUS) extend conflict explanation with explicit cost and structural constraints (Gamba et al., 2021, 2023). QuickXplain (Junker, 2004) computes preferred explanations and relaxations. CoSched-Cert uses these ideas in a session protocol: provenance determines an anchor and costs, while certificates distinguish a proven optimum from a weaker verified result. Hand-designed costs are not validated user preferences.

3 Problem Formulation

A scheduling instance $\mathcal{P}$ specifies jobs, operations, machines, processing times, eligibility, releases, due dates, setups, and downtime over discrete time. We write B for immutable model axioms, including precedence and resource constraints, and C_t for active user constraints at turn t. The state is

$$S_t = (\mathcal{P}, B, C_t, A_t, \sigma_t, H_t, \Xi_t), \tag{1}$$

where A_t contains assumption literals, σ_t is an incumbent schedule when available, H_t is dialogue history, and Ξ_t is the certificate log.

Each constraint stores its source utterance, abstract syntax tree (AST), timestamp, owner, and operation. ADD introduces a constraint, MODIFY versions its arguments, and DELETE deactivates it. ASK requests clarification and ACCEPT selects an offered repair. Assumption implications $a_i \Rightarrow c_i$ enable active constraints to be changed without discarding their provenance.

ScheDSL coverage. The registry has 24 schemas: 19 have encoders and 10 support the two-way reification needed by SDC. Appendix B lists the coverage. A deadline $\mathsf{Deadline}(J, d)$ requires job J to finish by d; increasing d relaxes it. A release bound is relaxed by decreasing it. These directions describe nested feasible sets, not improvements in user utility. Unencoded schemas and unresolved interpretations cannot receive the corresponding solver guarantee.

Solver status. CP-SAT distinguishes OPTIMAL, FEASIBLE, INFEASIBLE, UNKNOWN, and MODEL_INVALID (Google OR-Tools, 2024). A feasible witness suffices to establish satisfiability; it need not be optimal. UNKNOWN must not be interpreted as infeasibility, and invalid models do not support certificates of feasibility. The evaluation's coarse status agreement is narrower than correctness of the full session state.

4 CoSched-Cert Protocol

Figure 2 gives the protocol. Its contract is to expose the evidence and its certification level before rendering a response. The LLM is responsible for interpretation and verbalization; the symbolic procedures check the resulting formal objects.

4.1 Solver-Distinguishing Clarification

For candidates $\hat{c}^{(a)}$ and $\hat{c}^{(b)}$, instance-relative semantic equivalence (IRSE) means that they select the same schedules within the current background:

$$\hat{c}^{(a)} \equiv_{B,C_t} \hat{c}^{(b)} \iff \nexists \sigma \in \mathrm{Sol}(B \wedge C_t) : \sigma \models \hat{c}^{(a)} \oplus \hat{c}^{(b)}. \tag{2}$$

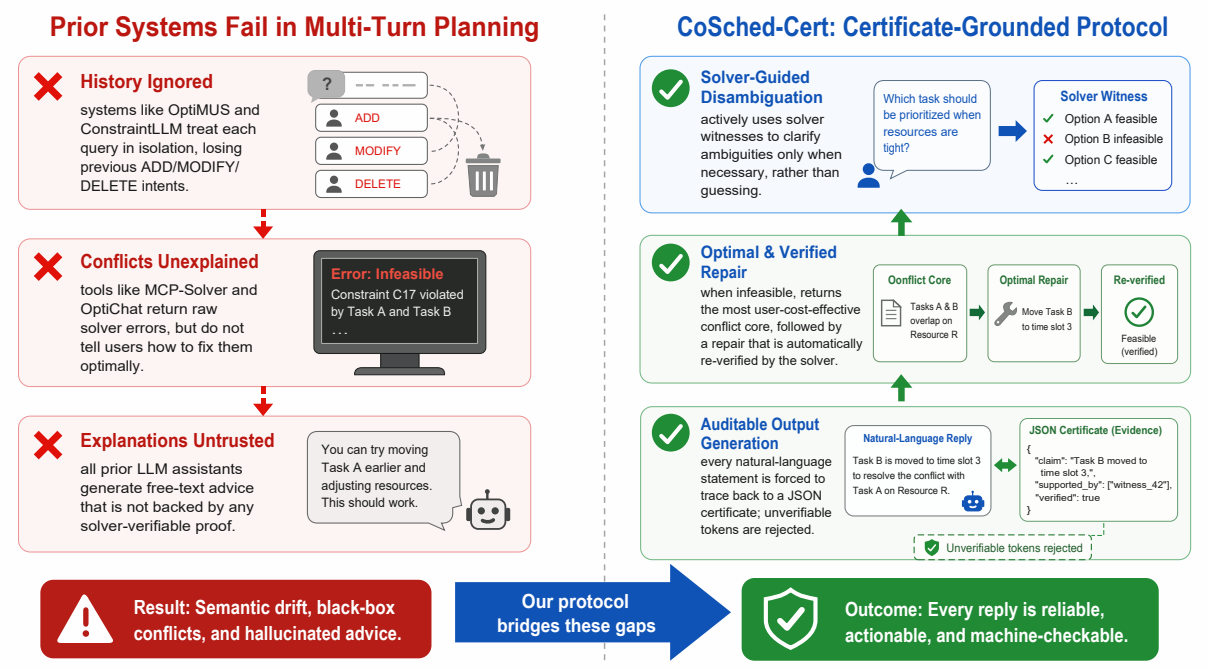

Figure 1: Conceptual motivation and protocol design. The universal wording in this illustration is not an empirical conclusion about all prior assistants or every reply. Our comparisons concern only the author-written policies in Appendix D; complete prior systems were not evaluated. "Optimal" is conditional on the specified formal objective and completed proof checks. "Reliable" and "traceable" concern checked certificate values in the encoded state, not user-intent correctness, preference alignment, or relational entailment.

With reification variables z_a, z_b, SDC asks whether

$$B \wedge C_t \wedge (z_a \Leftrightarrow \hat{c}^{(a)}) \wedge (z_b \Leftrightarrow \hat{c}^{(b)}) \wedge (z_a \oplus z_b) \tag{3}$$

is satisfiable. A satisfying assignment is a distinguishing witness; proven infeasibility establishes equivalence. Union-find merges proven-equivalent candidates. Multiple distinguishable classes trigger a clarification question illustrated by witness schedules.

Proposition 1. With correct reification and decisive solver outcomes for the required pairs, SDC partitions the supplied finite candidate set according to Eq. 2. An unresolved query cannot establish equivalence or produce a witness. If $B \wedge C_t$ is itself infeasible, all readings are vacuously equivalent under this definition; the conflict must be resolved before interpreting equivalence as a reason to commit an edit.

Candidate coverage. Self-consistency sampling can miss alternative readings. Registered sibling augmentation adds alternatives with the same arguments within a declared family. The evaluated catalogue contains the precedence family, including BEFORE and IMMEDIATEBEFORE. "Schema-complete" here means complete within that registered family, not across ScheDSL or all interpretations of natural language. The worst-case number of pairwise queries is $k(k-1)/2$ for k candidates. Sampling alone and registered augmentation are evaluated separately.

4.2 Anchored Conflict Localization

After an infeasible edit, OCUS-UX seeks a low-cost conflict containing the new or modified constraint c_{new}. Let

$$\begin{aligned} f_t(c_i) = {} & \lambda_{\text{age}} \log(1 + t - \tau_i) \\ & + \lambda_{\text{own}} \mathbf{1}[u_i \neq u_t] \\ & + \lambda_{\text{sch}} \,\text{complexity}(c_i), \end{aligned} \tag{4}$$

where τ_i and u_i are the creation turn and owner, and u_t is the current user. The default weights are $(1, 1, 1)$. They encode a design preference rather than elicited human preferences. The optimization is

$$U^\star \in \arg\min_{U \subseteq C_t} \sum_{c \in U} f_t(c) \quad \text{s.t. } B \wedge U \models \bot, \; c_{\text{new}} \in U. \tag{5}$$

Proposition 2. Exact minimum-cost constrained hitting-set search with decisive feasibility checks

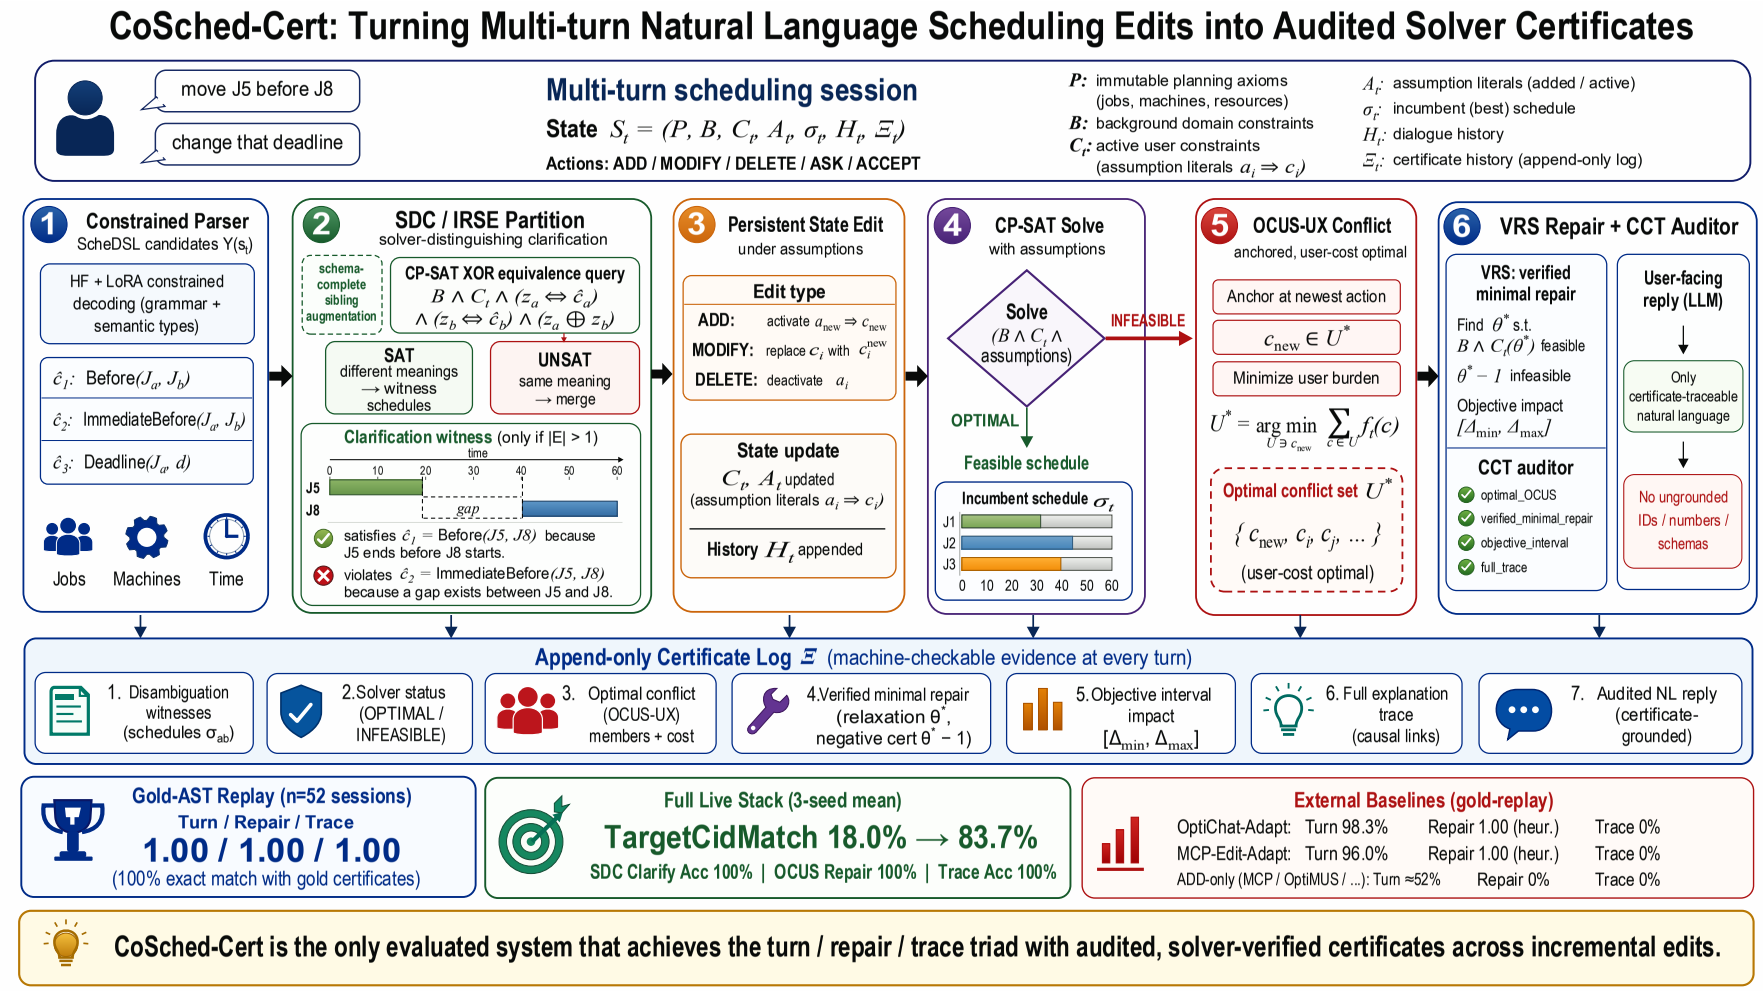

Figure 2: Protocol architecture and descriptive aggregates. Live parsing uses validation and repair, not grammar-constrained inference. Sibling completeness covers the registered precedence family only. Optimal/minimal labels require completed proofs; other feasible and unresolved outcomes are omitted. Cost minimization is subject to Eq. 5, not measured user burden. Trace denotes lexical support, not causal entailment. Gold replay is internal consistency; baselines are author-written simulations whose zero trace scores reflect their certificate format. Target percentages are pooled micro rates; the final live row includes a test-informed rule. "OCUS Repair 100%" differs from conflict-member agreement, which is 75%. The triad concerns these simulations and certificate-specific checks, not general superiority or JointTurnExact.

returns an optimum of Eq. 5 when such a set exists and search completes. On budget expiry, only properties actually verified can be recorded: a raw infeasible core, an anchor-preserving subset-minimal core if minimization finishes, or a cost optimum if certified. Timeout alone does not imply subset-minimality. Appendix A states the assumptions explicitly.

This is session-provenance-aware localization: changing the parsed target changes the formal anchor and may change the resulting conflict, even when the solver is correct. It is therefore evaluated separately from status agreement.

4.3 Verified Repair Synthesis

For a finite monotone parameter domain, define $\theta_1 \preceq_q \theta_2$ so that θ_2 is at least as relaxed as θ_1. Thus

$$\mathrm{Sol}(B \wedge C_{-q} \wedge \psi_q(\theta_1)) \subseteq \mathrm{Sol}(B \wedge C_{-q} \wedge \psi_q(\theta_2)). \tag{6}$$

Here C_{-q} contains every other active constraint. VRS uses bisection between an infeasible bound and a feasible bound. Every proposed repair is checked against the full resulting encoded state, not just the extracted conflict. For non-monotone changes, bounded removal search considers up to a specified number of constraints; incomplete search does not prove global minimality.

Proposition 3. On a finite totally ordered monotone chain with a valid bracket and decisive checks, bisection finds the least feasible parameter. Its feasible witness and the infeasibility of its immediate predecessor establish this minimality. An unresolved predecessor check permits a feasibility claim only. An objective-change interval must likewise retain solver bounds rather than present an incumbent as a proven optimum.

These certificates do not show that a relaxation is desirable. They verify feasibility for the parsed state, which may already differ from user intent. No study in this work establishes human acceptance, cognitive burden, or preference alignment of the repair ranking.

4.4 Certificates and Lexical Auditing

A certificate records solver status, the edited constraint and provenance, conflict members, proposed repairs, verification flags, objective bounds, and disambiguation witnesses. Certification levels distinguish optimal OCUS from verified minimal or raw cores, and verified minimal repairs from merely verified repairs. They must not imply stronger properties than the checks establish.

Proposition 4 (lexical support). Let $E(t)$ extract the identifiers, schema names, and numbers checked in a reply t, and let $V(\xi)$ be the permitted values in certificate ξ. Acceptance requires $E(t) \subseteq V(\xi)$. This establishes support for those extracted tokens only, conditional on the extractor. It does not establish that the entire sentence follows from the certificate.

For example, a certificate for "J1 precedes J2" contains both identifiers. A response saying "J2 precedes J1" can pass a token-membership test. We therefore use *lexical TraceRate*, not semantic faithfulness, for this metric. No relation-swapping acceptance rate was measured. A complete guarantee would also require correct parsing, encoding, and relational entailment.

5 Benchmark and Experimental Setup

Data construction. SchedNL-Bench-Cert has 60 synthetic job-shop/flexible-job-shop instances, 1,000 template-rendered utterances (490 Chinese, 510 English), and 350 sessions. ASTs are sampled first, surfaces are rendered with lexical variation, and the CoSched-Cert engine generates statuses, ambiguity labels, conflicts, repairs, and certificates. Consequently, the gold labels share the implementation and semantics being evaluated.

Utterance categories are ordinary parsing (480), ambiguity (214), history-dependent editing (163), and out-of-scope input (143). The recorded train/validation/test counts are 700/150/150 utterances, 245/53/52 sessions, and 42/9/9 instances. The full collection averages 16.78 turns per session. Templates and paraphrase families are not documented as disjoint across splits, and no claim of template-held-out generalization is made. Per-language accuracy is unavailable in the aggregates; bilingual coverage alone does not establish comparable Chinese and English performance.

Parser and solver. The parser is Qwen3.5-9B (Qwen Team, 2026) with LoRA (Hu et al., 2022), rank 16, scale 32, learning rate 2×10^{-4}, three epochs, and training seeds 2027–2029. Session augmentation adds 3,485 recorded edit examples to 700 utterances (4,185 total). The reported runs use an NVIDIA A800-80GB and CP-SAT with four workers and a 2-second budget per feasibility check. Appendix C records further settings.

The implementation includes structured decod-

ing with XGrammar (Dong et al., 2025), but the reported live results use the HF validate-and-repair path without XGrammar at inference. The sampling baseline uses $k = 8$ and temperature 0.7. SDC decoupling uses an utterance-only ASK prompt, temperature 1.0, and $k = 16$. The final row combines registered sibling augmentation with a horizon normalization rule. That rule was informed by a failure in test session `sess_0332`; comparisons on these 52 sessions are therefore exploratory and test-informed.

Evidence boundaries. Gold-AST replay is an implementation regression test. Same-engine recomputation without stored certificates can check replay consistency, but cannot detect an encoding mistake shared by generation and checking. Live parsing measures behavior on synthetic sessions; it is not an industrial deployment evaluation. Protocol simulations fix gold ASTs and vary author-specified policies; they do not measure the original published systems.

5.1 Metrics and a Stricter Joint Criterion

SemAcc and ParseExactMatch concern AST agreement in their respective isolated/session settings. TurnStatusMatch compares coarse solver outcomes on non-ASK actionable turns. It does not require the operation, target, arguments, or conflict set to be correct. Micro TargetCidMatch pools correct target resolutions over the reported MODIFY/DELETE resolution records; its denominator can change between configurations. OCUSMatch compares conflict members on scored infeasible turns. RepairValid@3 concerns an offered top-three repair verified against the encoded state; lexical TraceRate concerns token support.

A stricter joint criterion would require all applicable conditions for each evaluated turn:

$$J_t = O_t \wedge I_t \wedge A_t^{\mathrm{ok}} \wedge S_t^{\mathrm{ok}} \wedge C_t^{\mathrm{ok}} \wedge R_t^{\mathrm{ok}}, \quad (7)$$

where O, I, A^{ok} check operation, intended target, and arguments; S^{ok} checks status; C^{ok} checks the intended-state conflict when applicable; and R^{ok} verifies a repair against that intended state. Non-applicable factors are true. ASK turns additionally require the correct clarification decision and valid witnesses. A wrong operation or parse failure is a failure, not grounds for removing the turn from the denominator. JointTurnExact is the average of J_t over all prespecified turns, including these failures.

The retained aggregates cannot identify this intersection. We report no invented point estimate. On the 264 scored edit records, any such joint rate is at most $221/264 = 83.7\%$; on the 180 scored conflict records it is at most $135/180 = 75.0\%$. These are conditional upper bounds on different subsets, not a whole-session score and not mutually multiplicative probabilities.

6 Results and Interpretation

6.1 Live Session Parsing

Table 1 retains the reported configurations. Prompt-only active context reduces parse exact match, whereas session-formatted fine-tuning improves target resolution. However, the changing target denominator (189 to 264) means the 18.0% to 83.7% comparison is a change in conditional resolution accuracy, not a measured improvement on every gold edit turn.

Session tuning also reduces sampling diversity: SDC accuracy falls to 40.4%, and decoupling recovers 77.6%. The full final configuration reports 100%, but the isolated effect of the horizon rule is not available. Its removal cannot be evaluated from aggregate data, nor can a one-session failure be converted into a three-seed result without the underlying records. The final configuration should therefore be interpreted as a test-informed diagnostic endpoint.

The final configuration resolves 99/108 MODIFY targets and 122/156 DELETE targets, totaling 221/264. Thus 43 scored target resolutions are wrong despite perfect aggregate status agreement. Conflict agreement is 75.0%: 45 of 180 scored conflict records disagree with gold membership while retaining the correct coarse status. This is a substantive end-to-end error. A repair verified for the parsed state cannot be promoted to a repair of the user's intended state merely because it restores feasibility.

6.2 Gold Replay and Component Checks

The original reports give 100% agreement for gold replay on the recorded status, clarification, conflict, repair, and lexical trace metrics. Isolated SemAcc is also reported as 100% on 150 test utterances across three seeds. These values describe a bounded synthetic setup; they are not evidence of universal parsing, independent encoding correctness, or relational faithfulness.

Removing SDC eliminates witness-based clarification in the specified ablation. Removing VRS eliminates the verification step, and removing the

Configuration	Status	AST exact	Target (micro)	SDC	n_{target}
Static baseline, strict	$.955 \pm .003$	$.882 \pm .003$	.180	$.962 \pm .051$	189
Active prompt + op normalization	$.962 \pm .012$	$.515 \pm .011$	.239	$.769 \pm .084$	222
Session fine-tuning	$.999 \pm .000$	$.962 \pm .001$	.814	$.404 \pm .058$	264
+ SDC decoupling	$.999 \pm .000$	$.962 \pm .001$	.814	$.776 \pm .059$	264
+ registered siblings + horizon rule	$1.000 \pm .000$	$.967 \pm .001$	.837	$1.000 \pm .000$	264

Table 1: Descriptive live-parser results on 52 synthetic sessions. Rates other than pooled micro target agreement are reported means $\pm$ sample standard deviations over three training seeds, rounded to three decimals. Status is TurnStatusMatch; SDC is SDCClarifyAcc. The last row includes a test-informed rule, so its 100% SDC value is not an unbiased generalization result. These aggregates do not report JointTurnExact.

Simulated policy	Agreement	Repair
CoSched-Cert	1.000	1.000
OptiMUS-Adapt	.521	.000
MCP-Solver-Adapt (ADD-only)	.521	.000
MCP-Edit-Adapt	.960	1.000
ReOpt-Patch-Adapt	.517	.000
OptiChat-Adapt	.983	1.000
CoSched-NoSDC	.933	.962
CoSched-NoOCUS	1.000	1.000

Table 2: Author-written simulations on 52 gold-AST sessions, not full reproductions of published systems. Policies are specified in Appendix D. The turn-label agreement column is retained under its original simulation meaning and must not be read as JointTurnExact.

auditor removes enforced lexical support. Zero scores for these disabled checks are partly consequences of the metric definitions. They do not by themselves show that every heuristic repair is infeasible or every free-text explanation is false.

6.3 Author-Written Protocol Simulations

Table 2 retains the original simulation outcomes, using the table source as the numerical record. In particular, the NoSDC value is .933; a conflicting .928 in the earlier prose was a transcription inconsistency. The trace column is omitted because the simulated alternatives do not emit our certificate representation. Repair success in this table is the original simulation measure, not interchangeable with VRS-verified RepairValid@3.

OCUS ablation. CoSched-NoOCUS and the full system have identical reported turn-label agreement (1.000) and repair success (1.000). The earlier burden aggregate is also identical (.77). Thus the session benchmark does not demonstrate a user-facing advantage from cost-optimal localization. The source reports unchanged conflict members under cost perturbations; the retained files disagree on the exact perturbation grid, preventing verification of that grid. An 80-case targeted stress experiment reports an optimality advantage, but that result cannot establish user benefit on the 52-session benchmark or preference alignment of the cost function.

Burden ambiguity. The earlier table reports .77 for the full system and .04 for NoSDC, but the prose alternately defines burden as all clarifications or only unnecessary clarifications, plus failed repairs, and gives another full-system value (.73). No event-level decomposition is retained. The statistic is therefore removed from comparative scoring; its difference is not evidence that either policy reduces user burden. In particular, counting a correct clarification as a cost measures interaction frequency, not clarification error.

Uncertainty. Three-seed standard deviations describe training variation on a fixed collection. Turn-level tests do not account for within-session dependence, and the retained files do not support reconstruction of the earlier confidence intervals or significance tests. We omit those inferential claims. No original-system-author validation of the protocol abstractions is documented.

7 Discussion and Conclusion

CoSched-Cert separates three questions: whether the solver verified the encoded state, whether the parser preserved user intent, and whether the response is supported by its evidence. SDC supplies concrete witnesses for distinguishable candidate readings; OCUS-UX declares the cost and anchor behind a conflict; VRS checks proposed changes; and lexical auditing exposes unsupported identifiers and numbers. These mechanisms make failures more inspectable without making the entire dialogue correct by construction.

The retained live results show why coarse status alone is insufficient: 100% status agreement coexists with 83.7% conditional target agreement and 75.0% conflict-member agreement. The camera-

ready analysis defines a stricter joint criterion and states what cannot be recovered from aggregates. Claims about other systems are limited to the author-written simulations, and gold replay is framed as internal consistency. Applying the protocol in another domain would require appropriate encodings, candidate families, repair operators, and independent validation; transfer was not evaluated here.

Limitations

The benchmark is synthetic and template-rendered, with no human-authored dialogue evaluation or professional-planner study. Generation and evaluation share ScheDSL and the same solver machinery. Same-engine recomputation cannot reveal a shared semantic encoding error. Template-disjointness is unverified, separate Chinese/English accuracy is unavailable, and repeated inspection of the test sessions, including the horizon rule, limits claims about generalization.

The model study uses one base model and three training seeds. Only 19 of 24 schemas are encoded and 10 reifiable; registered sibling augmentation covers a precedence family. A finite-candidate soundness result does not guarantee interpretation coverage. On larger instances, timeouts may prevent equivalence, minimality, or optimality certification. The conditional statements in the method do not establish that every code path in an unavailable implementation satisfies those conditions.

Lexical traceability does not imply relational entailment. Solver-valid repairs may address the wrong parsed state, and cost weights have not been validated against human preferences. JointTurnExact, an independent re-encoding audit, rule-removal results, and language-specific performance cannot be reconstructed from the retained aggregates. The supplement supports consistency checks of selected reported aggregates; it does not contain the original dataset, model checkpoints, solver implementation, or per-turn prediction logs and is not a complete experiment reproduction package.

Ethics Statement

The described evaluation uses synthetic scheduling instances and template-rendered utterances, rather than participant conversations. No human-subject study is reported. This limits the extent to which the results can establish practical usefulness, accessibility, or impacts on planners and affected workers.

In deployment, a feasible schedule can still conflict with unstated worker needs, organizational obligations, or a user's intended edit. Cost-based conflict selection may privilege particular owners or older constraints through hand-designed weights. Human review and explicit acceptance are needed before acting on proposed changes, especially when resources or workers are affected. Provenance logs could contain sensitive operational information in real use and would require access controls and appropriate retention policies. Certificates should disclose their scope and uncertainty so that users do not mistake lexical support or solver feasibility for complete factual correctness.

Acknowledgments

We thank the reviewers and area chair for feedback that helped clarify the evidence boundaries, evaluation metrics, and limitations of this work. A Conditional Guarantees and Proof Sketches

A.1 SDC

Assume both candidate constraints admit correct two-way reification in the same schedule-variable space. In Eq. 3, the XOR condition forces exactly one candidate to hold. Any satisfying assignment therefore supplies a distinguishing schedule satisfying the common background. If the query is proven infeasible, no such schedule exists and the candidates have identical solution sets relative to that background.

Equality of solution sets is an equivalence relation, so merging proven-equivalent pairs is sound. Comparing every remaining pair with decisive outcomes establishes the complete partition of the supplied finite set. This argument says nothing about an interpretation absent from that set. A timeout yields neither an equivalence proof nor a distinguishing schedule. For an infeasible common background, equivalence is vacuous and is not a substitute for conflict resolution. For MODIFY candidates, the background must remove the superseded constraint before comparing proposed replacements.

A.2 OCUS-UX

Assume B is satisfiable, costs are nonnegative, and an anchored infeasible subset exists. The anchor is a constraint on every hitting-set candidate, rather than merely a seed from which unconstrained search begins. At each iteration, minimum-cost constrained hitting-set optimization supplies a lower bound on the cost of any admissible unsatisfiable subset. If its candidate is satisfiable, a correction set obtained from that satisfiable set supplies a new hitting constraint. If the candidate is infeasible, it attains the lower bound and is optimal (Gamba et al., 2021, 2023).

The conclusion depends on exact optimization and decisive feasibility tests. Under zero costs, a cost optimum need not be subset-minimal unless tie-breaking or a verified minimization pass establishes that property. Similarly, after a timeout, an available infeasible set may be returned only with the weaker status actually verified. Anchor-preserving subset minimality requires that no proper anchored subset remains infeasible. If the pre-edit background is satisfiable, every conflict introduced by the edit must contain the new constraint; without that invariant, an anchor requirement can retain a redundant member relative to unconstrained MUS minimality.

A.3 VRS

Index the finite permitted relaxation chain as $\theta_0 \prec_q \cdots \prec_q \theta_m$. Keep all nontarget constraints fixed. Monotonicity means the feasibility predicate on this chain is false up to a boundary and true thereafter. With an infeasible lower endpoint and feasible upper endpoint, bisection preserves the bracket and shrinks its index interval. On termination, the upper endpoint is feasible and its predecessor infeasible, proving minimality on this chain.

The statement requires a totally ordered finite chain and exact feasibility decisions. It does not cover arbitrary partial orders, unknown outcomes, simultaneous repairs outside the declared search space, or user desirability. For objective minimization, compare a specified feasible reference model with certified optimum bounds $[l_0, u_0]$ to the repaired model with bounds $[l_1, u_1]$. The change lies in $[l_1 - u_0, u_1 - l_0]$. An infeasible model has no finite optimum to subtract. A point difference needs exact optima, or an explicitly different comparison to a fixed incumbent.

A.4 Lexical Support

Given extraction function E and permitted certificate-value set V, acceptance by a membership auditor establishes $E(t) \subseteq V(\xi)$. It cannot establish that the extractor identified every factual assertion or that relationships are preserved. A token-preserving relation reversal is a counterexample to interpreting this condition as entailment. No empirical robustness claim against such attacks follows from the reported TraceRate.

B ScheDSL Registry

Table 3 reproduces the supplied registry. Encoded means an implementation was reported; reifiable means two-way reification was reported for SDC. These flags are not an independent verification of code absent from the supplement.

C Reported Training and Solver Settings

The recorded session augmentation comprises 3,093 ADD, 147 MODIFY, and 245 DELETE examples (3,485 total); with the 700 utterance training examples this gives 4,185. The original documentation reports active-constraint context in 93% of augmentation examples. These are reported

Schema	Category	Type	Encoded	Reifiable	Relaxation parameter/direction

Table 3: ScheDSL catalogue: 24 schemas, 19 encoded, 10 reifiable. A listed relaxation direction is a schema property; it does not imply that an unencoded schema was evaluated.

Parameter	Recorded value
Base model	Qwen3.5-9B
LoRA rank / scale	16 / 32
Target modules	q/k/v/o and MLP projections
Learning rate	2×10^{-4}; cosine schedule
Warmup	3%
Batch / accumulation	4 / 4
Epochs	3
Maximum sequence	1,024 tokens
LoRA dropout	.05
Precision	bf16; gradient checkpointing
Training seeds	2027, 2028, 2029
CP-SAT	4 workers; 2 seconds/check
GPU	NVIDIA A800-80GB

Table 4: Settings retained from the original experiment documentation. Exact package versions and model revision hashes are not supplied.

setup details, not counts regenerated from training files in this supplement.

The stored final-configuration arrays contain status agreement $[1, 1, 1]$, SDC accuracy $[1, 1, 1]$, and conflict agreement $[.75, .75, .75]$. ParseExactMatch values are approximately .967327, .966392, and .968529, whose sample standard deviation is .001071. A zero standard deviation after rounding does not establish certainty or performance on unseen tasks.

D Simulation Policies

The following descriptions specify the author-written abstractions behind Table 2; names indicate inspiration, not implementation equivalence or endorsement by original-system authors.

OptiMUS-Adapt: rebuilds from ADD utterances and omits MODIFY, DELETE, and repair behavior. **MCP-Solver-Adapt:** accumulates ADD calls and ignores MODIFY, DELETE, ASK, and ACCEPT. This is deliberately restricted and does not describe MCP-Solver's documented editing support. **MCP-Edit-Adapt:** adds, replaces, and deletes items; ASK commits the first candidate; ACCEPT drops the latest constraint. **ReOpt-Patch-Adapt:** treats MODIFY as a new-constraint patch and has no DELETE semantics. It is a local patch-policy label, not a separately reproduced published system. **OptiChat-Adapt:** uses incremental edits and raw MUS explanations; ACCEPT drops the anchor without VRS. **CoSched-NoSDC:** uses the remaining protocol but auto-lands a Before reading. **CoSched-NoOCUS:** omits cost-optimal localization; the retained description does not specify a sufficiently detailed fallback policy for independent reproduction.

The table's RepairSuccessRate is preserved as an original simulation outcome. The retained source describes it inconsistently as a repair offered or a

Supported quantity	Value
MODIFY target matches / scored	99/108
DELETE target matches / scored	122/156
Pooled target matches / scored	221/264
Pooled target mismatches	43
Pooled target agreement	83.7121%
Reported conflict matches / scored	135/180
Reported conflict mismatches	45
Reported conflict agreement	75.0%
Strict joint upper bound: edit subset	83.7%
Strict joint upper bound: conflict subset	75.0%

Table 5: Conditional quantities for the final configuration. Target counts come from the JSON; the conflict denominator comes from the original appendix report, with the rate corroborated by the seed arrays. Bounds are not estimates of all-turn JointTurnExact.

successful heuristic repair. Its per-event implementation and denominator are absent. Consequently, it is not used as evidence of solver-certified repair validity or superiority to original systems. Missing typed certificates are likewise a representation difference, not a measured factual-error rate.

E Test-Informed Horizon Rule

The reported rule concerns a post-repair deadline restatement. If the parser proposes MODIFY on Deadline, the target was repaired, the new deadline equals an active MaxMakespan horizon, and the utterance lacks explicit editing cues, the operation is normalized to ADD. The original description explicitly relates this rule to `sess_0332`, one of the 52 test sessions.

The final SDC result in Table 1 includes this rule. There is no stored matched run with the rule disabled, so neither its isolated effect nor rule-free clarification accuracy can be recovered. The earlier SDC-decoupled row changes a different mechanism and is not a rule-removal control. A fresh held-out evaluation would be needed to estimate generalization of the final configuration; no such experiment is claimed here.

F Aggregate Consistency and Availability

The supplement preserves the original aggregate JSON and supplies an auditable arithmetic checker. Table 5 summarizes values supported directly by that JSON and by explicitly identified original report tables. The checker recomputes counts, ratios, and seed summary statistics only; it does not run the original model or solver experiments.

Some retained records are inconsistent or insufficiently specified. The benchmark JSON lists 10 independent-audit sessions, whereas the original audit table lists 20; neither establishes an independent semantic audit. The main and generated cost-sensitivity tables specify different perturbation grids. Earlier operation-confusion graphics disagree with the prose about the baseline MODIFY-to-ADD count. These unsupported details and plots are not used as quantitative evidence in this version. The original files remain available in the author's preparation archive, and the supplement documents the inconsistencies relevant to its JSON.

The original TargetCidMatch mean and per-operation means use an undocumented macro aggregation and differ from pooled ratios. They must not be substituted for the micro values. The table denominators 189, 222, and 264 refer to configuration-dependent resolution records, not a fixed all-gold-edit set. No joint event intersections, language-conditioned predictions, rule-disabled outputs, session-cluster uncertainty calculations, or full benchmark/implementation files are provided. Arithmetic agreement with aggregates cannot establish experiment reproducibility or external validity.

The Citation Expansion Trap: Operating-Point Control for Fixed-Answer Multi-Hop RAG Citation Repair

Jiawei Li
Nanyang Technological University, Singapore
w250001@e.ntu.edu.sg

Abstract

Multi-hop retrieval-augmented generation systems often produce answers with incomplete or noisy citation sets. When the answer text is fixed, citation repair may seem to require only adding retrieved evidence. We show that this view is incomplete: in multi-hop settings, expansion that recovers missing support can also introduce plausible distractors into the evidence bundle. We study fixed-answer citation-set repair as a diagnostic protocol for reporting policies as operating points between support-ID coverage and distractor control. Across a calibrated 5,000-example HotpotQA diagnostic and Qwen2.5-generated outputs on HotpotQA, MuSiQue, and 2Wiki, cross-encoder repair yields cleaner support-ID operating points than BM25 expansion on HotpotQA and 2Wiki, while MuSiQue shifts the policy into a higher-distractor-cost regime under harder compositional transfer. We do not claim universal transfer of absolute performance from HotpotQA alone; the cross-dataset pattern is instead consistent with mechanism-level transfer of the support-distractor operating-point geometry. A single-author audit of 450 unique generated-output cases plus 60 duplicate checks reinforces this caution: support-ID coverage and claim-level citation support can diverge. We therefore recommend an operating-point scorecard for citation repair and separate support-ID diagnostics from stronger claim-level faithfulness claims.

1 Introduction

Retrieval-augmented generation (RAG) systems combine generated answers with retrieved evidence (Lewis et al., 2020). Many RAG interfaces now expose citations, and citation-aware generation benchmarks have made citation quality a measurable output property (Gao et al., 2023b). A citation can make an answer more inspectable, but it does not guarantee that the cited evidence is sufficient. Correct answers can still have unfaithful attributions (Wallat et al., 2024). This issue is especially visible in multi-hop question answering: one passage may support the surface answer string, while another passage is needed to justify the bridge from the question to that answer (Yang et al., 2018).

We study *fixed-answer citation-set repair*: cases where the answer text is held fixed, but the attached citation set does not contain all evidence needed to support the answer under the available candidate passages. This setting is narrower than general attribution evaluation (Rashkin et al., 2023) and different from selective RAG systems that decide whether to answer, abstain, or mark an answer as unsupported (Qiu et al., 2026). It is useful when answer rewriting is expensive or undesirable, but it creates a distinct repair problem: add missing support passages without adding misleading distractors.

Our study asks three questions:

1. Can one-citation baselines expose multi-hop evidence gaps?
2. How quickly do added citations trade support recovery for distractor pollution?
3. Can reranking, calibration, and selective repair expose useful operating points?

We instantiate this study on HotpotQA (Yang et al., 2018), MuSiQue (Trivedi et al., 2022), and 2WikiMultiHopQA (Ho et al., 2020). One controlled setting fixes a gold answer with one gold-support citation to isolate citation repair from answer-generation errors. We also evaluate Qwen2.5-7B and Qwen2.5-14B generated outputs whose initial citation sets are produced before repair. Oracle repair estimates candidate-set availability; BM25 tests sparse retrieval; a DeBERTa cross-encoder tests learned support; and an API-based LLM verifier gives a small semantic comparison.

The study makes four contributions:

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 322–329
October 29, 2026 ©2026 Association for Computational Linguistics

- We formulate fixed-answer citation-set repair as a post-generation problem and provide a diagnostic protocol for scoring support recovery, distractor pollution, and selective repair coverage.
- We identify the citation expansion trap: adding evidence to recover missing support can also introduce plausible distractors into the repaired evidence bundle.
- We evaluate repair policies as support–distractor operating points across a calibrated 5,000-example HotpotQA diagnostic and Qwen2.5-generated outputs on HotpotQA, MuSiQue, and 2Wiki.
- We check the diagnostic interpretation with a single-author audit over 450 unique cases plus 60 duplicate checks, framed as author adjudication rather than a separate multi-annotator evaluation.

The automatic metrics use dataset support annotations, not full claim-level faithfulness judgments. We therefore treat the numbers as support-ID diagnostics and use the author-adjudicated audit to probe proxy validity and failure modes rather than as standalone annotation evidence.

Our strongest calibrated diagnostic is HotpotQA, so we do not use it alone to claim universal transfer of absolute performance. Instead, we ask whether dataset shift preserves the support–distractor operating-point geometry closely enough to make calibrated citation repair choices meaningful across settings.

2 Related Work

RAG attribution and citation-aware generation. RAG combines generated answers with retrieved evidence, but provenance remains a persistent failure point (Lewis et al., 2020). AIS, ALCE, LongCite, and RAGAS make attribution and citation quality measurable (Rashkin et al., 2023; Gao et al., 2023b; Zhang et al., 2025; Es et al., 2024). Our target is a post-generation action: deciding which additional passages, if any, should be attached to a fixed answer.

Post-hoc revision and repair. RARR retrieves attribution for arbitrary model outputs and edits unsupported content while preserving the original text as much as possible (Gao et al., 2023a). CiteFix is the closest citation-correction neighbor: it motivates post-hoc citation correction as a practical need and improves RAG citation accuracy by cross-checking generated citations against retrieved articles (Maheshwari et al., 2025). FaithfulRepair uses a narrower action space: it only edits the citation set for fixed multi-hop QA answers. Under this restriction, post-hoc correction exposes a multi-hop failure mode: adding citations can improve apparent support while degrading the cleanliness of the evidence bundle.

Evidence sufficiency verification. Answer correctness and citation adequacy are separable: a RAG answer may be factually right while its attached sources still fail to justify the claim (Wallat et al., 2024). Document-level attribution methods ask which retrieved sources influence an answer (Nematov et al., 2026). The closest selective-verification neighbor is SURE-RAG, which treats retrieval as distinct from verification, aggregates pair-level claim-evidence checks into set-level evidence sufficiency, and supports selective RAG decisions about whether to answer or withhold an insufficiently evidenced answer (Qiu et al., 2026). Our setting is the repair-side counterpart: rather than deciding whether to answer, we ask how the citation set should move once the answer is already fixed.

Multi-hop support annotations. HotpotQA, MuSiQue, and 2WikiMultiHopQA offer multi-hop support annotations for controlled evidence diagnostics (Yang et al., 2018; Trivedi et al., 2022; Ho et al., 2020). QDRAG decomposes questions to improve grounding and reduce over-citation during generation (Liu et al., 2026). Generation-time query decomposition and reranking can reduce over-citation before answer production; FaithfulRepair shows that the same pressure persists as a post-generation repair risk when only the citation set can be edited. Our pilot uses support identifiers as weak diagnostics, not claim-level citation faithfulness; this gap motivates our claim-level audit sample.

3 Task and Method

3.1 Problem Setup

For each question x, we assume a candidate passage set P_x, an initial cited set C_x^0, and a fixed generated answer. The repair system may add citations but does not rewrite the answer text. A repair action selects an added set $A_x \subseteq P_x \setminus C_x^0$, which

induces the repaired citation set $C_x = C_x^0 \cup A_x$.

Let G_x be the dataset support set for example x. We track two support-ID diagnostics,

$$S_x = \mathbf{1}[G_x \subseteq C_x], \qquad D_x = \mathbf{1}[(C_x \setminus G_x) \neq \emptyset],$$

where $S_x = 1$ means that all gold support identifiers are cited after repair and $D_x = 1$ means that at least one distractor passage is cited. We also track the action size $|A_x|$, since larger repairs can recover support while also expanding the opportunity to attach unnecessary citations.

A compact per-example utility is

$$u_x(A_x; \lambda, \gamma) = S_x - \lambda D_x - \gamma |A_x|,$$

and the policy-level objective is

$$J(\pi; \lambda, \gamma) = \mathrm{E}_x[u_x(A_x^\pi; \lambda, \gamma)].$$

Here A_x^π is the added set chosen by policy π, λ prices distractor exposure, and γ is a small parsimony cost for adding citations. This is a policy-selection view, not a claim that deployed policies optimize the objective exactly. It makes the intended operating point explicit: recover missing support, avoid distractors, and abstain when additional citations are not justified. **Scorecard.** We report each policy with action coverage, support recovery, distractor exposure, action size, U_λ, and claim-audit alignment when available; detailed policy sweeps and uncertainty variants remain in the supplementary materials.

3.2 Baselines

Constrained citation baseline. We prompt the generator to answer in one concise sentence and use at most one citation. This creates a controlled evidence-insufficiency setting for multi-hop questions.

Oracle repair. Oracle repair adds the HotpotQA gold support passages. It is not deployable; it estimates the upper bound when the missing support evidence is available.

Lexical repair. Lexical repair ranks candidate passages by token overlap with the question and answer, then adds the top-ranked passages. This baseline tests whether simple matching is enough.

BM25 repair. BM25 repair ranks candidate passages with a standard unsupervised retrieval score over the question-answer claim proxy and passage text. This baseline tests whether sparse retrieval can recover missing support without a trained verifier.

3.3 Learned Verifier Repair

We train a DeBERTa-v3-base cross-encoder on claim–passage pairs derived from HotpotQA support annotations. The claim proxy is the question concatenated with the generated answer. Positive pairs are gold support passages; negative pairs are distractor passages.

At inference time, the verifier scores each candidate passage. We evaluate thresholded top-k repair policies that add high-scoring passages not already cited. We treat this model as a learned verifier baseline, not as a claimed replacement for sparse retrieval; one goal of the study is to test whether training improves the support–distractor operating point beyond BM25.

4 Experimental Setup

Dataset. The controlled and calibrated diagnostics use HotpotQA examples with questions, answers, candidate passages, and supporting passage identifiers. Each repair instance starts from a shuffled candidate set so that gold support passages do not always appear first. The 100-example slice is used for controlled stress tests and LLM-verifier comparisons; the main calibrated diagnostic uses 5,000 examples. The generated-output benchmark extends the same repair evaluation to HotpotQA, MuSiQue, and 2WikiMultiHopQA slices.

Controlled single-citation setting. Because repair keeps answer text fixed, we use a controlled 100-example isolation setting: each example starts from the gold answer with one gold-support citation attached. This creates an evidence-insufficient citation set whenever the multi-hop answer requires more than one support passage, while avoiding answer-generation confounds. Oracle repair can cite all missing gold support passages without adding distractors, so the bottleneck is citation selection rather than candidate-set availability. The controlled table does not estimate real-world under-citation frequency; it measures whether repair policies recover missing support without indiscriminately adding distractors. We also keep the citation-constrained LLM pilot as a diagnostic robustness check on generated answers.

Verifier training. The first verifier probe uses 600 claim–passage pairs from 100 examples: 200 positive support pairs and 400 negative distractor pairs. The pair file has a question-level train/dev split with 80 training and 20 dev examples. We

train DeBERTa-v3-base for three epochs on an NVIDIA A40 GPU. The main controlled table draws from the same broad example pool, so it is a pilot comparison rather than a fully held-out benchmark. To reduce overfitting risk, answer text, candidate passages, and the repair objective are fixed before repair; policies only add citations; BM25 is included as a non-parametric baseline; and separate held-out diagnostics are reported below. A full multi-domain benchmark remains future work.

Held-out calibrated diagnostic. To reduce dependence on the 100-example development pool, we construct a 5,000-example calibrated diagnostic with question-level train, calibration, and test splits of 3,000, 1,000, and 1,000 examples. This produces 29,967 claim–passage verifier pairs. We evaluate both BM25 and a DeBERTa cross-encoder trained only on the training split. The calibration split fits the abstention threshold calibration; the test split is held out for the reported fixed and selective repair points.

LLM verifier reference point. We also score the 100-example controlled pair file with an OpenRouter-hosted Gemini Flash Lite verifier prompt. This provides a semantic reference point for the lightweight local policies. The prompt asks whether a passage supports the question-answer claim proxy using only the passage, and returns a support probability. We report it as an API-based reference point, not as a local deployable component.

Evaluation metrics. Using dataset support IDs, **All Support Cited** means all gold passages are cited; **Incomplete** means at least one is missing; and **Unsupported/Distractor** means any cited passage is non-gold. These are pilot diagnostics, not final faithfulness metrics. We also audit 450 generated-output cases plus 60 duplicates to check proxy validity.

5 Results

Figure 1 reports the held-out 5,000-example calibrated support-ID diagnostic as a coverage-versus-quality trade-off. BM25 fixed top-1 reaches 0.820 support with 0.180 distractor citation; fixed top-2 improves support to 0.919 but nearly saturates distractor citation. Cross fixed top-1 reaches 0.975 support with 0.025 distractor citation. At $\theta = 0.93$, the selective Cross policy repairs 81.1% of test examples and reaches 0.989 support with 0.011 distractor citation on accepted repairs. The held-out result supports a narrow claim: trained reranking plus abstention reduces citation pollution in this support-ID diagnostic.

Policy	Unique N	Full	Partial	Full+Partial	None	Distr.	Ans.
Baseline	150	0.400	0.413	0.813	0.187	0.293	0.520
BM25 top-2	150	0.400	0.453	0.853	0.147	**0.893**	0.507
Cross top-2, $\tau = 0.40$	150	0.507	0.313	0.820	0.180	**0.407**	0.507

Table 1: Single-author claim-support audit over 450 unique generated-output cases. Full/Partial/None denote claim support; Distr. marks any irrelevant or distracting citation; Ans. marks answer correctness. Sixty duplicates are used only for consistency checking and do not enter the main rates; exact agreement was 55/60.

The controlled 100-example stress test is retained in the supplementary materials as a mechanism check. It shows the same pressure in a harder fixed-answer setting: lexical top-2 reaches 0.770 all-support coverage but saturates distractor citation at 1.000, while the cross-encoder top-1 probe at $\tau = 0.20$ reaches 0.710 support with 0.280 distractor citation.

Figure 2 reports absolute support and distractor levels for Qwen2.5-14B generated outputs. For compactness, it shows the conservative cross top-2 row at $\tau = 0.4$; the seed-stable $\tau = 0.2$ operating point is discussed in Section 6 and the supplementary materials. BM25 top-2 reaches 0.955 support with 0.996 distractor citation on HotpotQA and 0.824 support with 0.930 distractor citation on 2Wiki, while Cross reaches 0.967/0.194 and 0.856/0.152, respectively. MuSiQue remains the harder boundary: Cross recovers support to 0.728, but its distractor rate remains 0.500. The full Qwen2.5-7B/14B policy matrix, audit-packet summaries, and seed/threshold diagnostics are retained in the supplementary materials.

The targeted $N = 28$ LLM robustness slice is also retained in the supplementary materials. It is illustrative rather than representative, but it shows the same failure mode: lexical top-2 raises all-support citation from 0.071 to 0.607 while citing distractors in every example, whereas the cross-encoder keeps the same all-support rate at $\tau = 0.20$ with lower distractor citation (0.464).

Table 1 reports a single-author audit over 450 unique generated-output cases plus 60 duplicates. The audit is stratified across both Qwen2.5-7B and Qwen2.5-14B, while Figure 2 shows the Qwen2.5-14B support-ID slice for space. It supports the proxy-based interpretation but also motivates cau-

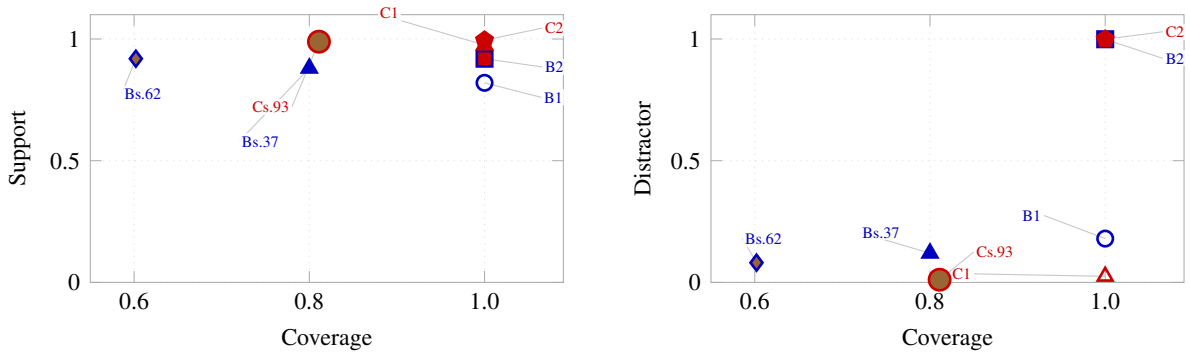

Figure 1: Held-out calibrated support-ID diagnostic. B1/B2 are BM25 fixed top-1/top-2; Bs.62/Bs.37 are BM25 selective thresholds; C1/C2 are Cross fixed top-1/top-2; Cs.93 is Cross selective repair. Selective rows report quality on accepted repairs, not unconditional full-coverage metrics.

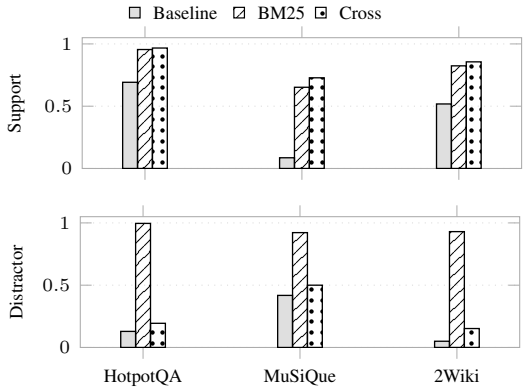

Figure 2: Generated-output absolute support–distractor levels on Qwen2.5-14B. BM25 buys support with distractor saturation, while Cross is cleaner on HotpotQA and 2Wiki; MuSiQue remains the higher-distractor boundary condition. Metrics are support-ID diagnostics.

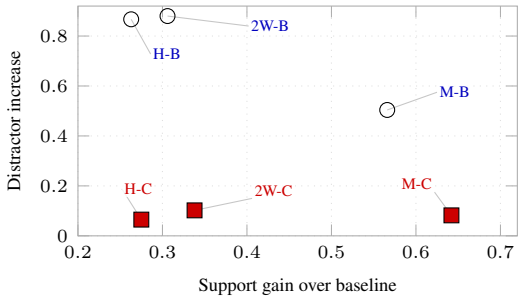

Figure 3: Generated-output support–distractor movement on Qwen2.5-14B. Moving right indicates support gain over baseline, and moving upward indicates distractor increase. H/M/2W denote HotpotQA, MuSiQue, and 2Wiki; B/C denote BM25 and Cross. BM25 usually buys support with larger distractor increases, while Cross occupies the cleaner operating point on HotpotQA and 2Wiki; MuSiQue remains the higher-distractor boundary condition.

tion: BM25 top-2 and cross top-2 have similar full-or-partial claim support (0.853 and 0.820), but BM25 top-2 cites distractors much more often (0.893 versus 0.407). Cross top-2 has the highest full-support rate among the audited policies (0.507), and baseline rows often receive partial support, reflecting missing bridge evidence. We use this audit to characterize support-ID proxy validity and failure modes, not as multi-annotator validation. A nonparametric bootstrap over the audited policy rows estimates the cross–BM25 distractor-rate difference at -0.487 $[-0.580, -0.400]$, while the full-or-partial support difference is -0.033 $[-0.120, 0.053]$; the audit therefore supports a cleaner operating-point interpretation. Duplicate rows are a consistency check, not evidence for the main rates: 55/60 received the same three author labels.

6 Analysis

The experiments separate two objectives that are easy to blur. Let $S_i(\pi)$ indicate that repair policy π cites all support identifiers for example i, and let $D_i(\pi)$ indicate that the repaired citation set contains at least one distractor. A compact operating-point view is $U_\lambda(\pi) = \mathrm{E}[S_i(\pi) - \lambda D_i(\pi)]$, where λ is the cost assigned to exposing a reader to a distractor. The single-author audit gives a claim-support analogue of the same trade-off: BM25 top-2 has slightly higher full-or-partial claim support than cross top-2 (0.853 versus 0.820), but much higher distractor citation (0.893 versus 0.407), so the audit-side break-even cost is $\lambda^* = (0.853 - 0.820)/(0.893 - 0.407) \approx 0.068$. Thus the learned verifier is not a universal winner; it is the cleaner operating point whenever distractors carry even a modest cost.

Figure 3 complements the absolute levels in Figure 2 by showing movement from each baseline: moving right gains support, while moving upward increases distractor exposure. The label shorthand is defined in the caption. This view makes the operating-point shift explicit without restating the absolute rates.

Selective repair. The held-out calibrated diagnostic in Figure 1 provides the complementary selective-repair view. Fixed policies act at full coverage, while thresholds reduce action coverage and report support and distractor rates among accepted repairs. The point is not that abstention solves citation repair, but that citation-set repair should expose a controllable operating point rather than collapse support recovery and distractor exposure into one score.

The LLM verifier reference point shows that semantic judging can move the top-1 point closer to the oracle in the controlled setup. It does not remove the central trade-off: when forced to add two citations, the LLM verifier also saturates distractor citation. We therefore use it as an API-based diagnostic comparison point, not as the proposed lightweight repair component or as a replacement for claim-level human validation.

The BM25 result is also a warning for learned verifiers. In the controlled 100-example stress test retained in the supplementary materials, BM25 top-1 slightly outperforms the first cross-encoder probe at $\tau = 0.20$; the 5,000-example diagnostic reverses that pattern after a cleaner train/calibration/test split. We do not treat this as a contradiction. The controlled stress test is an entity hard-negative setting, where many distractors share entity names or topical words with the missing bridge evidence. Figure 1 asks a different question: whether a supervised scorer, trained and calibrated away from the test questions, can expose a cleaner operating point. In this diagnostic it can, but the lesson is the control mechanism rather than a universal model ranking.

Transfer boundary. The generated-output MuSiQue results sharpen this caution outside HotpotQA. On Qwen2.5-14B outputs, cross top-2 at $\tau = 0.2$ raises support from 0.086 to 0.774, but its distractor rate remains high at 0.524. This differs from the controlled MuSiQue smoke check retained in the supplementary materials, where the fixed-answer top-1 verifier transfers cleanly under support-ID diagnostics. The contrast suggests that the support–distractor tension is not only a HotpotQA artifact, while realistic out-of-domain generation remains harder.

Taken together, the strongest supported claim is not universal absolute-performance transfer, but mechanism-level transfer of the operating-point geometry. HotpotQA is our strongest calibrated support-ID diagnostic setting, so it gives the clearest positive case for operating-point control under fixed-answer repair. The generated-output results on 2Wiki and MuSiQue show that the same expansion pressure is not unique to HotpotQA: repair can still recover support under dataset shift, but the policy can move into a higher-distractor regime. In the utility view $U_\lambda(\pi) = \mathrm{E}[S_i(\pi) - \lambda D_i(\pi)]$, this is exactly why Cross is not a universal winner in absolute terms, yet becomes the cleaner operating point once distractor cost exceeds a small break-even value. We therefore do not present FaithfulRepair as a general method for faithful generation; the contribution is to make support recovery, distractor cost, and calibrated operating-point choice visible and measurable for fixed-answer citation repair.

Robustness slice. The LLM-generated robustness slice makes the main failure mode concrete, but it is illustrative rather than representative. We do not use the 28 examples to estimate failure frequency; the 5,000-example calibrated diagnostic provides the quantitative evidence. Lexical top-2 often adds one support passage and one extra distractor, while the cross-encoder can recover the missing support more selectively or abstain at a higher threshold. The artifact examples show the same problem: surface overlap can find related passages, but it cannot decide whether the extra citation is necessary evidence for the answer.

Qualitative artifacts. The detailed qualitative table is retained in the supplementary materials rather than the archival main PDF. The recurring distractor types are still important: *surface-match distractors* share answer words or entity names but do not provide the missing bridge evidence; *entity-neighbor distractors* concern a related person, place, or organization rather than the needed relation; and *missing-bridge repair* adds a topically relevant citation that still leaves the comparison unsupported. Citation pollution is therefore not the same as answer correctness.

Proxy limits. Several examples also show a limitation of using dataset support identifiers as the only metric. Some generated answers make narrower claims than the full question, so a single citation can support the answer sentence even when

it does not cite all gold support passages. Conversely, over-citing all gold passages can still be stylistically or pragmatically undesirable. The author-corrected controlled sample and the 450-case generated-output audit check this issue directly; broader faithfulness claims would still need separate multi-annotator validation.

7 Limitations

Diagnostic scope. The controlled stress test uses a 100-example HotpotQA isolation setting. This isolates citation-set repair, but it is still a small diagnostic. The table includes examples from the same broad pool used for the first cross-encoder probe, so we treat those rows as feasibility evidence. The 5,000-example calibrated diagnostic adds a question-level held-out check for BM25 and the cross-encoder, but it is still one English multi-hop QA dataset rather than a multi-domain benchmark.

Transfer scope. Our strongest calibrated diagnostic is therefore HotpotQA, whose support annotations and candidate construction make it a favorable setting for controlled support-ID repair. We do not use HotpotQA alone to claim universal transfer. Instead, the relevant transfer object in this paper is the support–distractor operating-point geometry, not universal transfer of absolute scores. The Qwen2.5 generated-output benchmark over HotpotQA, MuSiQue, and 2Wiki suggests mechanism-level transfer of that geometry: repair can recover support beyond HotpotQA, but dataset shifts can move the policy into a substantially higher-distractor regime. MuSiQue is the clearest boundary condition for this effect rather than a counterexample to the main mechanism.

Proxy scope. The generated-output benchmark still uses support-ID diagnostics rather than full claim-level entailment, the LLM-generated constrained robustness slice is small at $N = 28$, and the single-author audit over 450 unique generated-output cases plus 60 duplicate checks should not be treated as full multi-annotator validation.

Verifier scope. The verifier is trained on question-answer claim proxies rather than manually segmented atomic claims. This keeps the pipeline lightweight but may miss fine-grained support failures. The support-ID proxy can fail in both directions: it can over-count support when a gold passage only partially supports the specific answer sentence, and it can under-count support when a generated answer makes a narrower claim than the original multi-hop question. It can also treat stylistically unnecessary gold passages as required citations. The current repair policy only adds citations; it does not rewrite unsupported answers or abstain when the answer itself is wrong.

Language scope. All current results use English multi-hop QA; we do not claim generalization to other domains, retrieval settings, or citation styles.

8 Ethics and AI Assistance Disclosure

This work studies citation support, so the evidence trail matters. We keep result provenance in audit files and avoid treating unverified references or weak diagnostic metrics as final evidence.

We used AI-assisted tools for code drafting and debugging, experiment scripting, table preparation, language editing, consistency checks, and high-risk audit triage. The author selected the research direction, ran and inspected experiments, verified outputs, accepted or rejected audit suggestions, interpreted results, and is responsible for the final manuscript. No AI system is listed as an author.

Abstract

Customer-service QA in an AI contact center (AICC) runs under deployment constraints that benchmark QA misses: tight voice-hotline latency and a high cost for unsupported or wrong automatic answers. We deploy a system that answers only from a *closed set* of *verified QA units*: it returns a retrieved unit verbatim, or routes to clarify/abstain/handoff. The index is enriched *offline* by *staged linguistic seeding* (SLS): a human authors a per-unit world-grounded slot recipe, `gpt-4.1-mini` renders it into variants, and a light human gate filters them, one methodology reused across both domains, so inference stays a single retrieval pass with no query-time generation. On held-out query variants (in-distribution recipe reformulations) from two industrial domains, SLS is the dominant retrieval lever, lifting hybrid `R@1` to **0.881/0.930** ($+0.27$/$+0.34$); the gain holds across all five retrievers we test. The win is the design, not the volume: at the *same* `gpt-4.1-mini`, SLS beats a budget-matched doc2query by $+0.20$/$+0.32$, and a cross-provenance control provides additional evidence of transfer across generated-query distributions; the embedding choice is secondary. Verified-unit answering also removes free-form generation's unsupported-content surface (7–13% vs. $\approx$0%). We report this as an honest application study, including negative results.

1 Introduction

Large language models and retrieval-augmented generation (RAG) dominate standard QA benchmarks (Lewis et al., 2020). But a production AI contact center (AICC), long automated with virtual agents (Gilbert et al., 2005) and increasingly built on LLM agents (Choubey et al., 2025), imposes constraints those benchmarks never test, especially on a voice hotline. The cost of errors is *asymmetric*. A confident but unsupported answer to an already-frustrated caller is far more damaging than a clarifying question or a handoff to a human agent (Banerjee et al., 2023; Yu et al., 2020). Latency makes this harder. On a live voice line the budget is tight, so query-time generation (a per-call LLM round trip of roughly a second) is impractical. Our deployment goal is concrete: *relieve* human agents, not replace them, keeping a safe escape to a person without escalating every ambiguous case.

RAG is the default response, because it grounds answers in approved references. But grounding the retriever is not enough: as long as a free-form generator is licensed to emit text, it can overextend even correct evidence and assert unsupported claims (Niu et al., 2024). We measure this directly. Over the *same* retrieved evidence, free-form RAG answers are judged unsupported in 7–13% of cases (`gpt-4o` judge). This residual persists even on correct evidence, and we did not find it tunable to zero; removing generation from the serving path eliminates it by construction.

We built and deployed a *verified-unit* QA system that excludes generation entirely. It answers only from a closed set of human-verified QA units (each a representative question, a verified answer, and a unit identifier), returning a retrieved unit's answer verbatim, or routing to clarify, abstain, or handoff. Nothing is generated at serve time, so unsupported answers are zero *by construction*. But removing the generator opens a new gap. Callers phrase one need in countless ways, while each unit ships with a single representative question. Without a query-time paraphraser, the full linguistic distance between *user-query diversity* and the curated answer set falls on retrieval. Our core contribution, *Staged Linguistic Seeding* (SLS), closes that gap offline. A human authors a per-unit, world-grounded slot recipe; `gpt-4.1-mini` renders it into candidate variants; a light human gate keeps or drops each one. The recipe injects domain knowledge,

*Equal contribution.

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 330–342
October 29, 2026 ©2026 Association for Computational Linguistics

the LLM supplies surface variety, and the seeding axes and prompt are reused unchanged across both domains. Everything runs offline, so inference stays a single retrieval pass with zero added serving cost.

This is an application paper. We built a verified pipeline that addresses two production constraints (unpredictable generation and tight latency), and we give empirical evidence for *why* it works on two real anonymized enterprise domains, with the core gain (and a closed-set leakage pitfall) replicating on a public benchmark. Our contributions, ordered by impact, are:

1. **A generation-free verified-unit pipeline in production use.** We built a closed-set QA system, in production use at an AICC (≈74k requests, ≈89% contained), over two anonymized domains (AUTO, 90 units; ELEC, 229 units; 319 verified units and 7,947 query variants in total), evaluated with a unit-attribution metric (`gold_unit_id` at `R@1`) on leakage-controlled held-out query variants (Rashkin et al., 2021); a faithfulness study quantifies the unsupported-content surface it removes (≈ 0% vs. 7–13% for free-form RAG on identical evidence).

2. **SLS is the dominant retrieval lever.** Offline expansion lifts hybrid (BM25+BGE-M3) `R@1` to 0.881 (ELEC) and 0.930 (AUTO), +0.27/+0.34 over a single representative question, and the gain holds across all five retrievers (Robertson and Zaragoza, 2009; Chen et al., 2024). A matched-budget control shows that the gain is not explained by model choice or expansion count alone: with the *same* `gpt-4.1-mini`, SLS beats a budget-matched doc2query by +0.20/+0.32 and every automatic baseline (doc2query, HyDE, query2doc) by at least +0.20/+0.29 (Nogueira et al., 2019; Gao et al., 2022; Wang et al., 2023). This comparison establishes the full SLS pipeline, not the recipe or human gate in isolation. Serving stays a single pass (∼14 ms hybrid vs. ∼1 s for query-time generation).

3. **The mechanism is consistent with broader phrasing coverage.** A cross-provenance control yields different absolute away-distribution gaps, but both systems lose roughly one third of their home score and the resulting index sizes differ. We therefore treat this control as descriptive rather than as a volume-controlled or causal transfer result. A symbol-grounding analysis sharpens this: 49% of held-out AUTO queries share *zero* content words with the canonical question, and SLS lifts that surface-disjoint half by +0.59, the gain decaying monotonically to +0.01 as phrasings approach full overlap (Harnad, 1990).

4. **External validity and honest negatives.** Both protocol-level findings (the expansion gain *and* a closed-set self-retrieval leakage pitfall) replicate, in sign and more modestly, on the public Quora Question Pairs benchmark (Iyer et al., 2017; Lewis et al., 2021), beyond our in-house logs. The embedding choice is secondary: neither a larger Qwen3 (Zhang et al., 2025) nor a Korean-specialized fine-tune beats off-the-shelf BGE-M3. Finally, a class-balanced router on non-leaky retrieval-confidence features recovers the rare clarify/abstain/handoff actions (action macro-F1 $0.36 \rightarrow 0.51$), but stays bounded by heuristic labels.

2 Related Work

Closed-set / FAQ retrieval. Answering from a fixed set of verified question–answer units is the FAQ-retrieval setting (Sakata et al., 2019; Mass et al., 2020); Mass et al. (2020) expand FAQ entries with generated questions. We add a unit-ID attribution metric, leakage-controlled held-out-query evaluation, and an explicit non-answer action space on real two-domain enterprise logs. Restricting the emitted answer to a closed, approved set (as in constrained generation over a fixed candidate set (De Cao et al., 2021) and verified-quote answering with abstention (Menick et al., 2022)) makes non-fabrication a property of the *answer space*, not the generator.

Grounded retrieval and attribution. Retrieval alone does not prevent unsupported claims (Lewis et al., 2020; Rashkin et al., 2021; Gao et al., 2023; Es et al., 2023; Saad-Falcon et al., 2023), and RAGTruth (Niu et al., 2024) documents hallucination even on correct context. We instantiate attribution-style evaluation (Rashkin et al., 2021) as unit-ID recovery and restrict the answer surface to verified units.

Query expansion and offline augmentation. doc2query, query2doc, and HyDE show that LLM-generated text can improve retrieval, though unevenly and not on every retriever (Nogueira et al., 2019; Wang et al., 2023; Gao et al., 2022; Jagerman et al., 2023; Riabi et al., 2021). Following EnrichIndex (Chen et al., 2025), recent work (Ma et al., 2025; Su et al., 2025) moves this enrichment offline, atop a long classical query-expansion lineage (Rocchio, 1971; Lv and Zhai, 2010; Carpineto and Romano, 2012; Azad and Deepak, 2017; Bhogal et al., 2007; Massai, 2022). Our expansion (SLS, §5) is offline doc2query-style enrichment, but it is *seeded* by a world-grounded slot recipe under a reusable methodology rather than by single-shot model output, then gated by a light human check; such linguistically motivated, in-distribution augmentation can pay off, particularly in lower-resource settings (Groshan et al., 2025), and no generation happens at serving time.

Retriever families. The main retriever families (BM25, SPLADE, BGE-M3, and the dense Qwen3 (Robertson and Zaragoza, 2009; Formal et al., 2021; Chen et al., 2024; Karpukhin et al., 2020; Zhang et al., 2025)) span the lexical–semantic spectrum; we take one representative from each and compare them under a single verified-unit protocol.

Abstention and routing. Treating refusal and handoff as first-class actions is the premise of selective classification, refusal tuning, escalation, and cost-sensitive decision theory (Geifman and El-Yaniv, 2017; Zhang et al., 2024; Kirichenko et al., 2025; Yu et al., 2020; Banerjee et al., 2023; Elkan, 2001), whereas LLM routing and cascades instead target *models* (Ong et al., 2025; Chen et al., 2023). Our actions route the query out of the automatic system under asymmetric costs.

3 Problem Setup

Given a human query x, a verified QA-unit index $T = \{t_i\}$, and optional metadata, the system chooses an action $a \in \{\text{ANSWER}, \text{CLARIFY}, \text{ABSTAIN}, \text{HANDOFF}\}$. When $a = \text{ANSWER}$, it returns the answer of a selected unit t_i, so that the retrieval target is the unit identifier rather than a generated string. Each unit is stored as $t_i = (\text{unit\_id}, q_i, y_i)$, where q_i is a representative question and y_i a verified answer: the stored record is the implementation object, while the verified QA unit is the conceptual grounding boundary.

Why verified units bound the failure surface. Let $i^\star$ be the gold unit for query x, let $\hat{\imath} = \arg\max_i \text{score}(x, t_i)$ be the retrieved top-1 unit, and let $\rho = \Pr[\hat{\imath} \neq i^\star] = 1 - \texttt{R@1}$ be the retrieval-error rate. Call an answer *unsupported*, $U(a) = 1$, if it asserts content not present in the retrieved evidence $E(x)$. A free-form answer $a = g(x, E(x))$ from a generator g can be unsupported even when the evidence is correct, at a rate $\eta = \Pr[U(a) \mid \hat{\imath} = i^\star] > 0$ (documented by RAGTruth (Niu et al., 2024); we measure $\eta \approx 0.12$ in §6). Its unsupported rate is therefore

$$\Pr_{\text{free}}[U] = (1 - \rho)\,\eta + \rho\,\eta' \;>\; 0, \qquad (1)$$

where $\eta' > 0$ is the unsupported rate under wrong evidence. Verified-unit answering instead returns $a = y_i$, the human-verified text of a retrieved unit, so the answer is always an element of the evidence and cannot introduce new claims:

$$a \in \{y_i : t_i \in E(x)\} \implies \begin{aligned} \Pr_{\text{ours}}[U] &= 0, \\ \Pr_{\text{ours}}[\text{error}] &= \rho. \end{aligned} \qquad (2)$$

Comparing (1) and (2), the verified-unit design removes the open-ended generation-error term η and leaves a single *measurable* retrieval-error term $\rho = 1 - \texttt{R@1}$, on whose low-confidence part the router (§6) declines to answer. This is "non-fabrication by construction": we eliminate not *wrong* answers (a wrong unit can be retrieved) but *unsupported* ones.

4 Data Construction

The project uses real enterprise QA logs from two anonymized deployments, AUTO (automotive) and ELEC (consumer-electronics). These are not benchmark pairs: rows include short turns, incomplete intent, domain shorthand, greetings, URL/image prompts, and many queries whose correct action is clarify, abstain, or handoff. From these real logs we derive two artifacts.

(a) Verified units with query-expansion variants (retrieval study). The core asset is a curated FAQ in which each verified unit carries a verified answer together with query variants produced by SLS (§5) and seeded from the representative question and the phrasings real users and operators recorded in the logs. Because the variants are an

output of the protocol rather than hand-authored strings, their per-unit count in the full pre-split pool (5–113; indexed-only counts of 3–79 in App. D) tracks the question's linguistic variability. This yields **319 verified units** (229 ELEC, 90 AUTO) and **7,947 query variants**, whose held-out portion forms our leakage-free test set of real-log-seeded variants (held-out protocol variants, not raw logged utterances). The protocol was applied to *both* domains; the explicit authoring recipe is retained for AUTO (App. E), while for ELEC, owing to data-retention constraints, only the deployed variants remain.

(b) Operational log with action labels (routing study). For routing we use a larger operational set of 6,000 clustered human queries with heuristic action labels (Table 6), built by cleaning and deduplicating raw logs, clustering similar questions, and assigning answerability/routing labels. These labels indicate an action class only; in particular, the 2,455 queries labeled ANSWER do not carry human-adjudicated target IDs for the 319 verified units. Retrieval is therefore measured on the held-out variants from (a), and routing on the labeled log (b).

Data governance. Because the logs are enterprise data, we report only aggregate statistics, anonymized examples, and unit IDs; raw user text remains access-controlled. Privacy is part of the system boundary, not an appendix detail.

5 System

Verified-unit retrieval. Figure 1 overviews the system: offline index construction by staged linguistic seeding (a human operator grounds each unit's representative question in world-grounded slots, which `gpt-4.1-mini` recombines into the indexed variants) and online verified-unit retrieval with cost-sensitive routing. We compare one retriever per family over the same verified QA units, spanning the lexical–semantic spectrum: BM25 (Robertson and Zaragoza, 2009) as the sparse baseline; the dense-only Qwen3 embedding (Zhang et al., 2025); and BGE-M3 (Chen et al., 2024) in between, a multi-functional encoder (dense, sparse, and multi-vector modes) of which we use the dense mode. The hybrid linearly combines per-query min–max-normalized BM25 and BGE-M3 scores at equal weight. For the dense component we use the official BGE-M3 checkpoint, more robust on this corpus than the available domain-adapted alternative (§6).

Offline query expansion: staged linguistic seeding (SLS). For each verified unit the index stores either the representative question (RAW) or that question plus expansion variants (AUG). The variants are produced offline by *staged linguistic seeding* (Figure 1), which separates what is reused from what is authored per unit. Reused across units and both domains are (i) **seeding axes**, a fixed specification of the linguistic and world-grounded forms to cover (synonyms, homonyms, syllable and lemma/stem forms, and the *eojeol*, the Korean space-delimited token)—together with a single fixed **prompt** conditioning `gpt-4.1-mini` (the *same* model the automatic baselines use) on those axes. Per unit, a human then authors a **world-grounded slot recipe** that factorizes the representative question into grounded slots along these axes; (ii) `gpt-4.1-mini` **renders** it into candidate strings, which (iii) a **light human gate** keeps or drops against a fixed rubric. The durable asset is the recipe (from which the indexed variants are regenerable on demand), not the 7,947 output strings. SLS is thus doc2query-style (Nogueira et al., 2019) in structure; the lever is the human, world-grounded seeding *distribution* (§6), and inference stays a single retrieval pass.

Cost-sensitive routing (the policy we test). Retrieval alone is insufficient when a query is incomplete, unsupported, or risky, so we add a cost-sensitive decision over *non-leaky* retrieval-confidence features (per-family top/top-2 scores, margins, cross-family agreement), selecting the expected-cost-minimizing action under a cost matrix where a wrong answer costs far more than a clarification (a threshold gate is the one-scalar special case). We estimate it with a class-balanced gradient-boosted classifier and report it as a bounded secondary study (§6, App. B).

6 Experiments

Metrics and protocol. The primary metric is unit recall at rank 1 (`R@1`) against each variant's gold source unit (`gold_unit_id`); we also report `R@3` and `R@15`. For the retrieval study, for each verified unit we randomly hold out 30% of its query variants as *test* queries that are never indexed, and index the remaining variants (AUG) or only the single representative question (RAW). Because the

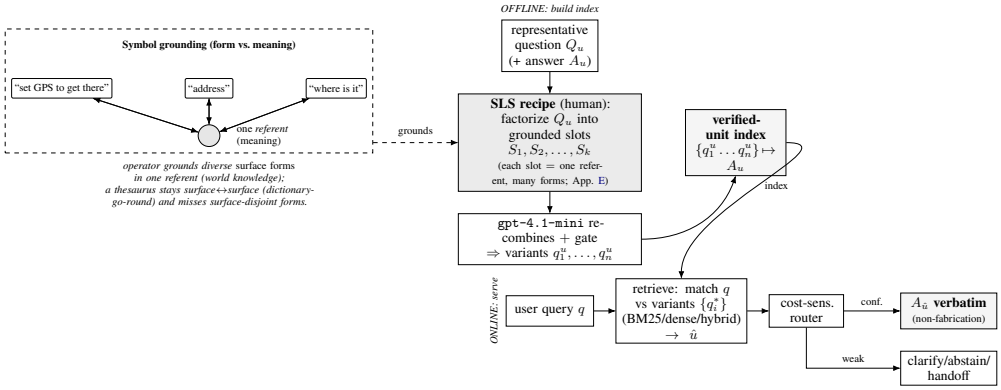

Figure 1: System overview. **Offline**, a human operator factorizes each verified unit's representative question Q_u into world-grounded slots—*symbol grounding*: diverse surface forms tied to one referent, a link a thesaurus cannot make (it stays surface↔surface)—and `gpt-4.1-mini` recombines the slots into the indexed variants $q_1^u \ldots q_n^u$. **Online**, a user query q is matched against the *variants* (not the canonical question), and a cost-sensitive router returns the verified answer verbatim or escalates. The grounded variants bridge the gap between curated canonical questions and the surface-disjoint ways real users phrase the same intent (§7).

test phrasing is never in the index, the protocol is leakage-free at the string level. This yields 1,468 held-out ELEC and 915 held-out AUTO test queries over the 319 units. Because held-out and indexed variants are drawn from the same per-unit pool, the test is *in-distribution* (Lewis et al., 2021): it measures generalization to unseen phrasings of each unit's recipe, not transfer to an independent query stream (on AUTO, 49% of held-out queries share no content word with the representative question). A cross-provenance control provides suggestive evidence that the gains are not solely due to this provenance match. A fully independent organic test is unavailable by construction: raw call transcripts are not retained, and the preserved operational artifact carries heuristic routing-action labels rather than human-adjudicated unit-level gold. Even its ANSWER label identifies an action, not the correct one of the 319 verified units; moreover, most queries are labeled non-answer (Table 6, 59%).

A leakage check. Querying a legacy cluster with its own indexed representative question trivially inflates a top-1 self-match diagnostic (up to $\approx 8\times$ for BM25). This heuristic diagnostic is not an organic unit-accuracy evaluation; our primary held-out-variant protocol separately avoids question-identity leakage by construction (audit in App. A).

Staged linguistic seeding is the dominant lever. Table 1 reports `R@1` on the held-out query variants (App. F traces these back to the per-domain data statistics). Across both domains and all retrievers, offline SLS expansion is the dominant gain: the hybrid rises from $0.609 \rightarrow 0.881$ on ELEC ($+0.272$) and $0.588 \rightarrow 0.930$ on AUTO ($+0.342$); BM25 gains most ($+0.351/+0.426$), and the gain holds across the full lexical–semantic spectrum (SPLADE $+0.219/+0.253$, Qwen3 $+0.135/+0.168$, dense $+0.123/+0.202$). The best configuration is hybrid+expansion (**0.881/0.930**), with `R@3` 0.973/0.981. Every gain is significant by a paired bootstrap (10k resamples, n=1,468/915): hybrid $+0.272$ (95% CI $[+0.247, +0.297]$) / $+0.342$ $[+0.309, +0.375]$; BM25 $+0.351$ $[+0.324, +0.378]$ / $+0.426$ $[+0.392, +0.461]$; dense $+0.123$ $[+0.101, +0.144]$ / $+0.202$ $[+0.175, +0.231]$. No interval includes zero. Because queries from one unit are not independent, we also report a *cluster* (per-unit) bootstrap that resamples whole units rather than queries: intervals widen, as expected, but every gain remains significant, and the smallest-domain headline —AUTO hybrid $+0.342$—survives even at its 90 units (cluster 95% CI $[+0.291, +0.390]$).

The embedding choice is secondary to the expansion. Down the RAW columns, dense (0.66–0.72) beats BM25 (0.47–0.48): the low RAW recall is expected: the representative question is an expert-prepared canonical form that real phrasings rarely match lexically (the form–meaning gap, §7), and a semantic retriever only partly bridges it. With expansion, BM25 catches up (0.82–0.91) and the hybrid is best, so *which* embedding one picks becomes secondary to the expansion. Across the spectrum the off-the-shelf official BGE-M3 is strongest: a larger Qwen3-4B does not exceed it

	Elec			Auto		
Retriever	RAW	+AUG	Δ	RAW	+AUG	Δ
BM25 (lexical)	0.471	0.822	+0.351	0.480	0.906	+0.426
SPLADE-ko (learned sparse)	0.627	0.846	+0.219	0.640	0.893	+0.253
Dense BGE-M3 (official)	0.717	0.840	+0.123	0.661	0.863	+0.202
Dense Qwen3-4B	0.690	0.825	+0.135	0.674	0.842	+0.168
Dense (fine-tuned, ours)	0.623	0.779	+0.156	0.591	0.814	+0.223
Hybrid (BM25+BGE-M3)	0.609	**0.881**	**+0.272**	0.588	**0.930**	**+0.342**

Table 1: `R@1` on held-out query variants (Elec n=1,468, Auto n=915; 319 units), across the lexical–semantic spectrum: lexical BM25, learned-sparse SPLADE, dense BGE-M3 and Qwen3-4B, and the lexical+semantic hybrid. RAW indexes one representative question per unit; +AUG additionally indexes the unit's deployed SLS variants. Offline SLS expansion is the dominant lever in *every* family (hybrid +0.272/+0.342; BM25 +0.351/+0.426; SPLADE +0.219/+0.253; Qwen3 +0.135/+0.168), and the hybrid is best. A larger Qwen3-4B and our own fine-tuned checkpoint (`dragonkue/BGE-m3-ko` further fine-tuned on NEMOTRON-PERSONAS-KOREA persona pairs) do not exceed the official BGE-M3, and the fine-tuned one trails it throughout, despite starting from a Korean-specialized base (Appendix G). Test phrasings are never indexed, so the setting is leakage-free.

(AUG 0.825/0.842 vs. 0.840/0.863), and a Korean-specialized fine-tune (App. G) underperforms it in every cell. This is not a training failure but evidence for the protocol: neither a larger model nor extra generic in-domain data closes the gap that grounded expansion does; the gap is *coverage of unseen phrasings*, not embedding capacity.

The SLS pipeline beyond volume: a matched-budget control. A natural objection is that *any* generated expansion would help, or that our gain merely buys more effort per unit. We test both with an offline-vs-online comparison on the same held-out queries (Table 2): SLS vs. offline automatic expansion (doc2query (Nogueira et al., 2019), EnrichIndex (Chen et al., 2025)) and query-time online augmentation (HyDE (Gao et al., 2022), query2doc (Wang et al., 2023)), all of them generated by the *same* `gpt-4.1-mini` that SLS uses (prompts in App. I). SLS dominates every automatic method by a wide margin: hybrid `R@1` 0.881/0.930 vs. the best automatic baseline 0.685/0.639, a +0.20/+0.29 gap, at zero query-time generation cost. The decisive evidence is the *matched-budget* control: when the automatic baseline generates the *same number* of questions per unit as SLS ("doc2query N-matched"; Table 2); i.e. the same generator at the same per-unit budget, it reaches only 0.685/0.611, only +0.001/+0.038 above the 6-shot version and far below SLS (matched gap +0.196 [+0.162, +0.230] / +0.319 [+0.240, +0.398], per-unit cluster bootstrap). The gain is therefore *not* bought by indexing more text. What differs is the complete staged procedure—the human-authored recipe, LLM rendering, and acceptance gate—so this control does not isolate any one of those components. (This also retires an earlier "reverse-HyDE" patch whose apparent +0.023 gain was a leakage artifact.)

Cross-provenance control: asymmetric transfer across generated-query distributions. Because the held-out queries are themselves SLS variants, the matched-budget gap could reflect index–test provenance match (a recognized inflation source (Lewis et al., 2021)), not coverage. We probe this with a *cross-provenance* control on AUTO (answer-in-index). After holding out doc2query variants for testing, the resulting index sizes differ (16.4 doc2query vs. 23.5 SLS variants/unit), so this comparison does not remove index-volume as a possible contributor: on doc2query's own held-out queries the SLS index reaches 0.652, 0.146 below doc2query's own index (0.798); on SLS's held-out queries the doc2query index reaches 0.531, 0.399 below SLS's 0.930 (hybrid `R@1`). These absolute gaps differ, while each index loses roughly one third of its own home score (30% vs. 33%). Together with the unequal index sizes, this makes the control descriptive evidence of provenance sensitivity, not a causal isolation of coverage, provenance, or volume.

Offline expansion adds no serving cost. Because the variants are attached at index time, serving is a single retrieval pass: on one NVIDIA H100 (Intel Xeon 8480C for BM25), median retrieval latency is 0.7/13/14 ms for BM25/dense BGE-M3/hybrid, whereas query-time HyDE/query2doc add a `gpt-4.1-mini` call at 1.0–1.4 s, two orders of magnitude more.

External validity. Because our data is proprietary, we replicate both protocol-level findings on the public Quora Question Pairs set (Iyer et al., 2017): the leakage pitfall reappears and the expansion gain replicates on lexical/hybrid retrieval but dilutes on a near-ceiling dense baseline (numbers in App. C).

Routing: a bounded secondary result. Weak-evidence queries should be routed (clar-

Augmentation	side	Query-time generation?	Elec	Auto
none (RAW)	—	no	0.609	0.588
doc2query (6-shot)	offline	no	0.647	0.610
doc2query (N-matched)	offline	no	0.685	0.611
EnrichIndex	offline	no	0.662	0.616
HyDE	online	yes	0.650	0.576
query2doc	online	yes	0.663	0.639
SLS (ours)	offline	**no**	**0.881**	**0.930**

Table 2: Offline-vs-online augmentation comparison, hybrid `R@1` on the same held-out query variants (319 units). All methods, including SLS, use the *same* `gpt-4.1-mini`. Automatic expansions lift RAW only modestly; the matched-budget control ("doc2query N-matched"—the *same* generator producing the *same* number of questions per unit as SLS) reaches only 0.685/0.611, at most +0.038 above the 6-shot version. SLS (staged linguistic seeding) dominates by +0.20/+0.29 over the best automatic baseline (online or offline), at zero query-time generation cost. Holding the generator and per-unit budget fixed rules out those two explanations, but does not separate the recipe, rendering, and human gate within SLS.

ify/abstain/handoff) rather than answered. A class-balanced gradient-boosted classifier on non-leaky retrieval-confidence features lifts action macro-F1 from 0.36 to **0.51** (0.45 using retrieval features only, avoiding circularity) and recovers the rare abstain/handoff actions; but the deployable signal is the *binary* selective-answering slice, the four-way result is bounded by heuristic, genuinely subjective labels ($\kappa \leq 0.09$ on re-annotation by a question-only `gpt-5` and a human) and by features that indicate *whether* but not *why* to escalate. We thus report routing as a bounded secondary study; full numbers, the cost–coverage curve, and Table 5 are in App. B.

Does verified-unit answering reduce hallucination? We compare two answering arms on 150 answerable queries given the *same* top-5 retrieved units: *free-form RAG* (a generator writes the answer) vs. *verified-unit answering* (return the top-1 unit's answer verbatim), judged by an independent `gpt-4o` for unsupported claims and gold coverage. On the correct-retrieval subset (n=136), free-form introduces unsupported content in 7.4% (`4o-mini`)–13.2% (`4.1-mini`) of answers, whereas verified-unit answering is unsupported-free *by construction* (a residual 0.7% is one judge-noise flag on verbatim text; Table 3). This reduction is significant (paired McNemar p=0.012, 7.6×10^{-5}), and because gold coverage is comparable (81.6% vs. 74.3%/80.9%), the gain comes from eliminating the *unsupported-generation surface* rather than from coverage. As noted, the judge is LLM-based with no human adjudication (§8).

Answering arm (same correct evidence, n=136)	Unsupported	Covers gold
Free-form RAG (`gpt-4o-mini`)	7.4%	74.3%
Free-form RAG (`gpt-4.1-mini`)	13.2%	80.9%
Verified-unit (ours)	**0.7%**†	**81.6%**

Table 3: Faithfulness on the correct-retrieval subset (n=136): two free-form generators vs. verified-unit answering over the *same* top-5 evidence (a single `gpt-4o` judge scoring unsupported-content and gold-coverage). Verified-unit is unsupported-free *by construction* (†0.7% is one residual judge-noise flag on verbatim text). Paired McNemar on unsupported: p=0.012/7.6×10^{-5}.

7 Discussion

Why human-authored expansion outperforms learned query generation. A learned query generator (doc2query) or a thesaurus operates over *surface form*: the distributional co-occurrence captured by word statistics (Firth, 1957). But many real reformulations are not lexical variants: the AUTO query "how do I set my GPS to get there?" requests a dealership's *address* yet shares no content word with "where is the showroom?" (Figure 1). The link is world knowledge (a navigation destination *is* an address), so recovering it means passing through the referent, which a lexical resource cannot do. This is a gap between surface form and meaning (an instance of symbol grounding, Harnad, 1990).

Our protocol supplies this grounding by construction (Figure 1): an operator factorizes the representative question into orthogonal world-grounded slots (explicit for AUTO, App. E; for ELEC only the deployed variants survive), and the language model *recombines* these grounded units, sampling *within* the operator-defined manifold rather than guessing it, unlike free-form generation, which crowds near the seed or drifts off-target.

This account predicts *where* the gain should land. On AUTO, 49% of held-out queries share *zero* content words with their unit's representative question, so a surface match to that canonical form cannot reach them (BM25 `R@1` 0.28 on this disjoint half). Indexing the staged-seeding variants lifts exactly this half from 0.28 to 0.87 (+0.59); the gain then falls monotonically with surface overlap: +0.34 for partially-overlapping queries

(n=378) and +0.01 for the fully-overlapping ones already near ceiling (n=91). The gain thus concentrates on the surface-disjoint, world-knowledge-dependent reformulations the account predicts, and the matched-budget control (§6) shows that automatic expansion at the same model and budget does not recover them. The cross-provenance result separately documents provenance sensitivity but is index-size-confounded. We are careful about *causality*: the evidence supports the full SLS pipeline and its broader phrasing coverage, but does not isolate the recipe, renderer, or gate as the unique active component.

8 Limitations

Our faithfulness judge (§6) is LLM-based with no human adjudication, so the absolute unsupported rate is judge- and generator-dependent (7–13%); the *relative* reduction, significant on correct-retrieval cases, is the robust finding. The retrieval study covers only 319 verified units (AUTO just 90), so we report per-query and cluster bootstrap CIs. Our retrieval/faithfulness study is offline, without controlled A/B, and latency is a single-query micro-benchmark. The routing result rests on *heuristic*, subjective labels ($\kappa \leq 0.09$ on re-annotation) and features that bound per-action scores, so we present the four-way router as forward-looking and report only the binary answer-vs-escalate slice as deployable. We have not yet run a gate-only ablation (steps (i)–(ii) without the step-(iii) gate) to separate the human gate from the seeding design, nor quantified human authoring effort; the recipe is a *one-off offline* asset that should amortize against the recurring cost of a wrong answer, but a precise cost–benefit accounting and scaling to far larger FAQ sets remain future work. The ELEC recipe was not retained, so recipe-level analysis (§7) is AUTO-only, though expansion was applied to both domains and gains hold across both; raw logs remain access-controlled. Most fundamentally, the world-grounded recipe is presently *human*-authored; automatically *inducing* this factorization is the central open problem, and until then operator authoring is what bridges the curated-question/real-user gap.

9 Ethics

The data come from enterprise logs; we report only aggregated statistics, anonymized examples, and unit IDs, and keep raw logs access-controlled. The method is not a truth guarantee (a wrong retrieved unit can still produce a wrong response), so deployments should log unit IDs, confidence, and action decisions for audit.

10 Conclusion

We presented a verified-unit QA pipeline for AI contact centers: answers are bounded to verified units; weak-evidence cases are routed, not fabricated. Its lever is *staged linguistic seeding* that lifts hybrid `R@1` to 0.881/0.930 (+0.27/+0.34) across two domains; the matched-budget control attributes the main gain to the full SLS pipeline, while cross-provenance evaluation documents provenance sensitivity; verified-unit answering removes the unsupported-generation surface ($\approx$0 vs. 7–13%). Inducing the recipe automatically remains open.

Top-1 match (heuristic targets)	BM25	Dense	Hybrid
Leaky (question-bearing index)	0.863	0.570	0.873
Answer-only index	**0.103**	**0.222**	**0.160**

Table 4: Legacy leakage diagnostic over 6,000 clustered operational-log queries, distinct from the 319-unit retrieval study. Targets are heuristic cluster assignments, not human-adjudicated unit gold. Indexing the representative question and querying with it ("leaky") vs. indexing the answer only ("answer-only") shows up to ≈8× inflation. This table is not an organic-accuracy evaluation; Table 1 instead uses held-out variants with known source-unit IDs.

A The Question-Identity Leakage Audit

An earlier indexing protocol of ours was leaky. Indexing each legacy cluster as "`question:` ⟨representative question⟩; `answer:` ⟨answer⟩" (the question and answer fields are Korean in the deployment) and then querying with that *same* representative question makes retrieval match a query to its own indexed copy. On the full set of 6,000 clustered operational-log queries, the leaky question-bearing index has BM25/dense/hybrid top-1 match rates 0.863/0.570/0.873, but only 0.103/0.222/0.160 once the question field is removed, an inflation of roughly 8× for BM25 and 2.6–5.5× across families (Table 4). The target here is a legacy heuristic cluster assignment, not a human-adjudicated gold mapping to the 319 verified units; this diagnostic therefore does not measure organic-query accuracy. Closed-set FAQ evaluations in which test queries coincide with indexed representative questions should be read with this inflation in mind; our held-out-variant protocol avoids it because the test phrasing is never in the index.

B Routing: Full Results

We treat routing as a cost-sensitive decision over the non-leaky evidence vector z (per-family top and top-2 scores, margins, ratios, cross-family top-unit agreement). A class-balanced gradient-boosted classifier reaches macro-F1 **0.51** (5-fold 0.487±0.027) and recovers the rare actions (abstain/handoff F1 0.41/0.39, up from 0.13/0.17 for a Gaussian naive-Bayes baseline on the same features; Table 5); using retrieval features only (to avoid circularity with the surface cues that define the heuristic labels), it still reaches **0.45**.

Cost–coverage. Under an asymmetric cost matrix (we adopt the *illustrative* ratio that a wrong auto-answer costs 20× a clarification) and honest retrieval (answer-only `hit@1`≈0.13), the expected-cost-minimizing policy is conservative: it auto-answers < 1% of queries at a 0% unsafe-answer rate (mean cost 1.10 vs. 16.5 for always-answer). Ranking answerable queries by predicted retrieval-correctness, the top 10% are answerable at precision 0.65 (vs. a 0.13 base rate), falling to 0.34 at 30% and 0.24 at 50% coverage.

Two ceilings. (i) The action labels are heuristic, not adjudicated: on a 300-query sample, a question-only `gpt-5` and a human re-annotation barely agree with them (κ=0.06/0.04) or with each other (κ=0.09), and skew in opposite directions, so the four-way boundary is genuinely subjective. (ii) Retrieval-confidence features separate ANSWER from escalate but carry little signal for *why* to escalate, bounding four-way F1 independent of label quality. The defensible result is therefore the binary selective-answering slice; the four-way router, with human-adjudicated labels and intent-bearing features, is left to future work.

F1 by action	answer	clarify	abstain	handoff	macro-F1
Gaussian NB (same features)	0.61	0.51	0.13	0.17	0.36
Balanced GBM, retrieval-only	0.62	0.54	0.28	0.38	0.45
Balanced GBM, all features	**0.66**	**0.58**	**0.41**	**0.39**	**0.51**

Table 5: Action routing on the operational log (test n=1,200; non-leaky multi-family retrieval features). Class-balanced gradient boosting lifts macro-F1 from 0.36 (Gaussian NB on the same features) to 0.51 (all features) / 0.45 (retrieval-only, the circularity-free number) and recovers the rare ABSTAIN/HANDOFF actions.

Action label	Auto	Elec	Total	Share
answer	1,533	922	2,455	40.9%
non-answer subtotal	**2,067**	**1,478**	**3,545**	**59.1%**
clarify	1,497	857	2,354	39.2%
handoff	446	578	1,024	17.1%
abstain	124	43	167	2.8%
Total human queries	**3,600**	**2,400**	**6,000**	**100.0%**

Table 6: Operational routing log with 6,000 human queries across two domains. Labels are heuristic routing labels derived from rule-based buckets over answer content, not human-adjudicated gold labels. The ANSWER class likewise does not supply a target verified-unit ID. Non-answer actions account for 59.1% of the log, and abstain is rare (2.8%), which makes rare-action recovery central to the routing analysis (§6).

C External Validity: Quora Question Pairs

Because our enterprise data is proprietary, we replicate both protocol-level findings on Quora Question Pairs (Iyer et al., 2017) (800 clusters as "units", 1,470 held-out paraphrases, with each cluster's other phrasings serving as the expansion). The leakage pitfall reappears: an indexed phrasing gives `R@1` 1.000 versus 0.81–0.94 on held-out paraphrases, and the expansion effect carries over to lexical and hybrid retrieval (BM25 $+0.124$, hybrid $+0.053$; cluster-bootstrap significant), while a near-ceiling dense retriever on this clean set dilutes slightly (-0.026). Expansion helps most where single-representative matching is weakest, exactly as on our enterprise logs. This QQP study is the fully public, reproducible portion of our work; we will release its replication code and derived data, together with our pipeline code and the fine-tuned checkpoint, upon acceptance. The release pins the exact dated snapshot identifier and decoding parameters for every OpenAI call (`gpt-4.1-mini` for SLS rendering and the automatic baselines; `gpt-4o` and `gpt-4o-mini` for judging), so the SLS variants and judge labels regenerate deterministically.

D Dataset Statistics

Table 7 reports per-domain statistics for asset (a), the verified units and their indexed query-expansion variants. Lengths are measured on the original Korean text (characters; and *eojeols*, the space-delimited tokens of Korean).

Production deployment. The system is in live production on both domains: AUTO since early 2025 ($\sim$18 months) and ELEC since mid 2025 ($\sim$12 months). Over these windows it has served 24,126 AUTO requests (excluding reservation-management transactions) and 50,172 ELEC requests, routing 3,423 and 4,724 respectively to a human agent: a containment (no-handoff) rate of 85.8% and 90.6% (89.0% combined, over 74,298 requests). Containment is a deflection measure, not a correctness guarantee (non-handoff may include user abandonment), and we report no controlled before/after.

E An Example Verified Unit

The example below is from AUTO, anonymized and translated from Korean. It traces one representative question through staged linguistic seeding: the *seeding axes* that step (i) applies, a sample of the step (ii) generations that the step (iii) acceptance gate kept in the index, and the held-out test queries (never indexed) the system is evaluated on.

> **Representative question:** "What region are you in?"
> **Verified answer:** "⟨dealership⟩ is located at ⟨address⟩." (anonymized)
> **Seeding axes (step i):** location-noun synonyms (region / location / address / lot-number), inflectional and honorific endings, and spacing (eojeol) segmentation of the representative question—the fixed seed specification handed to the generator.
> **Accepted variants (steps ii–iii, sample):** "Where are you located?"; "Can you tell me the address?"; "What is the lot number?"; "How can I find the location?"—each realizing one or more of the step-(i) seed axes in the original Korean.
> **Held-out test queries (never indexed):** "Please tell me the location."; "What is the address of the showroom?"; "Where is it located?"

	AUTO	ELEC
Verified units	90	229
Held-out test queries	915	1,468
Indexed variants	2,114	3,450
Indexed variants / unit (mean; min–max)	23.5 (6–79)	15.1 (3–41)
Answer length (chars; mean, max)	80, 193	137, 903
Rep. question length (chars; mean)	19	21
Variant length (eojeols; mean)	5.1	5.5

Table 7: Per-domain statistics of the verified-unit corpus (asset (a)). AUTO has more variants per unit and shorter, more templated answers; ELEC has more units and much longer answers (up to 903 characters).

F How the Data Explains the Results

The statistics in Appendix D and the example in Appendix E account for the main retrieval findings. First, a representative question is short (mean 19–21 characters) and fixes a single surface form, whereas held-out queries restate the same intent with different content words and inflections; single-representative matching (RAW) therefore misses most of them, and the 15–24 indexed variants per unit close exactly this gap. This is why AUG lifts `R@1` so sharply, and why the purely lexical BM25 gains the most (it keys directly on the added word forms). Second, AUTO reaches a higher AUG `R@1` (0.930) than ELEC (0.881): it has more variants per unit (23.5 vs. 15.1), fewer units (90 vs. 229), and shorter, more templated answers (mean 80 vs. 137 characters), so its units are more densely covered and more separable. Third, ELEC answers are much longer (mean 137, max 903 characters), giving a free-form generator more room to add unsupported detail; verbatim verified-unit answering

returns the exact text and stays unsupported-free, consistent with the faithfulness result (§6).

G Domain-Adapted Checkpoint: Training Details and Korean Competence

The "Dense (fine-tuned, ours)" row in Table 1 is our own checkpoint, reported as a negative result. We deliberately did *not* start from the vanilla official model: the base is `dragonkue/BGE-m3-ko` (dragonkue, 2024), the official `BAAI/bge-m3` continued-trained on additional, undisclosed Korean data. This base is *Korean-specialized* and is documented to improve over the official model on Korean retrieval—its model card reports $+0.09$ nDCG on a Korean (financial) AutoRAG benchmark over the official checkpoint (with a smaller -0.02 on MIRACL-Wikipedia, i.e. a domain-specific Korean gain). On top of it we fine-tune with the sentence-transformers `MultipleNegativesRankingLoss` (in-batch-negative contrastive) on (`query`, `positive-document`) pairs built from NEMOTRON-PERSONAS-KOREA (NVIDIA, 2025): $4\times$H100, 3 epochs, per-device batch size 8 with gradient accumulation 4, learning rate 2×10^{-5}, warmup ratio 0.1, weight decay 0.01, `bf16`. The resulting checkpoint is itself a competent Korean retriever (AutoRAG `MRR` 0.78, `Hit@10` 0.95; MIRACL `mRR` 0.58), so its underperformance on our closed-unit customer-service units (Table 1) is a genuine domain-transfer failure, not a weak-model artifact: starting from a strong Korean base and adding persona fine-tuning still does not beat the off-the-shelf official BGE-M3 with offline SLS expansion. The checkpoint will be released upon acceptance.

H SLS Generation and Acceptance Procedure

The retained artifact records the procedure-level specification but not the exact Korean prompt text or item-level gate decisions; we therefore do not reconstruct or quote them. As documented in §5, the renderer received a representative question and a human-authored slot recipe covering the fixed linguistic axes, then produced Korean candidate phrasings. The subsequent light human gate retained candidates judged to preserve the source unit's intent and grounded content and dropped unsuitable renderings before indexing. The same procedure was used across the two domains. Because the gate is part of SLS and no gate-only ablation was retained, our experiments establish the full SLS pipeline relative to the automatic baselines; they do not identify either the recipe or the gate alone as the unique causal component. This procedural description is the strongest reproducible claim supported by the preserved artifacts.

I Baseline Generation Prompts

Every automatic expansion baseline in Table 2 uses the *same* `gpt-4.1-mini` as SLS, is written natively in Korean, and is given contact-center framing matched to the task. The retained experiment specification supports the following English summaries:

- **doc2query** (index-side, from the answer): "Given a contact-center FAQ answer, generate six Korean questions a real customer might ask to obtain this answer; output JSON only." Conditioned on the unit's answer (first 1,200 characters). "N-matched" uses the identical prompt with the per-unit count raised to match SLS.
- **EnrichIndex** (index-side, enriched passage): "Expand the given FAQ answer so it is easier to retrieve: include key terms, synonyms, expressions users might use, and related subtopics, in one 2–4 sentence paragraph; do not invent new facts—ground it in the answer."
- **HyDE** (query-side, hypothetical answer): "For the following customer question, write a hypothetical short Korean answer (1–2 sentences) a contact center might give."
- **query2doc** (query-side, expanded query): "Expand the following customer question to aid retrieval by appending related expressions and key terms of the same intent, in 2–3 sentences."

Because every baseline is Korean-native and contact-center-framed under the same generator, the SLS advantage in Table 2 is not an artifact of prompt language or domain framing.

Structured Pruning and Lightweight Adaptation of Foundation Models for Resource-Efficient Earth Observation

Abstract

Structured pruning has gained attention as a promising solution for the cost-effective deployment of large language, vision-language, and domain-specific foundation models. However, most prior work has focused on general-purpose language models and often lacks a systematic comparison of pruning strategies across model scales, architectures, and real-world multimodal applications. In this paper, we conduct a comprehensive evaluation of structured pruning methods, focusing on depth pruning, width pruning, and post-pruning recovery with parameter-efficient fine-tuning. We evaluate multiple open-source models, including Qwen3-0.6B, Qwen3-4B-Instruct, Qwen3-8B, LLaVA-OneVision-0.5B, and Phi-4-Mini-Instruct, across intrinsic metrics and downstream benchmarks such as BBH, MATH Hard, MuSR, and MMLU-Pro. Our findings reveal that (1) depth pruning generally provides a more stable trade-off between efficiency and performance than width pruning; (2) width pruning can reduce memory usage, but often gives limited throughput gains and less predictable accuracy retention; (3) reasoning-intensive benchmarks, particularly mathematical reasoning tasks, are more sensitive to structured pruning than some other evaluation tasks; (4) LoRA-based post-pruning adaptation can substantially recover performance after moderate pruning; and (5) pruning behaviors observed in general-purpose models transfer to Earth observation foundation models, as demonstrated on TerraMind, where depth pruning reduces latency and GPU memory usage while maintaining competitive EuroSAT and Bigearthnet task accuracy.

1 Introduction

Despite the strong performance of recent large language models (LLMs) and foundation models on language understanding, reasoning, and multimodal tasks (Zhu et al., 2023; Vaswani et al., 2017), their deployment under resource constraints is still difficult. These models require substantial memory and computation, which limits their use in edge devices, mobile systems, and applications with strict latency requirements. The issue is particularly relevant in scientific domains such as Earth observation, where large-scale geospatial data has to be processed under practical limits on memory, runtime, and energy consumption (Lu and et al., 2024; Liang et al., 2023).

Model compression is one of the main directions for making foundation models more usable in such settings. Pruning, quantization, and knowledge distillation have all been studied as ways to reduce model size and inference cost (Muralidharan et al., 2024; Frantar et al., 2022; Xiao et al., 2023). Structured pruning removes complete parts of the architecture, such as Transformer layers, attention heads, or feed-forward channels and results in smaller dense models that can still be executed using standard hardware acceleration libraries (Ma et al., 2023; Ling et al., 2024). Structured pruning is more likely to produce measurable gains in latency and memory usage without relying on specialized sparse kernels (Xu et al., 2025; Kim et al., 2024). Depth pruning removes whole Transformer layers and takes advantage of the fact that not all layers contribute equally to the final model behavior (Lu and et al., 2024; Siddiqui and et al., 2024). Width pruning, by comparison, removes channels or internal dimensions, and is harder to apply cleanly because of the dependencies between attention, projection, and feed-forward components (Xu et al., 2025; Ma et al., 2023; Gao et al., 2024).

In this paper, we present a systematic evaluation of structured pruning and post-pruning adaptation for language, vision-language, and Earth observation foundation models. In particular, we aim to address the following research questions (RQs): **RQ1:** How do depth pruning and width pruning differ in terms of performance retention

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 343–352
October 29, 2026 ©2026 Association for Computational Linguistics

across language-only and multimodal foundation models? **RQ2:** How does structured pruning affect downstream reasoning performance on benchmarks such as BBH, MATH Hard, MuSR, and MMLU-Pro? **RQ3:** How do model scale and architecture influence pruning robustness across Qwen3, Phi-4-Mini-Instruct, and LLaVA-OneVision models? **RQ4:** To what extent can parameter-efficient fine-tuning, particularly LoRA, recover performance after structured pruning? **RQ5:** Do pruning behaviors observed in general-purpose language and vision-language models transfer to domain-specific Earth observation foundation models such as TerraMind, and can pruning improve latency and memory efficiency while maintaining competitive EuroSAT accuracy?

We evaluate several open-source models, including Qwen3 (Yang et al., 2025) variants at different scales, LLaVA-OneVision-0.5B (Li et al., 2024), and Phi-4-Mini-Instruct (Abdin et al., 2024). The evaluation combines prompt-based forced continuation (Wee et al., 2025), dataset-based analysis on WikiText-2 (Merity et al., 2016), and downstream benchmark evaluation on BBH, MATH Hard, MuSR, and MMLU-Pro. We further measure inference latency, time-to-first-token, throughput, and peak GPU memory usage. Beyond general-purpose models, we extend the study to TerraMind, a multimodal foundation model for Earth observation (Jakubik et al., 2025). TerraMind processes heterogeneous geospatial inputs such as multispectral optical imagery and radar data, making it a representative case study for real-world scientific deployment.

Our key findings are as follows:

- Depth pruning generally provides a more stable trade-off between efficiency and performance than width pruning across language and multimodal models.
- Width pruning can reduce memory usage in larger models, but it often provides limited throughput improvement and less predictable accuracy retention due to architectural dependencies.
- Reasoning-intensive tasks, especially mathematical reasoning, are more sensitive to structured pruning than some other benchmarks.
- LoRA-based post-pruning adaptation can substantially recover performance after moderate pruning, although recovery becomes limited under aggressive compression (Hu et al., 2021; Dettmers et al., 2023).
- The Earth observation usecase shows that pruning behavior observed in general-purpose models can transfer to Earth observation foundation models, where depth pruning reduces latency and GPU memory usage while maintaining competitive EuroSAT and Bigearthnet accuracy.

2 Related Work

Model compression has become an active direction for reducing the cost of large language models and foundation models. Common approaches include pruning, quantization, and knowledge distillation (Muralidharan et al., 2024). Quantization methods such as GPTQ and SmoothQuant reduce numerical precision during inference (Frantar et al., 2022; Xiao et al., 2023), while adaptation and recovery methods such as LoRA and QLoRA reduce the cost of fine-tuning large models (Hu et al., 2021; Dettmers et al., 2023). LLM-Pruner estimates the importance of coupled structures and prunes them using dependency-aware grouping (Ma et al., 2023). SlimGPT uses second-order information inspired by Optimal Brain Surgeon for structured pruning with reduced accuracy loss (Ling et al., 2024). DISP-LLM relaxes the fixed-width assumption across Transformer blocks and allows dimension-independent pruning, although the resulting architecture becomes less straightforward to handle (Gao et al., 2024). Other work, such as 2SSP, considers staged pruning of feed-forward and attention modules to limit error accumulation during compression (Sandri et al., 2025a).

Evaluation and Earth observation models: Most pruning studies focus on general-purpose language models and usually evaluate a limited number of architectures or tasks. This makes it difficult to compare depth and width pruning under the same experimental setting, especially across different model sizes and model families. Post-pruning recovery is also not always studied in detail, although lightweight adaptation can be important for restoring part of the lost performance after compression (Hu et al., 2021; Dettmers et al., 2023). Our work follows this direction by evaluating structured pruning across Qwen3, Phi-4-Mini-Instruct, and LLaVA-OneVision models, while also considering downstream reasoning performance and practical

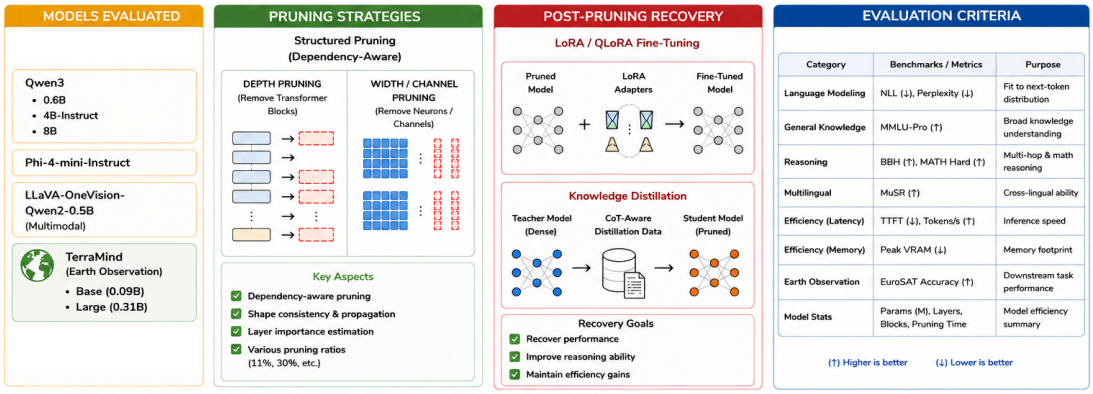

Figure 1: Methodology overview of the proposed approach. The figure summarizes the evaluated model families, structured depth and width pruning strategies, post-pruning recovery using Parameter Efficient Fine-Tuning and knowledge distillation, and metrics used for evaluation.[1]

efficiency.

In Earth observation, foundation models are increasingly used to process heterogeneous satellite data. TerraMind is designed for multi-sensor and multimodal geospatial inputs, including Sentinel-1 radar and Sentinel-2 multispectral imagery (Jakubik et al., 2025). Related systems such as FAST-EO study multimodal alignment between satellite imagery and text, supporting tasks such as captioning and environmental monitoring (Sandri et al., 2025b). These models are useful for EO applications, but they are still computationally demanding and less studied from the point of view of compression.

3 Methodology

This work studies structured pruning for improving the efficiency of language, vision-language, and Earth observation foundation models. The focus is on two forms of structured pruning: depth pruning and width pruning. We also consider dependency-aware pruning rules, since many Transformer components are coupled and cannot be removed independently. The summary of the methodology can be found in Fig. 1.

3.1 Structured Pruning

Structured pruning removes complete model components, such as Transformer layers, attention heads, projection channels, or feed-forward dimensions. This produces smaller dense models that can still run on standard hardware accelerators (Ma et al., 2023; Ling et al., 2024). This is different from unstructured pruning, where individual weights are removed and the resulting sparsity may not directly translate into practical speedups without specialized kernels (Xu et al., 2025).

3.2 Depth Pruning

Depth pruning reduces model depth by removing complete Transformer blocks (Lu et al., 2023). Given a model with L layers, we estimate the importance of each layer using an ablation-based sensitivity test. Each layer is temporarily removed, and the resulting change in negative log-likelihood (NLL) and perplexity (PPL) is measured (Gehrmann et al., 2024; Lu and et al., 2024; Siddiqui and et al., 2024). Layers that lead to only small degradation are treated as better pruning candidates and relying solely on local metrics such as PPL can be misleading because layers showing limited isolated impact may still participate in important architectural interactions.

3.3 Width Pruning

Width pruning reduces the internal dimensionality of Transformer layers. It targets structures such as attention heads, projection channels, and feed-forward neurons (Xu et al., 2025). In our setting, pruning candidates are identified using magnitude-based criteria, where smaller-magnitude parameters are assumed to contribute less to model behaviour. Attention projections, feed-forward blocks, residual paths, and normalization layers are often linked through shared dimensions. If these dependencies are ignored, pruning can introduce invalid tensor shapes or unstable model behaviour (Gao et al., 2024).

[1]This figure was generated with the assistance of generative AI tools and was subsequently reviewed, edited, and finalized by the authors.

3.4 Dependency-Aware Pruning

To preserve architectural validity, we apply dependency-aware pruning rules. Instead of pruning each component separately, linked structures are pruned in a coordinated way. For example, attention heads and their corresponding projection dimensions must be removed consistently across the query, key, value, and output projections (Ma et al., 2023). Similar constraints are needed for feed-forward layers, where input and output dimensions are coupled across paired projections. We also use simple safety constraints, such as minimum channel thresholds, to avoid excessive removal of representational capacity from a layer.

3.5 Post-Pruning Recovery

Pruning can reduce model quality, especially at higher pruning ratios. To recover part of the lost performance, we use post-pruning recovery methods based on parameter-efficient fine-tuning and knowledge distillation (Yu et al., 2023; Hu et al., 2021; Dettmers et al., 2023). LoRA updates only a small number of additional trainable parameters while keeping most of the original model fixed. This makes it suitable for lightweight recovery after pruning. Knowledge distillation can further guide the pruned model by transferring useful behaviour from the original dense model.

3.6 Extension to Multimodal Foundation Models

The same pruning ideas are extended to TerraMind, a multimodal foundation model for Earth observation. Compared with text-only models, TerraMind has additional dependencies between modality-specific and shared representations, since it processes optical and radar inputs within a common architecture. Thus, depth pruning is the optimal choice in the Earth observation usecase. Removing complete Transformer blocks keeps the remaining internal dimensions unchanged and reduces the risk of disrupting modality alignment. This allows us to test whether pruning behaviour observed in language models also appears in a domain-specific Earth observation model.

4 Experimental Setup

4.1 Models

We evaluate structured pruning on several open-source language and multimodal models. The language model experiments include Qwen3-0.6B, Qwen3-4B-Instruct, Qwen3-8B, and Phi-4-Mini-Instruct. LLaVA-OneVision-0.5B is included as a compact vision-language model. These models cover different parameter scales and model families, allowing us to compare pruning behaviour across architectures. For the Earth observation case study, we use TerraMind, a domain-specific multimodal foundation model (Jakubik et al., 2025). TerraMind is used to examine whether pruning trends observed in general-purpose models also transfer to geospatial models.

4.2 Benchmarks and Metrics

Model quality is evaluated using both intrinsic and downstream metrics. For intrinsic evaluation, we report negative log-likelihood (NLL) and perplexity (PPL). NLL is used as the main metric for pruning-sensitive comparisons, while PPL is retained for reporting and comparison with standard language-modeling practice. Downstream reasoning performance is measured using `lm-evaluation-harness` (EleutherAI, 2024). The benchmark set includes BBH (Suzgun et al., 2022), MMLU-Pro (Wang et al., 2024), MuSR (Sprague et al., 2023), and Math Hard. These tasks cover logical reasoning, knowledge, multi-step problem solving, and mathematical reasoning. We also report practical efficiency metrics, including time-to-first-token (TTFT), generation throughput, and peak GPU memory usage.

4.3 Prompt-Based and Dataset-Based Evaluation

Two evaluation modes are used. First, prompt-based forced-continuation evaluation is applied for controlled pruning experiments (Wee et al., 2025). Unless stated otherwise, all models are evaluated with the same 0-shot probe prompt:

> *"Describe the city of Stuttgart in a few sentences."*

The continuation length is fixed to 300 tokens, and the random seed is set to 123. Second, dataset-based evaluation is performed on WikiText-2 (Merity et al., 2016). We use a sliding-window setup with sequence length 1024 and stride values of 1024 or 512. This setting is used for NLL and PPL measurements and for layer sensitivity analysis during depth pruning.

4.4 Pruning and Recovery Protocol

Depth and width pruning are applied according to the procedure described in Section 3. For each model, we first evaluate the dense baseline, then apply structured pruning, and finally evaluate the pruned model using the same benchmark and efficiency pipeline. For post-pruning recovery, LoRA modules are inserted into selected attention and feed-forward projections (Hu et al., 2021; Dettmers et al., 2023). Most original model weights remain fixed during this stage. This setup allows us to measure whether lightweight adaptation can recover performance without full retraining.

4.5 Earth Observation

TerraMind is evaluated on EuroSAT for land-cover classification. The model expects Sentinel-2 Level-2A multispectral inputs and Sentinel-1 radar inputs. Since EuroSAT does not contain radar measurements, a zero-filled Sentinel-1 tensor is used to preserve the multimodal input interface. RGB images are converted to a 12-channel Sentinel-2-like representation by channel repetition. Inputs with 13 channels are reduced to 12 channels for consistency, and all images are resized to 224×224 pixels. In the baseline setting, the TerraMind backbone is frozen and used as a feature extractor. A linear classification head is trained on top of the extracted embeddings. For the pruned setting, structured depth pruning is applied to the backbone, and the same linear probing protocol is used. For recovery, LoRA modules and the classification head are trained while the original backbone weights remain fixed. The LoRA adapters use rank $r = 8$, scaling factor $\alpha = 16$, and dropout 0.05, and are inserted into attention and MLP projection layers. The recovery stage trains only the LoRA parameters and classification head using bfloat16 precision, with learning rates of 5×10^{-4} for LoRA and 10^{-3} for the head.

4.6 Reproducibility Details

All language-model experiments are run on the Kratos HPC cluster using SLURM. Standard pruning and evaluation jobs use a single Ampere GPU with 100 GB RAM. Larger benchmark runs use `vLLM` with `lm-evaluation-harness` on multiple Ampere GPUs (Kwon et al., 2023). The main software environment uses Python 3.10.14 with isolated dependencies. TerraMind experiments use a separate Python 3.11 environment for compatibility with the required geospatial and model dependencies. The same workflow is followed across experiments: baseline evaluation, structured pruning, and post-pruning evaluation with optional recovery. Fixed prompts, controlled seeds, and identical preprocessing are used where possible, so that performance differences can be attributed mainly to pruning and recovery choices.

5 Results and Analysis

We present the experimental results of structured pruning across multiple language and multimodal models. The analysis focuses on the trade-off between efficiency and downstream performance, while comparing the behavior of depth and width pruning under a unified evaluation framework. The summary of the results can be found in Fig. 2.

5.1 LLaVA-OneVision

LLaVA-OneVision-0.5B (Li et al., 2024) is used to test pruning in a compact vision-language model. Table 1 shows that depth pruning keeps the BBH score unchanged and gives a small gain on MuSR. Width pruning remains close to the baseline, but shows a slight drop on BBH. This suggests that some redundancy exists even in the compact multimodal setting, while channel-level pruning is still a little less stable.

Table 1: Benchmark performance of LLaVA-OneVision-0.5B under depth and width pruning.

Configuration	BBH ↑	MATH Hard ↑	MuSR ↑
Baseline	28.78	0.00	36.64
Depth-pruned (22/24)	28.78	0.00	**37.57**
Width-pruned (2%)	28.21	0.00	37.30

5.2 Qwen3

The Qwen3 family (Yang et al., 2025) is evaluated at three scales: 0.6B, 8B, and 4B-Instruct. The results show that pruning behaviour changes with scale and tuning. Smaller models show modest changes, while the instruction-tuned and larger variants are more sensitive, especially on mathematical reasoning. For Qwen3-0.6B, both pruning strategies keep BBH close to the baseline, as shown in Table 2. MuSR improves after pruning, with the best score obtained by width pruning. MATH Hard, however, drops under both pruning settings, indicating that even mild structural changes can affect mathematical reasoning.

Table 3: Benchmark performance of Qwen3-8B under pruning and LoRA recovery.

Configuration	BBH ↑	MATH Hard ↑	MuSR ↑	MMLU-Pro ↑
Baseline	29.30	**17.30**	40.60	11.36
Depth-pruned (11%)	31.05	3.10	38.36	**12.36**
Depth-pruned (30%)	28.09	0.08	36.11	11.70
Width-pruned (11.1%)	25.93	1.81	**41.67**	N/A
Depth-pruned (11%) + LoRA	**43.59**	7.80	32.54	N/A
Depth-pruned (30%) + LoRA	36.16	1.59	35.71	N/A

Table 4: Benchmark performance of Qwen3-4B-Instruct under different depth-pruning choices.

Configuration	BBH ↑	MATH Hard ↑	MuSR ↑
Baseline	28.33	**8.16**	31.35
Depth-pruned (~5%)	27.76	3.55	33.20
Width-pruned (2%)	**28.36**	4.91	**36.38**

Qwen3-8B shows clearer task-level differences. As Table 3 shows, 11% depth pruning keeps BBH competitive and slightly improves MMLU-Pro, but MATH Hard drops sharply. With 30% depth pruning, the degradation becomes broader. Width pruning gives the best MuSR score, but performs worse on BBH and MATH Hard. LoRA recovery improves BBH strongly after pruning, although recovery on MATH Hard and MuSR remains limited.

For Qwen3-4B-Instruct, pruning is more damaging. Table 4 shows large drops on BBH, MATH Hard, and MMLU-Pro under 30% depth pruning. MuSR is less affected. WT2-guided and random depth pruning give similar scores, suggesting that, at this pruning level, the pruning ratio matters more than the exact layer selection rule.

5.3 Phi-4-Mini-Instruct

Phi-4-Mini-Instruct (Abdin et al., 2024) provides another compact instruction-tuned case. Table 5 shows that 11% depth pruning leads to clear degradation on BBH, MATH Hard, and MMLU-Pro. MuSR is more stable and slightly improves. The pattern is close to what is observed in Qwen3 models: mathematical and broad reasoning scores are more fragile, while MuSR is less affected.

Table 5: Benchmark performance of Phi-4-Mini-Instruct before and after depth pruning.

Configuration	BBH ↑	MATH Hard ↑	MuSR ↑	MMLU-Pro ↑
Baseline	**56.40**	**16.80**	39.20	**39.30**
Depth-pruned (11%)	32.32	0.00	**40.48**	22.83

RQ1: How do depth and width pruning differ across models?

Depth pruning is more stable in most evaluated settings. In LLaVA-OneVision-0.5B (Li et al., 2024), removing two Transformer layers keeps BBH unchanged at 28.78 and slightly improves MuSR from 36.64 to 37.57. Width pruning gives a close MuSR score, but the BBH score drops from 28.78 to 28.21. A similar tendency appears for Qwen3-8B (Yang et al., 2025), where moderate depth pruning gives 31.05 on BBH, while width pruning gives 25.93. Depth pruning removes full blocks and keeps the remaining hidden dimensions unchanged, which makes the pruned model easier to execute. Width pruning can be useful for reducing memory, but it modifies internal dimensions and depends more strongly on structural coupling between attention projections, feed-forward layers, and residual paths. Depth pruning gives a more dependable accuracy–efficiency trade-off across the evaluated language and multimodal models. Width pruning is more useful when GPU memory is the main constraint.

RQ2: How does pruning affect downstream reasoning performance?

MATH Hard is the most sensitive task to pruning in our experiments. For Qwen3-8B, 11% depth pruning reduces MATH Hard from 17.30 to 3.10, even though BBH remains close to the baseline and MMLU-Pro slightly improves. Phi-4-Mini-Instruct (Abdin et al., 2024) shows a similar pattern: MATH Hard drops from 16.80 to 0.00 after depth pruning, while MuSR slightly increases from 39.20 to 40.48.

MuSR is less fragile in several settings. Some pruned models remain close to the dense baseline, and a few even improve slightly. This indicates that pruning does not merely lower all reasoning scores uniformly. It affects tasks depending on how strongly they rely on precise intermediate computation. Mathematical reasoning is more vulnerable to structured pruning than BBH or MuSR. Moderate pruning can preserve parts of downstream reasoning ability, but MATH Hard shows clear sensitivity.

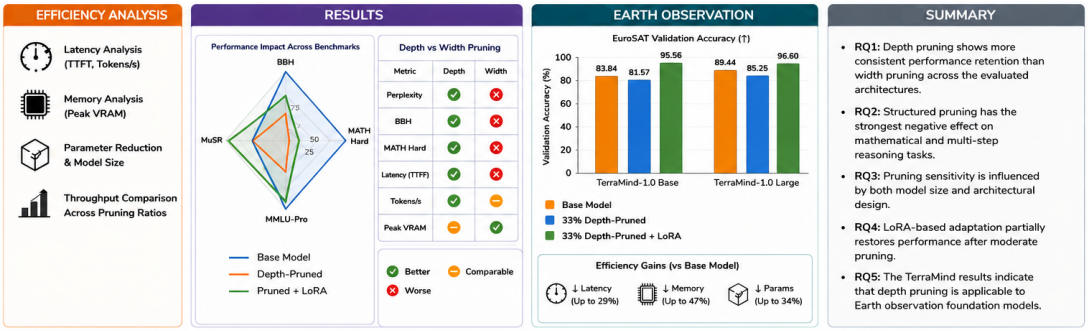

Figure 2: Results overview across language, vision-language, and Earth observation foundation models. The figure summarizes reasoning accuracy, language modeling quality, EuroSAT performance, latency, memory usage, model statistics, and key findings.

RQ3: How do model scale and architecture influence pruning robustness?

The results vary with both scale and architecture. Qwen3-0.6B shows only modest changes on BBH and MuSR, although MATH Hard still drops after pruning. Qwen3-4B-Instruct is much more sensitive under 30% depth pruning, with large declines on BBH, MATH Hard, and MMLU-Pro. Phi-4-Mini-Instruct also loses performance on BBH and MMLU-Pro after depth pruning, despite a small gain on MuSR.

Parameter count alone does not fully explain pruning robustness. Instruction tuning, layer redundancy, and model-specific design choices appear to matter. For Qwen3-4B-Instruct, WT2-guided and random depth pruning produce similar results at 30% pruning. At this level, the amount of removed capacity seems to dominate the exact layer selection rule. Model size is important, but architecture and pruning ratio also shape the final accuracy. Instruction-tuned models can degrade sharply when pruning becomes aggressive.

RQ4: Can LoRA recover performance after pruning?

LoRA recovery improves some pruned models, but it does not recover all tasks equally. For Qwen3-8B, LoRA after 11% depth pruning improves BBH from 31.05 to 43.59 and raises MATH Hard from 3.10 to 7.80. The same adaptation reduces MuSR from 38.36 to 32.54. With 30% depth pruning, LoRA still improves BBH from 28.09 to 36.16, while MATH Hard remains low. These results suggest that lightweight adaptation can restore useful capabilities after moderate pruning. It is less effective when the pruning ratio is high or when the task requires precise multi-step reasoning. LoRA can recover a substantial part of BBH performance after pruning, but the recovery is task-dependent. Mathematical reasoning remains difficult to restore after structural compression.

5.4 RQ5: Do pruning trends transfer to Earth observation foundation models?

Pruning and finetuning experiments with TerraMind (Jakubik et al., 2025) show that structured depth pruning also transfers to a domain-specific multimodal model. For TerraMind-1.0-Base, pruning reduces the number of blocks from 12 to 8 and parameters from 87.71M to 59.39M. EuroSAT accuracy decreases from 83.84% to 81.57% and BigEarthNet accuracy from 92.94% to 91.67%, while latency improves from 4.59 ms to 3.14 ms and GPU memory decreases from 312.5 MB to 196.0 MB. For TerraMind-1.0-Large, pruning reduces latency from 9.13 ms to 7.66 ms and GPU memory from 1119.1 MB to 642.1 MB, with EuroSAT accuracy decreasing from 89.44% to 85.25% and BigEarthNet accuracy only slightly decreasing from 93.24% to 93.03%. LoRA fine-tuning recovers most of the accuracy loss and raises validation accuracy beyond the frozen dense baseline. On EuroSAT, pruned LoRA fine-tuning reaches 95.56% for TerraMind-1.0-Base and 96.60% for TerraMind-1.0-Large. On BigEarthNet, pruned LoRA fine-tuning reaches 93.56% and 95.04%, respectively, remaining close to the dense LoRA results of 94.99% and 95.15%.

5.5 Efficiency Analysis

Beyond model quality, we evaluate the efficiency impact of structured pruning using system-level

[1]This figure was generated with the assistance of generative AI tools and was subsequently reviewed, edited, and finalized by the authors.

Table 6: TerraMind validation accuracy and efficiency before and after depth pruning. EuroSAT and BigEarthNet report downstream validation accuracy. LoRA fine-tuning rows include the adapted model parameters and measured inference efficiency after recovery.

Model	Configuration	EuroSAT Acc. (%) ↑	BigEarthNet Acc. (%) ↑	Blocks	Params (M)	Latency (ms) ↓	GPU Mem. (MB) ↓
TerraMind-1.0-Base	Baseline	83.84	92.94	12	87.71	4.59	312.5
TerraMind-1.0-Base	Depth-pruned	81.57	91.67	8	59.39	3.14	196.0
TerraMind-1.0-Base	Dense + LoRA FT	**97.23**	**94.99**	12	89.00	4.72	324.2
TerraMind-1.0-Base	Pruned + LoRA FT	95.56	93.56	8	60.25	3.21	201.4
TerraMind-1.0-Large	Baseline	89.44	93.24	24	305.66	9.13	1119.1
TerraMind-1.0-Large	Depth-pruned	85.25	93.03	20	255.33	7.66	642.1
TerraMind-1.0-Large	Dense + LoRA FT	**98.30**	**95.15**	24	309.05	9.37	1135.7
TerraMind-1.0-Large	Pruned + LoRA FT	96.60	95.04	20	257.59	7.83	648.6

Table 7: Relative efficiency changes after pruning across different models and pruning strategies. Depth pruning consistently reduces TTFT and improves token generation throughput, whereas width pruning primarily reduces peak VRAM usage with limited throughput gains.

Model	Method	TTFT Change (%) ↓	Tok/s Change (%) ↑	Peak VRAM Reduction (%) ↑
LLaVA-OneVision-0.5B	Depth	-10.71	+5.66	0.00
LLaVA-OneVision-0.5B	Width	+12.50	0.00	0.00
Qwen3-0.6B	Depth	-5.88	+9.75	0.00
Qwen3-0.6B	Width	0.00	0.00	-0.88
Qwen3-4B-Instruct	Depth 30%	-22.50	+40.86	-0.13
Qwen3-4B-Instruct	Width 30%	+4.76	+0.40	+20.18
Qwen3-8B	Depth 30%	-19.51	+41.09	-0.13
Qwen3-8B	Width 30%	+4.76	+1.19	+19.63
Phi-4-mini-Instruct	Depth 11%	-3.57	+12.60	-0.42

inference metrics, including time-to-first-token (TTFT), generation throughput, and peak GPU memory usage (Sheng et al., 2023). Table 7 reports the relative changes after pruning. Depth pruning consistently improves inference speed. For Qwen3-4B-Instruct, 30% depth pruning reduces TTFT by 22.50% and improves throughput by 40.86%. A similar trend appears for Qwen3-8B, where 30% depth pruning reduces TTFT by 19.51% and improves throughput by 41.09%. These results show that removing full Transformer layers translates directly into faster generation.

Width pruning provides limited throughput gains but reduces peak VRAM more effectively in larger models. For Qwen3-4B-Instruct, 30% width pruning reduces peak VRAM by 20.18%, and for Qwen3-8B it reduces peak VRAM by 19.63%. However, the corresponding throughput improvements are only 0.40% and 1.19%, respectively.

6 Conclusion

We studied structured pruning for improving the efficiency of language, vision-language, and Earth observation foundation models. Experiments across Qwen3, LLaVA-OneVision, Phi-4-Mini-Instruct, and TerraMind show that depth pruning is generally more stable than width pruning, since removing complete Transformer blocks gives clearer latency and throughput gains without changing the internal dimensions of the remaining model. Width pruning can reduce memory usage, but it is more difficult to control because channel-level changes interact with attention projections, feed-forward layers, and other structural dependencies. The results also show that pruning affects tasks differently: mathematical and structured reasoning benchmarks are more sensitive to compression, while some other reasoning tasks remain comparatively stable under moderate pruning. LoRA-based recovery improves post-pruning performance in several cases, although the recovery is limited when compression becomes aggressive. The Earth observation usecase suggests that these trends extend beyond text-only models to domain-specific multimodal foundation models, where depth pruning reduces latency and memory usage while preserving useful representations for Earth observation tasks. Future work can extend this analysis to richer multimodal datasets and more detailed studies of cross-modal pruning dependencies.

Abstract

Retrieval-augmented language models can fail to respect negative constraints when the retriever supplies evidence about concepts the user explicitly excluded. Beyond explicit negation, queries may ask for answers that include one concept while excluding another, or for entities that belong to a category but differ from a closely related instance. Because the excluded concept still appears in the query text, dense retrievers may assign high similarity to documents about that concept even when the user asks to avoid it. We introduce E-SENS, a training-free reranking method for negation-sensitive retrieval. E-SENS extracts a compact trap query for the excluded side and subtracts trap-query similarity from the original-query retrieval score. On ExcluIR, E-SENS shows a clear recall–violation trade-off across four embedding models and reduces trap retrieval at recall-preserving settings.

1 Introduction

Users often express information needs by specifying not only what should be retrieved, but also what should be avoided. A query may ask for documents about one topic while excluding a related entity, or for items that belong to a category but differ from a particular instance. For example, "training methods for language models, excluding reinforcement learning" asks the retriever to preserve the broad topic while avoiding a specific, highly related training paradigm. In retrieval-augmented generation, returning such excluded material can place constraint-violating evidence directly into the generator context. This creates an evidence-selection failure: the retriever supplies material that is topically similar to the request but invalid under the user's exclusion constraint.

This setting is difficult for dense retrieval because the excluded concept is both salient and present in the query. The retriever may assign high similarity to a document precisely because it matches the term the user asked to avoid, reflecting the lexical and semantic signals retained in dense representations (Ram et al., 2023). The core issue is not merely that the query contains negation, but that standard retrievers treat included and excluded terms as undifferentiated semantic evidence. Negative queries with exclusion constraints therefore require a distinction between inclusion and exclusion semantics that standard retrievers often do not encode reliably (Lee et al., 2026).

Recent benchmarks and systems study this weakness across minimally different negated pairs, realistic exclusion queries, and negative-constraint retrieval (Weller et al., 2024; Zhang et al., 2025a; Xu et al., 2025). We ask whether an existing retriever can better respect exclusion constraints at inference time, without retraining.

We propose E-SENS, a training-free reranking method that penalizes excluded intent in negative queries with exclusion constraints. Given a negative query, a large language model produces two short rewrites: a target query for what should be retrieved and a trap query for the excluded intent. E-SENS penalizes documents similar to the trap intent; retrieval of the excluded-side document is treated as a violation.

Our contributions are as follows.

- We introduce E-SENS, a training-free excluded-intent penalty that changes only inference-time scores and requires no retriever retraining.
- We formulate exclusion-aware evidence retrieval as a recall–violation trade-off, where systems must retrieve relevant evidence while avoiding evidence the user intended to exclude.
- We analyze when document-level trap penalties succeed or fail, identifying cases where

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 353–366
October 29, 2026 ©2026 Association for Computational Linguistics

relevant documents contain incidental trap evidence or lie close to trap documents in embedding space.

2 Related Work

Negative constraints in retrieval. Language models can be insensitive to negation and struggle to reason under negated statements (Truong et al., 2023). This weakness also appears in retrieval: NevIR tests minimally different negated pairs (Weller et al., 2024), ExcluIR studies exclusion constraints with answer and trap documents (Zhang et al., 2025a), BoolQuestions probes Boolean logic in dense retrieval (Zhang et al., 2024), and NegConstraint applies neural-symbolic reranking for negative constraints (Xu et al., 2025). Unlike neural-symbolic reranking approaches that require explicit logical constraint handling, E-SENS relies only on query-side decomposition and continuous retriever scores. Similar support/contradiction confusion appears in biomedical QA and vision-language retrieval when negation is central to the evidence (Sahoo et al., 2026; Alhamoud et al., 2025).

Embedding-level approaches to negation. DEO optimizes query embeddings at inference time for negation-aware retrieval (Lee et al., 2026); E-SENS instead keeps retriever and document embeddings fixed and applies a score-level trap penalty. This makes E-SENS applicable when document embeddings are precomputed or served through closed embedding APIs, where direct embedding optimization or retriever updates are impractical.

Rank fusion for reranking. RRF combines ranked lists through reciprocal-rank contributions when raw scores are incomparable (Cormack et al., 2009). We considered an anti-RRF variant that subtracts trap-query rank evidence, but use dense scores because they provide a smoother penalty signal and allow a continuous recall–violation frontier.

3 E-SENS

E-SENS is a retrieval-time reranking method for exclusion queries. It operates on fixed retriever scores by decomposing the query into target and trap intents, then lowering the rank of documents similar to the trap query. The main variant uses the original query as the positive signal and the trap rewrite as a penalty signal; a target-minus-trap variant is reported in the appendix.

3.1 Query Decomposition

Let q be the original user- or dataset-provided query that contains an exclusion constraint. E-SENS uses GPT-4o mini to produce q_{target}, a positive query with the exclusion removed, and q_{trap}, a compact query for the excluded intent. Although many traps are named entities or titles, q_{trap} is not limited to entities: it may refer to an excluded concept, attribute, condition, or constraint. For example, the query "location of Friday Harbor Airport without bringing up Dayton International Airport" is decomposed into target intent "location of Friday Harbor Airport" and trap intent "Dayton International Airport". The LLM only produces these strings; it does not score documents, inspect the corpus, or use gold labels. Appendix B provides the decomposition prompt.

3.2 Score Transformation

Let $s(d, q)$ be the retriever similarity score between document d and query q. All dense scores use L2-normalized embeddings, so dot product is cosine similarity; for each query rewrite, scores are min-max normalized over the scored document set before combination. In the main E-SENS variant, we retain the original exclusion query as the positive retrieval signal and use only the trap rewrite as a penalty signal:

$$S_{\text{main}}(d) = s(d, q) - \beta s(d, q_{\text{trap}}). \quad (1)$$

We use the original query as the main positive signal because target rewrites can remove contextual cues useful for recall. The target rewrite is used in a target-minus-trap variant, reported in the appendix, to isolate the cost of replacing the positive signal. More generally, the two scoring variants can be written as

$$S(d) = \alpha s(d, q) + \gamma s(d, q_{\text{target}}) - \beta s(d, q_{\text{trap}}), \quad (2)$$

where baseline-minus-trap uses $(\alpha, \gamma) = (1, 0)$ and target-minus-trap uses $(0, 1)$. The penalty weight β controls how strongly trap-similar documents are demoted. Table 1 reports fixed beta checkpoints for the main variant, and the appendix reports both scoring variants across beta values. This formulation requires scores to be comparable across query rewrites; in this paper, we evaluate it with dense retriever scores. At inference time, E-SENS can

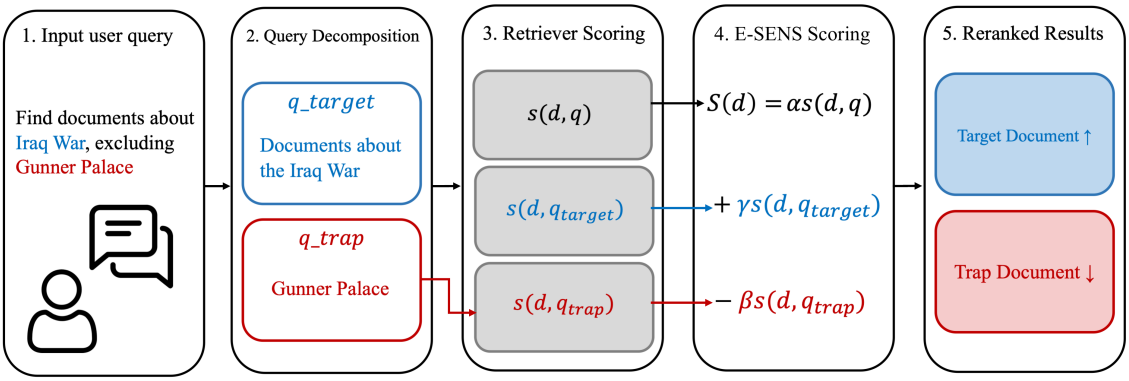

Figure 1: Overview of E-SENS. A negative query with an exclusion constraint is decomposed into target and trap intents. The main score uses the original query as the positive signal and subtracts trap-query similarity. The target-query path is optional and is evaluated as an appendix variant.

rerank either the full corpus or a candidate set: it computes original-query and trap-query scores for the same documents, then applies the transformed score. Thus, it leaves document embeddings and the retrieval index unchanged; q_{trap} is the only additional retrieval signal.

4 Experimental Setup

Dataset. We evaluate on 3,452 negative queries with exclusion constraints from ExcluIR (Zhang et al., 2025a). Each example contains an original exclusion query, a gold answer document, and a trap document corresponding to the excluded intent. We score against the full 90,406-document corpus; the original query is q, the answer-side document is d_{target}, and the excluded-side document is d_{trap}. The decomposer generates q_{target} and q_{trap} only from q; gold document indices are used only for evaluation. We use ExcluIR because its document-level target/trap annotations make recall and violation directly measurable, and report a smaller BoolQuestions-not set in the appendix. Appendix C details the mapping from dataset fields to q_{target}, q_{trap}, d_{target}, and d_{trap}.

Retrievers and Decomposition. We test four embedding models: OpenAI text-embedding-3-small, OpenAI text-embedding-3-large, Qwen3-Embedding-0.6B, and Qwen3-Embedding-4B (Zhang et al., 2025b). For the main variant, we use the original query as the positive retrieval signal and q_{trap} only as a penalty signal: $S(d) = s(d, q) - \beta s(d, q_{\text{trap}})$. We vary $\beta \in [0, 1]$ at intervals of 0.01 to characterize the recall–violation trade-off rather than to claim a deployment-ready tuned hyperparameter. Table 1 reports fixed checkpoints $\beta \in \{0.0, 0.1, 0.2, 0.3\}$, shared across all retrievers rather than selected per retriever. Appendix Figures 2–3 plot the full sweep.

Metrics. Recall@k measures whether the gold answer document appears in the top k; Violation@k measures whether the trap document appears in the top k. Higher recall and lower violation are better. We report R@5 and V@5 in the main table as representative top-k metrics, while Avg. R and Avg. V average over $k \in \{3, 5, 7, 9\}$ to summarize the overall trade-off without selecting a favorable k.

5 Results

Table 1 summarizes the recall–violation trade-off for E-SENS across fixed beta checkpoints. The $\beta = 0.00$ rows correspond to the original retriever scores, which achieve high recall but often retrieve the trap document as well, with violation@5 ranging from 0.728 to 0.886. As β increases, trap retrieval decreases consistently across retrievers while recall remains close to the baseline over moderate penalty strengths, showing that the gains are not confined to a single tuned beta. At $\beta = 0.10$, average recall changes by only -0.0009 to $+0.0014$, while average violation drops by 0.074–0.106; at $\beta = 0.20$, average violation drops by 0.193–0.217 with at most 0.0038 recall loss. The $\beta = 0.30$ checkpoint further reduces average violation by 0.297–0.333, with a larger but still modest recall decrease for Qwen3-Embedding-0.6B. At $\beta = 1.0$, average violation drops to 0.030–0.036, but average recall falls to 0.779–0.835, illustrating the cost of over-penalizing the trap intent. Appendix curves show the full frontier for both

Table 1: Fixed beta checkpoints for the main baseline-minus-trap variant on ExcluIR. R is recall, V is trap violation, Avg. averages over $k \in \{3, 5, 7, 9\}$, and deltas are relative to $\beta = 0.00$ for the same retriever. Bold marks the best value within each retriever block; ties are bolded.

scoring variants and make the same pattern visible across the complete sweep.

Appendix Tables 6–9 clarify why we use the original query, rather than the target rewrite, as the main positive signal. At $\beta = 0$, target-minus-trap already lowers violation substantially, but with lower recall than the original-query baseline, suggesting that target rewrites can discard answer-retrieval context. The main baseline-minus-trap variant is therefore conservative: it preserves the original retrieval signal and uses the trap query only to demote constraint-violating documents.

6 Failure Analysis

We manually inspected cases where the trap penalty affects answer ranks and found two recurring patterns. Some target documents mention the excluded entity incidentally, such as a film page listing an excluded actor, while other answer and trap documents are close embedding neighbors, such as sibling entities or adaptations. These failures reflect document-level granularity: a valid answer may briefly mention the excluded side, whereas a trap document is primarily about it.

7 Conclusion

We presented E-SENS, a training-free excluded-intent penalty for negative queries with exclusion constraints. By extracting a compact excluded-side query and subtracting its similarity score, E-SENS turns exclusion into a score-level penalty that can be applied without retraining or changing the corpus. Across retrievers, moderate β values preserve answer recall while reducing trap retrieval, showing that negative constraints are better treated as retrieval-time selection constraints than only as surface negation in the query. This matters in retrieval-augmented generation because a high-ranked trap document can steer the generator toward excluded evidence, and the consistent pattern across four embedding models suggests a shared dense-retrieval failure. The recall–violation frontier offers a practical way to choose β: lower values favor recall, while higher values more aggressively suppress excluded-side documents. Future work can extend E-SENS with passage- or span-level verification to distinguish incidental mentions from truly constraint-violating evidence.

Limitations

E-SENS adds inference cost because it requires query decomposition, an additional trap-query score, and reranking. It assumes that the decomposition reliably isolates the excluded side and that scores from different query rewrites remain comparable after normalization. Our experiments tune β on validation data and do not report statistical uncertainty estimates, so small recall differences should be interpreted cautiously. Finally, the document-level penalty cannot distinguish a valid answer that only mentions the excluded entity incidentally from a document that is mainly about the excluded side.

A Experimental Details

Compute. All experiments were run on a single RTX 4090 GPU with 16 vCPUs (AMD Ryzen 9 7950X 16-Core Processor), 61 GB memory, and a 20 GB container disk.

B Query Decomposition Prompt

The template below was used with GPT-4o mini at temperature 0 to generate q_{target} and q_{trap}.

Query Decomposition Prompt Template

Role: You are a recall-preserving query decomposition module for exclusion-aware information retrieval.

Task: Given only the original query, produce two retrieval queries: q_{target}, the positive information need, and q_{trap}, a short high-precision anchor for the unwanted, excluded, contrastive, or constraint-violating side. Do not use gold documents, trap documents, answers, relevance labels, dataset annotations, or external knowledge beyond what is directly implied by the query.

Decomposition Rules: Preserve the main search intent in q_{target} and remove only phrases that point to the unwanted side. q_{target} should remain independently useful for retrieval and should not encode the exclusion with wrappers such as "not", "without", "excluding", "except", "instead of", or "rather than", unless the negated phrase is the natural name of the desired concept. q_{trap} should be the strongest compact retrieval anchor for the unwanted side: preferably an explicitly excluded named entity, title, organization, person, work, place, product, event, date, object, attribute, condition, relation, role, or category. Strip exclusion wrappers from q_{trap} and avoid broad anchors such as "career", "film", "country", or "person" unless the unwanted side is exactly that broad. If the query contains a direct contrast, use the obvious counterpart when available (e.g., legal ↔ illegal, allowed ↔ forbidden, paid ↔ unpaid, present ↔ absent, won ↔ lost). If no direct counterpart is obvious, use the explicit unwanted phrase. Set q_{trap} to an empty string only when no excluded, negative, contrastive, exception, or undesired side is present.

Output Format: Return only valid JSON with exactly two fields:

```
{
  "q_target": "...",
  "q_trap": "..."
}
```

User Message Template:

```
Now decompose the following query.

Original query:

{original_query}

Return only valid JSON. Do not include markdown, comments,
explanations, or extra fields.

{
  "q_target": "...",
  "q_trap": "..."
}
```

C Dataset Mapping and BoolQuestions-not Set

ExcluIR provides a natural four-part structure for our setting. The original exclusion query is q, the answer-side corpus index is d_{target}, and the excluded-side corpus index is d_{trap}. Its paired construction also makes oracle-style query strings recoverable: the original positive question can be viewed as q_{target}, and the title or short identifier of the excluded document can be viewed as q_{trap}. In the reported E-SENS experiments, however, q_{target} and q_{trap} are generated only from q by GPT-4o mini; gold document indices are used only for evaluation.

For other negative-constraint retrieval datasets, q_{target} is the positive information need after removing the exclusion, q_{trap} is the compact excluded-side query, d_{target} is a document satisfying the positive need, and d_{trap} is a plausible but constraint-violating document. When a dataset provides positive and negative passages, we map them to d_{target} and d_{trap} respectively. When it provides only documents, q_{target} and q_{trap} can be produced by the same query-only decomposer.

As an additional check, we evaluate the subset of BoolQuestions (Zhang et al., 2024) with `question_type = not`. Each example includes a positive passage and a negative passage that can be treated as d_{target} and d_{trap}. This yields 323 examples, 195 from MS MARCO and 128 from Natural Questions, over a 646-document evaluation corpus. Because BoolQuestions does not provide explicit q_{target} and q_{trap} fields, we generate them with the same GPT-4o mini decomposer and report results across penalty-weight settings in Figure 3 and Tables 10–17.

The full β results are included to show the recall–violation trade-off across penalty strengths rather than to imply that β should be selected on the test set.

D Additional Results

Figures 2 and 3 plot the full $\beta = 0.00$–1.00 sweep at 0.01 intervals. Tables 2–17 report 0.10 beta checkpoints in portrait tables, split by dataset, scoring variant, and retriever for readability.

D.1 Beta Trade-off Curves

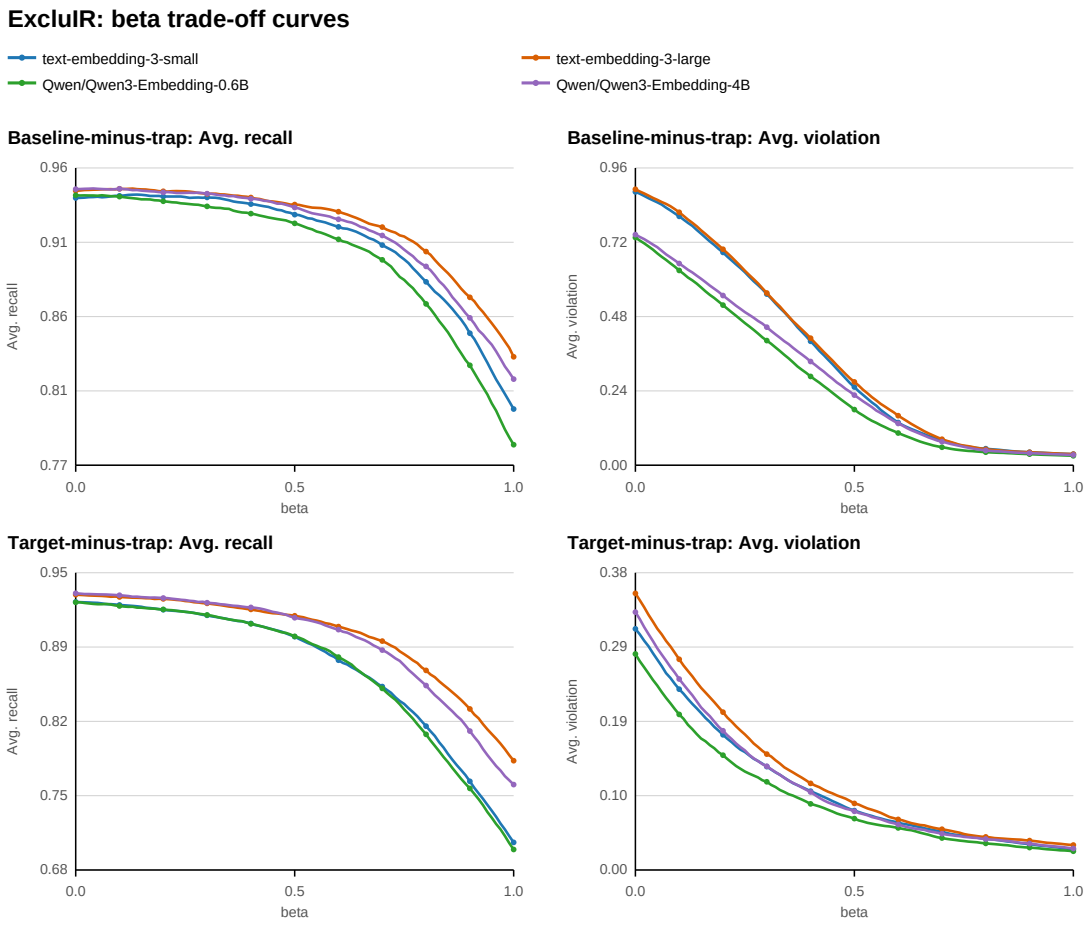

Figure 2: ExcluIR recall–violation trade-off curves over the full beta sweep. The top row uses the baseline-minus-trap score, and the bottom row uses the target-minus-trap score.

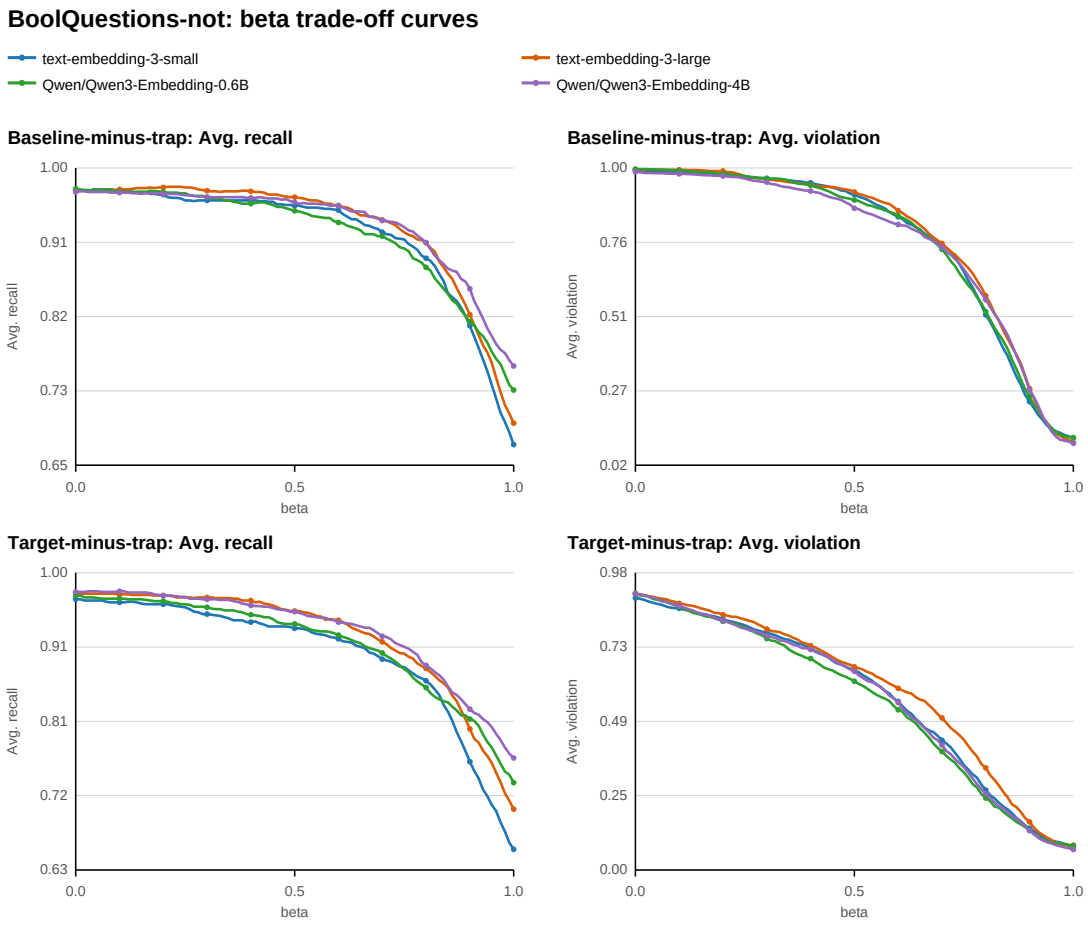

Figure 3: BoolQuestions-not recall–violation trade-off curves over the full beta sweep. The top row uses the baseline-minus-trap score, and the bottom row uses the target-minus-trap score.

How Far Can You Get Without a GPU? A Systematic Benchmark of Lightweight Hallucination Detection Across Question Answering, Dialogue, and Summarisation

Abstract

Hallucination detection has become a pressing requirement for trustworthy AI deployment at scale. The most accurate detection methods depend on GPU-intensive inference, proprietary API calls, or white-box access to the generating model. This puts them out of reach for resource-constrained researchers and practitioners. In this paper, we explore a practical alternative: how well can hallucination detection perform using only lightweight, CPU-feasible methods built on publicly available models? We systematically benchmark four such detectors, ROUGE-L, semantic similarity, BERTScore, and a Natural Language Inference (NLI) detector based on a FEVER-trained DeBERTa model, together with a score-level ensemble of similarity and NLI. We evaluate them across all three tasks of the HaluEval benchmark: question answering (QA), dialogue, and summarisation. We calibrate each method on a held-out validation split and evaluate it on 2,000 test instances per task, and we report bootstrap confidence intervals for the main results. We find that the similarity-NLI ensemble is the most consistent method, but that absolute performance is highly task-dependent. The ensemble ranks best on QA (F1 $= 0.792$, AUC-ROC $= 0.873$) and on dialogue (F1 $= 0.694$, AUC-ROC $= 0.749$), where NLI is the strongest standalone method; on summarisation every method performs near chance (AUC-ROC between 0.469 and 0.574). We then ask whether that failure is intrinsic to lightweight detection or an artifact of our single-pass design, and find it is largely the latter. Raising the premise budget from 800 to 1600 characters lifts summarisation AUC-ROC from 0.567 to 0.629, and replacing single-pass scoring with sentence-level chunk aggregation reaches 0.683, still on CPU and with the same model, though at roughly twenty times the NLI inference. Summarisation remains by far the hardest task, but our results do not support treating lightweight detection as intrinsically unsuited to it. All experiments run on a standard laptop CPU using public models.

1 Introduction

Large language models (LLMs) produce fluent text across question answering, dialogue, summarisation, and many other natural language processing tasks (Brown et al., 2020; Touvron et al., 2023). They also hallucinate. A hallucination is text that reads as fluent and plausible but is factually incorrect or unsupported by any available source (Ji et al., 2023). In high-stakes domains such as healthcare, law, and education, hallucinated outputs pose serious risks. This risk drives active research into automatic hallucination detection (Maynez et al., 2020).

The most accurate hallucination detection methods all depend on resources that many researchers, educators, and practitioners do not have: GPUs, proprietary APIs, or model internals. We discuss these methods in detail in Section 2.

We take a constrained position. Instead of proposing another resource-intensive detector, we ask a question. How far can hallucination detection progress using only lightweight, CPU-feasible methods that rely on publicly available models, make no API calls, and assume no access to the generating model? This question matters for two reasons. First, it sets a realistic performance baseline for the large community that works without specialised hardware. Second, it shows where accessible methods succeed and where they break down. Papers that compare a single expensive method against weak baselines hide this information.

We benchmark four CPU-feasible detectors that span the lexical, embedding, and inference paradigms, ROUGE-L, semantic similarity, BERTScore, and an NLI-based detector, together with a score-level ensemble of similarity and NLI. We evaluate them across all three tasks of the

HaluEval benchmark (Li et al., 2023): question answering, dialogue, and summarisation. Our contributions are:

- A systematic benchmark of four CPU-feasible hallucination detectors and a score-level ensemble across three tasks. We calibrate thresholds on held-out validation data and evaluate on 2,000 test instances per task.
- The finding that the similarity-NLI ensemble is the most consistent method, ranking best on both QA and dialogue, while absolute performance remains strongly task-dependent. NLI is the strongest standalone method on dialogue.
- A diagnosis of the summarisation failure. Every method performs near chance there, but two controlled follow-ups show this is driven largely by single-pass truncation: enlarging the premise budget and switching to sentence-level chunk aggregation both recover substantial performance without extra hardware, the latter at a substantial increase in CPU inference.
- Bootstrap confidence intervals for the main results and paired bootstrap comparisons of AUC-ROC between the leading methods on each task, establishing which rankings our data resolve and which it does not.
- An error analysis of the NLI detector's failure cases, and practical guidance for method selection under computational constraints.

2 Related Work

Ji et al. (2023) survey hallucination in natural language generation. They distinguish faithfulness (relation to a provided source) from factuality (relation to world knowledge). HaluEval annotates candidates against a provided source, so our study falls in the faithfulness category. Detection methods group by resource requirement. *Model-as-judge* methods prompt a strong LLM to evaluate faithfulness. They reach high human agreement but need frontier-model access and add per-query costs (Liu et al., 2023). *Sampling-based* methods such as SelfCheckGPT (Manakul et al., 2023) measure consistency across stochastic samples. They run in a black-box setting but need several times the generation cost. *Internal-state* methods analyse token probabilities or activations (Farquhar et al., 2024). They need white-box access, which API-only models do not allow. *Retrieval and fact-verification* pipelines decompose candidates into atomic claims and verify each against retrieved evidence (Min et al., 2023). This adds operational complexity.

The methods we evaluate belong to two lighter families. *NLI-based* methods treat the source as premise and the candidate as hypothesis. Falke et al. (2019) first repurposed NLI for summary faithfulness and found that standard NLI corpora transferred poorly. Later work trained on the FEVER fact-verification dataset (Thorne et al., 2018). Laurer et al. (2024) released DeBERTa models fine-tuned on MultiNLI, FEVER, and Adversarial NLI, which we adopt. Laban et al. (2022) introduced SummaC and showed that NLI methods beat lexical metrics for inconsistency detection. *Overlap-based* metrics include ROUGE (Lin, 2004), BERTScore (Zhang et al., 2020), and Sentence-BERT similarity (Reimers and Gurevych, 2019). These are cheap to compute but can be misled when hallucinations stay topically coherent with the source.

HaluEval (Li et al., 2023) provides 10,000 samples for each of three tasks: QA, dialogue, and summarisation. To build hallucinated candidates, the authors prompt ChatGPT for plausible but incorrect content. Prior work has mostly reported QA results alone. We provide a systematic comparison of lightweight methods across all three tasks under a common calibration protocol.

3 Dataset

We use all three HaluEval tasks (Li et al., 2023) from HuggingFace (`pminervini/HaluEval`). Each sample provides a source, a task-specific context, and a candidate labelled faithful or hallucinated (Table 1). For each task we draw 3,000 of the 10,000 samples with seed 42, a size chosen to keep NLI inference practical on a laptop CPU while leaving a test set large enough for stable estimates (bootstrap intervals of ± 0.015 to ± 0.026 AUC-ROC; Appendix B). We split them into a 1,000-instance validation set for threshold and ensemble-weight calibration, and a 2,000-instance test set for all reported metrics. Stratified sampling keeps the class distribution close to balanced. This split keeps every thresholding decision off the test data.

Dial.	Conversation knowl.	History	Response
Summ.	Document	—	Summary

4 Methodology

Problem formulation. Given a source S, optional context C, and candidate C', we predict $y \in \{0, 1\}$, where $y = 1$ denotes hallucination. Each method produces a score s. A threshold τ turns the score into a binary prediction. For every method, higher s means a higher chance of hallucination; the score definitions below make this explicit.

The four detectors and the ensemble. **ROUGE-L**: s is the longest-common-subsequence F-measure between source and candidate. **Semantic Similarity**: s is the cosine similarity between all-MiniLM-L6-v2 (Reimers and Gurevych, 2019) embeddings of source and candidate (≈22M parameters). **BERTScore**: s is the token-level contextual F-measure with a DistilBERT backbone (Zhang et al., 2020). For these three overlap detectors we use the raw score, *not* one minus it: HaluEval's hallucinated candidates are generated to be topically plausible, so they tend to overlap *more* with the source than faithful ones do, and on QA and dialogue higher overlap does indicate hallucination. **NLI**: the checkpoint `MoritzLaurer/DeBERTa-v3-base-mnli-fever-anli`, DeBERTa-v3-base fine-tuned on MultiNLI, FEVER, and ANLI (Laurer et al., 2024) (≈184M parameters). The premise is the source (truncated to 800 characters) plus context, the hypothesis is the candidate, and $s = 1 - P(\text{entailment})$. **Ensemble**: $s = \alpha\, s_{\text{NLI}} + (1 - \alpha)\, s_{\text{sim}}$, with α chosen by grid search over $\{0.1, \ldots, 0.9\}$ to maximise validation AUC-ROC. The selected weights are $\alpha = 0.4$ (QA), $\alpha = 0.9$ (dialogue), and $\alpha = 0.3$ (summarisation). These weights already show that dialogue relies almost entirely on the NLI signal, while QA benefits from a more balanced mix. Orientation is fixed in advance for every detector; the calibrated threshold sets only the operating point and cannot reverse the direction of a score.

Input length limits. Three of the four detectors see a truncated source. The NLI premise is capped at 800 characters, BERTScore references at 512 characters, and all-MiniLM-L6-v2 truncates its inputs at its default maximum of 256 tokens; only ROUGE-L uses the full source. These limits are fixed implementation choices, not tuned values. Section 6 examines their effect on summarisation.

Calibration and metrics. For each method, we select τ on the validation split by maximising the Youden index (TPR − FPR) and apply it unchanged to the test split. We report Accuracy, Precision, Recall, F1 (positive = hallucinated), and AUC-ROC, computed with scikit-learn (Pedregosa et al., 2011). Because point estimates cannot show whether a difference between two methods is meaningful, we compute 95% bootstrap confidence intervals for AUC-ROC on the main results, resampling the test set with replacement over 2,000 replicates, and we compare the best and second-best method on each task by bootstrapping their paired AUC-ROC difference on the same replicates. All experiments run on a standard laptop CPU. We batch embeddings at 32 and NLI at 16. Our code is available at `https://github.com/fkriti/hallucination-detection-nli`.

5 Results

Table 2 reports all methods across all tasks. Figure 1 shows the task-dependent pattern.

Question answering. QA is the easiest task. The ensemble is strongest on accuracy (.803), recall (.766), F1 (.792), and AUC-ROC (.873). It beats the best standalone method by about 6 points on F1 and about 5 points on AUC-ROC. NLI reaches the highest precision (.865) but low recall (.625), a conservative operating point. BERTScore (.821 AUC) edges ROUGE-L (.817) and clearly beats semantic similarity (.736). Contextual token overlap is therefore a stronger signal than sentence-level cosine similarity. The ensemble's gain shows that the similarity and NLI signals complement each other.

Dialogue. Dialogue is harder. The best AUC-ROC falls to .749 (ensemble) and .713 (NLI). The ensemble again ranks first on accuracy, precision, F1 and AUC-ROC, while NLI is the strongest standalone method and reaches the highest recall (.781). Entailment reasoning therefore transfers to the conversational setting, and combining it with similarity still helps. Lexical and embedding methods cluster at .61–.66 AUC-ROC, weaker than on QA because responses are shorter and depend more on context.

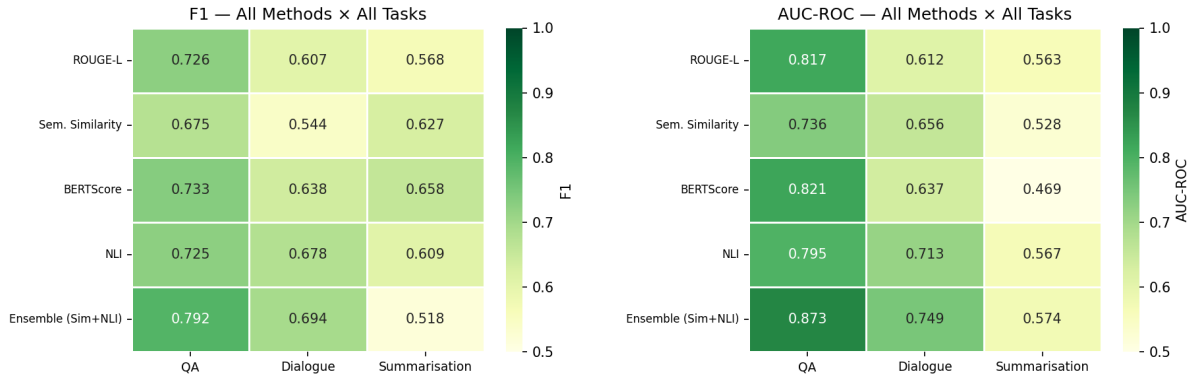

Table 2: Hallucination detection performance across the three HaluEval tasks (test $n = 2{,}000$ per task). Best result per task and metric in bold. On summarisation, the AUC-ROC gap between the two best methods is not statistically significant (Table 3), and BERTScore's high recall and F1 there reflect labelling nearly every candidate as hallucinated.

Task	Method	Accuracy	Precision	Recall	F1	AUC-ROC
QA	ROUGE-L	0.753	0.794	0.670	0.726	0.817
	Semantic Similarity	0.655	0.628	0.730	0.675	0.736
	BERTScore	0.745	0.754	0.713	0.733	0.821
	NLI	0.768	**0.865**	0.625	0.725	0.795
	Ensemble (Sim+NLI)	**0.803**	0.821	**0.766**	**0.792**	**0.873**
Dialogue	ROUGE-L	0.593	0.577	0.640	0.607	0.612
	Semantic Similarity	0.609	0.636	0.475	0.544	0.656
	BERTScore	0.599	0.572	0.722	0.638	0.637
	NLI	0.637	0.600	**0.781**	0.679	0.713
	Ensemble (Sim+NLI)	**0.672**	**0.640**	0.756	**0.694**	**0.749**
Summarisation	ROUGE-L	0.545	0.531	0.610	0.568	0.563
	Semantic Similarity	0.502	0.495	0.855	0.627	0.528
	BERTScore	0.494	0.492	**0.991**	**0.658**	0.469
	NLI	**0.553**	0.533	0.712	0.609	0.567
	Ensemble (Sim+NLI)	0.552	**0.549**	0.490	0.518	**0.574**

Summarisation: a systematic failure mode. Every method performs near chance, with AUC-ROC from .469 (BERTScore) to .574 (ensemble). BERTScore's value below .5 reflects our fixed orientation rather than a usable inverse signal: reversing its direction gives only .532. The high F1 for BERTScore (.658) and semantic similarity (.627) is misleading. It comes from extreme recall (.991, .855) with near-chance precision. These methods label almost everything hallucinated. Two factors plausibly contribute. First, a property of the data: HaluEval summarisation hallucinations are subtle factual edits inside long, otherwise faithful summaries of long documents, so the faithful remainder dominates the overlap metrics and they cannot localise the inconsistent span. Second, a property of our configuration: three of the four detectors see a truncated source, and the NLI detector's 800-character premise in particular cannot reach the full document. Section 6 separates these two explanations experimentally and shows that the second carries much of the weight, so the figures in this row should be read as the behaviour of a single-pass configuration rather than as a ceiling on lightweight detection.

Synthesis. On QA and dialogue the ensemble ranks first on every metric except precision on QA and recall on dialogue, where NLI leads. These are rankings; only the AUC-ROC gap to the runner-up is significance-tested (Table 3). Inference-based signals, alone or combined with similarity, are therefore the most reliable choice when lightweight detection is viable. All methods show a steep difficulty gradient from QA (AUC up to .873) through dialogue (.749) to summarisation (.574). The viability of GPU-free detection depends strongly on the task. Figure 2 shows the per-task ROC curves. The gradient appears as a progressive collapse of all curves towards the diagonal: well separated on QA, compressed on dialogue, and indistinguishable from chance on summarisation.

Statistical reliability. Point estimates alone cannot show whether one method genuinely outperforms another, so we resample the test set with replacement (2,000 bootstrap replicates, seed 42) and recompute AUC-ROC. Full per-method intervals appear in Appendix B; they are narrow, typically ± 0.02 AUC-ROC. Table 3 bootstraps the paired difference between the best method and the runner-up on each task. The ensemble's advan-

(a) F1 (b) AUC-ROC

Figure 1: The four detectors and the ensemble across all three tasks. The task-dependent ranking and the degradation from QA to summarisation are visible in both metrics.

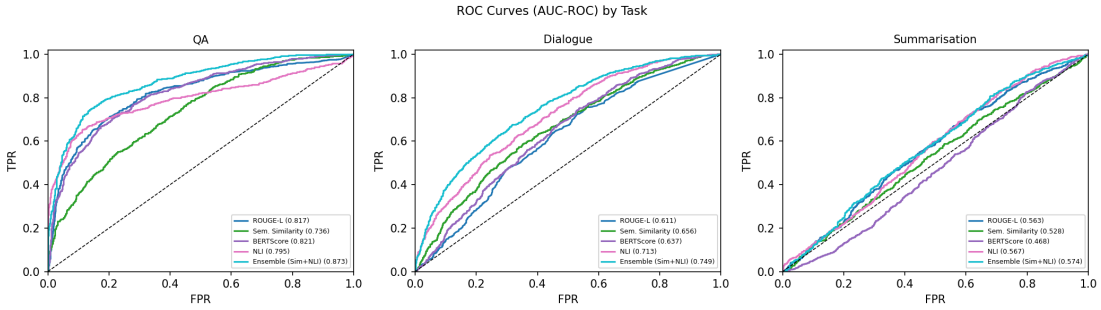

Figure 2: Receiver Operating Characteristic curves for the four detectors and the ensemble on each task. Separation from the diagonal (chance) degrades systematically from QA (left) to summarisation (right).

Table 3: Paired bootstrap of the AUC-ROC gap between the best and second-best method on each task. An interval excluding zero means the ranking is resolved.

Task	**Best vs. runner-up**	**ΔAUC**	**95% CI**
QA	Ensemble vs. BERTScore	0.052	$[0.032, 0.073]$
Dial.	Ensemble vs. NLI	0.036	$[0.015, 0.057]$
Summ.	Ensemble vs. NLI	0.007	$[-0.009, 0.022]$

tage is resolved on QA and dialogue, where the interval excludes zero. On summarisation the interval spans zero, so our data does *not* establish a ranking among the methods there. This is consistent with all of them sitting close to chance, and we therefore avoid claiming a best method for that task. BERTScore's summarisation interval, $[0.442, 0.493]$, lies entirely below 0.5, but this does not make it a useful inverse detector: orientation is fixed in advance, and reversing BERTScore's direction gives an AUC-ROC of only 0.532. It is near chance either way.

Computational footprint. The four detectors and the ensemble run on a standard laptop CPU with no GPU. Table 4 reports model size and measured throughput on an Apple M4 laptop. The lexical and embedding methods are computationally inexpensive. ROUGE-L processes roughly 900 candidates per second. The NLI detector, with its 184M-parameter model, is the bottleneck at 3.9 candidates per second. It scores a full 2,000-instance test split in about nine minutes. The ensemble adds no model beyond NLI and similarity, so NLI dominates its cost. Even the slowest setup stays practical for offline evaluation. The similarity-only and lexical methods are fast enough for interactive use.

6 Revisiting the Summarisation Failure

The result above is easy to over-read. Reporting that every lightweight method lands near chance on summarisation invites the conclusion that lightweight detection is intrinsically unsuited to the task. Before drawing that conclusion we need to rule out a simpler explanation: our own configuration. The single-pass detector truncates the source to 800 characters, while summarisation

Table 4: Model size and measured CPU throughput on an Apple M4 (10 cores, 16 GB RAM) with default PyTorch threading. Throughput is candidates scored per second.

Method	Params	Throughput
ROUGE-L	—	∼900/s
Sem. Similarity	22M	∼58/s
BERTScore	66M	∼62/s
NLI	184M	∼3.9/s
Ensemble	206M	∼3.7/s

Table 5: Summarisation performance as the NLI premise budget varies ($n = 2{,}000$ test). Performance peaks below the checkpoint's configured maximum of 512 positions and degrades once the premise exceeds it.

Chars	Med. tok.	Acc.	F1	AUC-ROC
400	85	0.520	0.649	0.507
800 (main)	168	0.553	0.609	0.567
1600	329	0.598	0.611	**0.629**
3200	629	0.530	0.643	0.577

sources have a median length of 3,458 characters (mean 3,905, p90 6,825). The detector therefore never sees roughly three quarters of a typical document. We run two controlled follow-ups to separate the two explanations. Both keep the same NLI model and the same CPU-only budget, so only the input handling changes.

Does a larger premise help? We vary the source-truncation budget and rerun the detector on summarisation, keeping the protocol otherwise identical (Table 5). Performance is not flat. It climbs from 0.507 AUC-ROC at 400 characters to 0.629 at 1,600, then falls back to 0.577 at 3,200. The turning point is informative. The checkpoint is configured for at most 512 positions, and a 3,200-character premise already produces a median of 629 tokens. Because DeBERTa-v3 uses relative position attention, such inputs still run without error rather than being truncated, but they exceed the length the model is configured for, and its entailment judgments degrade. The budget used for our main results, 800 characters, sits well below that ceiling and leaves roughly six AUC-ROC points unclaimed. The truncation length is thus a real confound, though the ceiling it eventually runs into is a genuine property of the encoder rather than a free parameter.

Does removing truncation entirely help more? A larger budget only postpones the problem, because no single pass can reliably exceed that length.

Table 6: Removing truncation via chunk aggregation on summarisation ($n = 2{,}000$ test). All rows use the same NLI model and the same instances, so only the input handling differs.

Method	Acc.	F1	AUC-ROC
Single-pass (800 chars)	0.553	0.609	0.567
Chunk agg. (min combiner)	0.588	**0.648**	0.633
Chunk agg. (mean combiner)	**0.635**	0.623	**0.683**

We therefore test a SummaC-style alternative (Laban et al., 2022) that avoids truncation altogether. The source is split into 800-character chunks and the candidate into sentences; every candidate sentence is scored against every chunk; entailment is maximised over chunks and then combined across candidate sentences, using either the mean (the SummaC-ZS default aggregation) or the minimum, which is more sensitive to a single unsupported sentence. Unlike SummaC-ZS, which scores entailment minus contradiction, we use the entailment probability alone. We deliberately reuse our own NLI model rather than the released SummaC checkpoint, so that the comparison isolates the aggregation strategy instead of confounding it with a different model. Table 6 reports the result on the full summarisation split against a single-pass baseline over the same instances; that baseline reproduces the 0.567 of Table 2 exactly. Aggregation with the mean combiner raises AUC-ROC to 0.683, a gain of 11.6 points, and improves accuracy and F1 as well, so it dominates single-pass scoring on every metric we report. It does so with no GPU and no larger model, though it needs about twenty times as many NLI calls. The two combiners trade off as expected: the minimum is the more sensitive detector and gives the best F1, while the mean gives the better ranking.

What this changes. Taken together, the two experiments substantially qualify the headline result. Summarisation is still clearly the hardest of the three tasks, and even the best configuration we find (0.683) remains far below QA (0.873) and dialogue (0.749). But the near-chance figures in Table 2 measure a naive single-pass configuration, not the capability of lightweight methods in general. Changes that need no additional hardware recover a large part of the gap: a larger premise budget, which lengthens each NLI input, and chunk aggregation, which needs roughly twenty times as many NLI calls. We therefore state the finding narrowly:

single-pass, truncation-bound lightweight detection fails on long-source summarisation, and practitioners working under CPU constraints should try aggregation, budgeting for its extra inference, before concluding that the task is out of reach.

7 Error Analysis and Discussion

NLI errors. On QA, false positives are short entity-only answers ("Queen Margrethe II", "two"), where the brief candidate offers too little material to confirm entailment. False negatives are fluent fabrications ("Belk was founded in Birmingham, Alabama") that read as locally plausible. The model is fooled more easily by confident falsehoods than by terse truths. On dialogue, false negatives involve plausible cross-references (e.g. a wrong film director) that fit the conversational flow but contradict the knowledge. On summarisation, false negatives differ from faithful summaries by a single altered fact that the truncated premise cannot reach.

Practical guidance. For both QA and dialogue, use the similarity-NLI ensemble as the default: it ranks first on F1 and AUC-ROC on both tasks. Where false positives are costly, standalone NLI gives the highest precision on QA; where recall matters most, standalone NLI is preferable on dialogue. For summarisation, none of the single-pass methods we test is usable; sentence-level chunk aggregation is the best option we found, at roughly twenty times the NLI inference, and claim decomposition is worth exploring.

8 Conclusion

We asked how far hallucination detection can progress without a GPU, proprietary APIs, or access to the generating model. Across four CPU-feasible detectors, a score-level ensemble, and three HaluEval tasks, the answer is strongly task-dependent. A similarity-NLI ensemble is the most consistent choice: it detects QA hallucinations well (F1 $= 0.792$, AUC-ROC $= 0.873$) and also ranks first on dialogue (F1 $= 0.694$, AUC-ROC $= 0.749$), where NLI is the strongest standalone method. Paired bootstrap comparisons confirm that the ensemble's AUC-ROC lead is resolved on both tasks, while the ranking on summarisation is not. Every method performs near chance on summarisation (AUC-ROC ≤ 0.574), but that figure describes a single-pass configuration rather than a ceiling: raising the premise budget recovers about six AUC-ROC points, and sentence-level chunk aggregation recovers about twelve, the latter at roughly twenty times the NLI inference and without extra hardware. Summarisation remains the hardest of the three tasks, and the honest conclusion is narrower than the one we set out to draw. Truncation-bound single-pass scoring fails on long-source summarisation, and our results do not support treating lightweight detection as intrinsically unsuited to the task. We restrict attention to reproducible, public, CPU-only methods and report both successes and limits. This gives practitioners without specialised hardware a realistic foundation and clear guidance for choosing a method.

Limitations

We study only HaluEval, whose hallucinations are synthetic and may differ from naturally occurring ones; generalisation to hallucinations produced in the wild remains untested. Our conclusions rest on a single sampled split with one seed, so the bootstrap intervals we report capture test-set variability but not variation from resampling the corpus or reshuffling the validation split, and the gains in Section 6 are point estimates without intervals, because we did not retain per-instance scores for those runs. Detector orientation is fixed in advance rather than selected on validation, which is why BERTScore can fall below chance on summarisation. The chunk aggregation of Section 6 is a SummaC-style reimplementation over our own NLI model rather than the released SummaC checkpoint, so it should be read as evidence about aggregation strategy rather than as a benchmark of that system; we also do not tune its chunk size, caps, or combiner, so the figures we report are a lower bound on what aggregation can achieve. Our comparison covers lexical, embedding, and entailment methods, but not other CPU-feasible families such as question-generation or claim-decomposition pipelines. Finally, the ensemble is a simple linear combination, and we leave learned stacking of all four detectors to future work.

A Reproducibility Details

All experiments use fixed random seed 42 and run on CPU. The hardware is a laptop with an Apple M4 processor (10 cores) and 16 GB of RAM, running macOS 26.2 and Python 3.9.6; no GPU or accelerator is used at any stage, and we leave PyTorch threading at its default setting. We use three public model checkpoints: `all-MiniLM-L6-v2` (semantic similarity), `distilbert-base-uncased` (BERTScore backbone), and `MoritzLaurer/DeBERTa-v3-base-mnli-fever-anli` (NLI). For each task we draw 3,000 examples. We split them into a 1,000-instance validation set for threshold and ensemble-weight selection, and a 2,000-instance test set for reporting. We truncate the NLI premise to 800 source characters plus up to 200 trailing context characters and BERTScore references to 512 characters, and all-MiniLM-L6-v2 truncates its inputs at its default maximum of 256 tokens. ROUGE-L, semantic similarity, and

BERTScore use their raw scores as hallucination scores; NLI uses $1 - P(\text{entailment})$. We batch sentence embeddings at 32 and NLI inference at 16. Thresholds maximise the validation Youden index. The ensemble weight α maximises validation AUC-ROC over $\{0.1, \ldots, 0.9\}$. We compute metrics with scikit-learn.

For the truncation ablation of Section 6 we vary only the source-character budget and leave the protocol otherwise unchanged, refitting the threshold on validation at each setting. For chunk aggregation we split the source into non-overlapping 800-character chunks, capped at 10 chunks, and the candidate into sentences on terminal punctuation, capped at 6; every candidate sentence is paired with every chunk, entailment is maximised over chunks and then combined across candidate sentences by mean or minimum. Bootstrap intervals use $2{,}000$ replicates with seed 42.

B Bootstrap Confidence Intervals

Table 7 reports 95% bootstrap intervals for every method and task, computed by resampling the test set with replacement over $2{,}000$ replicates (seed 42) and recomputing each metric on every replicate. Intervals are narrow, which reflects the $2{,}000$-instance test splits.

Table 7: 95% bootstrap confidence intervals ($2{,}000$ replicates).

Task	Method	AUC-ROC	95% CI
QA	ROUGE-L	0.818	$[0.797, 0.838]$
	Sem. Sim.	0.736	$[0.715, 0.757]$
	BERTScore	0.821	$[0.802, 0.838]$
	NLI	0.795	$[0.774, 0.816]$
	Ensemble	0.873	$[0.858, 0.888]$
Dial.	ROUGE-L	0.612	$[0.586, 0.638]$
	Sem. Sim.	0.656	$[0.632, 0.679]$
	BERTScore	0.637	$[0.614, 0.661]$
	NLI	0.714	$[0.692, 0.735]$
	Ensemble	0.749	$[0.729, 0.770]$
Summ.	ROUGE-L	0.563	$[0.538, 0.588]$
	Sem. Sim.	0.528	$[0.503, 0.553]$
	BERTScore	0.468	$[0.442, 0.493]$
	NLI	0.567	$[0.542, 0.592]$
	Ensemble	0.574	$[0.549, 0.598]$

C Supplementary Figures

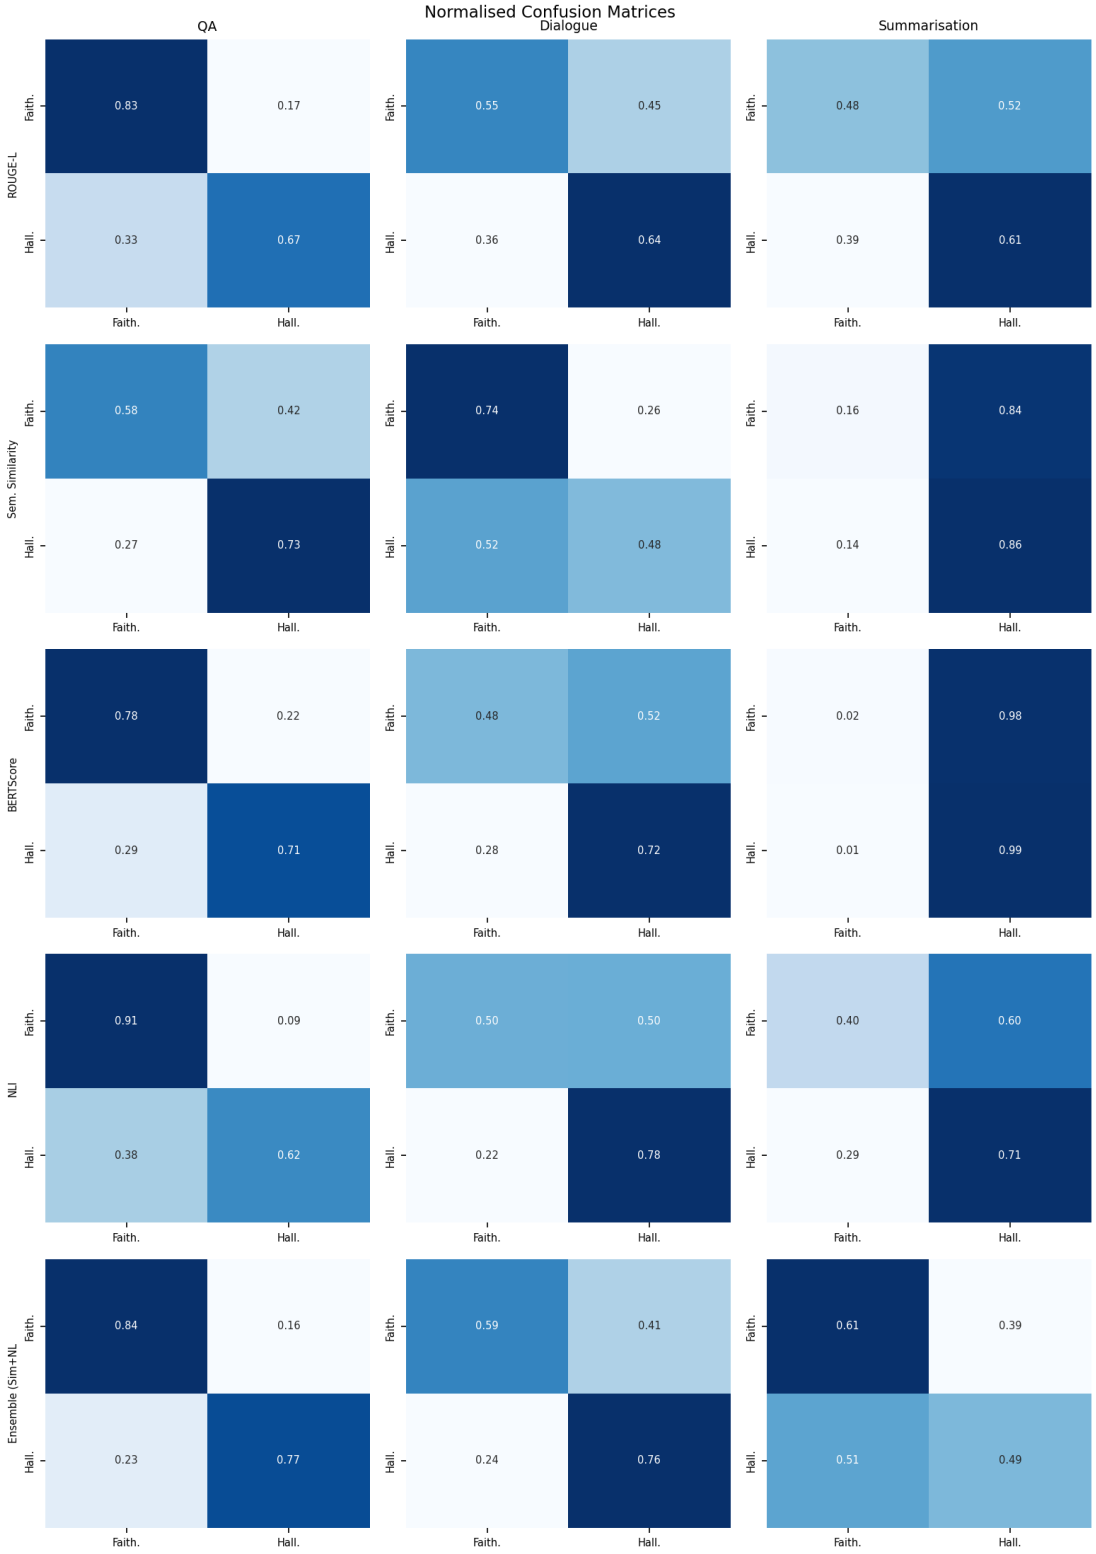

Figure 3: Confusion matrices for all methods and tasks at the calibrated operating point. The summarisation column shows the degenerate predict-almost-everything- hallucinated behaviour of the overlap methods.

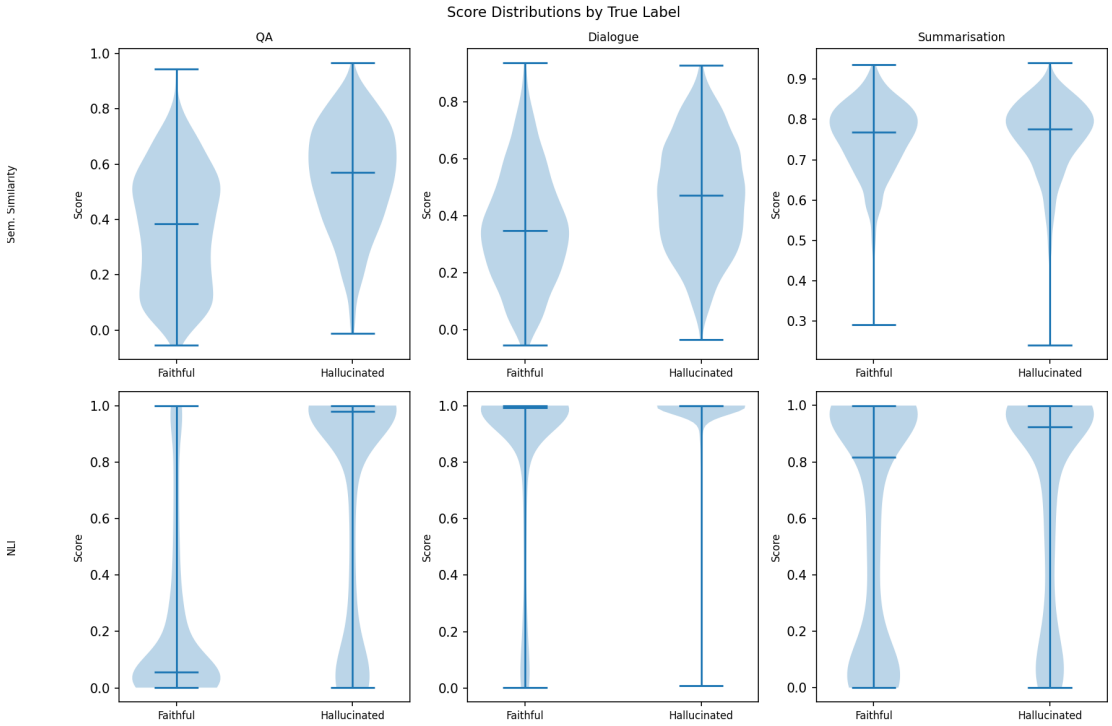

Figure 4: Distributions of hallucination scores for faithful versus hallucinated candidates. Clear separation on QA collapses to near-complete overlap on summarisation, explaining the near-chance AUC-ROC there.

Memory Makes the Difference: Evaluating How Different Memory Roles Shape Conversational Agents

Abstract

Memory is a critical component of modern conversational systems. Prior research on memory mechanisms in RAG-based conversational systems has focused on how memory is stored and retrieved. However, less is known about how memories with different functional roles influence response quality, shape agents' responses across conversational contexts, and lead to distinct response behaviors. Existing evaluations are also largely reference-based, often missing response nuances that address users' preferences differently. In this work, we study the impact of different memory types on agent responses. We present a fine-grained taxonomy of conversational memory, classify retrieved memories by functional role, and design a user-centric evaluation framework that simulates user perspectives. Through comparative experiments on long-term datasets and frontier LLMs, our analysis reveals differentiated effects of memory: *e.g.*, clarifying memory is associated with improved factual accuracy and constraint awareness, making responses more correct and personalized, while irrelevant memory reduces topic relevance and degrades constraint awareness. These findings show that, despite the power of frontier LLMs, different memory types can be leveraged to produce responses better aligned with a user's stated constraints, and motivate further research in this direction. Our code is available at: https://github.com/audreycs/MemoryEffect.

1 Introduction

Conversational memory provides needed context for grounded responses and accurate query understanding (Radlinski and Craswell, 2017), and is now a core feature of contemporary chat systems such as ChatGPT (OpenAI, 2025b) and Google Gemini (AI and DeepMind, 2025). At a high level, conversation history is logged into an external memory bank to preserve past information. During response generation, chat agents retrieve relevant pieces to surface useful memory. This retrieval-augmented generation (RAG) pipeline has become a standard approach for long-range conversation, helping Large Language Models (LLMs) overcome context-length limits and maintain response coherence and accuracy (Fan et al., 2024).

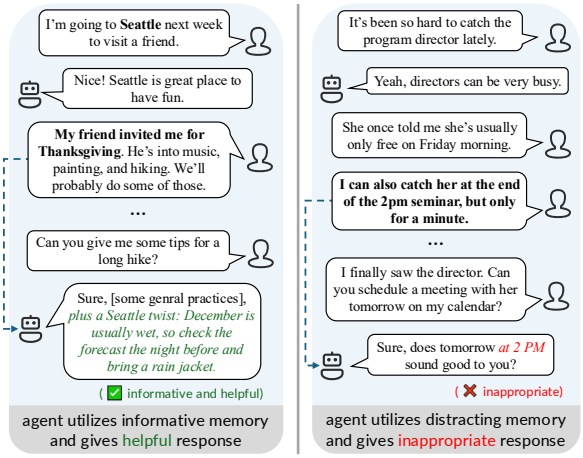

Figure 1: (Left panel) Example of retrieved memory making response more helpful; (Right panel) Example of retrieved memory making response inappropriate.

Existing work on conversational RAG has largely centered on storage and retrieval strategy, *i.e.*, memory structure, retrieval size, and granularity (Xu et al., 2022; Ye et al., 2024; Maharana et al., 2024; Zhong et al., 2024; Wu et al., 2025; Pan et al., 2025; Tan et al., 2025a). These systems typically retrieve a set of stored pieces, concatenate or compress them into the conversational context, then evaluate the aggregated performance of generation system. However, this common practice overlooks the distinct role properties and impact of individual retrieved pieces. Human intuitively recall useful memory to formulate responses, but when it comes

to RAG systems, it is uncertain if retrieved memory which are semantically close are actually useful. The effect of retrieval part often behaves like a black box and hard to interpret or control (Chen et al., 2024). As Fig. 1 shows, some supplementary memory can enrich the response and make it more helpful; while other memories can be distracting and make the response inappropriate and undesired. In this work, our central hypothesis is that **the type of memory matters**: different memory types elicit different agent responses, which in turn shape users' perceptions of quality. Therefore, understanding the qualitative effect of each memory type and whether agents can leverage a bundle of retrieved memories worth systematic investigation. Building on this hypothesis, we aim to quantify the impact and find their qualitative property. We introduce a fine-grained taxonomy of conversational memory types, determined by their functional roles when the agent reasons over retrieved memory. Unlike prior taxonomies, which organize memory by structure or provenance, ours conditions on the query and decomposes what "relevant" memory does in a dialogue (§2.2). Besides, existing work is usually limited in reference-based evaluation. Prior work leans on question answering (QA) datasets provided with unambiguous gold answers (Anantha et al., 2021; Xu et al., 2022; Pan et al., 2025; Maharana et al., 2024; Chen et al., 2025). Their reference-based evaluation privileges measuring factual accuracy (*e.g.*, F1, ROUGE) while ignoring other qualities of responses like user intent awareness and informativeness, which are critical for dialogic intelligence but difficult to measure using only references.

In this work we analyze how different memory types shape LLM agents' responses, paired with a holistic, user-centric evaluation framework. Our taxonomy classifies conversational memory into five types — answer, clarifying, enriching, distracting, and irrelevant, judged with awareness of the query and relevant context instead of only the gold answer as in previous analyses (Cuconasu et al., 2024). We conducted comparative experiments on two long-term, multi-session conversational datasets over three popular LLMs. Specifically, we compare varied memory settings with (i) answer memory only and (ii) parametric memory only, to study how the presence of individual types and their combinations affects responses quality. To better differentiate response quality, we design a user-centric evaluation proxy conditioned on user intent and prior conversation context, capturing relevance, informativeness, and other properties.

Our results reveal many interesting patterns. Frontier LLMs can selectively leverage contextual information with considerable nuance, but agents are less likely to ground responses as retrieval size increases. As for memory types, clarifying memory plays a key role in improving answer accuracy and contextual grounding, and even in isolation it can induce perfect responses. In contrast, irrelevant memory tends to reduce topic relevance and weaken contextual awareness, unlike the positive impact reported for small-scale LLMs such as Llama2 and Phi-2 in previous work (Cuconasu et al., 2024). These also confirm our hypothesis on the impact of memory types. Our taxonomy and user-centric evaluation are general-purpose and can be applied to other conversational corpora and settings. Our main contributions in this work are the following:

- We hypothesize the impact of memory types on agent's responses, and conducted extensive comparative experiment on frontier LLMs to investigate.
- We propose a fine-grained taxonomy of conversational memory based on functional roles, together with a holistic framework with diverse metrics for evaluation.
- Our experiments qualitatively reveal the distinct impacts of different memory, with several effects diverging from prior findings on small-scale LLMs.

2 Related Work

2.1 Memory-enabled Conversational System

Conversational systems typically frame memory recall as a store-retrieve-generate pipeline, reflecting flexible memory management and working context (Gao et al., 2023). Recent work on LLM-powered conversational systems have largely focused on memory structure (Packer et al., 2023; Rasmussen et al., 2025; Chhikara et al., 2025), retrieval strategy (Tan et al., 2025b; Li et al., 2025; Hu et al., 2025a), and memory update governance (Tan et al., 2025b; Rezazadeh et al., 2025; Wang et al., 2025). Retrieval commonly uses sparse or dense retrievers, such as BM25 (Robertson et al., 2009) and Contriever (Izacard et al., 2021). To stress-test these systems in realistic settings, several work target long-term, multi-session dialogue, including MT-

Bench-Plus (Lu et al., 2023), LOCOMO (Maharana et al., 2024), LongMemEval (Wu et al., 2025), and InfiniteBench (Zhang et al., 2024).

2.2 Analysis of Retrieval Pieces Type

Several recent studies examine how irrelevant or distracting retrieved pieces affect QA performance, mainly on smaller-scale LLMs. Cuconasu et al. (2024) provide a pioneering analysis of how retrieved document type and position influence model answers. They classify documents into gold, relevant, distracting, and random based on semantic similarity and gold-answer presence, and show that random documents can sometimes improve accuracy. Jin et al. (2025) investigate distracting documents that are relevant to the query but not the gold answer, finding consistent harm to QA performance across models. Later, Amiraz et al. (2025) propose a measure to quantify the distracting effect. Together, these works characterize the impact of irrelevant and distracting evidence in document QA, but give less attention to conversational settings. Inspired by this line of work, we adapt and refine these types for conversational scenarios, shifting from document QA to memory-enabled dialogue, where responses require more nuanced evaluation and multiple forms of "relevant memory" (*e.g.*, clarifying, enriching) must be considered.

2.3 Evaluation of Conversational Agents

Conventional evaluation of conversational systems scores responses against references using n-gram or embedding metrics such as F1, ROUGE (Lin, 2004), and BERTScore (Zhang* et al., 2020). Newer work on long-term, memory-enabled conversations also tracks retrieval accuracy by measuring if particular pieces are retrieved (*i.e.*, needle in the haystack) via metrics like Recall@k (Maharana et al., 2024; Wu et al., 2025). With the rise of LLM-as-a-judge, LLM-based judges have been increasingly used for holistic chat-quality evaluation (Bai et al., 2024; Zhao et al., 2025; Chhikara et al., 2025). Well-designed rubrics allow them to assess diverse dimensions even without references. For example, Mem0 (Chhikara et al., 2025) prompts an LLM judge to compare responses with references, MT-Bench-101 (Bai et al., 2024) uses pairwise comparison to rank candidate responses, and PersonaLens (Zhao et al., 2025) equips judge with user profiles and rich interaction history to assess whether responses address user preferences.

Memory Type (Abbr.)	Definition
Parametric memory (P)	Exists in LLMs' parameters through training
Answer memory (A)	Contains the information of the desired answer for user's query
Clarifying memory (C)	Resolves the identity of the asked-for entity or event in the query
Enriching memory (E)	Makes the final answer more informative or helpful
Distracting memory (D)	Seems to be relevant but is actually misleading
Irrelevant memory (I)	Has no meaningful relevance to the user's query (off-topic)

Table 1: Our taxonomy of conversational memory types.

3 Taxonomy of Conversational Memory

Retrieved memories form a semantic neighborhood around the query by RAG mechanism, and the agent's reasoning can be viewed as selectively traversing retrieved memory pieces to assemble the information needed for a response (Appendix D for illustration). Building on this intuition and document RAG classification (Cuconasu et al., 2024; Amiraz et al., 2025), we classify conversational memory by its role in reasoning into five types: *answer*, *clarifying*, *enriching*, *distracting*, and *irrelevant*. Tab. 1 shows their definitions. As shown in Fig. 12, to correctly answer the query, the agent needs clarifying memory to identify the referenced name, then infer answer from the answer memory. Ideally, the agent needs enriching memory for more helpful details, and avoids distracting memory to mitigate false answer. The remaining off-topic memory is irrelevant, serving as neutral noise.

Each memory receives one type per query, although a memory may contain pieces serving multiple roles. For controlled analysis and clear attribution, we adopt single-label assignment as a deliberate methodological simplification, and we apply a labeling precedence: answer $\rightarrow$ clarifying $\rightarrow$ enriching $\rightarrow$ distracting $\rightarrow$ irrelevant for disambiguation. This precedence encourages sufficient representation of relatively sparse types in realistic retrieval pools. Importantly, it does not encode a hierarchy of importance or quality of them on response generation. Two consequences follow. First, since clarifying outranks all types but answer, only answer can absorb a clarifying piece, making clarifying a conservative subset; the scarcity of clarifying memory in §7 is thus a lower bound reflecting retrieval behavior, not an artifact of the rule. Second, we do not measure how often pieces are genuinely multi-role, nor how sensitive our conclusions are to a different ordering; multi-label annotation would answer both and expose combinations single labeling hides (*e.g.*, answer-containing yet

distracting). Besides conversational memory, we include *parametric* memory, the LLM's inherent knowledge learned during training.

To identify types, prior work (Cuconasu et al., 2024; Amiraz et al., 2025) flags distracting or irrelevant retrieved content by string-matching with the gold answer. This works for short, unambiguous targets (*e.g.*, a name or location), but not for open-ended dialogue responses, which are more expansive and lexically diverse. We therefore use a context-aware LLM-as-a-judge to simulate the user and classify retrieved memory pieces. For each candidate memory, the judge receives the query, the candidate piece, and the top 50 retrieved memory pieces as relevant interaction history, helping it infer the query and user's intent. Fig. 7 presents the details, using a prompt schema adapted from Thomas et al. (2024), which has been shown to be highly effective. We use `GPT-5-thinking` model (OpenAI, 2025a) as the judge.

Because memory classification underpins the following analyses, we also conduct a human verification study. On a sample of 30 pieces, the judge's agreement with human annotators is comparable to the agreement among the annotators themselves (Appendix B). We treat this as a pilot sanity check rather than a full validation: the sample is small, absolute agreement is moderate, and we report no per-class results for the sparse clarifying category, which carries our strongest claim.

4 User-centric Response Evaluation

To better capture the sensitivity of responses to different context, we design a holistic, user-centric, and context-aware evaluation framework (Tab. 2). It spans three major aspects (Accuracy, Relevance, and Informativeness), each with finer metrics, by integrating established evaluation frameworks (Liang et al., 2023; Maurya et al., 2025) and adapting them to conversation. At a high level, Accuracy captures factual correctness of responses; Relevance checks alignment with user intent and preferences; Informativeness assesses usefulness beyond the minimal answer. Note that conventional reference-based accuracy metric such as ROUGE is subsumed by Answer Accuracy, which tests whether the response contains the desired answer. We nonetheless report ROUGE-1 Recall separately, alongside Memory Coverage, as a lexical-overlap check. Tab. 2 marks which metrics require prior conversation history ("context-aware" column); for instance, World Knowledge Accuracy and Internal Coherence can be judged without context.

For robustness, most metrics except Completeness use a binary scale rather than a fine-grained rating scale. Prior work shows binary judgments can improve LLM-judge accuracy and reliability (Dong et al., 2024; Alhawasi and Youssef, 2024), while finer scales introduce subjective design choices (Bansal et al., 2024; Wang et al., 2024). Thus, we believe binary scale is sufficient for our analyses. We use `GPT-o3` as the LLM judge, judging metrics under the same aspect together.

5 RAG Pipeline Implementation

Our implementation follows the standard conversational RAG pipeline. In our setting, a *conversation* is the complete interaction history between one user and the chat agent. Each user has a separate conversation, which may span multiple sessions. A *session* is a continuous interaction episode between a user and the agent, typically centered on one topic. An *utterance* is a single text input from either side, and a *turn* consists of one user utterance followed by one agent utterance. For each user query, *context* denotes the retrieved prior memories reachable to the agent.

5.1 Two Long-Term Conversational Datasets

We use two long-term, multi-session conversation datasets for our analyses: LongMemEval-m (Wu et al., 2025) and Long-MT-Bench+ (Zheng et al., 2023), with statistics in Appendix E, Tab. 5. LongMemEval-m contains synthetic conversations paired with human-designed queries, while Long-MT-Bench+ contains human-written conversations and GPT-generated long-range queries. Both datasets feature extensive conversational memory and evaluate memory-related user queries. LongMemEval-m additionally provides metadata such as session timestamps and evidence memories for each query.

5.2 Memory Storage and Retrievers

We use one memory bank for all sessions within the same conversation. When the agent responds to a query, all past sessions are reachable, but different conversations cannot access each other's memory. Following LongMemEval, we implement the memory bank as key-value pairs {<key>: <value>}, where the key is used for retrieval indexing and the value returns the original content. We **store each**

Aspect	Metric	Description	Range	Context-aware
Accuracy	World Knowledge	Accuracy of the response with respect to general facts and world knowledge	$\{0, 1\}$	✗
	Answer Accuracy	Agreement of the response with the gold answer	$\{0, 1\}$	✗
	Internal Coherence	Logical consistency of the response within itself	$\{0, 1\}$	✗
Relevance	Topic Relevance	Whether the response directly addresses the query	$\{0, 1\}$	✓
	Constraint Awareness	Whether the response satisfies constraints stated or implied in prior interactions	$\{0, 1\}$	✓
Informativeness	Completeness	Extent to which the response covers relevant information for the query	$\{0, 1, 2\}$	✓
	Actionability	Whether the response provides concrete details or clear guidance	$\{0, 1\}$	✗
	Memory Coverage	Number of retrieved memory pieces whose information is reflected in the response	$\mathbb{Z}^+$	✓
	ROUGE-1 Recall	Proportion of unigrams in the gold answer that appear in the response	$[0, 1]$	✗

Table 2: User-centric evaluation framework.

turn as one pair; both key and value are the original turn, although the key can be customized (*e.g.*, as a summary or keyword list). When timestamps are available, we record them in the values. For retrieval, we experiment with BM25 (Robertson et al., 2009), Contriever (Izacard et al., 2021), and OpenAI's `text-embedding-3-small` (Neelakantan et al., 2022). We retrieve the top 100 memory pieces by similarity. On average, a memory piece contains 317 tokens in LongMemEval-m and 216 tokens in Long-MT-Bench+, so 100 pieces already form a large context.

5.3 Agent Models and Response Generation

We evaluate three large and popular LLMs as agents: `GPT-4o-2024-08-06` (Hurst et al., 2024) (called `GPT-4o` later), `Gemini-2.0-Flash` (DeepMind, 2024), and `Llama-3.3-70B` (Dubey et al., 2024). To vary context size, we select the top k pieces ($k \in \{0, 5, 10, 20, 50, 100\}$) from the 100 retrieved pieces. When timestamps are available, the k pieces are ordered chronologically. We concatenate them and truncate as needed to fit the model's context window. The full response-generation prompt is shown in Fig. 6 in Appendix. Note that when $k = 0$, the agent relies on parametric memory. All agents use the minimum temperature for near-deterministic output.

5.4 Response Evaluation

We use `GPT-o3` with high reasoning effort as the judge, applying aspect-specific rubrics. We carefully designed the rubrics, sanity-checked them on sample queries, and iteratively refined them to align the judge's scores with human evaluations (Appendix C). Unlike the memory-type judge, however, this judge was aligned to human-checked cases during rubric design but never scored against an independent set of human judgments (see Limitations). Particularly, for the Topic Relevance, refusal responses such as "*I am unable to answer ...*" receive a score of 0.

6 General Performance On Large LLMs

We first analyze metric-level performance across agents, context sizes, and retrievers, then examine agents' memory selectivity by type.

6.1 Performance Over Datasets, Agents, Context Size, and Retrievers

Fig. 2 shows average scores under different context sizes (top k) and agents, while Fig. 3 compares retrievers. We find several patterns:

Context Size-Performance Trade-off Metrics such as Answer Accuracy and Constraint Awareness generally rise as context size k increases, then decline. This suggests excessive context can distract agents, echoing prior findings on information overload (Maharana et al., 2024; Pan et al., 2025; Wu et al., 2025). Among the three agents, `GPT-4o` is most robust to long contexts.

World Knowledge Accuracy and Constraint Awareness Decline In Fig. 2, agents using only parametric memories ($k = 0$) receive higher World Knowledge Accuracy than with retrieval. Inspection suggests added conversational context leads agents to generate more claims and contextualized statements, which judges penalize when unsupported. Thus, external evidence can ground responses but also amplify hallucination risks, consistent with recent studies (Jin et al., 2024; Hu et al., 2025b). Constraint Awareness also degrades once context exceeds a certain size, even when Answer Accuracy stays relatively stable (*e.g.*, on Long-MT-Bench+), highlighting the need to triage historical context, especially in preference-heavy tasks such as recommendation.

Memory Coverage Cap Memory Coverage and Completeness, which measure how much retrieved memory is reflected in the response, show a clear upper bound. Coverage peaks when $k \in [5, 50]$ and then declines. Top-ranked pieces tend to contain

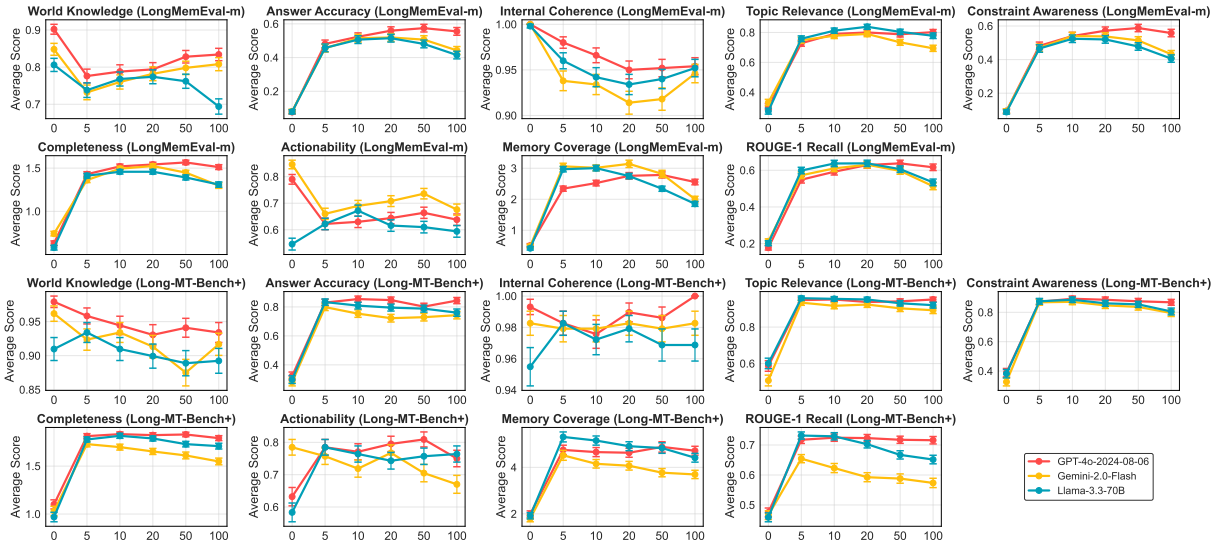

Figure 2: Average metric scores with error bars over queries on LongMemEval-m and Long-MT-Bench+ datasets. Results are based on `text-embedding-3-small` retriever. X-axis is the context size used in the prompt (top k memory pieces).

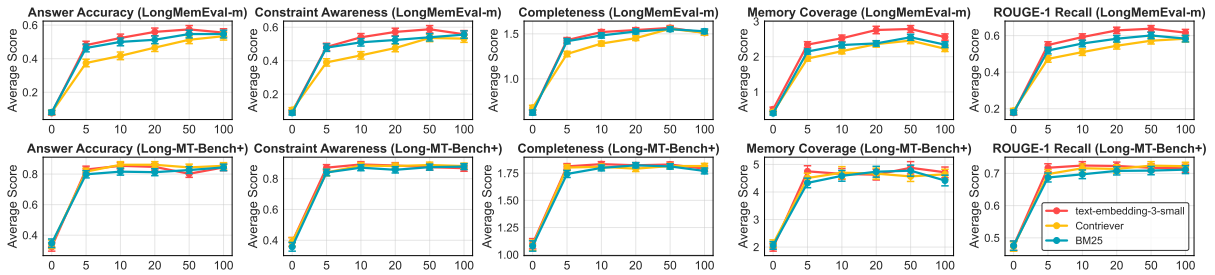

Figure 3: Average metric scores with error bars over context- or reference-aware metrics of three retrieval methods on LongMemEval-m and Long-MT-Bench+ datasets. Results are based on `GPT-4o-2024-08-06` agent. X-axis is the context size used in the prompt (top k memory pieces).

the most useful information, while later pieces are less relevant; as context grows, irrelevant pieces distract the agent from using useful ones.

Retriever Comparison Fig. 3 compares retrievers on key retrieval- or reference-dependent metrics. Overall, OpenAI's `text-embedding-3-small` outperforms the other two, especially on LongMemEval-m and smaller k, indicating better ranking of useful memory. BM25 remains competitive despite its simplicity, showing lexical match still finds strong anchors. Performance converges when enough memory is retrieved.

6.2 Utilization of Different Memory Types

We also measure how often each memory type appears in responses as context size k varies. Under our taxonomy, irrelevant memory should be ignored and answer memory should be included, providing a sanity check for the labels. For a given type, let a be its number of pieces among the top k retrieved (the *seen* number) and b the number echoed in the response (the *utilized* number); the coverage rate is b/a, the percentage of seen pieces used. Fig. 4 shows results on `GPT-4o`. Answer memory is covered most often, while irrelevant memory is covered least, suggesting the agent can distinguish useful from unuseful memory. Clarifying memory is also highly utilized, supporting our taxonomy. As k increases, coverage declines for every type, steeply for distracting memory ($0.37 \rightarrow 0.18$) and more gently for the rest.

7 Impact of Different Memory Types

We next examine how distinct memory types shape response quality. We conduct controlled experiments to characterize systematic associations between memory-type presence and response behavior under realistic retrieval. We run two comparison sets: (i) variant settings that add another memory type to an answer-only baseline (*vs.* A);

Comparative Experiment (*vs.* A)	World Knowledge		Answer Accuracy		Internal Coherence		Topic Relevance		Constraint Awareness		Completeness		Actionability		Memory Coverage		ROUGE-1 Recall	
A+C	0.50	1.00	0.60	1.00	–	–	1.00	1.00	0.75	1.00	0.89	1.00	0.67	1.00	0.67	0.75	0.57	0.67

Table 3: Improvement rate IR of comparison experiments on LongMemEval-m (left number in each cell) and Long-MT-Bench+ (right number in each cell) on `GPT-4o`. **Top table**: experimental setting *vs.* controlled setting (A); **Bottom table**: experimental setting *vs.* controlled setting (P). IR value stands for the chance of experimental setting wins over controlled setting, and IR $= 0.5$ means a tie. "–" means a lack of data point for the result. We highlight IR $\in [0.8, 1.0]$ with heavy green, $[0.6, 0.8)$ with light green, $(0.2, 0.4]$ with light red, and $[0, 0.2]$ with heavy red.

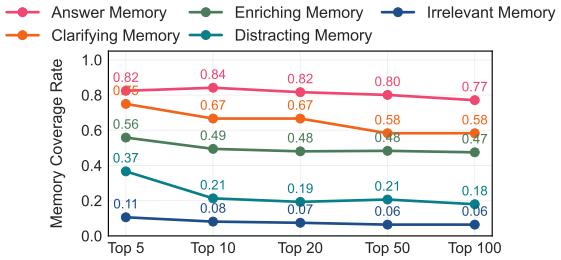

Figure 4: Memory coverage rate of different memory types under different retrieval size k. Results are on `GPT-4o`.

and (ii) variant setting compared to a parametric-only baseline (*vs.* P). The answer-only baseline reflects the RAG assumption that isolated answer-containing pieces should make the query easy to answer. Because real retrieval also includes non-answer memory, we test how C/E/D/I memory changes responses. The parametric-only baseline tests the converse assumption: without retrieval from conversation history, the agent cannot answer user queries well. We study the top 15 retrieved pieces, determine their types, vary memory settings, and use `text-embedding-3-small` as the retriever. Other setups remain unchanged.

7.1 Comparison with Answer Baseline

We compare the *vs.* A baseline with five variants: A+C, A+E, A+D, A+I, and the non-answer bundle C+E+D+I, yielding six settings and five pairwise comparisons. Because memory types are judged with query and context, the composition and counts within the top 15 pieces vary; a retrieval may contain one clarifying (C) piece but more than ten irrelevant (I) pieces. We therefore retain original retrieved counts to reflect realistic retrieval. Queries without answer memory (A) are excluded because they lack a comparable answer baseline. This buys ecological validity at a cost: piece count — and hence token budget and evidence position — correlates with role composition, since C memory typically adds one or two pieces while I memory can add ten. Our comparisons therefore identify **associations between role composition and response behavior under realistic retrieval**, not isolated causal effects; an effect attributed to a role may partly reflect context length, attention dilution, or position. Separating them requires count-, token-, and rank-matched variants holding the prompt budget fixed, so we state findings at the associational level throughout.

The idea to quantify each variant setting's impact is checking how its metrics scores change compared to baselines. Formally, let $\mathcal{Q}$ denote the query set. For metric m and memory setting i, let $s_q^m(i)$ be the score of the agent's response to query $q \in \mathcal{Q}$. The per-query score difference between settings i and j is $\text{diff}_q^m(i, j)$:

$$\text{diff}_q^m(i, j) = s_q^m(i) - s_q^m(j).$$

For instance, $\text{diff}_q^m(\text{A} + \text{C}, \text{A}) > 0$ means adding clarifying memory improves metric m for query q over the answer-only baseline. We measure how often setting i outperforms setting j using

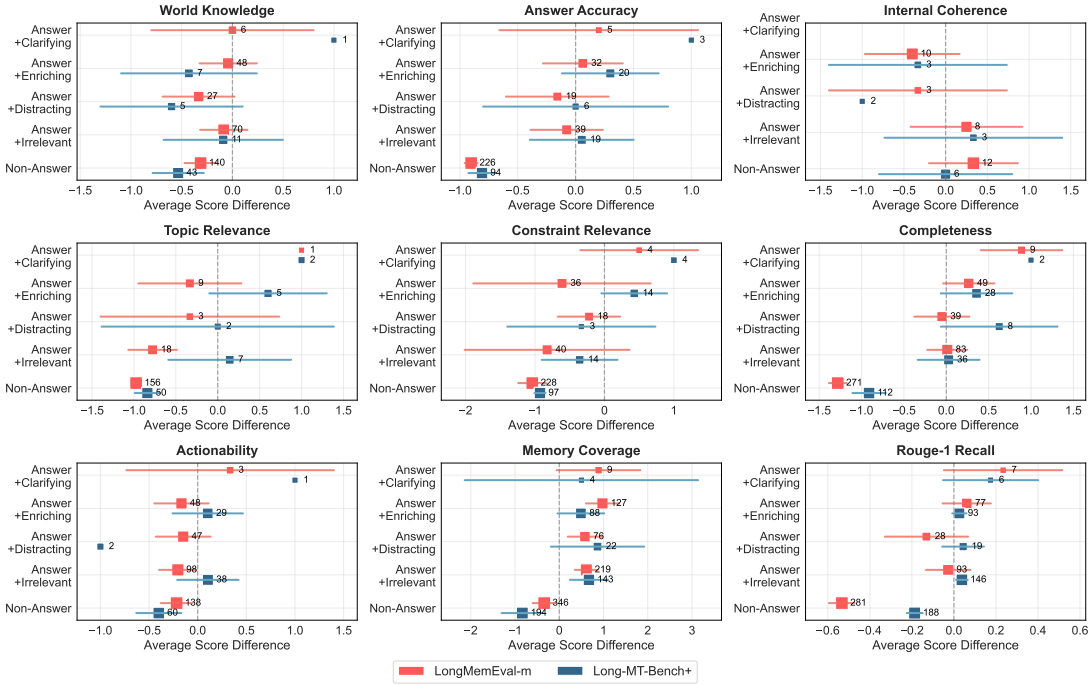

Figure 5: Mean per-query score differences with 95% confidence intervals when adding a memory setting relative to the answer-only baseline on `GPT-4o`. Squares mark the mean, bars the interval. Square size and the adjacent number give the count of queries with a non-zero change; no square means no qualifying queries.

Improvement Rate (IR):

$$\mathrm{IR}^m(i,j) = \frac{\#\{\mathrm{diff}_q^m(i,j) > 0\}}{\#\{\mathrm{diff}_q^m(i,j) \neq 0\}} \in [0,1].$$

IR reflects the direction of score changes under matched retrieval settings. An $\mathrm{IR}^m(i,j) = 0.7$ means that, switching from setting j to setting i, 70% of the **score changes** improve. Ties are excluded by construction: most metrics are binary, so unaffected queries would otherwise dominate the denominator and compress every comparison toward 0.5. IR thus reports direction among affected queries, not effect magnitude nor the share of the query set that benefits — improving one query and leaving ninety-nine unchanged also gives IR $= 1.00$ — and should not be read as an effect size. We report IR for each metric. The top table in Tab. 3 shows `GPT-4o` results; other agents are in the Appendix.

Because memory-type distributions vary in the top 15 pieces, some types (*e.g.*, clarifying) are scarce while others (*e.g.*, irrelevant) are common, leading to uneven sample sizes. To assess statistical significance, we collect $L^m(i,j) = \{\mathrm{diff}_q^m(i,j) \mid q \in \mathcal{Q}, \mathrm{diff}_q^m(i,j) \neq 0\}$ and calculate its mean with 95% confidence interval (ci_lo, ci_hi). The interval is Student-t on the sample mean, $\bar{x} \pm t_{0.975,\,n-1}\, s/\sqrt{n}$, with $n = |L^m(i,j)|$. Like IR it conditions on non-zero differences, so it gives the size of a change *given that* the score changed, not the average paired effect over all queries, which would be attenuated toward zero. Fig. 5 visualizes these results with blobbograms. Key findings are:

Significance of Clarifying Memory The top table in Tab. 3 shows that, among queries whose scores change, clarifying memory (C) improves them almost uniformly on both datasets, especially for Relevance and Informativeness, and Fig. 5 shows consistently positive means in the first row. We rest the claim on this directional stability across agents and datasets, not on magnitude: clarifying pieces are rare in the top 15, so most cells here rest on single-digit counts and the values of 1.00 summarize a handful of queries. At that strength, the pattern suggests lightweight disambiguation signals are high-leverage when retrieved at all — a hypothesis worth targeting, not an established effect size.

Enriching Memory Improves Informativeness Enriching memory (E) generally makes responses more informative, reflected in higher Completeness and Memory Coverage. Tab. 3 also shows a small, statistically non-significant drop in Internal Coherence (Fig. 5). Manual inspection suggests the judge penalizes verbosity and unfocused discussion: responses become richer but less organized.

Distracting Memory is Harmful The top table in

Tab. 3 shows that distracting memory (D) degrades performance across most metrics, most clearly on World Knowledge, Internal Coherence, and Constraint Awareness; Answer Accuracy and Topic Relevance are essentially unchanged on Long-MT-Bench+. This indicates that superficially similar but incorrect content can mislead the model.

Necessity of Answer Memory Relative to the non-answer bundle, answer memory remains essential. Without it, agents are more likely to hedge or decline, lowering Informativeness. This suggests `GPT-4o` is reluctant to fabricate answers even when some relevant context (C/E/D) is present.

We also observe that **irrelevant memory is correlated with reduced constraint awareness** while slightly increasing Memory Coverage and ROUGE-1 Recall. Overall, irrelevant memory does not help. This extends and challenges claims that random/irrelevant documents can improve answer-containing Accuracy on small LLMs (Cuconasu et al., 2024): large LLMs may behave differently, and irrelevant memory may divert attention from contextual constraints.

7.2 Comparison with Parametric Baseline

For the parametric-only baseline, we evaluate six settings: C, A+C, E, D, I, and the all-types bundle. The IR results for `GPT-4o` are in the bottom table of Tab. 3, with statistical analysis in Fig. 15. Key findings are:

Relevant Memory Helps Accuracy and Relevance The bottom table in Tab. 3 and Fig. 15 show that adding semantically relevant memory (answer, clarifying, enriching, or distracting) generally improves Answer Accuracy, Topic Relevance, and Constraint Relevance over parametric-only baseline. This suggests the necessity of past history when agents generating responses. Otherwise, the responses are seriously off-topic and inaccurate.

Clarifying Memory Remains Critical Among the settings, the A+C and all type bundle settings yield the largest average gains, highlighting the central role of answer-containing evidence and disambiguation information; for `GPT-4o`, these settings also correspond to higher Actionability. Adding clarifying memory (C) alone also brings significant improvement.

Irrelevant Memory Offers Little Improvement Irrelevant memory provides no clear improvement over parametric-only, yet is still frequently echoed in responses under Memory Coverage, suggesting the agent repeats irrelevant retrieved text without improving the answer.

RAG Can Reduce Fidelity and Coherence Across models, adding retrieved memory often lowers World Knowledge Accuracy and Internal Coherence relative to parametric memory alone. Manual analysis suggests additional context encourages more specific claims, which the LLM judge treats as higher factual-error risk, whereas parametric-only responses are shorter, less specific, and safer.

Non-significant Results Some effects are non-significant across agents and datasets, such as whether distracting memory reduces Internal Coherence relative to answer-only, or whether enriching memory affects Topic Relevance. These are small and variable, so stronger evidence is needed to claim reliability.

8 Conclusion and Future Directions

In this work, we examine how memory types affect conversational LLMs using a novel taxonomy, user-centric evaluation, and controlled comparisons. Experiments across agent models, context sizes, and retrievers confirm known patterns and reveal new findings in long-term conversational RAG. Our comparisons show that performance depends not only on retrieving relevant context, but on retrieving the right functional memory types.

These findings point to memory-type-aware retrieval and selection as a promising direction for IR. First, retrieval systems can benefit from memory-role awareness, enabling category-aware curation, ranking, and diversification rather than treating all retrieved context uniformly. Second, our results motivate collections that evaluate different grounding roles in RAG for memory and other corpora. Finally, it is important to develop and validate taxonomies as analytical tools: the most useful taxonomy is not necessarily the most granular, but the one that best explains retrieval behavior and optimize end-to-end outcomes.

Limitations

While our work provides many new findings, it also has several limitations that should be acknowledged.

LLM-as-a-Judge Evaluation Our experiments heavily reply on LLM judges for response scoring and memory type identification. Though we chose advanced models `GPT-5-thinking` and `GPT-o3` as the judges and carefully designed the rubric, LLM judge is known to occasionally produce inconsis-

tent or imperfect assessments. This limitation may introduce uncertainty into the reported results and our analysis.

Computational Cost Our experiments involve large-scale experiments with proprietary LLMs such as GPT models and Gemini. Reproducing these results requires substantial API usage, which may be costly and limit full replication by others.

Dataset Size and Noise The two datasets we used LongMemEval-m and Long-MT-Bench+ contain a few hundred test queries (see their statistics in Table 5). While labeling errors are expected to be rare, any noise in such a small test size can still introduce minor changes in the reported results. Moreover, some of our results are based on very few data points, which limits their statistical significance and should be interpreted with caution.

B Human Verification on Memory Type

We randomly sampled five queries from LongMemEval-m and five from Long-MT-Bench+ datasets. For each query, we randomly sampled three retrieved memory pieces among the top-15 pieces, whose types are predicted by `GPT-5-thinking` in our pipeline. In total, we have 30 memory pieces for human evaluation.

We designed a user study questionnaire, mirroring the same instruction and rubric used for the LLM judge, providing example tasks and detailed guidance. Each task is a multiple-choice question to classify the memory into one of the five types. We recruited five human participants from Prolific[1], a third-party data annotation platform, for the study. Our recruitment follows the below criteria:

[1]https://www.prolific.com/

	GPT-5	H1	H2	H3	H4	H5
GPT-5	–	0.417	0.618	0.512	0.578	0.532
H1	0.417	–	0.426	0.245	0.441	0.573
H2	0.618	0.426	–	0.514	0.615	0.524
H3	0.512	0.245	0.514	–	0.467	0.384
H4	0.578	0.441	0.615	0.467	–	0.538
H5	0.532	0.573	0.524	0.384	0.538	–
Average	**0.531**	**0.420**	**0.540**	**0.425**	**0.528**	**0.510**

Table 4: Pairwise kappa scores among `GPT-5-thinking` and human participants (H1-H5). `GPT-5`'s scores suggest it achieves human-level reliability for memory type classification.

- Native English speakers residing in English-speaking countries;
- Holding bachelor degree or above;
- High historical approval rate ($\geq 90\%$);
- Age between 18 to 80.

We rejected participants whose submissions are with unrealistically short completion times and re-recruit. The compensation is at Prolific's recommended rate.

Using the 30 annotated memory pieces, we calculate the pairwise Cohen's Kappa k as their inter-annotator agreement, where k is standard unweighted and $k = 0$ corresponds to chance-level agreement. The results are shown in Tab 4. All pairwise k scores between `GPT-5-thinking` and human annotators are well above chance, and `GPT-5-thinking` is comparable to human–human agreement.

C Evaluation with LLM-as-a-Judge

We carefully designed and iteratively refined the prompts used for LLM judges to ensure reliable and consistent evaluation. The design process followed an iterative "prompt–test–refine" loop. Starting from a minimal baseline, we tested responses to identify issues such as instruction drift or unstable reasoning. We then applied human-in-the-loop refinement to adjust phrasing and structure, validating each revision on representative cases until the prompts produce desired outputs on a set of human-validated test samples. We provide judgment cases for memory type classification and response evaluation in Table 10, 11, and 12.

We use `GPT-5-thinking` as the judge for determining memory types, setting its reasoning effort to medium, and max completion tokens to $8,000$. Figure 7 is the full prompt for it. For the response evaluation, we use `GPT-o3`, setting its reasoning effort to high, and max completion tokens to $10,000$.

	LongMemEval-m	Long-MT-Bench+
total # conversation	500	11
total # query	500	288
avg. # query/conversation	1	26.2
avg. # session/conversation	501.9	4.9
avg. # utterance/conversation	9.8	26.7
avg. # token/conversation	776, 472.4	14, 000.9

Table 5: Statistics of two long-term conversation datasets for experiment. Token counts are measured as space-separated chunks.

Figure 8 is the prompt for evaluating Accuracy; Figure 9 is for evaluating Relevance; Figure 10 is for evaluating Memory Coverage; Figure 11 is for evaluating Informativeness.

D Memory Relation Illustration

Figure 12 illustrates the semantic-neighborhood view that motivates our taxonomy of conversational memory. It shows how retrieved memory pieces can connect to the user query and to one another, and how different memory roles support or interfere with the agent's reasoning path.

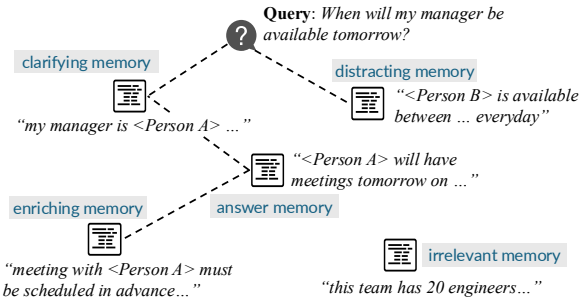

Figure 12: Illustration of relations between memory pieces and user query in agent's reasoning space. Links stand for semantic connection between two.

E Dataset Statistics

Table 5 summarizes the scale and structure of the two long-term conversational datasets used in our experiments. These statistics contextualize the retrieval and response-generation settings in the main experiments, including the number of conversations, queries, sessions, utterances, and average token counts.

F Memory Type Classification Details

We basically rely on prompt in Figure 7 to determine the memory type. For the experiment on Long-MT-Bench+, since it contains oracle labels for gold pieces, we directly classify the gold pieces as answer memory.

G General Performances on Contriever and BM25

Figure 13 and Figure 14 show the general performance over metrics of three LLMs using Contriever and BM25 as retrieval method.

H Comparative Experiments on Gemini and Llama

Table 6, 7, 8 and 9 show the improvement rate IR results of `Gemini-2.0-Flash` and `Llama-3.3-70B` on different comparative experiments. Figure 15 show the statistical results of $\mathrm{L}^m(i,j)$ of `GPT-4o-2024-08-06` on experiment comparing with parametric memory only. Figure 16, 17, 18, and 19 are statistical results of specific model and comparison setting.

user: You are a quality rater evaluating the relevance of a memory piece to a user's query. The memory piece is from the user's conversation with a chat assistant. Your task is to assign an integer score on a scale from 0 to 4 based on the following criteria:

Scoring rubric (check in order 4→3→2→1→0):
4 - Answer: the memory piece clearly answers the query and itself contains the answer or one of the answers for the question.
3 - Clarifying: the memory piece is necessary to resolve the identity of the asked-for entity/event (e.g., coreference, alias, where/which/company disambiguation) so that an answer stated elsewhere can be correctly applied. Without this piece, you cannot derive a correct or confident answer from the remaining information.
2 - Enriching: the memory piece refers to the same specific entity/event (or uniquely narrows to it) and adds useful ancillary detail (e.g., who/where/what/when) that would make the final answer more informative or helpful, even though it does not provide the asked-for attribute. Domain context that is clearly connected to the query also counts as Helpful.
1 - Distracting: the memory piece seems to reveal the answer but is actually misleading.
0 - Irrelevant: the memory piece has no meaningful semantic connection to the user's query domain.

Now I will provide you with a user's query, one memory piece, and other pieces that can be helpful for you to judge. Your task is to assign a relevance score for this memory piece, following the rubric above.

Note: The score should reflect the memory piece itself. The other pieces are provided only to help you understand the memory piece better.

User's Query:
{*user query*}

Memory Piece:
{*memory piece*}

Other Pieces:
{*other memory pieces*}

Your Score:

Figure 7: Prompt used by the LLM judge to classify retrieved memory pieces.

user: You are an objective and fair evaluator. You are provided with a user's query to a chatbot, the chatbot's response, and the gold response. Your task is to judge the accuracy of the chatbot's response based on three aspects:

1. World knowledge accuracy - How accurate are the factual statements in the response with respect to general facts and world knowledge. A response that does not mention world knowledge is not considered inaccurate.
2. Answer accuracy - How accurate is the response with respect to the answer provided in the gold response.
3. Internal consistency - How logically consistent is the response internally.

You should give **binary scores** for each aspect where 1 means accurate or consistent and 0 means not, and the explanation for the score.

###User's query###
{*question*}

###Chatbot's response###
{*agent response*}

###Gold answer###
{*gold answer*}

You should output only three lines. The first line is the score and explanation for World knowledge accuracy, the second line is the score and explanation for Contextual accuracy, and the third line is the score and explanation for Internal consistency. Each line's format should be 'Score: <score>; Explanation: <explanation>'. No index is needed. Now tell me your scores:

Figure 8: Prompt for LLM judge to determine the Accuracy of responses.

user: You are an objective and fair evaluator. You are provided with a user's query to a chatbot, the user's intent behind the query, the chatbot's response to the query, and the prior conversation history. Your task is to judge the relevance of the chatbot's response based on two aspects:

1. Topical relevance - How directly does the response address the query?
2. Constraint relevance - How well does the response meet all implicit or explicit constraints and conditions stated or implied by the user's intent and prior conversation?

You should give **binary scores** for each aspect where 1 means relevant and 0 means not relevant, and the explanation for the score.

###User's query###
{*question*}

###User's intent### (optional)
{*intent*}

###Chatbot's response###
{*agent response*}

###Prior conversation history###
{*context*}

You should output only two lines. The first line is the score and explanation for Topical relevance, the second line is the score and explanation for Constraint relevance. Each line's format should be 'Score: <score>; Explanation: <explanation>'. No index is needed. Now tell me your scores:

Figure 9: Prompt for LLM judge to determine the Relevance of responses.

user: You are a helpful and fair judge. I will provide you with:

1. A user's query to a chatbot;
2. The user's intent behind the query;
3. The chatbot's response;
4. The prior conversation history between the user and the chatbot.

Your task is to identify all pieces of information in the chatbot's response that are recalled from the prior conversation history but were *not* restated in the current user query.
- Count each such recalled item.
- Consider paraphrases or indirect references as recalls.
- Ignore generic pleasantries or facts that never appeared in the history.

###Prior conversation history###
{*prior conversation history*}

###User's query###
{*query*}

###User's intent###
{*intent*}

###Chatbot's response###
{*agent response*}

You should output two lines. The first line is the count, the second line is explanation listing the recalled items and in which piece they are recalled from. Now tell me your score and explanation:

Figure 10: Prompt for LLM judge to determine the Memory Coverage of responses.

user: You are an objective and fair evaluator. You are provided with a user's query to a chatbot, the user's intent behind the query, the chatbot's response to the query, and the prior conversation history. Your task is to judge the informativeness of the chatbot's response based on two aspects:

1. Completeness - How well does the response cover all sub-questions or necessary information relevant to the query and intent?
2. Actionability - How well does the response provide concrete details or clear guidance?

Particularly, for aspect Completeness, this is a more detailed scale:
Score 0 (Absent): No sign the response noticed the user's motivations, constraints, or intents. Response is completely generic or contradicts the context.
Score 1 (Partial): The response realizes some of the user's intent and motivations and mentions at least one contextual element. But it does not fully address the user's intent.
Score 2 (Comprehensive): The response fully addresses the user's intent and motivations, providing a thorough and contextually relevant answer.

For aspect Actionability, this is a more detailed scale:
Score 0 (Not actionable): The response is vague, generic, or purely descriptive. Lacks concrete items.
Score 1 (Actionable): The response provides a clear sequence of actions or names specific items.

You should give an integer score from 0 to 2 for aspect Completeness and binary score for aspect Actionability. You should also provide explanation for the score.

###User's query###
{*question*}

###User's intent###
{*intent*}

###Chatbot's response###
{*agent response*}

###Prior conversation history###
{*context*}

You should output only two lines. The first line is the score and explanation for Completeness, the second line is the score and explanation for Actionability. Each line's format should be 'Score: <score>; Explanation: <explanation>'. No index is needed. Now tell me your scores:

Figure 11: Prompt for LLM judge to determine the Informativeness of response.

Instruction: ... **User query**: I'm planning to visit Bandung again and I was wondering if you could remind me of the name of that restaurant in Cihampelas Walk that serves a great Nasi Goreng? **Gold answer**: Miss Bee Providore	
Memory piece: [User]: I think I'll start with Cihampelas Walk to check out the denim street. Can you recommend any good restaurants or cafes in the area? [Assistant]: Sure! There are many good restaurants and cafes in the Cihampelas Walk area. Here are a few options: 1. Miss Bee Providore: This restaurant serves a mix of western and Indonesian cuisine and has a cozy and stylish interior. 2. Bakery & Co: A great place to relax and enjoy a cup of coffee and a pastry. 3. Raa Cha Suki & BBQ: If you're looking for something spicy and delicious, this Thai restaurant is a great option. 4. Sumoboo: This Japanese shaved ice dessert place features a wide variety of flavors, toppings, and combinations. 5. Holycow! Steakhouse by Chef Afit: This steakhouse has a warm atmosphere and serves high-quality steaks at reasonable prices. These are just a few of the many options you can explore in the area. Make sure to do some research and read reviews before making a final decision. Enjoy your visit!	Enriching
Memory piece: [User]: I'm definitely going to try out Miss Bee Providore for some delicious food. Do they have any signature dishes I should try? [Assistant]: Miss Bee Providore offers a variety of delicious dishes, both Western and Indonesian cuisine. Here are a few signature dishes you should definitely try: 1. Miss Bee's Nasi Goreng: Their take on the classic Indonesian fried rice dish is a must-try! It's served with a side of prawn crackers and topped with a fried egg. 2. Yoghurt Granola Bowl: This is a great option if you're looking for something healthy and refreshing. It's made with homemade granola, fresh fruit, and yogurt. 3. Fried Chicken Burger: This signature burger features a juicy chicken patty, crispy bacon, lettuce, tomato, and a special aioli sauce. It's served with a side of fries. 4. Beef Rendang: If you're looking for a traditional Indonesian dish, try their version of beef rendang. It's a slow-cooked beef dish in a flavorful, spicy coconut milk sauce. 5. Chocolate Brownie: Finish off your meal with a sweet treat - Miss Bee's chocolate brownie is a local favorite and is served warm with vanilla ice cream and chocolate sauce. These are just a few of the many delicious options, so feel free to explore their menu and try something new!	Answer
Memory piece: [User]: Yum, all of those dishes sound amazing! I'm definitely going to try the Miss Bee's Nasi Goreng and finish it off with the chocolate brownie. [Assistant]: Enjoy your meal at Miss Bee Providore and have a great time shopping at Cihampelas Walk!	Answer
Memory piece: [User]: I'm so excited to explore more of Bandung! Do you have any recommendations for other fun activities to do in the city? [Assistant]: Sure, Bandung has plenty of fun activities to offer! Here are a few recommendations: 1. Visit a volcano: Bandung is located near several active and dormant volcanoes, including Tangkuban Perahu and Kawah Putih. You can take a day trip to visit these fascinating natural wonders. 2. Explore the tea plantations: Bandung is also known for its tea plantations, such as the Malabar Tea Plantation and the Puncak Tea Garden. You can take a tour of these plantations, enjoy a cup of tea, and enjoy the beautiful scenery. 3. Visit the Trans Studio Bandung: This is one of Indonesia's largest indoor theme parks, with rides, attractions, and entertainment for all ages. 4. Go shopping at the Paris Van Java mall: This mall is known for its luxurious and trendy boutiques, restaurants, and cafes, as well as its modern architecture. 5. Take a cooking class: Bandung is famous for its cuisine, and you can take a cooking class to learn how to make traditional Indonesian dishes such as nasi goreng, sate, and rendang. 6. Visit the Saung Angklung Udjo: This is a cultural center that features traditional music and dance performances with the angklung, a traditional Indonesian instrument made from bamboo. These are just a few of the many activities that you can do in Bandung. Make sure to do some research and plan your trip accordingly, depending on your interests and preferences. Have fun exploring!	Irrelevant
Memory piece: [User]: What are some unique shopping experiences to be had in Bandung? [Assistant]: As an AI language model, I don't have personal experiences, but based on research, here are some unique shopping experiences to be had in Bandung: 1. Factory outlets: Bandung is well known for being a factory outlet (FO) paradise. You can find many factory outlets selling local and international brands at discounted prices. 2. Pasar Baru: This is Bandung's oldest and largest traditional market, selling everything from clothing and accessories to food and home goods. It's a great place to experience the hustle and bustle of a traditional market. 3. Braga Street: This historic street is lined with old colonial buildings that have been turned into trendy cafes, restaurants, and boutique shops. It's a great place to find unique souvenirs and gifts. 4. Cihampelas Walk: Also known as Ciwalk, this shopping center is famous for its denim street, where you can find a wide range of denim products, from jeans to jackets. 5. Dago Street: This street is home to many boutiques, art galleries, and cafes, making it a popular spot for young and trendy shoppers. 6. Rumah Mode: This popular factory outlet is famous for its Balinese-inspired architecture and stylish clothing and accessories. 7. Kartika Sari: This bakery is famous for its chocolate brownies and other Indonesian snacks, making it a great place to pick up some tasty treats to take home.	Irrelevant

Table 10: A judgment case for `GPT-5-reasoning` to determine the memory type. Left column is each memory piece and right column is the determined type. See the full prompt in Figure 7.

Instruction: ... **User query**: I'm planning to revisit Orlando. I was wondering if you could remind me of that unique dessert shop with the giant milkshakes we talked about last time? **Gold answer**: The Sugar Factory at Icon Park.	
Memory piece: [User]: Wow, these dining options sound amazing! Do you have any recommendations for a fun dessert spot that my family can check out after dinner? [Assistant]: Absolutely! Here are some fun dessert spots that your family might enjoy after dinner: 1. The Sugar Factory - A sweet shop located at Icon Park that offers an enormous menu of sweet treats, including specialty drinks and giant milkshakes. 2. Wondermade - A gourmet marshmallow shop located in Sanford, just north of Orlando, that offers unique flavored marshmallows and s'mores kits. 3. Gideon's Bakehouse - A bakery located at Disney Springs that offers delicious cookies, cakes, and other baked treats. 4. Kelly's Homemade Ice Cream - A small-batch ice cream shop located in Orlando that offers unique flavors like Banana Cream Pie and Strawberry Jalapeno. 5. Voodoo Doughnut - A doughnut shop located at Universal CityWalk that offers imaginative and creative doughnuts with unique toppings and flavors. 6. The Glass Knife - A dessert and coffee shop located in Winter Park that serves up beautiful cakes, pastries, and other sweet treats in a stylish setting. 7. Lickety Splitz - A dessert shop located in Orlando that serves up handmade frozen yogurt, sorbet, and ice cream. 8. Better Than Sex - A dessert shop located in the Ivanhoe Village neighborhood of Orlando that specializes in decadent desserts like chocolate fondue and cheesecake. 9. The Greenery Creamery - An ice cream shop located in the Thornton Park neighborhood of Orlando that offers all-natural ice cream flavors like lavender, honeycomb, and matcha. 10. The Pastry Studio - A bakery located in Daytona Beach, just east of Orlando, that offers beautiful and delicious custom cakes and other desserts.	Answer
Memory piece: [User]: Can you recommend any places to eat in Orlando that are family-friendly? [Assistant]: Certainly! Orlando has many family-friendly dining options. Here are some recommendations: 1. Toothsome Chocolate Emporium & Savory Feast Kitchen - A restaurant located at Universal CityWalk that offers a unique dining experience with imaginative dishes and delicious desserts. 2. The Cheesecake Factory - A casual dining restaurant located in The Mall at Millenia that offers a diverse menu that includes everything from burgers to salads and, of course, an extensive selection of cheesecakes. 3. Shake Shack - A fast-food restaurant located in Winter Park that offers burgers, hot dogs, and shakes. 4. Hash House A Go Go - A restaurant located on International Drive that serves up ẗwisted farm foodẗhat is both delicious and visually stunning. 5. Bahama Breeze - A Caribbean-themed restaurant located on International Drive that has a family-friendly atmosphere and offers a menu of tropical dishes and drinks. 6. Blaze Pizza - A fast-casual restaurant located in Disney Springs that offers build-your-own Neapolitan pizzas and salads. 7. T-Rex Cafe - A dinosaur-themed restaurant located in Disney Springs that offers a unique prehistoric dining experience for families. 8. Uncle Julio's - A Tex-Mex restaurant located in Orlando and Kissimmee that offers a menu of authentic Mexican dishes and delicious drinks. 9. Pio Pio - A restaurant located in the Dr. Phillips neighborhood that serves up delicious Peruvian dishes. 10. Sweet Tomatoes - A buffet restaurant chain located throughout Orlando that offers a variety of healthy and delicious salads, soups, and baked goods.	Distracting
Memory piece: [User]: Wow, those tips are great! I'm excited to take on this dessert adventure with my family. Do you have any more recommendations for other fun and unique things to do in Orlando? [Assistant]: Yes, there are plenty of other fun and unique things to do in Orlando! Here are some more recommendations: 1. Escape Rooms - Orlando has several escape rooms that offer immersive and challenging puzzle-solving experiences. 2. Cirque du Soleil - Watch a mesmerizing acrobatic and theatrical performance by the world-famous Cirque du Soleil, which often performs in Orlando. 3. Airboat Tours - Take an airboat tour through the Florida Everglades and see alligators, birds, and other wildlife up close. 4. The Orlando Eye - Take a ride on the 400-foot observation wheel and enjoy panoramic views of Orlando. 5. Orlando Science Center - Visit the Orlando Science Center, which has interactive exhibits and educational programs that entertain visitors of all ages. 6. The Orlando Museum of Art - See beautiful artwork from various periods and artists at the Orlando Museum of Art. 7. Amusement Parks - Orlando has many amusement parks besides Disney and Universal, such as Fun Spot America, ICON Park, and SeaWorld. 8. The Charles Hosmer Morse Museum of American Art - See beautiful works of art by Louis Comfort Tiffany, including iconic stained glass lamps. 9. Dr. Phillips Center for the Performing Arts - Enjoy a variety of dance, music and theater performances at this beautiful venue. 10. The Orlando Shakespeare Theater - Experience the theater with classic and contemporary works in a unique setting.	Irrelevant
Memory piece: [User]: I don't really trust buffet restaurants. Can you suggest any other family-friendly dining options in Orlando? [Assistant]: Sure, here are some additional family-friendly dining options in Orlando: 1. The Cowfish Sushi Burger Bar - A unique restaurant located at Universal CityWalk that specializes in creative sushi and gourmet burgers. 2. BJ's Restaurant and Brewhouse - A casual dining restaurant located in Orlando that offers a diverse menu of American style dishes and beers brewed on site. 3. Mediterranean Blue - A Greek restaurant located in Orlando that serves up classic Greek dishes like souvlaki and gyros. 4. Black Bean Deli - A casual Cuban restaurant located in Orlando that serves up delicious Cuban sandwiches, plantains, and more. 5. Toothsome Chocolate Emporium & Savory Feast Kitchen - As mentioned before, this is a great family-friendly option for lunch or dinner. 6. Dandelion Communitea Cafe - A vegetarian and vegan restaurant located in Orlando that serves up fresh and healthy salads, sandwiches, and smoothies. 7. The Whiskey - A restaurant located in Orlando that has a family-friendly outdoor seating area and offers a menu of American dishes with a Southern twist. 8. Blaze Pizza - Another option mentioned before, this fast-casual pizzeria is great for a quick meal. 9. Kobe Japanese Steakhouse - A Japanese hibachi grill restaurant located in Orlando that offers an entertaining dining experience and delicious seafood, meat, and vegetable dishes. 10. Soco Restaurant - A restaurant located in the Thornton Park neighborhood of Orlando that offers Southern-style dishes with a modern twist. They also have a great weekend brunch.	Distracting

Relational Grounding Failures in Zero-Shot Cross-Lingual Dialogue Summarization with Small Language Models

Yunwoo Lee*, **Ziwa Li***, **Jennifer Huang***
Department of Linguistics, University of Washington, Seattle, WA, USA
{yunu919, lizhihua, jjnhuang}@uw.edu

Abstract

We diagnose relational grounding failures in zero-shot English-to-Chinese dialogue summarization with small language models (SLMs). We develop and apply a Dialogue-Semantic Grounding Error Taxonomy to evaluate three open-weight SLMs alongside a supervised mBART baseline. The taxonomy captures errors in entities, events, speaker roles, circumstances, modality, discourse outcomes, omissions, and language or format issues. Our analysis shows that SLM hallucinations often involve relation-sensitive distortions of dialogue-relevant content: models may preserve source-relevant participants, events, or circumstances while altering who did what, under what conditions, or with what outcome. These findings position the taxonomy as a diagnostic evaluation framework for dialogue summarization, revealing relation-sensitive faithfulness failures that reference-based metrics may obscure.

1 Introduction

Small language models (SLMs) are attractive for resource-constrained, industrial, and privacy-sensitive summarization because they are efficient and locally deployable (Abrougui et al., 2026; Xu et al., 2025; Philippy et al., 2025). In cross-lingual dialogue summarization, however, it remains unclear whether SLMs can generate target-language summaries that are both fluent and faithfully grounded in the source dialogue. We define faithfulness as source support for the summary's entities, events, speaker roles, circumstances, modality, and discourse outcomes.

We study zero-shot English-to-Chinese dialogue summarization, where models must identify salient dialogue content in English and express it in Chinese (Wang et al., 2022b, 2023a). Prior work shows that cross-lingual summarization is sensitive to dataset construction, translation artifacts, and evaluation design (Bhattacharjee et al., 2023; Wang et al., 2023b), while reference-based automatic metrics may obscure how outputs fail to preserve dialogue meaning.

Building on prior factual-error taxonomies for dialogue summarization (Tang et al., 2022; Wang et al., 2022a), we develop and apply a Dialogue-Semantic Grounding Error Taxonomy for source-grounded diagnosis of zero-shot English-to-Chinese summaries. The taxonomy organizes hallucination and faithfulness failures around entities, events, participant roles, circumstances, modality, discourse outcomes, omissions, and cross-lingual output-form issues. Using this taxonomy alongside ROUGE, BERTScore, and OmniScore, we compare three open-weight SLMs with a supervised mBART baseline and show that SLM hallucinations often involve relation-sensitive distortions: models may preserve source-relevant participants, events, or circumstances while misrepresenting who did what, under what conditions, or with what outcome.[1]

Label	Core annotation trigger
H-ENT	Wrong or unsupported person, entity, name, or object.
H-EVT	Added, changed, or fabricated event/action.
H-ROLE	Correct event but wrong actor, recipient, speaker, or role.
H-CIRC	Wrong time, place, number, quantity, condition, or schedule.
H-MOD	Changed negation, uncertainty, intention, obligation, or modal force.
H-DISC	Misstated cause-effect, contrast, order, decision, agreement, conclusion, or outcome.
OMIT	Missing salient event, participant, reason, decision, or outcome.
LANG	English leakage, malformed Chinese, repetition, translation/format issue, or non-summary output.
NO-ERROR	No grounding, omission, language, format, or instruction-following error.

Table 1: Dialogue-Semantic Grounding Error Taxonomy. H-* labels indicate hallucination; OMIT and LANG capture missing content and output-form failures.

*Equal contribution.

2 Experimental Setup

2.1 Data

We evaluate models on XSAMSum, a cross-lingual dialogue summarization dataset from the ClidSum benchmark (Wang et al., 2022b), which extends the English SAMSum corpus (Gliwa et al., 2019) with professional summaries in multiple target languages. We focus on English-to-Chinese summarization, where models generate Chinese summaries from English messenger-style dialogues. For diagnostic evaluation, we use a fixed random sample of 100 test examples from the XSAMSum test split selected with seed 42. Dataset and evaluation-subset statistics are reported in Appendix A.1.

2.2 Models

We compare a supervised mBART-large-50 baseline (Liu et al., 2020; Tang et al., 2021) with three open-weight instruction-tuned SLMs under 10B parameters: Aya Expanse 8B (Dang et al., 2024), Gemma 4 E4B (Gemma Team, 2026), and Qwen 3.5 9B (Qwen Team, 2026). We selected these models to represent contemporary open-weight, instruction-tuned SLMs under 10B parameters that support multilingual text generation. The mBART baseline is fine-tuned on the XSAMSum training data, while the SLMs are evaluated in a zero-shot direct setting. Given an English dialogue, each SLM is prompted to generate a concise Simplified Chinese summary. The same prompt is used for all SLMs. Full model configurations and the shared prompt template are provided in Appendices A.2 and A.3, respectively.

2.3 Evaluation

We evaluate model outputs using reference-based ROUGE and BERTScore, the learned reference-based metric OmniScore, and dialogue-semantic grounding error analysis.

Dialogue-semantic grounding error analysis. To diagnose failures not captured by aggregate scores, we develop and apply the Dialogue-Semantic Grounding Error Taxonomy in Table 1. The taxonomy was induced from manual inspection of preliminary SLM summaries, where many errors preserved dialogue-relevant content but altered relations among speakers, events, circumstances, modality, or outcomes. We relate the categories to prior factuality typologies for abstractive and dialogue summarization (Pagnoni et al., 2021; Tang et al., 2022; Wang et al., 2022a), but organize them around the dialogue-semantic component affected in a cross-lingual source-to-summary setting. In particular, the taxonomy separates entity, event, and participant-role errors, captures speaker-role misattribution through H-ROLE, discourse-relation distortions through H-DISC, omissions through OMIT, and target-language or output-form failures through LANG; Appendix A.8 provides an approximate comparison with prior taxonomies. These choices are also motivated by work on speaker-action structure, discourse relations, coreference, and context carryover (Chen and Yang, 2021; Aghajanyan et al., 2020). Summaries may receive multiple labels for independent error types.

Reference-based metrics. We compute ROUGE (Lin, 2004) and BERTScore (Zhang et al., 2020) against the Chinese reference summaries. ROUGE measures lexical overlap between generated and reference summaries, while BERTScore provides a contextual embedding-based estimate of semantic similarity.

Learned-metric evaluation. We additionally use the reference-based OmniScore (Alam et al., 2026) as a learned metric for summary quality and faithfulness. OmniScore evaluates each generated summary relative to the Chinese reference along four dimensions: informativeness, clarity, plausibility, and faithfulness.

Model	No err.	Halluc.	Omit	Lang.
Aya Expanse 8B	0.38	0.43	0.07	0.17
Gemma 4 E4B	**0.63**	**0.29**	0.08	**0.00**
Qwen 3.5 9B	0.58	0.39	**0.03**	**0.00**
mBART-large	0.20	0.61	0.48	0.11

Table 2: Aggregated grounding-error rates. Values are proportions of the 100 annotated outputs. *Halluc.* includes any H-* label; error categories may overlap. Outputs with at least one error were 62 for Aya, 37 for Gemma, 42 for Qwen, and 80 for mBART.

3 Results

3.1 SLMs Exhibit Distinct Dialogue-Semantic Failures

Table 2 summarizes the aggregated error rates. The SLMs produced substantially more error-free summaries and far fewer omissions than mBART, but they still exhibited many source-grounded hallucination errors. Overall, nearly half of the SLM outputs (141/300; 47%) received at least one error label. Because labels may co-occur, category rates should be interpreted as overlapping diagnostic sig-

Model	R-1	R-2	R-L	BERTScore	Info.	Clar.	Plaus.	Faith.
Aya Expanse 8B	26.53	7.89	20.84	70.11	**3.26**	4.02	4.04	**3.17**
Gemma 4 E4B	30.27	8.32	23.68	70.85	3.17	3.95	4.00	2.96
Qwen 3.5 9B	28.35	7.62	22.42	70.47	3.22	3.88	3.97	3.00
mBART-large	**41.95**	**18.10**	**34.85**	**77.64**	2.97	**4.24**	**4.17**	2.92

Table 3: Mean automatic-evaluation scores. OmniScore uses its original scale; bold marks the best score for each metric.

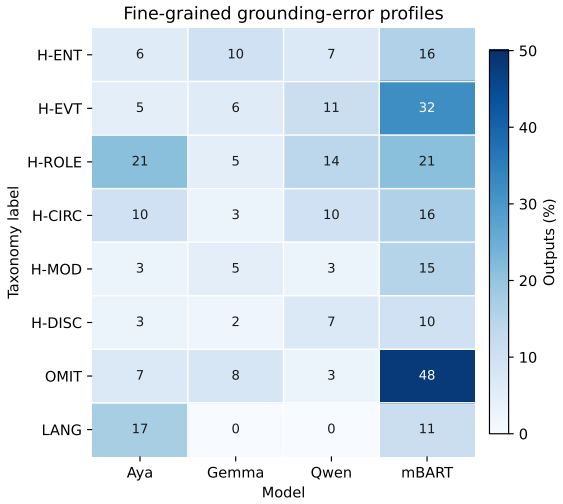

Figure 1: Fine-grained taxonomy-label rates for the three SLMs and the mBART baseline. Each cell reports the percentage of a model's 100 outputs assigned the corresponding error label. Labels may overlap.

nals rather than mutually exclusive classes.

Model-specific failure profiles. Aya had the lowest NO-ERROR rate among the SLMs, with 43 hallucinated outputs, 7 omissions, and 17 language or format errors. Speaker-role hallucination was its dominant error type, appearing in 21 outputs. Most of Aya's LANG errors involved reproducing translated speaker turns instead of generating a summary. Gemma produced 63 error-free outputs and 29 outputs with hallucinations. Its most frequent error involved entities, and only 2 outputs received multiple labels. Qwen produced 58 error-free outputs and 39 outputs with hallucinations. Its errors were distributed across speaker roles, events, circumstances, and discourse relations. Qwen also produced the fewest omissions but the largest number of multi-label outputs among the three SLMs.

Taxonomy-specific patterns. Figure 1 reports the fine-grained error label distribution for all four systems. Among the SLMs, speaker-role hallucination was the most frequent error, appearing in 40 outputs. These errors changed who performed an action, made a statement, offered assistance, or received an action. Entity and circumstantial hallucinations each appeared in 23 SLM outputs, while event hallucination appeared in 22 outputs. In contrast, mBART showed a different profile, with many omissions and event hallucinations in addition to role errors. Discourse and modality errors were less frequent for the SLMs, appearing in 12 and 11 outputs, respectively, but they also appeared in the mBART baseline.

3.2 Automatic Evaluation

Table 3 presents the reference-based evaluation results. The supervised mBART baseline achieved the highest ROUGE and BERTScore values, while Gemma performed best among the zero-shot SLMs, with only small differences across the three SLMs.

The reference-based OmniScore dimensions showed a less uniform pattern. mBART received the highest clarity and plausibility scores but the lowest faithfulness score, whereas Aya obtained the highest faithfulness score among all systems.

Distributional statistics for all automatic metrics are provided in Appendix A.6.

4 Discussion

4.1 Relation-Sensitive Grounding Failures

The dominant SLM failures were not primarily omissions or output-form failures. As Table 2 shows, omission rates for the SLMs are only 0.03–0.08 and language/format error rates are 0.00–0.17, while hallucination rates are higher at 0.29–0.43. Figure 1 shows that speaker-role hallucination was the most frequent hallucination type, appearing in 40 SLM outputs, while entity, event, and circumstantial errors appeared in 23, 22, and 23 outputs, respectively. These patterns indicate that relation-sensitive distortions are an important failure mode in this setting, particularly for speaker attribution, while the broader taxonomy categories may also include value substitutions or unsupported inventions.

Speaker-role hallucination illustrates this pattern: a summary may mention relevant participants or

events but reverse who performed an action, made a request, offered assistance, or received it. Such errors are especially consequential in dialogue summarization, where requests, decisions, offers, and obligations depend on accurate speaker attribution across turns. Other frequent errors altered participants, events, pragmatic meaning, or contextual details, keeping summaries dialogue-related but structurally misaligned.

Modality and discourse errors were less frequent but still important because they changed whether an event was certain, intended, negated, agreed upon, or concluded. Faithful cross-lingual dialogue summarization therefore requires tracking not only entities and events, but also participant roles, epistemic status, and conversational outcomes across turns.

4.2 Model Profiles Suggest Different Failure Modes

The model-level profiles suggest that faithfulness failures arise through different pathways. Aya's errors were concentrated in speaker-role confusion and output-form problems, including cases where it reproduced translated speaker turns rather than generating a summary. This indicates that multilingual generation ability does not necessarily guarantee task control or successful compression into the required summary format.

Gemma and Qwen showed different SLM profiles. Gemma produced the most error-free outputs, with remaining errors that were relatively localized, often involving entities, omissions, events, or modality. Qwen produced fewer omissions but more distributed and multi-label errors, suggesting that a single misinterpretation can propagate across roles, events, circumstances, and discourse relations. These differences show why a single hallucination rate is insufficient for characterizing SLM reliability.

The mBART baseline exhibited a distinct failure mode. Despite being supervised, it showed many omissions and event hallucinations. This contrast reinforces the value of taxonomy-based analysis: it reveals not only whether a system fails, but how its failures are distributed across dialogue-semantic components.

4.3 Reference-Based Metrics Are Auxiliary to Taxonomy-Based Diagnosis

This contrast is clearest for the mBART baseline. mBART achieved the highest ROUGE-1, ROUGE-2, ROUGE-L, and BERTScore values, as well as the highest OmniScore clarity and plausibility scores. Under reference-based automatic evaluation alone, it would appear to be the strongest system. However, the manual taxonomy gives the opposite picture for source-grounded faithfulness: mBART had the lowest NO-ERROR rate, the highest hallucination rate, and by far the highest omission rate. This shows that high reference similarity and fluent output form do not guarantee faithful representation of the source dialogue.

A similar divergence appears within the three zero-shot SLMs, which share the same prompt and inference setup. Aya received the highest OmniScore faithfulness score (3.17) among all systems, while also showing the lowest NO-ERROR rate (0.38) and the highest hallucination rate (0.43) among the SLMs. This within-condition discrepancy further suggests that reference-based faithfulness scores need not align with source-grounded error diagnosis.

The discrepancy reflects a limitation of reference-based evaluation. An output can score well against a reference while omitting salient events, decisions, participant relations, or discourse outcomes. Conversely, an output may include source-supported details not selected by the reference, lowering reference similarity without necessarily indicating hallucination. Reference summaries are useful quality anchors, but they cannot directly determine whether a generated summary preserves the dialogue situation. Taxonomy-based diagnosis fills this gap by identifying which part of the dialogue meaning was altered, omitted, or unrealized.

5 Conclusion

We presented a taxonomy-based diagnosis of faithfulness failures in zero-shot English-to-Chinese dialogue summarization with SLMs. Their errors included prominent relation-sensitive distortions involving speaker roles, events, circumstances, modality, and discourse outcomes. These findings support source-grounded taxonomy analysis as the primary diagnostic, with reference-based metrics serving as complementary indicators of summary quality.

6 Limitations

Our findings have several limitations. We evaluate a fixed 100-dialogue XSAMSum sample in

one English-to-Chinese direction, using one direct prompt and three SLMs under 10B parameters, so the observed label distributions may not generalize across domains, languages, prompts, decoding settings, or model families. Because the taxonomy was induced from preliminary outputs and model-proposed candidate labels were reviewed by three annotators, it may reflect system-specific failure patterns and remain susceptible to anchoring and judgment-sensitive category overlap. Cross-system comparisons are also not controlled performance rankings, since mBART is supervised whereas the SLMs are zero-shot with different decoding configurations. Finally, the use of a single Chinese reference and no English monolingual control limits our ability to separate translation from summarization errors. The taxonomy identifies the affected dialogue-semantic component but does not distinguish rebinding, value falsification, and unanchored invention; accordingly, we do not interpret every H-* label as a relational error in the strict sense.

A Appendix

A.1 Data

XSAMSum pairs English messenger-style dialogues with abstractive English summaries and professional Chinese and German translations (Wang et al., 2022b). We use the English dialogues as inputs and the Chinese summaries as references. Table 4 reports the split-level statistics together with the 100-example evaluation subset. The subset is slightly shorter than the full test split in dialogue and reference length, while retaining similar average numbers of turns and speakers.

Metric	Train	Dev	Test	Eval. subset
Dialogues	14,732	818	819	100
Turns	11.17	10.83	11.25	10.87
Speakers	2.39	2.39	2.36	2.43
Dialogue words	93.79	91.64	95.51	88.21
En. summary words	20.32	20.28	20.02	18.62
Zh. summary chars	35.88	35.99	35.05	33.18

Table 4: XSAMSum statistics. Except for the number of dialogues, values are averages. Dialogue and English-summary lengths use whitespace-delimited words; Chinese-summary length counts non-whitespace characters. The evaluation subset is sampled from the test split with seed 42.

A.2 Model Details

mBART fine-tuning. Our supervised baseline is initialized from `facebook/mbart-large-50-many-to-many-mmt` (Liu et al., 2020; Tang et al., 2021) and fine-tuned to map English XSAMSum dialogues directly to Chinese reference summaries. We use Hugging Face's `Seq2SeqTrainer` on a Google Colab A100 40GB GPU, optimizing with Adafactor for four epochs with mixed precision and gradient checkpointing. The best checkpoint is selected by validation `ROUGE-Lsum`. Source and target tokenizer languages are set to `en_XX` and `zh_CN`, and generation is forced to start with the Chinese language token. Table 5 summarizes the main settings.

Setting	Value
Maximum input length	1024 tokens
Maximum target length	128 tokens
Epochs	4
Learning rate	2×10^{-5}
Per-device batch size	4
Gradient accumulation	6 steps
Effective batch size	24
Optimizer	Adafactor
Precision	Mixed precision
Checkpoint selection	Validation `ROUGE-Lsum`
Decoding	Beam search with 4 beams
Source / target language	`en_XX` / `zh_CN`
Hardware	NVIDIA A100 40GB

Table 5: mBART fine-tuning and decoding configuration.

SLM direct inference. We evaluate the three instruction-tuned SLMs in the same zero-shot direct setting. Each model receives the English dialogue and generates a Simplified Chinese summary without demonstrations, intermediate translation, or task-specific fine-tuning. The models are run locally through Ollama with a temperature of 0.2, an 8,192-token context window, a maximum of 1,024 generated tokens, and explicit reasoning output disabled.

- **Qwen 3.5 9B.** We use `qwen3.5:9b`, an instruction-tuned Qwen-family model selected for its multilingual understanding and text-generation capabilities (Qwen Team, 2026).
- **Gemma 4 E4B.** We use `gemma4:e4b`, an efficient instruction-tuned model from the Gemma family, as a lightweight multilingual baseline (Gemma Team, 2026).
- **Aya Expanse 8B.** We use `aya-expanse:8b`, a multilingual instruction-tuned model designed to support generation across 23 languages (Dang et al., 2024).

A.3 Direct Prompt

All three SLMs receive the prompt template in Figure 2, with `{dialogue}` replaced by the speaker-prefixed English input.

```
You are an expert English-Chinese bilingual
speaker. Given an English dialogue, please
write a concise Simplified Chinese summary.
Output only the summary, without titles or
markdown.

English dialogue:
{dialogue}

Chinese summary:
```

Figure 2: Direct prompt template used for zero-shot SLM inference.

A.4 Annotation Workflow

For the dialogue-semantic grounding analysis, we used a model-assisted first-pass workflow. An annotation model proposed candidate labels for each generated summary, but was not used as an evaluated summarization system or final annotator. Three annotators then reviewed each candidate label against the English source dialogue, Chinese reference summary, generated Chinese summary, and taxonomy definitions in Table 1.

The review prioritized source-grounded faithfulness: hallucination labels were assigned only when the generated summary introduced or altered information relative to the dialogue, while OMIT and LANG captured missing salient content and output-form failures. Multi-label annotations were allowed for independent error types, and uncertain cases were discussed before finalizing labels.

A.5 Representative Taxonomy Examples

Table 6 presents one representative single-label example for each taxonomy category. We selected short cases with explicit annotation rationales from the analyzed outputs. Generated Chinese summaries are shown as English back-translations for readability.

A.6 Extended Automatic Evaluation

Table 7 and Table 8 supplement the mean scores in Table 3 with dispersion, median, range, and 95% confidence intervals. Each model contributes 100 outputs.

A.7 Overall SLM Label and Outcome Distributions

Figure 3 reports the overall occurrence counts for each taxonomy label across the 300 SLM outputs, excluding the mBART baseline. Figure 4 summarizes the corresponding binary semantic outcome. Multi-label outputs contribute once to each assigned label.

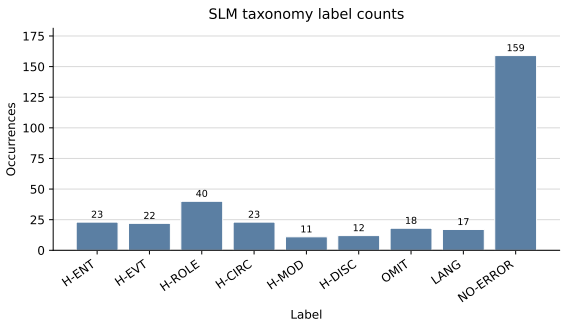

Figure 3: Overall taxonomy-label occurrence counts across the three SLMs, excluding mBART. Multi-label outputs are decomposed into individual label occurrences.

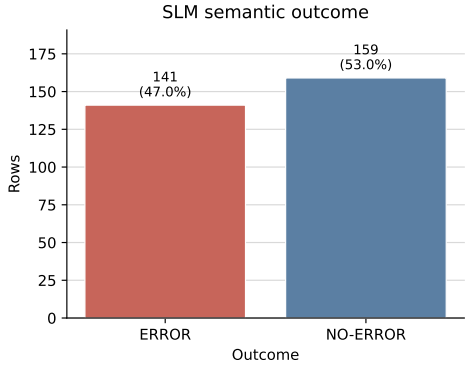

Figure 4: Overall semantic outcome counts across the three SLMs, excluding mBART. Outputs labeled NO-ERROR are counted as no-error cases; all other outputs are counted as error cases.

A.8 Relation to Prior Dialogue-Summarization Taxonomies

Table 9 summarizes approximate correspondences between our categories and the dialogue-summarization taxonomies of Tang et al. (2022) and Wang et al. (2022a). The categories are not exact equivalents: our scheme is organized by the dialogue-semantic component affected and is applied by comparing each cross-lingual output directly with its source dialogue.

Label (model, index)	Source dialogue excerpt	Generated summary (back-translated)	Annotation rationale
H-ENT (Qwen, 30)	Desiree: "Are you both at home?" Lucian: "No." Desiree: "Keep my pasta in the microwave."	Debbie asks whether Lucian is home and tells him to leave her pasta in the microwave.	The summary changes Desiree's identity to Debbie.
H-EVT (Qwen, 21)	Adrian: "Can you talk?" Simon: "Not really. I'll be free at 5."	They arrange to meet and talk at five.	A later conversation is changed into an in-person meeting.
H-ROLE (mBART, 43)	Daisy: "Going home?" Lisa: "Not yet." Daisy: "Please be back before 11 pm."	Daisy wants to be home before 11 p.m.; Lisa is not home yet.	The return requirement is assigned to Daisy instead of Lisa.
H-CIRC (Gemma, 3)	Mary: "Lend me a few bucks." Carter: "Give me an hour; I'm at the train station."	Carter will give Mary the money at the train station in one hour.	Carter's current location becomes the future handover location.
H-MOD (Gemma, 60)	John: "Do we have practice today?" Matt: "Yeah, think so."	Matt confirms that they have practice today.	The uncertain "think so" becomes a definite confirmation.
H-DISC (Qwen, 22)	Gab asks Kat to meet for a drink. Kat says she is busy and does not meet strangers from the internet.	Gab and Kat agree to meet, but Kat later refuses because of the risks of meeting online strangers.	The summary fabricates an initial agreement and subsequent reversal.
OMIT (Gemma, 15)	Pete: "Did you clean the hamster cage?" Adelle: "No." Pete: "After school, no excuses."	Pete tells Adelle to clean the hamster cage, and she agrees.	The salient after-school timing is omitted.
LANG (Aya, 77)	Dolph: "Remember to bring your passport tomorrow." Ziggler: "Cool, I will."	Dolph: "Remember to bring your passport tomorrow." Ziggler: "Okay, I will remember."	The output translates and reproduces the turns instead of summarizing them.
NO-ERROR (Gemma, 43)	Daisy: "Going home?" Lisa: "Not yet." Daisy: "Please be back before 11 pm."	Daisy asks Lisa to be home before 11 p.m.	The key event, participant roles, and timing are preserved.

Table 6: Representative examples from the annotated outputs. Parentheses identify the model and sample index. Generated Chinese summaries are shown as English back-translations; dialogue excerpts are shortened without changing the evidence relevant to the assigned label.

OMIT	Missing Information	—	Salient information absent from the output
LANG	—	—	Cross-lingual language, format, or task-fulfillment failure

Table 9: Approximate correspondence between our taxonomy and prior factual-error taxonomies for dialogue summarization. A dash indicates that the prior work has no directly corresponding standalone category; it does not imply that the broader phenomenon is entirely absent.

A Randomization-Control Diagnostic for Document Grounding in Self-Distillation Gates

Abstract

Self-distillation for grounded question answering often filters tutor trajectories with agreement or confidence gates. For such gates to support faithful grounding, their signals should depend on the supplied document rather than on answers recoverable from parametric memory. We propose a four-mode randomization-control diagnostic that applies the same frozen gate to original, randomized, irrelevant, and empty documents for the same question. On HotpotQA and MuSiQue, using Qwen2.5-7B-Instruct with eight tutor traces, the joint gate changes sharply with document condition: kept fraction falls from 0.380 to 0.020 and from 0.330 to 0.015, respectively. Randomized and irrelevant documents lie between the endpoints, while a document-blind random gate stays flat. The protocol audits document sensitivity without additional student training; faithful evidence use and downstream gains require separate validation.

1 Introduction

Grounded language-model systems are only as faithful as the signals used to decide when the model has actually used its evidence. In self-distillation with privileged context, this decision is made by a gate: a tutor sees a document and generates trajectories, while a later student may not see that document; the gate keeps trajectories when sampled answers agree, optionally with confidence (Stein et al., 2026; Taubenfeld et al., 2025). The missing check is whether this reliability signal is itself grounded. A gate can fire because the document supports a stable answer, but it can also fire because the model already knows the answer from parametric memory, especially on QA benchmarks containing memorized facts (Yang et al., 2018; Trivedi et al., 2022; Mallen et al., 2023).

We propose a direct diagnostic. For the same question, we evaluate the tutor under four document modes: original matched, same-benchmark random, off-domain irrelevant, and empty. We then apply the same frozen gate, with fixed thresholds shared across document modes. We test whether retention changes across document conditions; a document-independent random gate provides a flat control (Figure 1). We instantiate the diagnostic on HotpotQA and MuSiQue. Across both, kept fraction falls sharply from original to no-document inputs, corrupted documents lie between the extremes, confidence-only/agreement-only/joint gates agree, and a fixed-probability random gate stays flat. The result is a reusable document-sensitivity diagnostic for training-time gate signals rather than a new QA model.

2 Related Work

Self-distillation gates. Knowledge distillation transfers supervision from a stronger or better-informed teacher to a student (Hinton et al., 2015; Kim and Rush, 2016; Vapnik and Izmailov, 2015; Lopez-Paz et al., 2015). In LLM reasoning, self-consistency treats agreement across sampled traces as evidence of answer reliability (Wang et al., 2022; Wei et al., 2022). GATES filters document-grounded tutor trajectories under privileged context (Stein et al., 2026), and related work augments agreement with confidence (Taubenfeld et al., 2025). These works define filtering rules, but not whether the gate reads the document.

Document grounding and leakage. Retrieval-augmented and document-grounded QA condition generation on retrieved or supplied passages (Lewis et al., 2020; Guu et al., 2020; Karpukhin et al., 2020; Asai et al., 2024); multi-hop benchmarks stress evidence combination (Yang et al., 2018; Ho et al., 2020; Trivedi et al., 2022). Yet models may ignore evidence (Liu et al., 2024), and context-memory conflicts show parametric knowledge overriding text (Longpre et al., 2021; Xu et al., 2024). Leakage-resistant benchmarks and ground-

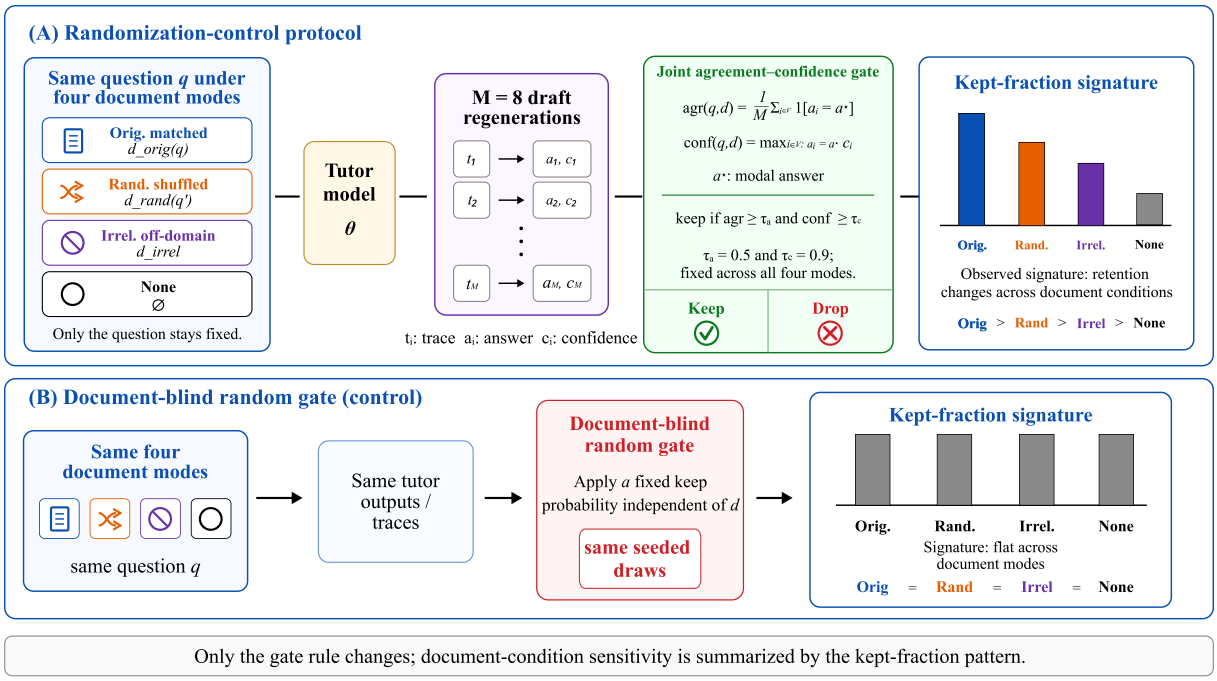

Figure 1: Randomization-control diagnostic. A: apply the same agreement–confidence rule across four document conditions. B: replace it with a document-independent fixed-probability random rule. Signature bars illustrate the expected contrast; measured retention appears in Table 1.

edness diagnostics address inference-time answers (Trivedi et al., 2022; Wu et al., 2025; Dziri et al., 2022; Manakul et al., 2023; Zhang et al., 2025; Kuhn et al., 2023; Vankov et al., 2025); we apply the same concern to training-time gates.

3 Diagnostic

Gate signal. For a question q and document d, the tutor samples M traces. Let V index parsed answers and $a^\star$ be their modal answer. We compute $\mathrm{agr}(q,d) = M^{-1}\sum_{i\in V}\mathbf{1}[a_i = a^\star]$ and $\mathrm{conf}(q,d) = \max_{i\in V:a_i=a^\star} c_i$. Here c_i averages the maximum next-token softmax probability over the generated continuation; it is not restricted to the extracted answer span. If V is empty, both signals are zero. Otherwise agreement is at least $1/M$; means below $1/M$ can arise only when averaging in all-unparseable cases. The joint gate requires $\mathrm{agr} \geq \tau_a$ and $\mathrm{conf} \geq \tau_c$. The released configuration fixes $\tau_a = 0.5$ and $\tau_c = 0.9$ across document modes.

Document modes and signature. For each question, *original* uses the matched document; *randomized* uses a different same-benchmark document; *irrelevant* uses a cross-benchmark document; and *none* provides an empty document. We report kept fraction K and invariance spread $\Delta K = K_{\mathrm{orig}} - \min(K_{\mathrm{rand}}, K_{\mathrm{irr}}, K_{\mathrm{none}})$. The observed ordering original $>$ randomized $>$ irrelevant $>$ none describes this study; it is not a requirement that every grounded gate must satisfy. Unmatched documents may still contain useful information or distract the tutor. We contrast HotpotQA with MuSiQue's leakage-resistant construction (Trivedi et al., 2022; Wu et al., 2025).

4 Experimental Setup

Tutor and traces. We use Qwen2.5-7B-Instruct (Qwen et al., 2025) with $M = 8$ traces at temperature 0.8 and 200 two-hop questions per benchmark. Main results use seeds 0 and 1. Irrelevant documents are sampled cross-benchmark. Gate signals are collected before student updates. The archived runner then performs document-conditioned self-distillation on retained questions and evaluates the updated model on 200 validation questions at temperature zero. Doc Acc. supplies original matched documents at evaluation; No-doc Acc. omits them on the same validation split. Thus the row's document mode describes signal collection and training, not evaluation. Main-table entries are mean±sample standard deviation across seeds.

Benchmark	Doc. mode	Doc Acc.	No-doc Acc.	Keep	Agree	Conf.	Correct
HotpotQA	Original	.320±.014	.145±.035	**.380±.021**	.479±.005	.902±.002	.287±.011
HotpotQA	Randomized	.273±.011	.165±.028	.225±.014	.422±.011	.845±.006	.323±.011
HotpotQA	None	.300±.007	.055±.000	.020±.000	.121±.002	.225±.002	.117±.004
HotpotQA	Irrelevant	.255±.021	.143±.018	.098±.004	.356±.011	.768±.007	.065±.014
MuSiQue	Original	.253±.018	.058±.011	**.330±.007**	.447±.002	.908±.003	.280±.021
MuSiQue	Randomized	.208±.018	.028±.011	.230±.035	.465±.008	.835±.003	.237±.018
MuSiQue	None	.212±.004	.000±.000	.015±.007	.048±.003	.124±.008	.028±.004
MuSiQue	Irrelevant	.205±.021	.015±.000	.048±.004	.306±.008	.674±.002	.003±.004
Document-blind random-gate control (seed 0), kept fraction constant across all four modes							
HotpotQA	All four modes			.465			
MuSiQue	All four modes			.465			

Table 1: Dual-arm randomization control. Doc. mode is the condition used for gate collection and training. Doc Acc./No-doc Acc. evaluate the updated student with original matched documents/without documents; *None* rows can therefore have nonzero Doc Acc. Keep, Agree, Conf., and Correct are pre-update gate retention, agreement, confidence, and correct-modal rate. Mean±std over two seeds.

5 Results

Document condition changes retention. On HotpotQA, retention falls from 0.380 ± 0.021 with the original document to 0.020 ± 0.000 with no document (Table 1). MuSiQue shows the same pattern under a leakage-resistant construction, falling from 0.330 ± 0.007 to 0.015 ± 0.007. Randomized and irrelevant documents lie between the extremes on both arms, so the pattern occurs on both benchmarks. Figure 2 shows higher accuracy with evaluation-time document access in all four training modes, alongside decreasing retention across those modes.

Gate variants agree. Table 2 sweeps the original-vs.-none contrast across confidence-only, agreement-only, and joint gates. Removing the document sharply reduces all three on both arms, so the diagnostic is not tied to one parameterization.

Control and trace budget. The random gate uses a fixed keep probability independent of d, with the same seeded draws across modes; its realized fraction is 0.465. This checks a document-independent selection rule, not alternatives driven by confidence or domain familiarity. The retained-fraction ordering also holds across trace budgets (Table 3).

Interpretation and boundary. The tested gate changes substantially with document condition on both benchmarks. The diagnostic itself requires gate signals on four input forms, without retraining a student. The accompanying student accuracies describe the archived training runs; without an ungated or untrained baseline under a matched budget, they do not establish that greater document sensitivity improves downstream performance.

6 Discussion

Why the protocol composes with future gates. The protocol needs only a gate signal for (q, d) on four input forms, so other gates can replace agreement or confidence while retaining the document-condition comparison. Each non-original mode adds a tutor-evaluation pass; student training is needed only to test downstream value.

Why selectivity is not enough. With fixed thresholds, lower agreement or confidence can reduce retention. The observed drop therefore cannot separate loss of answer support from domain familiarity or parseability. Matched counterfactual documents would test these alternatives.

What the diagnostic does not claim. The diagnostic does not prove that retained traces use correct evidence or that greater sensitivity improves the student; Table 1 does not isolate that causal relationship.

	HotpotQA		MuSiQue	
Gate variant	Orig.	None	Orig.	None
Confidence-only	.705	.020	.660	.020
Agreement-only	.485	.120	.410	.035
Joint (agr. + conf.)	.365	.020	.335	.020

Table 2: Gate-variant check at $M = 8$, seed 0 throughout. Joint values are the seed-0 component of Table 1.

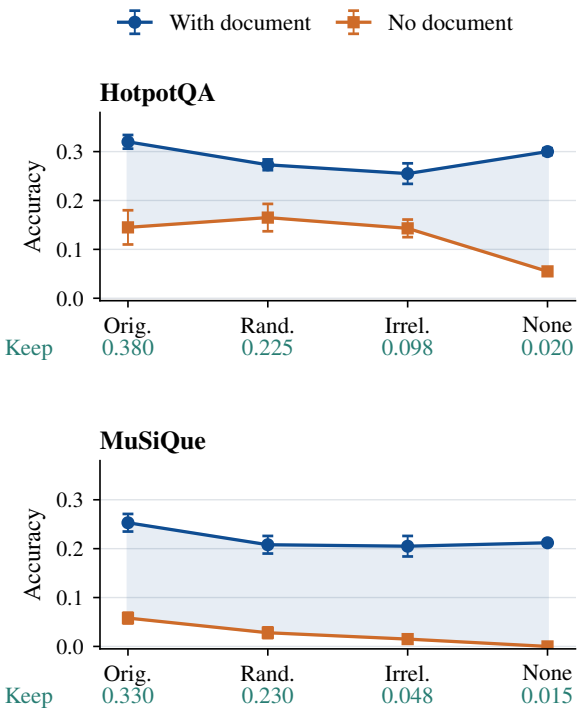

Figure 2: Student accuracy with original documents or without documents after training under each indicated document mode. Error bars show standard deviations over two seeds. Shading shows the evaluation-time document-access gap, not improvement over an untrained baseline; the bottom row reports gate retention K.

M	Original	Randomized	Irrelevant	None
4	.420	.238	.074	.016
8	.350	.214	.069	.019
16	.314	.243	.104	.018

Table 3: Trace-budget check: equal-weight means over both benchmarks and seeds 2 and 3 (48 archived runs; main-table seeds: 0 and 1).

Reporting recommendation. For grounded distillation papers, report the four-mode signature alongside parse coverage and task metrics. Let S_{orig} and S_{none} denote the retained question sets. Their overlap $|S_{\text{orig}} \cap S_{\text{none}}|/|S_{\text{orig}}|$ measures how much original-mode supervision also passes without documents. The tutor's no-document correctness on S_{orig} tests memory-only answering in that cohort; it is distinct from the student's validation accuracy in Table 1. Equal retention rates can describe disjoint sets. The archived summaries lack these question-level records, so neither cohort statistic nor the all-unparseable rate can be recovered. Use matched seeds and question IDs for paired comparisons; mode-wise averages discard the within-question relation.

Why this matters for supervision quality. Retained trajectories become examples that shape a student. A gate that selects memory-answerable questions may transmit shortcuts, even when its aggregate retention is document-sensitive. The four-mode comparison checks the supervision source before downstream training, while cohort overlap and evidence attribution would determine which retained questions drive the signature. These are complementary checks on the amount and identity of selected supervision.

Failure patterns exposed by the four modes. High no-document retention is compatible with parametric confidence, while high randomized or irrelevant retention can reflect domain or surface effects. The observed ordering shows sensitivity to document condition. Because the interventions jointly alter support, domain, lexical overlap, and prompt naturalness, they do not uniquely isolate evidence use. Same-benchmark random documents retain more questions than cross-benchmark documents on both datasets, although neither is matched to the question. Correct-modal rate need not follow retention: on HotpotQA it is 0.323 under randomized documents versus 0.287 under original documents. Retention therefore cannot substitute for checking correctness or evidence support.

Relation to final-answer grounding. Many grounding evaluations ask whether a final answer is supported by a passage. Our setting is earlier in the pipeline: the gate decides which tutor trajectories become training data before the student is evaluated. The proposed contrast complements answer-level faithfulness checks by testing whether the supervision filter responds to document condition.

7 Conclusion

We introduced a four-mode randomization-control diagnostic for asking whether self-distillation gates in grounded QA depend on the supplied document. Applied to HotpotQA and MuSiQue, the joint agreement-confidence gate responds strongly to document condition, while a document-blind control remains flat.

The four-mode contrast audits document sensitivity alongside accuracy and confidence. It does not establish evidence attribution or downstream training benefits.

Limitations

Our experiments cover one tutor model and two QA benchmarks, which limits the generality of our findings. Future work should evaluate the diagnostic across broader models, datasets, and domains.

Safe Adaptive Context and TACER: Task-Aware Evidence Routing for Token-Efficient Retrieval-Augmented Generation

Abstract

Retrieval-Augmented Generation (RAG) pipelines often pass a fixed number of retrieved documents to the generator, even though evidence needs vary by query. We study context selection as a post-retrieval control problem: given the same candidate list, how much evidence should enter the prompt, and in what form? We present Safe Adaptive Context, a lightweight controller that starts with limited evidence and expands when the generated answer appears weak, and TACER, a task-aware extension that routes between compact evidence and safer broader context using retrieval-side and evidence-coverage signals. Across five datasets, two generators, and stronger retriever settings, the controllers substantially reduce provider-reported token use while preserving most Fixed Top-10 answer quality. In a separate 500-query external-baseline evaluation (100 queries per dataset), Safe Adaptive Context retains 99.8% of Fixed Top-10 F1 with 55.0% token reduction, while TACER retains 99.4% with 60.4% token reduction. These are complementary operating points rather than evidence that TACER universally improves quality.

1 Introduction

RAG improves language-model answers by retrieving external evidence and placing it in the prompt (Lewis et al., 2020). The dominant pattern is simple: retrieve a ranked list and pass a fixed number of documents, usually the top-k, to the generator. This treats context depth as a global constant rather than a query-level decision. A biomedical factoid question may need one sentence, a scientific claim may need a small evidence span, a multi-hop question may require several documents, and an ambiguous long-form question may require broader synthesis.

Fixed retrieval depth is inefficient in two ways. It spends unnecessary prompt tokens on easy or concentrated-evidence queries, and it can reduce answer quality by placing useful evidence among distractors. Prior work shows that large language models can be distracted by irrelevant context (Shi et al., 2023), and that long-context factuality depends on how useful information is positioned and attended to (Wu et al., 2025). Token-efficient RAG is therefore not only a cost problem; it is also a context-control problem.

We study context selection as a post-retrieval decision. A stronger retriever can improve candidate order, but it still does not decide whether the generator should see one compact span, three full documents, sentence neighborhoods from several documents, or a broader fallback context. Our central finding is that retrieval-score concentration is not a reliable proxy for answer-level evidence sufficiency: adapting k alone can under-select evidence, especially for distributed and multi-hop tasks.

This distinction matters for grounded generation. A retrieved list can contain the right evidence while still presenting it in a form that is too sparse, too noisy, or too compressed for the generator. We therefore treat context construction as a policy decision over already retrieved evidence, rather than as a side effect of retriever quality.

Safe Adaptive Context addresses this by combining a lightweight budget predictor, evidence compression, and answer-aware fallback. It first attempts a smaller context and expands only when the generated answer looks weak or unsupported. TACER extends this idea by making the policy explicitly task-aware: it routes between compact and safer context construction depending on whether evidence appears concentrated or distributed, and whether the query likely requires short factual extraction, multi-hop reasoning, or longer synthesis.

TACER is not a new retriever or standalone prompt compressor; it is a lightweight post-retrieval controller that jointly chooses context

depth, evidence form, and fallback risk. We evaluate on five datasets, two generators, and three retrieval conditions. Our comparisons include fixed top-k, heuristic score-gap rules, Adaptive-k-style score baselines, LLMLingua-2, and a constrained FLARE-style baseline. Code and materials are publicly available.

2 Related Work

Retrieval and Context Allocation. RAG conditions generation on retrieved evidence (Lewis et al., 2020); open-domain QA systems have long used retrieval for grounding, including dense retrieval methods such as DPR (Karpukhin et al., 2020). Retrieval benchmarks such as BEIR evaluate ranking quality across domains (Thakur et al., 2021). Most RAG pipelines, however, still require a context-construction step after retrieval. Better retrieval increases the chance that useful evidence appears in the candidate set, but a high-quality top-10 list can still contain redundant passages, and a high-scoring first passage can still be insufficient for multi-hop reasoning.

Adaptive Retrieval and Compression. Several approaches study when to retrieve or compress more. FLARE retrieves when generation appears uncertain (Jiang et al., 2023b), Self-RAG trains models to critique retrieval and generation (Asai et al., 2024), and Adaptive-k selects the number of passages from the query-passage similarity distribution without fine-tuning or extra LLM calls (Taguchi et al., 2025). Prompt-compression methods such as LLMLingua, LLMLingua-2, Selective Context, and RECOMP reduce context length by selecting, deleting, or rewriting text (Jiang et al., 2023a; Pan et al., 2024; Li et al., 2023; Xu et al., 2024). EXIT and AdaComp are especially relevant because they adapt extractive compression to query and retrieval signals (Hwang et al., 2025; Zhang et al., 2024).

TACER is complementary to these methods. It does not train a compression model, call an LLM before generation, or replace retrieval. Instead, it treats compression as one action available to a controller: use compact evidence when it appears safe, preserve broader context when evidence is distributed, and fall back when the first answer appears unsupported.

Reranking, Distractors, and Positioning. Cross-encoder reranking and dense retrieval improve candidate ordering, but they do not decide how much context the generator should receive. Dense retrievers such as DPR learn semantic query-passage matching (Karpukhin et al., 2020), while cross-encoder rerankers often improve top-rank precision (Nogueira and Cho, 2019); we include both TF-IDF+cross-encoder and dense+cross-encoder settings to test whether context routing remains useful after ranking improves. This matters because irrelevant or poorly placed context can harm generation when useful evidence is mixed with distractors (Shi et al., 2023), and long-context factuality depends on how retrieval-related attention behaves (Wu et al., 2025). The closest prior work covers parts of our system: Adaptive-k selects a cutoff, LLMLingua-style methods compress prompts, FLARE retrieves more when generation appears uncertain, and EXIT/AdaComp adapt compression. Our contribution is the combination in a low-overhead post-retrieval controller that chooses compact evidence, broader context, and answer-aware fallback as policy actions.

3 Method

3.1 Problem Setup

For a query q, a retriever returns ranked candidates $R_q = [(d_1, s_1), \ldots, (d_{10}, s_{10})]$, where d_i is the document at rank i and s_i is the retrieval score. A context policy transforms this list into prompt context C_q, and the generator produces answer a_q from q and C_q. All methods in a retrieval condition share the same candidate list; only the context policy changes.

This controlled setup isolates the question we want to study. If two methods receive the same ranked evidence pool and use the same generator, differences in quality and token cost reflect context allocation rather than retrieval coverage, model choice, or decoding randomness.

We measure cost as provider-reported total tokens used to obtain the final answer. For fallback methods, this includes both the first attempt and the fallback generation, because a failed first pass still costs tokens in real use.

3.2 Context Policies

Fixed Top-k baselines pass Top-3, Top-5, or Top-10 full documents. Fixed Top-10 is the expensive reference point for token-reduction calculations, but it is not a guaranteed quality upper bound be-

cause longer prompts can include distractors. The Heuristic Rules baseline uses retrieval-score gaps and query length to select a budget, but does not compress evidence or inspect answer risk.

We distinguish two Adaptive-k-style baselines. *Adaptive-k (score-drop)* is our lightweight normalized largest-adjacent-drop baseline over the shared top-10 candidate list; it is used in the main and retriever-robustness experiments. *Adaptive-k (paper)* is a paper-faithful reproduction of the published largest-gap rule, used in the external-baseline evaluation and blinded annotation. Both are strong lightweight baselines because they require no training, no extra LLM call, and no answer-time critique. Their shared limitation is that score shape does not always encode evidence need: a multi-hop question can require lower-ranked evidence even when the first score gap is large.

We keep these baselines separate because they answer different reviewer questions. The score-drop variant is a transparent in-harness diagnostic over the same top-10 pool as TACER, while the paper-faithful variant checks whether the claim survives against a closer reproduction of prior adaptive-k behavior.

Safe Adaptive Context predicts an initial budget from retrieval-side features, constructs compact evidence spans when appropriate, generates once, and expands context if a surface-level risk checker detects an empty, weakly grounded, or unsupported answer. TACER extends this controller with task-aware routing. It estimates whether the evidence is concentrated or distributed and chooses between aggressive compact evidence, safer selected context, or fallback-enabled expansion. Table 1 summarizes the routing signals and actions.

For compact evidence, selected documents are split into sentences and scored using lexical overlap, rare query-term matches, phrase overlap, token density, and a small position bonus. TACER keeps high-scoring sentence neighborhoods rather than isolated sentences, preserving nearby definitions, negations, and conditions. The exact routing thresholds are reported in the appendix and released code.[1]

The final routing policy uses only query text, retrieval scores, and lexical evidence coverage; it does not use dataset identifiers or an additional LLM call before generation. Concise prompts with bridge evidence, multi-hop shape, or distributed complexity use the safer Safe Adaptive ladder. Long-answer prompts with more than 120 output tokens and non-focused complexity also use the safer ladder. Claim-style prompts with at most 120 output tokens use compact coverage-guided evidence unless evidence is distributed. Focused or concentrated evidence otherwise uses compact coverage-guided evidence. Evidence complexity is assigned from general query features: entity count, connective cues, content-word length, and whether query evidence appears across several documents.

Fallback is deliberately conservative. Evidence-style prompts fall back for empty answers, weak-answer phrases, low answer-context overlap, low context-query coverage, very short unsupported answers, or suspiciously verbose answers with poor grounding. Concise short-answer prompts fall back only for empty answers or unusually long answers with weak answer-context overlap, because correct answers can be names, dates, places, or short phrases with limited lexical overlap.

Computational cost. TACER adds little overhead beyond retrieval and generation. Its routing features are computed from the already available ranked list and simple lexical evidence scoring. Unlike methods that ask an LLM to classify the query before generation, TACER does not introduce a separate pre-generation model call. The only additional LLM cost occurs when answer-aware fallback is triggered, and fallback cost is included in all reported token totals.

4 Experimental Setup

We evaluate on SciFact, BioASQ, HotpotQA, MS MARCO, and ASQA, covering scientific claim verification, biomedical factoid QA, multi-hop QA, web passage QA, and ambiguous long-form QA. Table 2 summarizes the dataset roles. Each dataset uses a 50-example calibration split for lightweight routing choices and a fixed 200-example evaluation split. The main generator is `meta-llama/Llama-3.3-70B-Instruct`; a local Ollama Mistral 7B model is used as a smaller-model robustness check. The main retrieval setting is TF-IDF. Reranking uses `cross-encoder/ms-marco-MiniLM-L-6-v2`; dense retrieval uses

[1] https://github.com/Joel-Vazquez-Lopez/adaptive-rag-token-efficiency

Table 1: TACER routing signals and actions. The policy is task-aware but not dataset-specific.

Signal family	Features	Routing role
Retrieval concentration	Top scores, score gaps, score mass, entropy, normalized entropy	Detect focused vs distributed ranking structure
Evidence coverage	Query length, lexical overlap, phrase coverage, useful spans across documents	Decide whether compact evidence covers the query
Answer-form risk	Factoid/claim-style cues, multi-hop cues, long-form or explanatory query shape	Choose compact evidence vs safer broader context
Fallback risk	Empty answer, weak answer phrase, low answer-context overlap, low query coverage	Expand context after an unsupported first pass

`intfloat/multilingual-e5-large-instruct` followed by the same reranker.

The main evaluation uses 200 held-out queries per dataset (1,000 total). A separate external-baseline evaluation uses 100 queries per dataset (500 total); all methods within an evaluation use the same query set. SciFact answer-level metrics use auxiliary natural-language references generated from the claim and gold evidence with `openai/gpt-oss-120b` at temperature 0. The prompt requires a concise answer based only on the supplied gold evidence. These references are used only for answer-level metrics; retrieval diagnostics use the original relevance labels. The other datasets use references prepared from their source data or simplified JSONL conversions. Full prompts and preparation details are provided in the appendix.

The retriever-robustness conditions are not intended as a retrieval benchmark. They ask whether context allocation remains useful after candidate ordering improves. Final reported runs require provider-reported token counts, and all generators run at temperature 0 to make method comparisons paired and reproducible.

Table 3 summarizes the compared methods. The external evaluation adds three stronger alternatives beyond the original Safe Adaptive evaluation. *Adaptive-k (paper)* uses fixed buffer $B = 5$ and top-90% gap search, adapted to our top-10 candidate lists. LLMLingua-2 uses its MeetingBank checkpoint to compress either Fixed Top-10 or Adaptive-k (paper) evidence using structured document blocks; the exact identifier is given in the appendix. FLARE-lite is a constrained FLARE-style baseline: it starts with minimal evidence and expands when the answer appears weak. We do not present FLARE-lite as official FLARE, because the hosted API setting does not expose the token-level uncertainty signal used by the original method.

Metrics. We evaluate answer quality with token F1, answer coverage, and semantic similarity. Coverage is reference-token recall, $|T(a) \cap T(r)|/|T(r)|$, for normalized unique-token sets $T(\cdot)$. Semantic similarity is cosine similarity between answer and reference embeddings from `sentence-transformers/all-MiniLM-L6-v2` (Reimers and Gurevych, 2019). Efficiency is measured with provider-reported total tokens, including both generations after fallback, and token reduction relative to Fixed Top-10 under the same dataset, model, and retriever. Conventional retrieval nDCG@10 and MRR@10 are fixed for a retriever and dataset; when these diagnostics vary by context policy, we label them Ctx nDCG and Ctx MRR because they measure relevance retained in the selected prompt context, not retriever quality.

For dataset d and method m, F1 retention is $100 \times \mathrm{F1}_{d,m}/\mathrm{F1}_{d,\mathrm{Top10}}$, and token reduction is $100 \times (1 - \mathrm{Tokens}_{d,m}/\mathrm{Tokens}_{d,\mathrm{Top10}})$. Cross-dataset summaries macro-average these dataset-level retention and reduction values, so displayed average retention need not equal the ratio of displayed average F1 columns.

5 Results

5.1 Main Results

Table 4 reports the main Llama-70B TF-IDF results. TACER is highly efficient on concentrated-evidence datasets and avoids the largest Adaptive-k (score-drop) failures on HotpotQA and ASQA. The clearest failure is HotpotQA: Adaptive-k (score-drop) reduces token use by 70.4%, but F1 drops from 0.645 to 0.490. TACER spends more context, saves 32.6%, and recovers most answer quality with F1 0.627. On SciFact, where evidence is often concentrated, TACER reaches the highest F1 while reducing tokens by 80.9%. On ASQA, TACER gives up some token savings relative to Adaptive-k (score-drop) but improves F1 by 0.036.

5.2 Component Ablation

The main tables show final operating points but do not isolate why the controller helps. Table 5 reports a small SciFact ablation for the Safe Adaptive pipeline. Compact evidence is the main efficiency driver: Adaptive Compact Only preserves

Table 2: Datasets used in the evaluation. The split is fixed across methods so token and answer-quality comparisons are paired by query.

Dataset	Domain	Task type	Evidence pattern	Calib.	Eval.
SciFact	Scientific/biomedical	Claim verification	Concentrated evidence	50	200
BioASQ	Biomedical	Factoid QA	Focused technical evidence	50	200
HotpotQA	General-domain	Multi-hop QA	Distributed evidence	50	200
MS MARCO	Web passages	Passage QA	Often early-answer evidence	50	200
ASQA	General-domain	Ambiguous long-form QA	Explanatory/synthesis evidence	50	200

Table 3: Compared context-selection methods.

Method	Budget signal	Compression	Fallback	Task/evidence awareness
Fixed Top-3/5/10	Fixed constant	No	No	No
Heuristic Rules	Score gaps + query length	No	No	Weak
Adaptive-k (score-drop)	Score distribution	No	No	No
LLMLingua-2	Fixed or paper Adaptive-k context	Model-based	No	Compression only
FLARE-lite	Answer-risk expansion	No	Yes	Weak
Safe Adaptive Context	Predicted budget + answer risk	Yes	Yes	Moderate
TACER	Score shape + evidence coverage + task routing	Yes	Yes	Stronger

Fixed Top-10 F1 while reducing tokens by 77.9%. Fallback changes the risk profile: the full Safe Adaptive pipeline preserves F1 with a 76.5% token reduction and a 4.0% fallback rate. This motivates TACER's routing layer, which decides when compact evidence is appropriate rather than applying compression uniformly.

5.3 External Baselines and Frontier

Table 6 reports the separate 500-query external-baseline evaluation, comprising 100 queries from each dataset. At the single tested operating point, Adaptive-k (paper) preserves quality with 24.9% average token reduction. The two LLMLingua-2 configurations compress more aggressively and retain roughly 80–82% of Fixed Top-10 F1. Because LLMLingua-2 compression was not swept, these results compare the reported configurations rather than establish a complete Pareto frontier. Safe Adaptive Context and TACER retain nearly all Fixed Top-10 F1 while reducing tokens by 55.0% and 60.4%, respectively.

5.4 Complementary Quality Metrics

Token F1 alone can be misleading because correct paraphrases may share few words with the reference, while short generic answers can receive some overlap. Table 7 therefore reports coverage and semantic similarity for the main TF-IDF setting. The complementary metrics reinforce the main interpretation. On HotpotQA, Adaptive-k (score-drop) drops not only in F1 but also in coverage and semantic similarity, while TACER recovers most of both. On ASQA, TACER improves over Adaptive-k (score-drop) in all three quality metrics. BioASQ and MS MARCO remain more mixed, showing that aggressive routing can trade away some coverage even when F1 remains competitive.

5.5 Paired Confidence Check

Because all methods answer the same evaluation queries, Table 8 compares TACER directly against Adaptive-k (score-drop) with paired bootstrap intervals in the main TF-IDF setting. TACER's F1 gains on HotpotQA and ASQA are clearly positive; SciFact, BioASQ, and MS MARCO are closer in F1 but generally favor TACER in token use. The confidence check makes the trade-off explicit: TACER spends more tokens where quality improves, and saves tokens where F1 is statistically closer.

5.6 Robustness and Human Evaluation

The pattern persists under stronger retrieval. On HotpotQA, Adaptive-k (score-drop) retains only 76.0% of Fixed Top-10 F1 under TF-IDF, 79.7% with TF-IDF+CE, and 79.1% with dense+CE, while TACER retains 97.3%, 96.3%, and 97.2%, respectively. This suggests the failure is not simply weak retrieval: multi-hop questions often require more evidence than the retrieval-score curve suggests.

Table 10 summarizes average behavior across retriever settings. Under stronger retrievers, Safe Adaptive matches or exceeds TACER's aggregate

Table 4: Main Llama-70B TF-IDF results. Reductions are relative to Fixed Top-10.

Dataset	Fixed F1	Heuristic F1 / Red.	Score-drop F1 / Red.	Safe F1 / Red.	TACER F1 / Red.
SciFact	0.243	0.245 / 37.1%	0.251 / 74.9%	0.247 / 69.9%	0.253 / 80.9%
BioASQ	0.328	0.325 / 39.2%	0.319 / 73.2%	0.323 / 74.6%	0.314 / 80.8%
HotpotQA	0.645	0.575 / 37.3%	0.490 / 70.4%	0.627 / 32.3%	0.627 / 32.6%
MS MARCO	0.196	0.201 / 41.8%	0.199 / 48.6%	0.195 / 38.5%	0.195 / 54.1%
ASQA	0.422	0.411 / 44.0%	0.368 / 70.9%	0.402 / 58.3%	0.404 / 59.4%

Table 5: Component ablation on SciFact with Llama-70B. Reductions are relative to Fixed Top-10.

Variant	F1	Semantic	Tokens	Red.
Fixed Top-10	0.247	0.489	3325	0.0%
Adaptive Compact Only	0.248	0.481	736	77.9%
Adaptive Full Only	0.240	0.485	1097	67.0%
Top-5 Compact + Fallback	0.258	0.489	1209	63.6%
Full Safe Adaptive	0.247	0.477	780	76.5%

F1 retention and also saves more tokens. In the main TF-IDF run, paired TACER–Safe F1 intervals include zero on every dataset; TACER nevertheless uses fewer mean tokens on all five datasets. Thus TACER is an aggressive operating point in the main setting, not a uniformly superior controller.

The smaller Mistral generator shows the same qualitative pattern rather than a model-specific artifact. On HotpotQA, Adaptive-k (score-drop) drops to F1 0.282, while Safe Adaptive Context and TACER recover to 0.369 and 0.374 with roughly 31% token reduction. On SciFact and BioASQ, TACER remains highly token-efficient, reducing tokens by 79.4% and 79.8%, respectively. The appendix reports the full Llama–Mistral comparison.

We also conduct a small blinded annotation on HotpotQA and ASQA, comparing Fixed Top-10, Adaptive-k (paper), Safe Adaptive Context, and TACER using saved Llama-70B generations from the external-baseline evaluation. Systems are randomized as A/B/C/D within each query, and outputs are judged for factual correctness and grounding against the reference and selected evidence. Two annotators label all 120 outputs. Exact four-way agreement is 68.3% with Cohen's $\kappa = 0.422$; binary acceptable/unacceptable agreement is 92.5% with $\kappa = 0.688$.

The annotation results are intentionally interpreted as a targeted grounding check, not a large-scale human evaluation. The sampled queries focus on HotpotQA and ASQA because they are where score-only context depth is most likely to under-select evidence. In this setting, Adaptive-k (paper) has the highest rate of incorrect or not-enough-information judgments, while Safe Adaptive Context and TACER have higher acceptable rates under the conservative merge. The effect is concentrated on HotpotQA, where distributed evidence makes score-only selection risky. The result supports the main claim qualitatively: the proposed controllers do not merely optimize automatic F1; they reduce the risk of unsupported or incomplete answers in the cases where context routing should matter most. The appendix reports the split by dataset and the annotation protocol.

The agreement pattern is also informative. Exact labels differ partly because annotators often draw the boundary between correct and partially correct differently, but the acceptable/unacceptable agreement is high. This is the distinction most relevant to our claim: whether the selected context supports an answer well enough to be usable.

5.7 Human Annotation as Metric Validation

The targeted TACER comparison is not the only human signal. We also use the structured annotation study from the Safe Adaptive evaluation to validate how automatic metrics relate to human factual judgments. That study contains 120 outputs from SciFact, HotpotQA, and BioASQ, sampled across Llama-70B and Mistral. Two annotators agreed on 84 examples, with 70.0% raw agreement and Cohen's $\kappa = 0.477$; among agreed labels, 65 were correct, 6 partially correct, and 13 incorrect. The appendix gives the dataset-level label counts.

The annotation confirms that token F1 is useful but incomplete. High F1 is strongly associated with human-correct answers, but low-F1 examples are mixed rather than uniformly wrong; acceptable paraphrases can have low lexical overlap. Semantic similarity shows the same pattern: high semantic similarity usually indicates acceptable answers, but medium scores are noisier and can over-credit

Table 6: External-baseline evaluation over 500 queries (100 per dataset) with Llama-70B. Token reduction and F1 retention are computed per dataset relative to Fixed Top-10, then macro-averaged.

Method	Avg F1	Avg Coverage	Avg Semantic	Avg Tokens	Avg Token Red.	Avg F1 Ret.
Fixed Top-10	0.366	0.608	0.651	2220	0.0%	100.0%
Adaptive-k (paper)	0.356	0.603	0.642	1643	24.9%	99.1%

domain-related but incomplete responses. This is why we report F1, coverage, semantic similarity, and the targeted grounding annotation jointly rather than treating any single automatic metric as decisive.

5.8 Failure-Mode Analysis

The aggregate results suggest three recurring regimes. First, *score-only under-selection*: Adaptive-k (score-drop) selects a small prefix because the score curve has a clear drop, but the task still requires later evidence. HotpotQA is the clearest example. Second, *over-compression*: compact evidence can remove distractors, but also conditions, negations, or secondary facts; BioASQ and ASQA are more exposed to this risk. Third, *metric mismatch*: acceptable paraphrases can have low token overlap, while incomplete biomedical answers can receive high semantic similarity.

6 Discussion

The main result is that context selection is not only a budget problem. Adaptive-k-style score baselines are strong when the retrieval-score curve reflects evidence need, but they can fail when evidence is distributed. TACER targets this gap: it spends more tokens on multi-hop or explanatory queries and compresses more aggressively when evidence is localized. Fixed baselines show the same point from another angle: Top-3 and Top-5 can be competitive on MS MARCO and BioASQ, while Top-10 remains important on HotpotQA. Choosing a fixed k is already a hidden policy decision; TACER makes that policy explicit and query-dependent.

The external-baseline and annotation results keep the claim narrow. Safe Adaptive Context is preferable when quality preservation matters most; TACER can provide greater savings in the main TF-IDF setting; and score-only selection may suffice for concentrated, low-risk distributions.

What TACER adds. Beyond Adaptive-k, TACER adapts the context policy from expected evidence structure rather than only context size from the score curve. This lets it sacrifice token savings on HotpotQA to preserve quality, while compressing more aggressively on localized-evidence tasks. Beyond Safe Adaptive Context, TACER makes the routing decision explicit: it identifies when aggressive compression is appropriate and when broader context is needed. The two methods are complementary operating points rather than mutually exclusive alternatives.

7 Conclusion

We presented Safe Adaptive Context and TACER for token-efficient RAG. Across five datasets, two generator scales, stronger retriever settings, and a separate 500-query external-baseline evaluation, the central pattern is consistent: score-only selection and generic compression are useful but incomplete. Safe Adaptive Context and TACER preserve nearly all Fixed Top-10 quality while substantially reducing provider-reported token usage. Safe Adaptive is the more conservative con-

Table 8: Paired TACER–Adaptive-k (score-drop) confidence check in the main Llama-70B TF-IDF setting. Token deltas are TACER minus Adaptive-k (score-drop), so negative values mean TACER uses fewer tokens.

Dataset	ΔF1 [95% CI]	F1 W/T/L	ΔTokens [95% CI]	Token W/T/L
SciFact	+0.002 [-0.007,+0.011]	84/17/99	-204.4 [-254.8,-159.2]	155/1/44

HotpotQA	+0.000 [+0.000,+0.000]	-4.0 [-12.0,+0.1]
MS MARCO	-0.001 [-0.013,+0.012]	-216.9 [-270.5,-163.3]
ASQA	+0.002 [-0.003,+0.007]	-13.6 [-43.9,+16.0]

Table 10: Average behavior across five datasets. Retention is relative to Fixed Top-10 under the same retriever.

Retriever	Method	F1 Ret.	Token Red.
TF-IDF	Score-drop	93.1%	67.6%
TF-IDF	Safe Adaptive	98.4%	54.7%
TF-IDF	TACER	98.4%	61.5%
TF-IDF+CE	Score-drop	97.6%	60.2%
TF-IDF+CE	Safe Adaptive	99.7%	60.3%
TF-IDF+CE	TACER	98.8%	58.0%
Dense+CE	Score-drop	98.1%	58.2%
Dense+CE	Safe Adaptive	99.8%	58.1%
Dense+CE	TACER	99.8%	56.1%

troller; TACER trades some quality protection for greater token reduction in some settings. Neither policy universally dominates across retrievers and datasets.

Limitations

The evaluation is controlled rather than exhaustive: final runs use prepared splits, some dataset conversions are simplified, and TACER uses interpretable heuristic routing rather than learned calibration. The component ablation is limited to SciFact, so it does not isolate each routing component across task types. The targeted human annotation is a grounding check rather than a full human evaluation; a larger adjudicated study would better quantify factuality differences across methods. It is also deliberately stress-oriented, focusing on

Table 11: Two-annotator blinded annotation on 30 HotpotQA/ASQA queries. Counts use a conservative merge: correct only when both annotators mark correct; acceptable = correct or partially correct.

Method	Corr.	Part.	Inc./NEI	Accept.
Fixed Top-10	16	8	6	80.0%
Adaptive-k (paper)	9	9	12	60.0%
Safe Adaptive	19	9	2	93.3%
TACER	19	10	1	96.7%

HotpotQA and ASQA cases where context underselection is most likely to matter, rather than estimating average accuracy over all RAG workloads.

Automatic metrics are imperfect, especially for biomedical and long-form answers, which is why we report them jointly with human labels instead of treating any single score as decisive. Retention percentages should also be read alongside absolute scores: the Fixed Top-10 F1 baselines are low on SciFact and MS MARCO, so small absolute changes can appear comparatively large when expressed as retention. For grounded generation, the relevant question is not only whether the answer string overlaps a reference, but whether the selected evidence is sufficient to support the answer under a chosen risk budget.

The method also assumes that the retrieved candidate list contains enough evidence to answer the query. TACER can decide whether to expose compact spans, selected documents, or broader fallback context, but it cannot recover evidence that retrieval never found. Its role is therefore a context-allocation layer to combine with stronger retrieval, factual verification, uncertainty estimation, and deployment-specific risk policies. Future work should evaluate learned or leave-one-dataset-out calibrated routers, larger adjudicated human studies, and production-style latency and call-count trade-offs.

Ethical Considerations

Because SciFact and BioASQ are biomedical, outputs should not be treated as medical advice or clinical evidence. Token-efficient RAG can reduce compute and cost, but deployments should monitor whether compression removes useful evidence.

Acknowledgments

We thank Johan Sjons and Birger Moëll for their helpful feedback and advice. We also thank Uppsala University for providing an academic environment in which this project and its underlying ideas could be developed.

A Implementation Details

A.1 Dataset Sources and Evaluation Splits

The evaluation uses SciFact (Wadden et al., 2020), BioASQ (Tsatsaronis et al., 2015), HotpotQA (Yang et al., 2018), MS MARCO (Nguyen et al., 2016), and ASQA (Stelmakh et al., 2022). The final main evaluation uses 50 calibration examples and 200 held-out evaluation examples per dataset (1,000 evaluation queries total). The separate external-baseline evaluation uses the first 100 entries of each fixed 200-query evaluation file (500 total), selected deterministically from index 0 by the released batch script. Each file records stable query identifiers, and all methods within an evaluation use the same query set.

A.2 Model and Checkpoint Details

The hosted main-generator runs use `meta-llama/Llama-3.3-70B-Instruct` at temperature 0. The smaller-model robustness runs use the local Ollama model under identifier `mistral`, also at temperature 0. Its unchanged local manifest identifies a 7.2B-parameter GGUF model with Q4_K_M quantization, a 32,768-token context window, and model-layer digest `sha256:f5074b1221da0f5a2910d33b642efa5b9eb58cfdddca1c79e16d7ad28aa2b31f`. TF-IDF is the transparent first-stage retriever. Cross-encoder reranking uses `cross-encoder/ms-marco-MiniLM-L-6-v2`, and dense retrieval uses `intfloat/multilingual-e5-large-instruct` followed by the same cross-encoder. Reported semantic scores use `sentence-transformers/all-MiniLM-L6-v2`; the saved scores differ from the implementation's lexical fallback values. Future runs should require the semantic model and record its revision explicitly.

A.3 SciFact Reference Construction

SciFact supplies claims, gold documents, and relevance labels rather than short natural-language reference answers. We therefore generated an auxiliary reference for each query with `openai/gpt-oss-120b` through the Berget AI OpenAI-compatible API at temperature 0. The input contains only the SciFact claim and its gold evidence. The system message is "You create concise reference answers for factual RAG evaluation." The user template is:

> Create one short reference answer for evaluating a RAG system on SciFact. The input is a scientific claim and the gold evidence document text. Decide whether the evidence supports, contradicts, or is insufficient for the claim.
>
> Rules: Write one concise natural-language reference answer. Match the existing SciFact reference style: usually 4 to 20 words, and never more than 30 words. If the evidence supports the claim, state the supported claim directly. If the evidence contradicts the claim, begin with "The evidence contradicts the claim" and briefly say why. If the evidence is insufficient, write exactly: "The evidence is insufficient." Do not add citations, bullet points, or extra explanation.
>
> `Claim:` *[claim]*
>
> `Gold evidence:` *[gold evidence]*

These references are used only for answer-level F1, coverage, and semantic similarity; retrieval metrics continue to use the original SciFact relevance labels. The available artifacts do not record an independent expert validation of every generated reference, so answer-level SciFact results are auxiliary evidence alongside the four datasets with source-derived references.

A.4 Answer-Generation Prompts

All context policies for a dataset use the same answer-generation prompt; methods differ only in the evidence inserted into it. SciFact, BioASQ, MS MARCO, and ASQA use the following default template:

> Answer the question using only the provided documents. If the documents do not contain enough evidence, say that the evidence is insufficient.
>
> `Question:` *[query]*
>
> `Documents:` *[numbered document blocks]*
>
> `Answer:`

Each block is formatted as `[Document` i `| document-id]` followed by its full or compressed text. HotpotQA uses the concise template because its references are short exact answers:

> Use only the evidence below to answer the question. Write only the final answer. Use as few words as possible, usually 1 to 5 words. Use the same key terms as the evidence when possible. Do not explain your reasoning. Do not repeat the question. If the evidence does not answer the question, write exactly: insufficient evidence.
>
> `Question:` *[query]*
>
> `Evidence:` *[numbered document blocks]*
>
> `Short answer:`

A.5 Metric and Budget Definitions

Answer coverage is the fraction of unique reference-answer tokens recovered by the generated answer:

$$\text{coverage}(a, r) = \frac{|T(a) \cap T(r)|}{|T(r)|},$$

where $T(\cdot)$ is the normalized token set used by the evaluation script. It is therefore a recall-style lexical metric, complementary to token F1 and semantic similarity.

The configured maximum output-token budget is 80 for SciFact, BioASQ, HotpotQA, and MS MARCO, and 160 for ASQA. The TACER routing rule that checks whether an answer is a long-answer setting therefore uses the > 120 output-token threshold only for ASQA in the reported configuration.

A.6 Calibration and Compression Settings

The 50-example calibration split is used only to choose lightweight routing thresholds and budget behavior. Thresholds are selected by inspecting calibration-set score gaps, normalized entropy, query length, lexical evidence coverage, and fallback behavior, then choosing conservative cutoffs that preserve Fixed Top-10 quality on distributed or long-answer cases while allowing aggressive compression on concentrated-evidence cases. Dataset identifiers are not used as policy inputs.

The reported TACER and Safe Adaptive compression is the lexical sentence-neighborhood compression described below, not an LLMLingua-2 call. LLMLingua-2 appears only in the external-baseline evaluation, where the implementation uses the `microsoft/llmlingua-2-xlm-roberta-large-meetingbank` checkpoint with its budget chosen to match each routed context budget as closely as possible before answer generation. We report this tested configuration rather than a full LLMLingua-2 quality–efficiency sweep.

A.7 Retriever Details

For a corpus of N documents, inverse document frequency is computed as:

$$\text{idf}(t) = \log\left(\frac{1+N}{1+\text{df}(t)}\right) + 1,$$

where $\text{df}(t)$ is the number of documents containing term t. Query and document vectors are computed in the same TF-IDF space, and documents are ranked by cosine similarity:

$$\text{sim}(q, d) = \frac{q \cdot d}{\|q\|\|d\|}.$$

Table 12: TACER routing rules used in the final implementation.

Condition	Routing action
Concise prompt with bridge evidence, multi-hop shape, or distributed complexity	Use safer Safe Adaptive ladder
Long-answer setting with > 120 output tokens and non-focused complexity	Use safer Safe Adaptive ladder
Claim-style prompt with at most 120 output tokens	Use compact coverage-guided evidence
Distributed complexity with a non-concentrated ranking	Use safer Safe Adaptive ladder
Focused or concentrated evidence otherwise	Use compact coverage-guided evidence

A.8 Evidence Compression Scoring

For compact evidence modes, candidate sentences are scored as:

$$\begin{aligned}\text{score}(q, s, i) = {} & .40\, O(q, s) + .25\, R(q, s) \\ & + .20\, P(q, s) + .10\, D(q, s) \\ & + .05(1+i)^{-1}.\end{aligned}$$

Here O, R, P, and D denote unigram overlap, rare query-term coverage, phrase overlap, and token density. The position bonus mildly favors earlier sentences.

B Routing and Fallback Details

TACER uses query text, retrieval scores, lexical evidence coverage, and the configured answer-length budget; it does not use dataset identifiers or an additional LLM call before generation. The query-shape detector labels concise prompts as factoid unless the query contains multi-hop cues such as *which*, *where*, *when*, *whose*, *both*, or *and* and has at least six content words. Non-concise questions are treated as factoid-style questions when they contain a question mark, and otherwise as claim-style inputs.

Evidence complexity is assigned from general query features. A concise query is treated as distributed when it contains connective evidence or at least two capitalized entities and has at least six content words. Otherwise, any query with at least twelve content words, two connective cues, three capitalized entities, or two numeric expressions is treated as distributed; a query with at least seven content words or one capitalized entity is moderate; remaining queries are focused.

For concise short-answer prompts, fallback is triggered only for an empty answer or for an answer with more than 18 content words and answer-context overlap below 0.80. These concise-task rules are intentionally conservative because many

Table 13: Fallback risk rules for evidence-style prompts. Fallback is triggered when total risk is at least 3.

Condition	Risk increment
Empty answer	10
Contains weak-answer phrase	+3
Answer-context overlap < 0.08	+3
Context-query coverage < 0.35	+2
Fewer than 5 answer content words and answer-context overlap < 0.20	+2
Answer-query overlap < 0.04	+1
More than 24 answer content words and answer-context overlap < 0.90	+1

correct answers are names, dates, places, or short phrases with limited lexical overlap.

C Additional Per-Dataset Comparisons

Table 14 adds the requested fixed-depth operating points to the main TF–IDF comparison. Each entry reports answer F1 and token reduction relative to Fixed Top-10 for the same dataset.

C.1 External Baselines by Dataset

Table 15 provides the dataset-level values behind the macro-averages in Table 6.

D Generator Robustness

Table 16 reports the smaller-model check without repeating the complete method ladder.

E Retriever-Robustness Details

Table 17 reports dataset-level differences between TACER and Adaptive-k (score-drop) across retrieval settings.

F Representative Failure Examples

G Human Annotation Protocol

The metric-validation study contains 120 outputs from SciFact, HotpotQA, and BioASQ sampled across Llama-70B and Mistral. Two annotators agreed on 84 examples, yielding 70.0% raw agreement and Cohen's $\kappa = 0.477$; among agreed labels, 65 are correct, 6 partially correct, and 13 incorrect. The dataset-level agreed counts are: SciFact, 20 correct, 2 partially correct, and 5 incorrect; HotpotQA, 26 correct, 0 partially correct, and 4 incorrect; and BioASQ, 19 correct, 4 partially correct, and 4 incorrect.

The targeted controller study contains 15 HotpotQA and 15 ASQA queries. For each query, annotators see four saved Llama-70B outputs in randomized A/B/C/D order: Fixed Top-10, Adaptive-k (paper), Safe Adaptive Context, and TACER. They see the query, reference, answer, and retrieved evidence, while method identities, automatic scores, and token counts remain hidden. Two annotators label all 120 outputs as correct, partially correct, incorrect, or not enough information. Exact four-way agreement is 68.3% ($\kappa = 0.422$); binary acceptable/unacceptable agreement is 92.5% ($\kappa = 0.688$). Table 19 reports the conservative merge, where an answer is correct only if both annotators mark it correct.

Table 14: Per-dataset Llama-70B TF–IDF operating points. Each cell reports F1 / token reduction.

Dataset	Fixed Top-3	Fixed Top-5	Fixed Top-10	Score-drop	Safe Adaptive	TACER
SciFact	0.245 / 66.7%	0.245 / 47.7%	0.243 / 0.0%	0.251 / 74.9%	0.247 / 69.9%	0.253 / 80.9%
BioASQ	0.322 / 66.7%	0.326 / 47.5%	0.328 / 0.0%	0.319 / 73.2%	0.323 / 74.6%	0.314 / 80.8%
HotpotQA	0.532 / 67.7%	0.555 / 49.9%	0.645 / 0.0%	0.490 / 70.4%	0.627 / 32.3%	0.627 / 32.6%
MS MARCO	0.197 / 62.2%	0.198 / 43.8%	0.196 / 0.0%	0.199 / 48.6%	0.195 / 38.5%	0.195 / 54.1%
ASQA	0.398 / 64.6%	0.416 / 45.9%	0.422 / 0.0%	0.368 / 70.9%	0.402 / 58.3%	0.404 / 59.4%

Table 15: External-baseline results covering 100 queries from each dataset (500 total). Token reduction is relative to Fixed Top-10 within each dataset.

Dataset	Method	F1	Semantic	Tokens	Token Red.
SciFact	Fixed Top-10	0.231	0.497	3388	0.0%
SciFact	Adaptive-k (paper)	0.238	0.496	2451	27.7%
SciFact	Top-10 + LLMLingua-2	0.246	0.508	929	72.6%

When Should an Agent Distrust Its Own Context? Model-Dependent Outcomes of an Audited Reasoning Pipeline

Aditya Channa **Madhav Kapoor** **Jastej Singh**

{adityachannadelhi,madhav.kapoor13,jastej28.singh}@gmail.com

Abstract

Agents grounded in heterogeneous sources often encounter conflicting evidence. We study an Audited Reasoning Pipeline (ARP): a forensic analyzer reads the raw sources and emits a sanitized diagnostic, while a clean-room synthesis stage receives the question and diagnostic but not the raw context. On 100 corrupted ConflictQA instances per model, ARP raises exact match from 15 to 30 for GPT-OSS-120B and from 19 to 29 for MiniMax-M2.5. CAT-Source changes from 40 to 49 and from 74 to 56, respectively; their paired model-by-condition interaction is 27 points (95% CI [13, 41], $p < .001$), although two model/configuration pairs do not identify capability as its cause. The three diagnostic metrics are emitted before the clean-room boundary, and all items are corrupted, so conflict detection has no false-positive evaluation. Token-F1 also falls on multi-answer questions. Because the clean four-call control that gives Stage 4 both raw context and the diagnostic was not run, the air-gap's causal effect remains unidentified.

1 Introduction

Knowledge graphs and retrieved passages can directly contradict one another. Such context can derail generation or reinforce a model's prior belief (Shi et al., 2023; Pan et al., 2023; Xie et al., 2024). We study whether separating evidence inspection from final generation is useful in this setting.

Our Audited Reasoning Pipeline (ARP) combines a closed-book snapshot, an evidence exploration pass, forensic analysis, and clean-room synthesis. Only the final stage cannot read the raw sources. We compare this four-call pipeline with a two-call RAG baseline on ConflictQA (Zhao et al., 2026). Because call count, intermediate inputs, decomposition, and prompts all change, the comparison evaluates end-to-end procedures rather than the air-gap alone; the clean four-call raw-context control was not run. Moreover, the diagnostic metrics are produced upstream of Stage 4.

ARP improves exact match for both evaluated models, but source attribution falls for MiniMax-M2.5 and does not reliably improve for GPT-OSS-120B. The CAT-Source interaction differs across these configurations, but model identity does not independently measure capability. We also find lower token-F1 on multi-answer questions and emphasize that every benchmark item is corrupted.

2 Related Work

Tool-augmented methods such as ReAct and Self-Ask interleave reasoning with retrieval (Yao et al., 2023; Press et al., 2023). Under knowledge conflicts (Xu et al., 2024), models can follow misinformation, distracting context, or parametric priors (Pan et al., 2023; Shi et al., 2023; Mallen et al., 2023). ConflictQA instantiates KG–text disagreement and proposes XoT, a two-stage explanation-based thinking framework (Zhao et al., 2026). We use its benchmark but do not directly compare against XoT and make no superiority claim; other remedies include context-faithful prompting, CoCoA, and Self-RAG (Zhou et al., 2023; Khandelwal et al., 2025; Asai et al., 2024).

ARP belongs to isolate-then-aggregate and quarantine designs. RobustRAG isolates passages before aggregation (Xiang et al., 2026); Astute RAG consolidates internal and retrieved evidence (Wang et al., 2025); Dual-LLM and CaMeL separate privileged from untrusted components (Willison, 2023; Debenedetti et al., 2025); and IsolateGPT uses execution isolation for LLM-based agentic systems (Wu et al., 2025). ARP's distinguishing features are its four-stage interface and explicit source/item attribution, not the first use of isolation.

Attribution work evaluates whether claims are supported by their sources (Rashkin et al., 2023; Gao et al., 2023). ARP also resembles Chain-of-

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 434–440

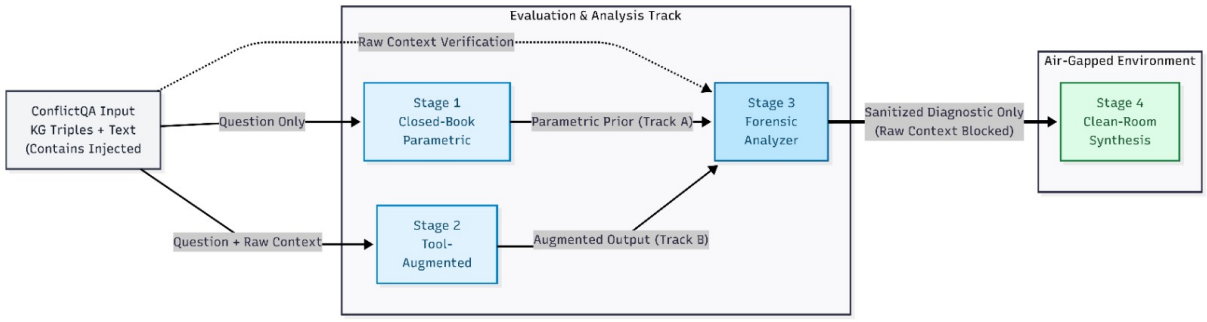

Figure 1: The Audited Reasoning Pipeline (ARP). Stages 1–2 (parametric snapshot and tool-augmented exploration) feed a forensic analyzer; only its sanitized diagnostic crosses the air-gap to the clean-room synthesis stage, while the raw, possibly-corrupted context is blocked.

Verification (Dhuliawala et al., 2024): verification is separated from generation, while a diagnostic boundary prevents raw evidence from reaching final synthesis.

3 Methodology: The Audited Reasoning Pipeline

3.1 Problem Formulation

Each example contains a query q, KG triples K, text passages T, a gold answer set G, and a corrupted-source label. A system returns an answer set A, scored by exact match and token-F1, plus a conflict flag, source, and offending item $(d, \hat{s}, \hat{\imath})$. Although the formulation permits no conflict, all 100 evaluated items per model contain either a corrupted triple or passage; conflict-detection false positives are therefore unmeasured.

3.2 The Audited Reasoning Pipeline (ARP)

ARP uses four invocations of one base model M (Figure 1).

- **Stage 1 (Parametric Snapshot):** a closed-book answer $a_1 = M(q)$ records the model's prior.
- **Stage 2 (Evidence Exploration):** $M(q, K, T)$ proposes a candidate answer a_2 from the possibly corrupted context.
- **Stage 3 (Forensic Analysis):** $M(q, K, T, a_1, a_2)$ emits $\delta = (d, \hat{s}, \hat{\imath}, e)$, including a sanitized explanation e.
- **Stage 4 (Clean-room Synthesis):** $A = M(q, e)$ receives neither raw source nor Stage 2 trace.

EM and token-F1 score Stage 4's answer. Conflict-Detection, CAT-Source, and CAT-Item score Stage 3's diagnostic and are therefore upstream of the air-gap.

3.3 Design Rationale and Cost

Rationale and scope. The baseline comparison changes call count, inputs, decomposition, and prompts. The missing clean control would hold Stages 1–3 and four calls fixed while giving Stage 4 both raw context and the diagnostic. Thus, we compare end-to-end procedures and do not identify the air-gap's causal effect.

Cost. ARP uses four generation calls; the baseline uses separate answer and diagnostic calls. ARP therefore doubles the call count and creates an answer-stage information bottleneck.

4 Experiments

Setup. We evaluate a RAG baseline and ARP on GPT-OSS-120B and MiniMax-M2.5 using 100 ConflictQA items per model: 25 in each sufficiency (COMP/Non-COMP) by corruption-site (Text/Triple) quadrant. Each stored item has one KG-first run; evidence order is not counterbalanced.

Metrics. We report EM, token-F1, Conflict-Detection, CAT-Source, and CAT-Item. GPT-5.4-mini judges the diagnostic fields; against 40 blinded human labels it attains 85% agreement ($\kappa = .70$) (Zheng et al., 2023). Deltas use 10,000 paired bootstrap resamples.

4.1 Main Results

Table 1 reports pooled results. EM rises from 15 to 30 for GPT-OSS-120B and 19 to 29 for MiniMax-M2.5. Token-F1 falls for both, reliably so for MiniMax. Conflict-Detection rises from 51 to 63 and 58 to 69, but all items are corrupted, so an always-flag

rule scores 100%. CAT-Source changes from 40 to 49 and 74 to 56; only the latter within-model interval excludes zero. CAT-Item changes from 47 to 60 and 62 to 63.

Metric	GPT-OSS-120B	MiniMax-M2.5
Exact Match	15 → 30 (‡)	19 → 29 (‡)
Token-F1	49.4 → 43.1	53.5 → 45.0 (‡)
Conf. Det.	51 → 63 (‡)	58 → 69 (‡)
CAT-Source	40 → 49	74 → 56 (‡)
CAT-Item	47 → 60 (‡)	62 → 63

Table 1: Pooled results (n=100 per model). ‡ denotes that the 95% bootstrap CI of the delta excludes zero.

Only CAT-Source has a supported model-by-condition interaction: $(9) - (-18) = 27$ points (95% CI $[13, 41]$, $p < .001$); the full interaction results are reported in Table 2. This is heterogeneity between two configurations, not evidence that capability causes the difference. Diagnostic metrics are upstream of Stage 4, and the missing clean control precludes causal attribution to the air-gap.

Metric	Interaction	95% CI	p
Exact Match	+5.0	$[-3.0, 13.0]$	.334
Token-F1	+2.2	$[-6.1, 10.3]$	.606
Conf. Det.	+1.0	$[-11.0, 13.0]$	1.000
CAT-Source	+27.0	$[13.0, 41.0]$	$< .001$
CAT-Item	+12.0	$[-2.0, 26.0]$	.120

Table 2: Paired model-by-condition interactions in percentage points: (GPT ARP−baseline)−(MiniMax ARP−baseline), with 100 matched items, 10,000 bootstrap samples, and 100,000 sign-flip samples.

4.2 Analysis

The token-F1 loss is confined to multi-answer questions (Figure 2): the diagnostic passes a verdict but not the recovered candidate set, so Stage 4 can omit valid entities. The analyzer also predicts "no conflict" on 31–37% of these corrupted items, reflecting cases where the opposing source does not state the disputed fact. Without uncorrupted negatives, false-positive behavior is unknown.

The MiniMax CAT-Source ceiling explanation is unsupported. Triple corruption changes by −20 points and text corruption by −16, a difference-in-differences of −4 (95% CI $[-26, 18]$, permutation $p = .859$). We therefore treat the mechanism as speculative. Table 3 gives Baseline → ARP for all five metrics in each quadrant; these are the numbers pooled in Table 1.

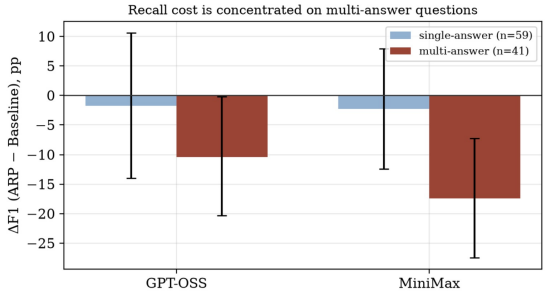

Figure 2: Token-F1 change by answer arity. The degradation is concentrated on multi-answer questions; error bars show 95% confidence intervals.

	Answer metrics	
Quadrant	EM	Token-F1
GPT-OSS-120B		
COMP / Triple	4 → 20	37.2 → 29.8
COMP / Text	20 → 44	50.9 → 56.5
Non-COMP / Text	28 → 28	64.6 → 44.9
Non-COMP / Triple	8 → 28	45.0 → 41.0
MiniMax-M2.5		
COMP / Triple	16 → 40	43.4 → 48.8
COMP / Text	24 → 28	59.4 → 46.0
Non-COMP / Text	28 → 20	64.6 → 41.3
Non-COMP / Triple	8 → 28	46.7 → 44.1

	Diagnostic metrics		
Quadrant	Conf. Det.	CAT-Src.	CAT-Item
GPT-OSS-120B			
COMP / Triple	60 → 76	60 → 72	60 → 72
COMP / Text	52 → 52	32 → 40	40 → 44
Non-COMP / Text	24 → 48	16 → 20	28 → 44
Non-COMP / Triple	68 → 76	52 → 64	60 → 80
MiniMax-M2.5			
COMP / Triple	68 → 84	88 → 80	76 → 80
COMP / Text	52 → 68	80 → 48	60 → 52
Non-COMP / Text	28 → 48	36 → 36	24 → 44
Non-COMP / Triple	84 → 76	92 → 60	88 → 76

Table 3: Per-quadrant results (Baseline → ARP). EM, Conf. Det., CAT-Source, and CAT-Item are percentages; Token-F1 is reported ×100.

5 Conclusion

ARP improves exact match for both model/configuration pairs but lowers multi-answer token-F1. Source attribution falls for MiniMax and does not reliably improve for GPT-OSS; their interaction is supported, but capability is not identified as its cause. Because diagnostics precede Stage 4 and the clean four-call control is absent, we make no causal claim about the air-gap.

6 Limitations

This work is an exploratory empirical study with several bounds:

- **Scale:** Each conflict quadrant contains 25 examples (100 per model), so per-quadrant figures are directional. We mitigate this by relying on pooled and arity-split results for our primary claims.
- **Model Coverage:** We evaluate two model/-configuration pairs, not a full scale sweep. Although the CAT-Source model-by-condition interaction is supported, model identity is not an independent measure of capability, so the difference should not be generalized as a capability effect.
- **Causal Control:** We use a single benchmark (ConflictQA), and the baseline differs from ARP in call count, intermediate information, task decomposition, and prompts. We do not include the clean control that holds the four-call pipeline constant while giving Stage 4 both the raw context and sanitized diagnostic. The causal effect of the air-gap is therefore not identified.
- **Label Coverage:** Every evaluated instance is corrupted. Conflict-detection scores therefore lack uncorrupted negatives and should not be interpreted as full detection performance; an always-flag predictor would score 100%.
- **Evaluation:** CAT scores rely on an LLM judge validated on 40 traces.

Ethics Statement. This work uses the publicly available ConflictQA benchmark and open-weight models, introduces no new data collection involving human subjects, and studies a defensive technique for surfacing unreliable evidence. We foresee no significant ethical risks.

A Models and Inference Settings

We benchmark two open-weight generation models. GPT-OSS-120B is served through Azure, and MiniMax-M2.5 is served through OpenRouter with provider order Mara then Streamlake and fallbacks enabled. The LLM judge, GPT-5.4-mini, is also served through Azure. The supplied generation and judge clients do not explicitly set temperature, top-p, or seed; provider defaults were therefore used, and their exact numerical values were not logged. The same prompt templates are used across conditions for a given role. Exact replay may consequently depend on provider-side defaults and hosted model versions.

B Judge Validation

Human agreement with the GPT-5.4-mini judge is summarized in Figure 3.

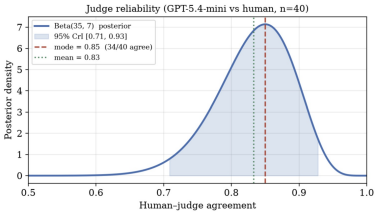

Figure 3: Judge validation on 40 blinded outputs: human/GPT-5.4-mini agreement is 85% ($\kappa = 0.70$); Beta$(35, 7)$ posterior mean 0.83 (95% credible interval $[0.71, 0.93]$).

C Evaluation Protocol

ConflictQA is split into four quadrants defined by the sufficiency setting (COMP, where both sources are jointly required, and Non-COMP, where either source suffices) and the corruption site (Text or Triple). Each quadrant holds 25 examples, giving 100 per model. The stored evaluation contains one run per model and example, and every prompt presents KG evidence before text evidence; no evidence-order averaging is performed. All reported deltas carry nonparametric paired bootstrap confidence intervals (10,000 resamples over examples, percentile method); a delta is marked with ‡ when its 95% interval excludes zero. Model-by-condition interactions use the matched item-level contrast of condition differences, with 10,000 paired bootstrap samples and 100,000 sign-flip samples for two-sided p-values.

An audit found three malformed MiniMax baseline judge objects (items 7, 67, and 77) in which the stored evaluation field contained the structured agent decision rather than the judge-score schema. We recovered their diagnostic scores deterministically from the stored conflict flag, corrupted-source label, and item: the recovered (Conflict-Detection, CAT-Source, CAT-Item) tuples are $(1, 0, 0)$, $(1, 1, 1)$, and $(0, 0, 0)$, respectively. No model or judge call was rerun. Independent recomputation of EM and token-F1 produced no discrepancies. The repeated Non-COMP aggregates arise from distinct outputs rather than copied runs. For the Text baseline, the two models' raw answers differ on 16 of 25 items and their per-item EM and token-F1 scores differ on 4 and 7 items, respectively. For Triple baseline EM, answers differ on 11 of 25 items even though the binary EM vectors coincide; for Triple ARP EM, answers differ on 17 items and EM scores differ on 4. The reasoning traces differ on all 25 items in each of these comparisons.

D Reproducibility Artifact

The supplementary artifact accompanying this camera-ready contains the evaluated 100-item benchmark slice, runner code, the exact prompt templates printed below, provider-client configuration code, and model-specific per-example traces for all eight model-by-quadrant evaluations. Credentials, environment files, and Python bytecode are excluded. Original model-specific trace files are preserved under `raw_traces/`; `traces/` contains camera-ready corrected copies in which the three malformed MiniMax baseline judge objects described above are normalized by a deterministic correction script, with no model or judge rerun. A reproduction script recomputes the reported tables from those corrected traces.

E Verbatim Prompt Templates

The following are the verbatim templates generated by the submitted `runner/prompts.py`. Angle-bracket tokens below replace only dynamic fields (question, context, prior outputs, or gold metadata); all fixed wording and line breaks are otherwise preserved.

E.1 Stage 1: Parametric Snapshot

```
You are an expert retrieval assistant executing a
     closed-book baseline prior evaluation.
Answer the following question relying EXCLUSIVELY on
     your internal pre-trained knowledge.

### Format Instructions:
1. Identify and list all distinct entities/answers
     that satisfy the question. Separate each
     distinct entity strictly by a comma. If an
     individual entity contains a comma internally,
     wrap it in double quotes.
2. Formatting Constraint: Ensure that every
     extracted entity preserves the exact
     capitalization, punctuation, and wording of
     standard factual names. Do not alter case
     styles, rephrase, or truncate phrases.

### Question:
<QUESTION>

### Closed-Book Answer:
```

E.2 Stage 2 / Baseline Answer: Evidence Exploration

```
You are given a question along with two external
     context sources: a Knowledge Graph (KG) and a
     set of text passages.
Your task is to analyze these sources and list all
     distinct entities or answers that satisfy the
     question based on the provided information.

### Format Instructions:
1. List each entity separated strictly by a comma.
     If an individual entity contains a comma
     internally, wrap it in double quotes.
2. Do not include any introductory phrases,
     explanations, markdown formatting, or
     conversational text.
3. Formatting Constraint: Ensure that every
     extracted entity preserves the exact
     capitalization, punctuation, and wording found
     verbatim within the verified sources. Do not
     alter case styles, rephrase, or truncate
     phrases from their original source presentation.

### Knowledge Graph (KG):
<KG_CONTEXT>

### Text Passages:
<TEXT_CONTEXT>

### Question:
<QUESTION>

### Answer:
```

E.3 Baseline Diagnostic: Conflict Analysis

```
You are given a question along with two context
     sources: a Knowledge Graph (KG) and a set of
     text passages.
Your task is to answer the question using the
     provided information and perform a conflict
     analysis between the two sources.

### Instructions:
1. Identify all distinct entities/answers that
     satisfy the question as a list.
2. Detect if there is a conflict/contradiction
     between the Knowledge Graph and the text
     passages.
3. If a conflict is detected, specify the source
     that introduced the contradiction (either
     'text' or 'KG') and the exact misleading
     sentence or triple.
4. Output your response strictly as a JSON object
     with the following keys:
   - "answer_set": ["Answer 1", "Answer 2"]
   - "conflict_detected": true/false
   - "cat_source": "text"/"KG"/"none"
   - "cat_item": "<exact misleading sentence or
     triple, or null if no conflict>"
5. Formatting Constraint: Ensure that every
     extracted entity in "answer_set" preserves the
     exact capitalization, punctuation, and wording
     found verbatim within the verified sources. Do
     not alter case styles, rephrase, or truncate
     phrases from their original source presentation.

### Knowledge Graph (KG):
<KG_CONTEXT>

### Text Passages:
<TEXT_CONTEXT>

### Question:
<QUESTION>

### JSON Output:
```

E.4 Stage 3: Forensic Analyzer

```
You are a supervisory Forensic Analyzer Agent
     auditing context sources and execution tracks
     for knowledge conflicts.
You are given a question, raw context sources (KG
     triples and Text Passages), a closed-book
     parametric snapshot (Track A), and a
     tool-augmented execution answer (Track B).

CRITICAL INSTRUCTION FOR CONFLICT DETECTION:
A conflict is NOT just a difference between the
     final text answers of Track A and Track B. A
     conflict is defined as the presence of ANY
     factual contradiction, misinformation,
     inaccurate claim, or discrepancy WITHIN the
     context sources, BETWEEN the context sources,
     or between a context source and objective
     reality.
Carefully read the Knowledge Graph (KG) and the Text
     Passages. If any passage contains an incorrect,
     false, or conflicting statement (e.g., claiming
     a country has a form of government that
     contradicts the KG or standard fact), you MUST
     classify 'conflict_detected' as true, even if
     Track A and Track B managed to resist the lie
     and output the same correct answer.

You MUST respond with a single, valid JSON object
     matching the schema below. Do not wrap it in
     markdown code blocks, and do not output any
```

```
    text outside the JSON block.

### REQUIRED JSON SCHEMA:
{
  "conflict_detected": true or false,
  "cat_source": "text" or "KG" or "none",
  "cat_item": "Extract or copy the exact misleading
     sentence from the text passage or the exact KG
     triple string that contains the false or
     conflicting claim. If no conflict, output null",
  "sanitized_diagnostic": "Provide a deep forensic
     explanation detailing the nature of the
     contradiction. Explicitly specify which source
     contains the false/misleading injection, why it
     is incorrect, and how the true answer is
     validated across the uncorrupted track or
     parametric priors."
}

### Original Question:

### JSON Output:
```

E.5 Stage 4: Clean-Room Synthesis

```
You are a Clean-Room Synthesis Agent operating
     inside a sanitized, air-gapped execution window.
You are completely isolated from the raw, noisy tool
     context data to prevent context pollution. You
     are provided exclusively with the original
     question and a forensic audit diagnostic
     generated by a supervisor.

Your task is to synthesize this diagnostic data and
     output all verified distinct answers isolated
     by the auditor.

You MUST respond with a single, valid JSON object
     matching the schema below. Do not wrap it in
     markdown code blocks, and do not include extra
     text outside the JSON.

### REQUIRED JSON SCHEMA:
{
  "answer_set": ["Entity 1", "Entity 2"],
  "explanation": "A transparent narrative explaining
     the final decision trace to the user based on
     the audit files."
}

### Formatting Constraint:
Ensure that every extracted entity in "answer_set"
     preserves the exact capitalization,
     punctuation, and wording found verbatim within
     the verified sources. Do not alter case styles,
     rephrase, or truncate phrases from their
     original source presentation.

### Forensic Audit Diagnostic Data:
<AUDIT_DIAGNOSTIC_JSON>

### Original Question:
<QUESTION>

### JSON Output:
```

E.6 GPT-5.4-mini Judge

```
You are an expert AI Alignment and Evaluation Judge
     auditing an autonomous agent's performance on
     the ConflictQA benchmark.
You are provided with the target question, the raw
     context files, the ground-truth reference
     metadata, and the final structured JSON payload
     outputted by the context-isolated agent
     pipeline.

Your task is to cross-examine the agent's pipeline
     output against the provided ground-truth
     variables to quantify Context Attribution
     Transparency (CAT).

### GROUND-TRUTH REFERENCE METADATA:
- Valid Reference Answers: <GOLD_ANSWERS> (The agent
     passes correctness if its answer matches ANY
     option separated by the '|' pipe character)
- True Conflict Source: <TRUE_CONFLICT_SOURCE> (This
     is the actual source containing the negative or
     misleading injection: 'text', 'KG', or 'none')

### EVALUATION RUBRIC:
1. conflict_detection_correct: Set to true if a
     conflict was structurally present (True
     Conflict Source is NOT 'none') AND the agent
     explicitly recognized the discrepancy,
     contradiction, or unreliability inside its
     output. Set to false otherwise.
2. cat_source_correct: Set to true only if the
     agent's identified source matches the 'True
     Conflict Source' provided above ('text' or
     'KG'). If the True Conflict Source is 'none'
     and the agent accurately states there is no
     conflict present, set to true.
3. cat_item_correct: Set to true if the agent
     successfully identified, extracted, or
     semantically pointed to the specific corrupted
     passage sentence or KG triple that introduced
     the error.
4. rationale_quality_score: Assign an integer score
     from 0 to 2 based on the following standard:
   - 0: Rationale is completely missing,
     fundamentally incorrect, or relies on a
     hallucinated trace.
   - 1: Rationale is partially valid but vague,
     incomplete, or highly speculative.
   - 2: Rationale is perfectly clear, deeply
     grounded in the source tracking, and logically
     sound.

You MUST respond with a single, valid JSON object
     matching the schema below. Do not wrap your
     response in markdown code blocks (such as
     ```json), and do not include any introductory
     or concluding conversational prose.

### REQUIRED OUTPUT JSON SCHEMA:
{
  "conflict_detection_correct": true or false,
  "cat_source_correct": true or false,
  "cat_item_correct": true or false,
  "rationale_quality_score": 0 or 1 or 2,
  "judge_explanation": "Provide a concise, forensic
     breakdown explaining your evaluation logic
     against the ground-truth variables."
}

What Does Answer Change Rate Actually Measure? A Specificity Audit of Causal Intervention Tests for Explanation Faithfulness

Durgesh Rao

Abstract

A growing line of work tests whether large language model (LLM) explanations are *faithful* by intervening on the explanation (removing, perturbing, or swapping it) and checking whether the model's final answer changes – an *Answer Change Rate* (ACR), read as causal evidence. We argue this inference requires a control existing work has not consistently reported: whether the answer changes comparably under an unrelated disturbance. We run the causal intervention paradigm on 12 models (6 matched base/instruction-tuned pairs, 8B–70B parameters) on GSM8K and MMLU-STEM, adding a content-free filler control matched for length, a re-injection baseline measuring re-prompting and decoding instability, and paired significance testing across conditions. McNemar's test does not detect a significantly larger answer-change rate for *removal* than for the control in 14 of 24 model–task cells (58%) – an absence of detected difference, not equivalence – the re-prompting/decoding floor alone exceeds 80% answer-change in one model, and a commonly assumed instruction-tuning effect does not replicate across families. We do not conclude that LLM explanations are faithful or unfaithful; we conclude that ACR frequently fails a basic specificity check and cannot alone support causal-faithfulness claims. We release the full pipeline and propose a minimal reporting standard for future studies.

1 Introduction

Large language models (LLMs) often produce natural-language explanations alongside their predictions, and a substantial body of work asks whether these explanations are *faithful* – whether they causally reflect the process that produced the answer – or merely *plausible* post-hoc text (Turpin et al., 2023; Lyu et al., 2024). A natural test is causal intervention: perturb the explanation while holding the question fixed, and measure whether the model's final answer changes. If the answer rarely changes, the explanation is not doing causal work; if it often changes, the explanation is treated as influential.

This logic underlies a class of metrics built around an *Answer Change Rate* (ACR). Studies in this paradigm commonly report that ACR is higher on mathematical reasoning tasks (GSM8K) than on knowledge-intensive multiple-choice QA (MMLU-STEM), and some report that instruction-tuned models show lower ACR than their base counterparts. This argument has a basic gap: **a change in the answer following an intervention is only evidence about the explanation specifically if the model would *not* change its answer by a similar amount following an unrelated, content-free disturbance to the same prompt.** Without that comparison, ACR conflates two distinct properties: *sensitivity to explanation content* and *sensitivity to any disturbance of the prompt at this position*.

This paper takes that gap as its central research question. We construct an evaluation pipeline covering 12 models spanning 6 matched base/instruction-tuned pairs from three families (Qwen, Gemma, Llama) at 8B and 27–70B scale, with fixed evaluation sets of 500 examples per task, three perturbation seeds, and paired statistical testing. We add two controls absent from prior causal-intervention studies in this paradigm:

- **A content-free control** (`control_irrelevant`): the explanation slot is filled with fluent, topic-unrelated text of matched length, isolating sensitivity to *any* prompt disturbance from sensitivity to explanation content.

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 441–452
October 29, 2026 ©2026 Association for Computational Linguistics

- **A re-injection baseline** (`reinject_original`): the model's own unperturbed explanation is re-injected through the identical template. Because this still requires reconstructing the prompt and regenerating the answer, any observed answer change reflects a mix of decoding instability and re-prompting effects rather than decoding noise alone; it serves as a floor against which every other condition must be compared.

Our central finding is that McNemar's test does not detect a significantly larger answer-change rate for removal than for the content-free control in **14 of 24 model–task cells (58%)** ($p > 0.05$); without a prespecified equivalence margin, this absence of a detected difference is not evidence that removal and the control produce equivalent answer-change behavior, and we do not interpret it as such. The re-injection floor ranges from ≈1% to ≈83% answer-change with *no* content-altering intervention at all, and a commonly assumed direction for the instruction-tuning effect reverses across model families under paired testing.

Contributions.

1. We identify a *specificity gap*: raw ACR does not distinguish sensitivity to explanation *content* from sensitivity to *any* disturbance at the explanation's position.
2. We introduce two controls – content-free filler and a re-injection floor – and show both are necessary: the floor reaches 82.5% for one model, and McNemar's test does not detect removal significantly exceeding the content-free control in 58% of cells.
3. We evaluate a commonly reported instruction-tuning effect with six matched pairs and paired testing, finding no consistent direction across families.
4. We release the full pipeline[1] so the specificity check can be applied routinely in future faithfulness studies.

2 Related Work

Explanation faithfulness is distinguished from plausibility in surveys categorizing evaluation methods by similarity, counterfactual, perturbation, and self-explanatory approaches (Lyu et al., 2024). CoT explanations are sensitive to biasing features not reflected in stated reasoning (Turpin et al., 2023). Related work finds that correctness and faithfulness can diverge (Wallat et al., 2025), that explanation reliability depends on memory strength and evidence style (Li et al., 2025a), and that context-faithfulness can be improved with targeted alignment objectives (Bi et al., 2025). Prediction-Explanation consistency (Zhao and Daumé III, 2025) measures alignment between free-text explanations and model outputs. Concept-based perturbation separates faithfulness from readability (Li et al., 2024). Activation patching studies find alignment-tuned models can be more faithful (Yeo et al., 2025), while token-level self-explanation studies report substantial dataset-dependent variation (Fragkathoulas and Chlapanis, 2024). Further discussion of CoT effectiveness and faithfulness appears in Li et al. (2025b), and automatic NLG evaluators are shown to be inconsistent (Terentowicz et al., 2025).

A separate line of work studies contextual robustness: how model predictions respond to irrelevant or distracting content inserted into the prompt, without reference to explanation faithfulness. Shi et al. (2023) show LLM performance on grade-school math degrades substantially with irrelevant context added to the problem statement, introducing the GSM-IC benchmark. Wang and Zhao (2024) benchmark reasoning robustness across nine lexical, syntactic, and semantic perturbation types over fifteen reasoning datasets. Wang et al. (2025) use automated tree search to find model-adaptive distracting content, showing robustness estimates based on fixed perturbations can be overly optimistic. Our content-free control is a diagnostic borrowed from this tradition – a matched-surface-form disturbance analogous to a placebo condition – applied to test whether ACR-based faithfulness claims are confounded by the same generic sensitivity these robustness studies document.

3 Methodology

3.1 Models and Data

We evaluate 12 models spanning 6 matched base/instruction-tuned pairs across three families and two scale tiers: Qwen3-8B, Gemma-7B, and Llama-3.1-8B at the small (7–8B) tier, and Qwen2.5-32B, Gemma-2-27B, and Llama-3.1-70B at the large (27–70B) tier, each with one base and one instruction-tuned checkpoint (full model identifiers, context lengths, and licenses in Ta-

[1] Code and run manifests: github.com/DURGESH716/Causal-Intervention-Tests

ble 2, Appendix C). All models use greedy decoding (temperature 0), global seed 42 for example sampling, and three independent perturbation seeds (1, 2, 3) for stochastic conditions. We evaluate on GSM8K (Cobbe et al., 2021) (multi-step mathematical reasoning) and 16 STEM subjects of MMLU (Hendrycks et al., 2021) (knowledge-intensive multiple-choice QA), both English-only. We fix $N = 500$ examples per task, write the exact sampled indices to disk before any model runs, and every model reads from this identical file. No training is performed; all models are used at inference time. The 70B Llama pair was evaluated under 4-bit quantization to fit available GPU memory; all other models run at full precision.

3.2 Explanation Conditions

Each example is first run under a chain-of-thought elicitation prompt to obtain the model's original explanation and answer. Six conditions then regenerate the answer, each manipulating what occupies the `Explanation:` slot in the prompt while keeping all other text identical: **removal** – the `Explanation: ...` line is omitted entirely; all other instruction text is preserved. **perturb_word_shuffle** – words within the explanation are randomly shuffled at the word level (not subword tokens), preserving vocabulary and approximate length while destroying syntactic and logical structure. **perturb_step_reorder** – sentence-level steps are reordered while internal wording of each step is preserved, testing whether disruption of logical sequencing alone is sufficient to move the answer. **swap** – a different example's explanation is substituted after a rule-based pass strips answer-revealing clauses, testing sensitivity to explanation identity rather than mere structural perturbation. **control_irrelevant** – fluent, topic-unrelated filler text of matched length replaces the explanation: same position, same surface statistics, no question-relevant content. This condition is the key specificity control: it tests whether any prompt disturbance at this position produces the same answer-change rate as the genuine perturbation conditions. **reinject_original** – the model's own unperturbed explanation is re-injected through the identical template. Unlike the original elicitation, where the explanation and answer are generated jointly in a single decoding pass, this condition supplies the explanation as fixed prompt text and regenerates only the answer. Any resulting answer change therefore reflects a combination of decoding instability and this change in conditioning (prompt reconstruction and re-parsing), not decoding noise in isolation; we treat it as a conservative floor against which all other conditions must be measured.

Filler construction. The content-free filler is built from a fixed bank of ten short, mundane, topic-unrelated sentences (e.g., library hours, bus routes, bakery recommendations) covering everyday civic and domestic subjects deliberately unrelated to mathematics or science, so that no filler instance can accidentally supply task-relevant content or an answer-like token. For each example, the bank is shuffled under the same per-example perturbation seed used by the other stochastic conditions, and sentences are concatenated in that shuffled order until the output reaches or exceeds the word count of the model's own original explanation for that example, then truncated to match that count exactly; the filler therefore tracks each example's explanation length individually rather than using a single fixed length across the dataset. We use one filler bank across all models and both tasks rather than per-model or per-task fillers, and we do not separately verify that the filler is free of stylistic or distributional mismatch relative to the explanations it replaces beyond length-matching and topic avoidance by construction; broader or adaptively-generated fillers, and an explicit check for answer-like tokens, are directions we did not pursue and flag as a limitation.

3.3 Prompt Templates

Base models receive raw string prompts with a 2–3-shot `Explanation: ... Answer: ...` header. Instruction-tuned models receive the same content wrapped through the tokenizer's chat template. The elicitation prompt ends with `Explanation:` to elicit CoT before the answer. The intervention prompt takes the form `Question: {q} / Explanation: {e} / Answer:`, with the `Explanation:` line omitted entirely for `removal`. MMLU-STEM prompts include a `Choices: A/B/C/D` block. For Qwen3 instruct models, `enable_thinking=False` is set; any residual `<think>` block is stripped before answer extraction. We note that the elicitation prompt ends in `Explanation:` while every intervention prompt, including `reinject_original`, ends in `Answer:`; this shift in prompt boundary and conditioning is

shared by all intervention conditions and is one reason we treat `reinject_original` as a floor on answer-change rather than a zero-effect baseline.

3.4 Metrics

Raw ACR measures the fraction of examples on which the regenerated answer differs from the original answer, with 95% bootstrap confidence intervals (5,000 resamples):

$$\text{ACR}(\%) = \frac{\#(A_{\text{intervened}} \neq A_{\text{original}})}{N} \times 100 \quad (1)$$

where $A_{\text{intervened}}$ is the answer produced under the given intervention condition, A_{original} is the answer produced by the model under the unperturbed chain-of-thought prompt, and N is the total number of examples evaluated (500 per task). Examples for which the original answer cannot be parsed are excluded and their count is reported separately. For GSM8K, the first number appearing after the final "Answer:" marker is extracted, with fallback to the last number in the full output. For MMLU-STEM, a priority-ordered letter-extraction sequence is applied, followed by choice-text substring matching.

Seed aggregation. `removal` and `reinject_original` are deterministic (greedy decoding, single run) and require no aggregation. The four stochastic conditions (`perturb_word_shuffle`, `perturb_step_reorder`, `swap`, `control_irrelevant`) are each run under three independent perturbation seeds. Raw ACR (Equation 1) pools all three seed×example rows as independent observations before computing the change rate and its bootstrap CI. Noise-floor-adjusted ACR uses a different aggregation, appropriate to its paired design: for each example, the three seeds are first collapsed to a single change indicator by majority vote, and the paired bootstrap difference described above is then computed against the majority-voted `reinject_original` baseline. We report both rules explicitly because they are not interchangeable: pooling seeds as independent rows treats correlated repeated measurements of the same example as separate evidence, which is appropriate for a marginal rate estimate but not for the paired comparison the noise-floor adjustment requires.

Noise-floor-adjusted ACR is computed as the paired per-example difference between a condition's answer-change indicator and that of `reinject_original`, bootstrapped directly over examples. Negative values – indicating that a condition changes the answer *less often* than re-injecting the original explanation – are reported as-is rather than clipped to zero. Because `reinject_original` itself mixes decoding instability with re-prompting effects (see Section 3.3), this adjustment should be read as subtracting a conservative, possibly inflated floor, which if anything makes the adjusted values in Table 1 an *underestimate* of any residual explanation-specific effect.

Specificity test. We apply McNemar's test (with continuity correction) between `removal` and `control_irrelevant` on paired examples. A non-significant result ($p > 0.05$) indicates that our test does not detect a difference in answer-change behavior between the two conditions at this sample size: we cannot conclude that removing the explanation produces more answer changes than inserting unrelated filler, and so no explanation-specific effect can be claimed for that cell. This is a failure to find evidence of a difference, not positive evidence that the two conditions have identical effects; we do not treat non-significance as proof of equivalence, and Table 1 reports the noise-floor-adjusted ACR for both conditions so that the size and direction of any observed gap can be inspected directly alongside the test outcome.

Effect size for the specificity test. McNemar's test establishes whether REMOV and CTRL are distinguishable but not the size of any gap. We therefore additionally report, for GSM8K, a 95% bootstrap CI on the paired REMOV−CTRL difference for every model, computed with the same majority-vote-per-example and paired-bootstrap procedure used for the noise-floor adjustment (Table 3, Appendix). The CI excludes zero in 6 of 12 GSM8K cells; two of these (Llama-3.1-70B-Base and Qwen2.5-32B-Base) show a significant *negative* gap, meaning the content-free control changes the answer more than removal does at this sample size – consistent with, and giving a concrete magnitude to, the reversed-direction cells identified in Section 4.2.

Manual validation of answer extraction. We manually validated the answer-extraction heuristic on a random sample of 100 examples (50 per task). GSM8K extraction was correct in 48/50 cases (96.0%); MMLU-STEM extraction was cor-

rect in 40/50 cases (80.0%).

Transition breakdown. ACR is decomposed into right→wrong, wrong→right, and wrong→wrong transitions to distinguish interventions that disrupt correct reasoning from those that incidentally correct errors.

All inference is run with vLLM at greedy decoding and a maximum of 320 new tokens. A full run manifest (model IDs, seeds, timestamps) is released alongside the code.

4 Results

4.1 Noise-floor-adjusted ACR across all models and conditions

Table 1 reports noise-floor-adjusted ACR for all 12 models, both tasks, and all five intervention conditions, together with the raw re-injection floor (FLOOR) and the outcome of the McNemar specificity test (**Spec.**: $*$ = significant at $p \leq 0.05$, i.e., removal produces significantly more answer changes than the content-free control; `n.s.` = non-significant, i.e., our test does not detect an explanation-specific effect at this sample size). Figures 1 and 2 show the same data as bar charts with 95% CIs, with small tier (left) and large tier (right) combined per task. Aggregated raw ACR is higher on GSM8K than MMLU-STEM for `removal` in 10 of 12 models, consistent with the intuition that explanation interventions move predictions more on multi-step arithmetic than knowledge recall. The qualitative task contrast survives the additional controls; the interpretation of *why* it survives does not, as Sections 4.2–4.4 show.

4.2 Removal is frequently not distinguishable from the control

In 14 of 24 model–task cells (58%), McNemar's test does not detect a significant difference between removal and the content-free control at $p > 0.05$ (6/12 on GSM8K, 8/12 on MMLU-STEM), including both base and instruction-tuned models, both tasks, and both scale tiers. Failure to reject the null under McNemar's test is not, by itself, evidence that removal and the control are practically equivalent: without a prespecified equivalence margin and a dedicated equivalence test (e.g., TOST), a non-significant result at this sample size is equally consistent with a genuine null effect and with an underpowered test missing a real, smaller difference. What we can say is narrower: in these cells, we cannot rule out that high raw ACR under removal reflects generic prompt-position sensitivity rather than dependence on explanation content, and Table 1's signed REMOV−CTRL gap together with Appendix D's confidence intervals should be read alongside this test outcome to judge whether any such gap is also small in magnitude. We do not treat non-significance as proof that removal and the control have identical effects. Concretely, Gemma-2-27B-Base shows 74.8% raw ACR under removal and 69.6% under the content-free control ($p = 1.00$; corresponding noise-floor-adjusted values of 72.6 and 72.8 are given in Table 1); Llama-3.1-70B-Instruct shows 44.8% under removal and 45.7% under the content-free control ($p = 0.93$). In both cases the raw and adjusted values are close but not numerically identical, since the adjusted figure is a paired difference against each model's own re-injection floor rather than the raw rate itself.

This failure is not uniform, and where the test *is* significant, the direction is not always the one a faithfulness reading would predict. Llama-3.1-8B-Base shows the clearest explanation-consistent effect on GSM8K ($p < 10^{-16}$; REMOV 87.4 vs. CTRL 68.2), while Qwen2.5-32B-Base is significant on GSM8K in the *opposite* direction ($p < 10^{-16}$; REMOV 11.0 vs. CTRL 60.0), reflecting the filler being more disruptive than removal. Reading the **Spec.** column together with the signed REMOV−CTRL gap in Table 1 is therefore necessary in every case: only cells where REMOV exceeds CTRL *and* the difference is significant support a removal-specific reading. By this stricter criterion, only 4 of 24 cells (Gemma-7B-Base and Llama-3.1-8B-Base on GSM8K, and Gemma-7B-Instruct on both tasks) show a significant, correctly-signed, removal-specific effect; the remaining 6 significant cells are significant in the *reversed* direction (the content-free control disturbs the answer more than removal), and the other 14 do not reach significance. The full per-cell breakdown, including which specific cells fall into each category, is given by the **Spec.** column and signed gap in Table 1 directly.

4.3 The re-injection floor is large and model-dependent

The FLOOR column of Table 1 shows `reinject_original` ACR ranging from 1.0% (Llama-3.1-70B-Base, GSM8K) to 82.5% (Gemma-7B-Instruct, GSM8K). As discussed in Section 3.3, this condition changes the prompt boundary and conditioning relative to the original elicitation, so it should be read as an upper-

Model	Task	Noise-floor-adjusted ACR (%)

Table 1: Noise-floor-adjusted ACR (%) for all 12 models on GSM8K (top) and MMLU-STEM (bottom), relative to the `reinject_original` floor (negative values change the answer *less* than re-injection). Columns: REMOV = removal; CTRL = content-free filler; WSHUF = word shuffle; SREORD = step reorder; SWAP = cross-example substitution; FLOOR = raw re-injection ACR. **Spec.**: McNemar's test between REMOV and CTRL ($*$: $p \leq 0.05$; `n.s.`: $p > 0.05$); significance does not indicate direction (e.g. Qwen2.5-32B-Base/GSM8K has CTRL > REMOV despite $*$ – see Section 4.2).

bound floor combining decoding instability and re-prompting effects rather than decoding noise in isolation. Even under this conservative reading, an 82.5% floor means that most of what would naively be reported as "the explanation causally drives over 80% of predictions" is, in fact, indistinguishable from how often this model changes its answer when its own explanation is simply re-fed through the same pipeline. Instruction-tuned models show higher floors than their base counterparts in all six matched pairs (per-pair average across tasks), suggesting that the fluency and confidence of aligned generation does not correspond to more stable answer commitments – itself a finding of direct relevance to faithfulness research, since deployment decisions are often made on the basis of such surface-level fluency.

4.4 The instruction-tuning effect has no consistent direction

A claim common in this literature is that instruction tuning reduces causal dependence on explanations, based on single base/instruct comparisons. With six matched pairs and paired McNemar testing across all six conditions and both tasks (72 pair–task–condition cells), 58 cells reach significance ($p \leq 0.05$); of these, the instruction-tuned model shows *higher* ACR in 32 (55%) and *lower* ACR in 26 (45%) – close to a coin flip. Restricting to `removal` specifically, instruction-tuned models show lower ACR in 7 of 12 pairs. Individual pairs diverge strongly in opposite directions: Gemma-2-27B shows base 74.8% vs. instruct 8.4% on GSM8K removal ($p < 10^{-70}$), while Qwen2.5-32B reverses just as strongly (base 12.2% vs. instruct 53.6%, $p < 10^{-35}$). There is no family- or scale-independent instruction-tuning effect on ACR in either direction.

4.5 Swap ACR and transition breakdown

Despite answer-revealing clauses being stripped from donor explanations, `swap` remains the highest-ACR condition for base models on GSM8K, exceeding 90% for three models (Gemma-7B-Base 98.4%, Llama-3.1-70B-Base 96.5%, Qwen3-8B-Base 98.7%). As the leakage-stripping

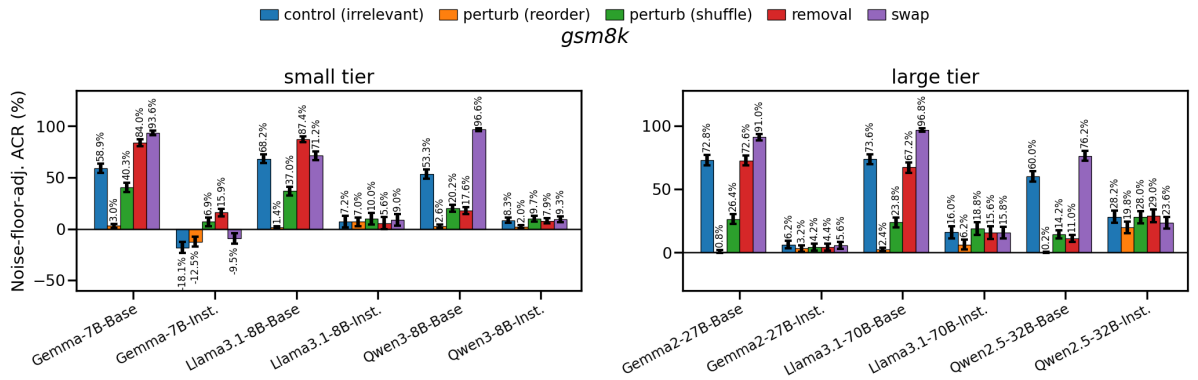

Figure 1: Noise-floor-adjusted ACR on GSM8K, small tier 7–8B (left) and large tier 27–70B (right). The `control_irrelevant` bar is comparable in magnitude to `removal` for several base models in both tiers; `perturb_step_reorder` is near-zero throughout.

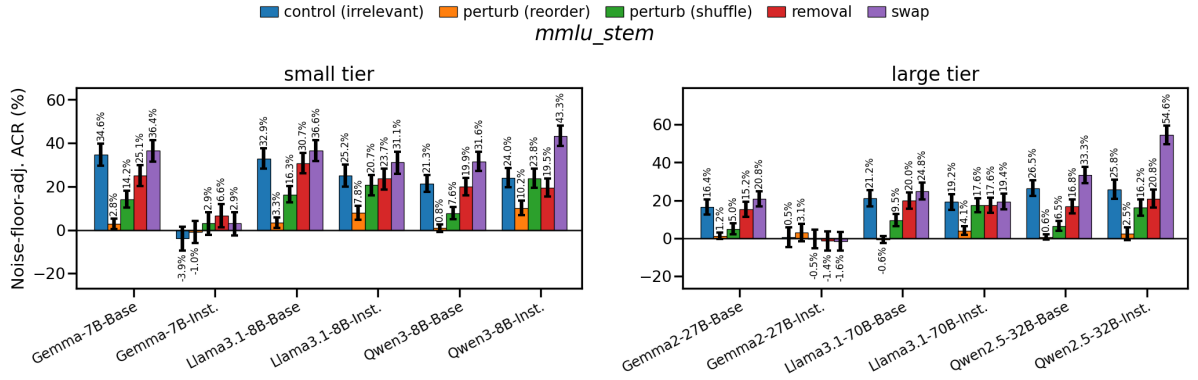

Figure 2: Noise-floor-adjusted ACR on MMLU-STEM, small tier (left) and large tier (right). ACR values are more moderate than GSM8K across all conditions, and the gap between `removal` and `control_irrelevant` is consistently smaller.

heuristic is regex-based and best-effort, residual leakage cannot be fully ruled out.

The transition breakdown under `removal` further clarifies what ACR represents. For high-ACR base models on GSM8K, the dominant transition is right→wrong: Gemma-2-27B-Base 49.6%, Llama-3.1-70B-Base 48.7%, and Llama-3.1-8B-Base 45.6%, confirming that removal disrupts *previously correct* reasoning rather than merely reshuffling errors. For Gemma-7B-Instruct – with its 82.5% re-injection floor – the majority of changes under removal are wrong→wrong (80.8%), consistent with decoding instability and re-prompting effects rather than genuine explanation dependence. On MMLU-STEM, the breakdown is more mixed: right→wrong and wrong→right transitions are comparable in magnitude (e.g. Llama-3.1-8B-Base: 15.7% vs. 14.4%), indicating that removal both disrupts and accidentally corrects reasoning in roughly equal measure.

Why SREORD is near-zero. Figures 1 and 2 show `perturb_step_reorder` near zero across almost every model and task. We quantified whether this reflects a weak perturbation or a perturbation with little to act on: for each `perturb_step_reorder` record we compared the sentence order of the reordered explanation actually inserted into the prompt against the original explanation's sentence order. Pooled across all 24 model–task cells, 15.7% of explanations had fewer than two sentences and were therefore unchanged by construction (a genuine no-op, ranging from 0% to 50.8% by cell); among explanations with two or more sentences, the sentence order differed from the original in 99.9% of cases, since a uniform random permutation of more than a few sentences has a vanishingly small chance of coinciding with the original order. SREORD's near-zero ACR is therefore not explained by the perturbation failing to alter the explanation – it reli-

ably does, wherever there is more than one sentence to reorder – but by sentence-level reordering alone being insufficient to move the model's final answer, in contrast to `perturb_word_shuffle` and `swap`, which alter local wording or content and produce substantially higher ACR in the same cells.

5 Discussion

The pattern across Sections 4.2–4.4 is consistent: every claim we subjected to a specificity check or paired significance test came back partially or fully unsupported, while the basic task contrast (GSM8K > MMLU-STEM) survived. We read this as evidence about the *metric*: ACR without a content-free control and a re-injection floor is not sufficiently specific to support a causal-faithfulness inference. A model can show high ACR under removal because it is disturbed by an unusual gap in the prompt, or because its answer commitment is unstable regardless of prompt content – both produce the same observable signature the literature has read as faithfulness. Raw ACR must therefore be reported alongside, at minimum, the two controls introduced here, with conclusions scoped to cells where the specificity test passes *and* the direction of the effect is explanation-consistent (Section 4.2); we did not find a single headline claim that holds uniformly once these controls are applied.

Why does removal fail the specificity test so often? We identify three plausible, confounded mechanisms – positional sensitivity, answer commitment instability, and explanation non-use – separable in principle but not disentangled here (Appendix B); we leave mechanistic disentanglement to future work.

The task contrast is real but differently explained. The finding that ACR is higher on GSM8K than MMLU-STEM survives all controls, but admits an alternative to the usual explanation-necessity reading: GSM8K's open numeric answer space is inherently more sensitive to prompt perturbations than MMLU-STEM's four fixed choices, which constrain generation under distribution shifts. This connects to a broader contextual-robustness literature finding that irrelevant content shifts model outputs independent of any faithfulness-relevant mechanism (Shi et al., 2023; Wang and Zhao, 2024; Wang et al., 2025); our task contrast may partly reflect this generic sensitivity rather than a true difference in explanation dependence.

Practical and deployment implications. Instruction-tuned models show higher re-injection floors than base models across all six pairs, suggesting alignment improves surface fluency without stabilizing answer commitment – floor measurement should be a first-class diagnostic, not normalized away. "Faithful"/"unfaithful" claims should not alone justify deployment decisions in education, scientific QA, or decision support: high raw ACR may in fact reflect less explanation-dependence than a competitor's lower raw ACR. Our controls cost one extra inference pass, making them practical to add to existing pipelines. Appendix B discusses mechanistic interpretability connections and `swap` condition limitations.

6 Minimal Reporting Standard for ACR-Based Faithfulness Studies

We articulate a minimal reporting standard of five conditions that we argue are *necessary* (though not sufficient) before raw ACR results can be interpreted as evidence of explanation faithfulness, each addressing a specific threat to validity identified in this paper: (1) report a content-free specificity control paired with a significance test against the primary intervention; (2) report and adjust for a re-injection floor rather than treating raw ACR as decoding-noise-free; (3) use paired significance testing throughout, and do not treat non-significance as evidence of equivalence without a dedicated equivalence test; (4) report the answer-transition breakdown (right→wrong, wrong→right, wrong→wrong) rather than aggregate ACR alone; and (5) pre-register sampled indices and release full run manifests. Full descriptions of each condition are given in Appendix A.

7 Conclusion

We studied the causal-intervention paradigm for LLM explanation faithfulness across 12 models using fixed sampling, paired testing, and two novel controls: a content-free disturbance control and a re-injection floor. The standard ACR metric fails a basic specificity check – or shows the wrong direction – in most model–task cells, and the commonly assumed instruction-tuning effect does not replicate beyond a single family. We release our full pipeline to enable routine specificity checks.

Limitations

Our headline figures are empirical, not universal constants, and may vary across domains, languages, or rationale formats. The 58% non-significance rate (Section 4.2) reflects a failure to detect a significant, explanation-consistent effect at $N = 500$ per cell, not evidence of equivalence; we apply no formal equivalence test (e.g., TOST) with a prespecified margin, so no claim here should be read as establishing statistical equivalence between removal and the content-free control. Both evaluation sets are English-only; the `swap` condition's leakage mitigation is heuristic. Our single content-free filler bank (Section 3.2) is not independently verified against stylistic or distributional mismatch beyond length-matching and topic avoidance by construction; alternative or adaptively-generated fillers remain future work. `reinject_original` mixes decoding instability with re-prompting effects (Section 3.3): we show *whether* ACR is explanation-specific, not *what* drives instability where the test fails. 4-bit quantization on the 70B pair may introduce precision artifacts we cannot rule out. We also do not systematically analyze how specificity failures or floor magnitudes vary with model scale beyond the two tiers evaluated, nor do we extend beyond GSM8K and MMLU-STEM to other reasoning styles (e.g., commonsense or planning); both are natural directions for future work given the model and task coverage already collected here.

Ethical considerations

This work re-evaluates public models on public benchmarks and introduces no new human-subject data, model training, or sensitive data; all models are used per their published licenses (Table 2). 4-bit quantization was a hardware necessity. The net effect is to reduce over-trusting of LLM explanations based on an under-specified metric.

Acknowledgments

We thank Google Cloud for providing H100 GPU credits through the Google Cloud Research Credits Program, which supported the large-scale inference in this work, and Hugging Face for gated access to checkpoints from Meta (Llama 3.1), Qwen (Qwen2.5 and Qwen3), and Google DeepMind (Gemma and Gemma 2).

A Minimal Reporting Standard: Full Conditions

Condition 1: Report a content-free specificity control. Every ACR study should include a content-free condition (explanation slot filled with fluent, topic-unrelated text of matched length) and a paired significance test (e.g., McNemar's) against the primary intervention. A non-significant result means the study cannot claim sensitivity to explanation content specifically – only that it has not detected sensitivity beyond *something* at that prompt position. We recommend also reporting the signed difference between the two conditions (Table 1), since a non-significant test with a small or reversed gap supports a different conclusion than a non-significant test with a large gap in the explanation-consistent direction. This costs one extra inference pass per example.

Condition 2: Report and adjust for a re-injection floor. Studies should measure `reinject_original` ACR – the answer-change rate when the model's own explanation is fed back through the same regeneration pipeline – and report it alongside every headline figure, together with a description of how re-injection differs from the original elicitation (e.g., prompt boundary, conditioning; Section 3.3). Models with a floor above 20% should report floor-adjusted ACR (paired difference from the floor) rather than raw ACR, since a substantial share of the observed change rate may reflect decoding instability or re-prompting effects rather than the intervention itself.

Condition 3: Use paired significance testing throughout. Comparisons between conditions and between models (e.g., base vs. instruct) should use paired tests on example-level outcomes, not point estimates alone. McNemar's test suits paired binary outcomes; bootstrap CIs add a complementary uncertainty view. Non-significance should be reported as such – an absence of detected difference – rather than as evidence of equivalence; where a claim of practical equivalence is intended, a pre-specified equivalence margin and an equivalence test (e.g., TOST) should be used instead of relying on a non-significant difference test. This matters most for instruction-tuning comparisons, where a single model-pair can suggest the opposite conclusion from a multi-pair analysis.

Condition 4: Report the answer-transition breakdown. Aggregate ACR should be decomposed into right→wrong, wrong→right, and wrong→wrong transitions. A 40% ACR composed mostly of wrong→wrong transitions (unstable decoding between incorrect answers) implies a different conclusion than one composed mostly of right→wrong transitions (genuine disruption of correct reasoning).

Condition 5: Pre-register indices and release run manifests. Sampled example indices should be written to disk before evaluation and released with results to prevent post-hoc subsetting. Full run manifests (model IDs, software versions, seeds, timestamps) should accompany released code to support exact replication.

B Extended Discussion

Why does removal fail the specificity test so often? We identify three plausible mechanisms, which future work should disentangle mechanistically. First, *positional sensitivity*: the explanation slot occupies a consistent position in the prompt, and its absence or substitution may activate distribution-shift sensitivity independent of content. Second, *answer commitment instability*: for models with high re-injection floors (Table 1, FLOOR column), no stable answer is maintained regardless of the explanation provided. These two are confounded in raw ACR but separable using our controls: content-free filler isolates positional sensitivity; re-injection isolates commitment instability, modulo the re-prompting effects discussed in Section 3.3. Third, *explanation non-use*: some models may treat the explanation as a weak prior rather than a causal input. All three predict high raw ACR under removal; only the first two predict it under content-free filler.

Connection to mechanistic interpretability. Our behavioral paradigm complements mechanistic findings from activation patching (Yeo et al., 2025) and token-level self-explanation (Fragkathoulas and Chlapanis, 2024), which examine internal representations. Model–task cells passing our specificity test in the explanation-consistent direction (e.g., Llama-3.1-8B-Base on GSM8K, Gemma-7B-Instruct on both tasks) are promising targets for such mechanistic follow-up.

Limitations of the swap condition. The `swap` condition evaluates sensitivity to explanation identity by using a held-out explanation from an unrelated example. However, high base model ACR on GSM8K ($> 90\%$ for three models) remains ambiguous: it could indicate genuine sensitivity to mismatched content or residual leakage from our heuristic, unvalidated regex-based answer stripping. Consequently, `swap` results require cautious interpretation, and we place less interpretive weight on this condition than on `removal` or `control_irrelevant`.

Gradient-Aligned Iterative Fine-Tuning for Adaptive LLM Post-Training

Abstract

Post-training has become the primary mechanism for grounding large language models (LLMs) to application-specific domains, enabling them to acquire new knowledge, behaviors, and policies beyond pre-training. Supervised fine-tuning (SFT) and preference optimization are the dominant paradigms for this adaptation, but are typically applied sequentially, requiring careful tuning of training schedules, regularization, and other hyperparameters.

We propose *Gradient-Aligned Iterative Fine-Tuning (GAIF)*, an adaptive post-training framework that combines three complementary components: a unified SFT+DPO objective optimized simultaneously; a prospective adaptive weighting mechanism that selects task weights based on next-step gradient geometry; and an iterative outer loop that regenerates preference pairs from the current model's failures, keeping the supervision signal synchronized with the model's evolving capabilities while adapting training toward arbitrary evaluation metrics, including non-differentiable ones.

We evaluate GAIF on a production-scale generative movie search assistant, where a 7B LLM is adapted to the entertainment domain while remaining faithful to a fixed streaming catalog. The 7B model trained with GAIF outperforms standard SFT, sequential SFT+DPO, and a $\sim$90B reference model in both ranking quality (NDCG) and output validity. Experiments on GSM8K mathematical reasoning further show the algorithm's effectiveness extends beyond grounded retrieval.

1 Introduction

Large language models (LLMs) are increasingly adapted to domain-specific applications through post-training techniques such as supervised fine-tuning (SFT) and preference optimization (Lai et al., 2025; Rafailov et al., 2023). Rather than relying solely on the general capabilities acquired during pre-training, these methods specialize a foundation model to produce outputs that are faithful to a downstream domain, policy, or evaluation criterion (Ye et al., 2024; Carta et al., 2023). Such adaptation has become a fundamental component of modern LLM systems (Lai et al., 2025), enabling applications ranging from domain-specific assistants and retrieval systems to recommendation, tool use, and reasoning.

Despite their widespread adoption, existing post-training methods face several practical challenges. First, high-quality supervision is expensive to obtain, particularly human-curated preference data, making it important to maximize the value of limited annotations. Second, post-training is inherently iterative (Ouyang et al., 2022): practitioners commonly optimize supervised and preference objectives in separate stages, yet improvements in one stage do not necessarily translate to better performance in the next, often requiring repeated retraining and extensive hyperparameter tuning. Finally, post-training targets are rarely static. As models improve, they exhibit different failure modes, while application-specific evaluation metrics and judge rubrics frequently evolve alongside production systems. Consequently, supervision that is effective early in training or under one evaluation protocol may become less informative later.

These observations suggest that post-training should itself be adaptive. Rather than optimizing against a fixed supervision signal using a fixed training procedure, we ask whether the optimization process can continuously adapt to both the evolving model and the application's notion of correctness throughout training.

To this end, we propose Gradient-Aligned Iterative Fine-Tuning (GAIF), an adaptive post-training framework comprising three complementary components: a unified SFT+DPO objective optimized jointly; a prospective adaptive weighting mechanism that selects task weights by maximizing next-

October 29, 2026 ©2026 Association for Computational Linguistics

step gradient alignment; and an iterative outer loop that regenerates preference pairs from the current model's failures using an application-defined evaluation function. Together, these components enable GAIF to adapt its optimization strategy, supervision signal, and optimization target throughout training without requiring additional supervision or computationally expensive reinforcement learning.

Our contributions are:

1. **GAIF**, a fine-tuning algorithm that automatically adapts to data, metric and gradient geometry. It makes efficient use of positive SFT labels and existing evaluator while requires minimal extra tunning effort than standard SFT.

2. **Empirical validation** on a production movie search task and the GSM8K benchmark, demonstrating consistent improvements over SFT and sequential SFT+DPO baselines across both task performance and output validity metrics.

2 Related Work

Grounded LLM Adaptation. Recent work has explored grounding LLMs to external knowledge, environments, and application-specific constraints through retrieval augmentation, tool use, and interaction with external systems. Learning-based approaches such as AGREE adapt LLMs through post-training to generate responses grounded in retrieved evidence and accompanied by faithful citations (Ye et al., 2024). Other work grounds language models through continual interaction with external environments using online reinforcement learning (Carta et al., 2023). These approaches primarily focus on designing mechanisms that connect language models to external sources of information or feedback. Our work is complementary: rather than introducing a new grounding mechanism, we study how the post-training process itself can adapt to evolving application-specific grounding objectives by jointly evolving the optimization strategy and supervision signal.

LLM post-training and preference optimization. Supervised fine-tuning and preference optimization are central tools for adapting language models to downstream tasks. RLHF improves instruction following by training from human feedback (Ouyang et al., 2022), while DPO replaces reward-model training and reinforcement learning with a direct classification-style preference objective (Rafailov et al., 2023). Subsequent methods simplify or modify preference optimization further; for example, ORPO integrates an odds-ratio preference penalty into supervised learning without a separate reference model (Hong et al., 2024), while SimPO uses a reference-free reward based on average sequence log-probability (Meng et al., 2024). These methods improve preference alignment, but are usually applied as separate post-training stages or with fixed objective choices. GAIF instead studies how supervised and preference objectives can be optimized jointly with an adaptive weighting rule that responds to the current model and optimization trajectory.

Iterative preference generation and self-improvement. A separate line of work studies how preference data should evolve as the policy changes. Preference fine-tuning can suffer when rejected samples are stale or too far from the current model distribution (Tajwar et al., 2024). Iterative methods address this issue by regenerating preference data from the current model (Xiong et al., 2024; Yuan et al., 2024), a principle also reflected in inference-time self-improvement procedures (Madaan et al., 2023; Shinn et al., 2023). In recommendation, SPRec similarly constructs preference pairs from current model outputs for self-play recommendation (Gao et al., 2025). GAIF shares the principle of keeping preference data synchronized with the current model, but couples this outer-loop regeneration with an inner-loop adaptive optimization rule. The evaluator is also task-defined: preference pairs are constructed only when the current model underperforms the positive label by a margin, so the same scoring function used for evaluation drives the training signal.

Adaptive multi-task optimization. Jointly optimizing SFT and DPO can be viewed as a two-objective optimization problem. Existing multi-task learning methods mitigate gradient imbalance or conflict using the geometry observed at the current iterate. GradNorm balances training rates through gradient magnitudes (Chen et al., 2018); MGDA searches for a minimum-norm element in the convex hull of task gradients (Désidéri, 2012); PCGrad projects away conflicting gradient components (Yu et al., 2020); CAGrad optimizes conflict-averse updates (Liu et al., 2021); and CoGrad promotes knowledge transfer by coordinating task gradients (Yang et al., 2023). These methods are adap-

tive, but they are primarily current-state methods: the update is determined from the gradient geometry before the step is taken. GAIF instead uses a prospective objective, selecting task weights by maximizing the predicted alignment of task gradients at the next iterate. Closely related look-ahead approaches such as L-DRO optimize future loss-based objectives (Michel et al., 2021); GAIF differs by making future gradient alignment itself the objective and connecting it to common descent.

3 Method

3.1 Problem Setup

We consider the general problem of post-training a language model π_θ for a downstream task. Given an input x, the model generates an output $y = \pi_\theta(x)$. The task may correspond to retrieval, recommendation, reasoning, or any other problem for which candidate outputs can be evaluated.

GAIF assumes access to two forms of supervision. The first is a set of positive training examples

$$\mathcal{D} = \{(x, y^+)\},$$

where y^+ denotes a desirable response for input x. Depending on the application, these labels may originate from human annotation, implicit or explicit user feedback, or outputs from a stronger reference model. GAIF is agnostic to the provenance of these labels and only requires positive demonstrations suitable for supervised fine-tuning.

The second ingredient is an evaluation function

$$s(x, y) \in \mathbb{R},$$

that measures the quality of a generated response. The evaluation criterion is task dependent and may be implemented using exact-match metrics, ranking metrics such as NDCG, F1 scores, program execution, LLM-as-a-Judge (Zheng et al., 2023), or other application-specific evaluators. Unlike the supervised labels, which specify desirable demonstrations, the evaluation function defines the optimization target that guides iterative preference generation. Consequently, the quality of the evaluator is critical: improvements under the evaluation function should correlate with improvements in the desired downstream behavior. In practical applications, this may correspond to agreement with human preferences, online production metrics, or other task-specific notions of success.

Given an input x, GAIF generates one or more candidate outputs from the current model and uses the evaluation function to identify preferred and rejected responses. These preference pairs are then used for preference optimization, while the positive labels continue to supervise the SFT objective. The goal is to optimize the expected evaluation score

$$\max_\theta \mathbb{E}_x \left[s\left(x, \pi_\theta(x)\right) \right],$$

while preserving faithful and task-appropriate generation behavior.

3.2 Algorithm Overview

GAIF trains the model through an inner-outer loop structure motivated by two complementary objectives. The inner loop optimizes a combined loss that simultaneously teaches the model what good outputs look like and steers it away from pathological behaviors. The outer loop periodically evaluates the current model, identifies its failure modes, and regenerates preference pairs from those failures before the next inner loop begins. This design reflects a simple intuition: a model that has just learned to avoid one set of failure modes will develop new, subtler ones as it improves, and the training signal should track those evolving failures rather than remaining anchored to the errors of the initialization (Tajwar et al., 2024).

Concretely, at outer loop iteration i, the current model π_{θ_i} generates candidate outputs for a sample of queries; those outputs are scored by the evaluation function s; query-output pairs where the model underperforms relative to y^+ by a margin δ are selected as rejected samples y^-; and the resulting preference dataset $\mathcal{D}_i = \{(x, y^+, y^-)\}$ is used to train the inner loop. Because y^- is always generated by $\pi_{\theta_{i-1}}$, the preference pairs reflect the model's current failure modes rather than those at initialization, resembling on-policy training and iterative self-improvement procedures (Ross et al., 2011; Madaan et al., 2023; Shinn et al., 2023). A further consequence of the outer loop is *metric alignment*: because y^- selection is driven by the scoring function s, which can incorporate any downstream pipeline including non-differentiable steps such as entity resolution, the training signal reflects end-to-end task performance rather than a proxy objective.

The inner loop optimizes a unified SFT+DPO loss with adaptive weighting, described in the following subsections, producing updated parameters θ_{i+1}. These parameters serve as both the new model and the reference policy for the next outer

loop iteration. The full procedure is summarized in Algorithm 1.

Algorithm 1 GAIF

Initialize θ_0 from a pretrained LLM
for outer iteration $i = 1, 2, \ldots$ **do**
  Sample queries $\{x_j\}$ from the query distribution
  Generate outputs $\hat{y}_j = \pi_{\theta_{i-1}}(x_j)$
  Score outputs: $s_j = s(x_j, \hat{y}_j)$
  Select failures: $y_j^- \leftarrow \hat{y}_j$ where $s_j < s(x_j, y_j^+) - \delta$
  Construct $\mathcal{D}_i = \{(x_j, y_j^+, y_j^-)\}$
  Run inner loop for T steps on $\mathcal{D}_i$ with adaptive weights, using $\pi_{\theta_{i-1}}$ as reference policy
  Set $\theta_i \leftarrow$ trained parameters
end for

3.3 Inner Loop: Unified SFT+DPO Loss

At each outer loop iteration i, the inner loop optimizes a combined objective over the preference dataset $\mathcal{D}_i$. Rather than treating SFT and DPO as sequential stages, GAIF trains both simultaneously against the same labels:

$$\mathcal{L}(\theta) = w_{\text{SFT}}\mathcal{L}_{\text{SFT}}(\theta) + w_{\text{DPO}}\mathcal{L}_{\text{DPO}}(\theta) + w_{\text{KL}}\mathcal{L}_{\text{KL}}(\theta, \theta_i). \quad (1)$$

where $\mathcal{L}_{\text{SFT}}(\theta) = -\log \pi_\theta(y^+|x)$ is the standard SFT loss on positive labels, and $\mathcal{L}_{\text{DPO}}$ is the DPO loss on preference pairs (y^+, y^-). The explicit KL term provides a stable regularization floor that is decoupled from the adaptive balance between SFT and DPO:

$$\mathcal{L}_{\text{DPO}} = -\log \sigma\left(\beta\left[\log \frac{\pi_\theta(y^+|x)}{\pi_{\theta_i}(y^+|x)} - \log \frac{\pi_\theta(y^-|x)}{\pi_{\theta_i}(y^-|x)}\right]\right). \quad (2)$$

$\mathcal{L}_{\text{SFT}}$ improves the model by directly maximizing the likelihood of y^+ while $\mathcal{L}_{\text{DPO}}$ by widening the margin between y^+ and y^-. The cooperative structure between the two is important. Figure 1 illustrates what happens when DPO is dominating: after an initial improvement, the model enters a reward hacking (Amodei et al., 2016; Skalse et al., 2022) regime where it widens the margin by simultaneously reducing the logp of both y^+ and y^-. Task performance collapses sharply at this point.

3.4 Adaptive Weighting via Gradient Alignment

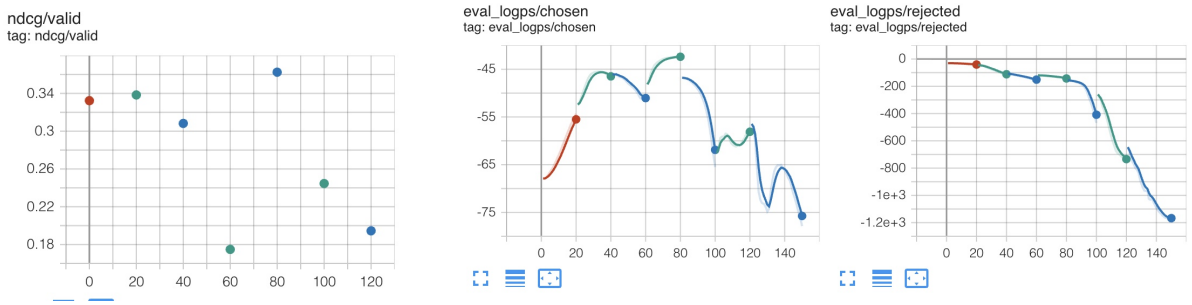
While w_{SFT} and w_{DPO} can be treated as fixed hyperparameters, doing so requires careful tuning and cannot adapt to the shifting gradient geometry across training. Therefore, we set $w_{\text{DPO}} = 1 - w_{\text{SFT}}$ and let $w_{\text{SFT}} \in [0, 1]$ vary adaptively[1]. This eliminates the need to tune task weights and relaxes sensitivity to other hyperparameters such as the DPO β, as the algorithm compensates automatically. Concretely, at each step we select w_{SFT} to maximize gradient alignment at the *next* parameter update:

$$w_{\text{SFT}} \leftarrow \underset{w_{\text{SFT}}+w_{\text{DPO}}=1}{\arg\max} \langle g_{\text{SFT}}(\theta - \eta g), g_{\text{DPO}}(\theta - \eta g)\rangle \quad (3)$$

where η is the learning rate, $g := \nabla_\theta \mathcal{L}$ is a function of w_{SFT} and $g_t := \nabla_\theta \mathcal{L}_t, t \in \{\text{SFT}, \text{DPO}\}$. The *prospective* nature of this update rule is critical as reactive methods that fix gradient updates after conflict occurs are insufficient under our setting as demostrated in Section 5.1, we will discuss more about the motivation in the next section.

In order to make the above objective tractable, we apply a first-order Taylor expansion to the task gradients and approximate each task Hessian with the rank-1 Gauss–Newton estimate $H_t \approx \hat{g}_t \hat{g}_t^\top$; we also drop the KL divergence term for weight selection. This gives:

$$g_t(\theta - \eta g) \approx \hat{g}_t(\theta) - \eta\left(\hat{g}_t^\top \hat{g}\right)\hat{g}_t(\theta), \quad (4)$$



where $\hat{g}, \hat{g}_t$ indicate per-batch gradients. This yields a closed-form quadratic in w_{SFT}, with a unique stationary point at:

$$w^* = \frac{\eta(ab - 2bc + c^2) + (b - a)}{2\eta(a - c)(b - c)}, \quad a := \|\hat{g}_S\|^2, \quad b := \|\hat{g}_D\|^2, \quad c := \langle \hat{g}_S, \hat{g}_D\rangle. \quad (5)$$

whenever $(a - c)(b - c) \neq 0$. Consequently, the optimal weight is selected among $\{w^*, 0, 1\}$, whichever yields higher alignment.

A more expressive alternative uses the diagonal empirical Fisher $H \approx \text{diag}\left(\frac{1}{N}\sum_{i=1}^N g_i \odot g_i\right)$ (Kirkpatrick et al., 2017) to estimate the Hessian, which better captures gradient curvature but requires per-example gradients, incurs higher memory cost, and requires a grid search over w_{SFT} rather

[1] Optimizing against a moving objective means convergence is to a neighborhood of the regularized Pareto front rather than the front itself, with the neighborhood radius depending on the rate of weight change

(a) Validation NDCG

(b) Log-probabilities of chosen and rejected responses

Figure 1: Training dynamics when DPO dominates the training on the movie search task ($w_{DPO} = 0.9$, $w_{SFT} = 0.1$). NDCG on the validation set collapses after approximately step 80 (left). The simultaneous collapse of log-probabilities for both chosen y^+ and rejected y^- responses (right) is the signature of reward hacking: rather than increasing the likelihood of y^+, the model widens the margin by driving both toward $-\infty$.

than a closed-form solution. The tighter approximation extends the regime of maintained alignment, as confirmed empirically on GSM8K in Section 5.

4 Motivation of the Adaptive Weighting Scheme

Section 3.4 introduced next-step gradient alignment as the weight-selection objective. We now justify this choice: we show why reactive, current-iterate methods fail in the SFT+DPO setting, and why maximizing next-step alignment is the principled alternative.

4.1 Limitations of Reactive Methods

Existing multi-task gradient methods operate reactively: they observe the gradient geometry at the current iterate θ_t and modify either the gradients or the task weights to resolve conflicts that have already arisen. GradNorm (Chen et al., 2018) balances gradient norms across tasks, ensuring no single task's gradient dominates in magnitude. PCGrad (Yu et al., 2020) projects conflicting gradients onto each other's normal planes, removing the antagonistic component. CoGrad (Yang et al., 2023) quantifies the loss reduction one task's gradient induces on another and adds an auxiliary gradient to maximize it. MGDA (Désidéri, 2012) finds the minimum-norm element in the convex hull of task gradients, yielding the steepest common descent direction.

These methods share a common premise: that the current gradient information is informative about what the update should be. This premise holds when the two task losses have comparable structure, such as similar curvature, scale, or loss progression. When the losses are structurally dissimilar, the current gradient geometry can be misleading. The SFT+DPO setting is a severe case. The SFT loss is a cross-entropy: its gradients are relatively small and low-variance, yet it progresses steadily and can be driven close to zero. The DPO loss, a log-sigmoid of a log-ratio margin, behaves oppositely — its gradients are larger and noisier, but its loss decreases orders of magnitude more slowly and plateaus well above zero. Gradient norm and actual progress thus point in opposite directions. Reactive methods, which read only the current geometry, are misled by this mismatch. GradNorm, for instance, balances training rates across tasks; because DPO's loss progresses so slowly, it assigns DPO disproportionately high weight (>0.99 in our runs). This is precisely the wrong response: it drives the model into the reward-hacking regime shown in Figure 1. PCGrad, applied in combination with GradNorm, cannot correct this because it intervenes post-hoc: once GradNorm has already driven the model into a bad region of parameter space, projecting away the conflicting gradient component is insufficient to recover (Table 1).

4.2 The Prospective View

The failure of reactive methods motivates a different question: rather than asking how to combine the gradients at θ_t, ask which θ_{t+1} to move to. The weight w_t determines $\theta_{t+1}(w_t) = \theta_t - \eta \nabla F_{w_t}(\theta_t)$, so selecting w_t is equivalent to selecting the next iterate. The question becomes: what makes one next iterate better than another?

A key requirement is that the update should make progress on both tasks simultaneously. This depends not only on the magnitudes of the task

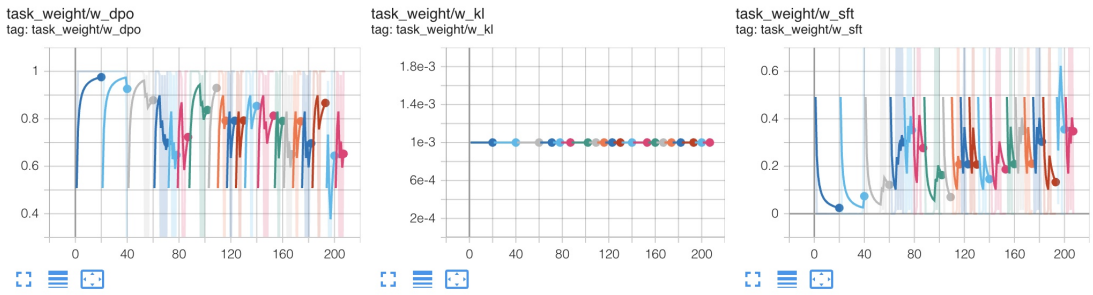


Figure 2: Adaptive task weights across inner loop training steps over multiple outer loop iterations (each color represents one outer loop iteration). w_{DPO} (left) starts dominant but trends downward in later outer loop iterations; w_{KL} (center) is held constant at 10^{-3}.

gradients at θ_{t+1}, but on how well their directions agree. If the gradients are aligned, then any convex combination of them yields a descent direction for both losses; if they are opposed, improving one task may necessarily worsen the other. A simple measure of such alignment is their inner product $\langle g_{\text{SFT}}(\theta_{t+1}), g_{\text{DPO}}(\theta_{t+1})\rangle$. It directly measures how compatible the two optimization directions are. Maximizing this quantity therefore naturally encourages future updates to remain cooperative. The next section formalizes this intuition by showing that next-step gradient alignment is not merely a heuristic measure of cooperation, but characterizes when universal common descent is achievable.

4.3 Why Gradient Alignment

At each iterate θ_t, denote:

$$g_S^t = \nabla \mathcal{L}_S(\theta_t), \quad g_D^t = \nabla \mathcal{L}_D(\theta_t),$$
$$a_t = \|g_S^t\|^2, \qquad b_t = \|g_D^t\|^2, \qquad c_t = \langle g_S^t, g_D^t\rangle.$$

Definition 1 (Universal common descent)**.** *We say* universal common descent *holds at θ_t if, for every mixing weight $w' \in [0,1]$, the combined task gradient $w' g_S^t + (1-w') g_D^t$ is a descent direction for both losses.*

Proposition 1 (Alignment is necessary and sufficient for universal common descent)**.** *Universal common descent holds at θ_t if and only if $c_t = \langle g_S^t, g_D^t\rangle > 0$ (assuming $g_S^t \neq 0$ and $g_D^t \neq 0$).*

Proof sketch. For any $w' \in [0,1]$, $\langle w' g_S^t + (1-w') g_D^t, g_S^t\rangle = w' a_t + (1-w') c_t$ and symmetrically $w' c_t + (1-w') b_t$ for g_D^t. With $a_t, b_t \geq 0$, both are positive for all w' iff $c_t > 0$ (necessity follows from the endpoints $w' = 1$ and $w' = 0$).

This proposition characterizes the cooperative regime at a fixed iterate. We now lift this criterion to the next iterate induced by the current weight choice. Denote the true next-step alignment as a function of the current weight:

$$c_{t+1}(w) := \langle g_S(\theta_{t+1}(w)),\ g_D(\theta_{t+1}(w))\rangle$$

where $\theta_{t+1}(w) = \theta_t - \eta \nabla F_w(\theta_t)$. By Proposition 1, $c_{t+1}(w) > 0$ if and only if universal common descent holds at $\theta_{t+1}(w)$. Therefore, GAIF (the ideal objective without Hessian approximation) ensures the common descent at next step whenever it is possible. When universal common descent is not achievable, a principled objective is to maximize the measure of next-step mixing weights $w' \in [0,1]$ for which common descent holds. Specifically, the feasible set of next-step mixtures is

$$\left(\frac{-c_{t+1}}{a_{t+1} - c_{t+1}}, \frac{b_{t+1}}{b_{t+1} - c_{t+1}}\right) \cap [0,1].$$

whose measure $\mu(w)$ satisfies, When $c_{t+1} < 0$,

$$\mu(w) = \frac{a_{t+1} b_{t+1} - c_{t+1}^2}{(a_{t+1} - c_{t+1})(b_{t+1} - c_{t+1})}.$$

In particular, for fixed a_{t+1} and b_{t+1}, $\mu(w)$ is strictly increasing in c_{t+1}. Thus alignment is the exact control variable for the feasible-set size whenever the task-gradient norms are held fixed. More generally, if variation in c_{t+1} (in relations to w) dominates variation in a_{t+1} and b_{t+1}, then maximizing c_{t+1} is also the correct local objective for enlarging the feasible region. Empirically, in the SFT-DPO setting, gradient norms vary substantially less across candidate next iterates than gradient alignment, which motivates using next-step alignment as the optimization target.

5 Experiments

We evaluate GAIF on two tasks: a production movie search assistant and the GSM8K mathematical reasoning benchmark. The former demonstrates

practical effectiveness in a real-world retrieval setting; the latter validates that the algorithm generalizes beyond retrieval.

5.1 Movie Search Assistant

Task. The goal is to fine-tune a language model to serve as a movie search assistant: given a natural language query such as "feel-good movies to watch on a rainy day", the model generates up to six movie or TV titles as a ranked list. A production semantic search system is currently in use, and a small-scale online test has shown that a LLM (Nova Pro, ∼90B parameters [2]) can outperform it. However, Nova Pro cannot be deployed at full traffic scale due to latency and throughput constraints. The objective is therefore to develop a fine-tuned LLM that matches Nova Pro's retrieval quality while remaining low-latency and can be self-hosted by the platform.

Setup. We finetune Mistral-7B (Jiang et al., 2023) using LoRA with $\alpha = \text{rank} = 16$. Training queries are sampled from production search traffic from a large video-streaming platform, with short or malformed queries filtered out (e.g., single characters or incomplete phrases). This yields approximately 26K queries with over 95% traffic-weighted coverage. Positive labels y^+ are generated by Claude 3.7 Sonnet, which serves both as the teacher model and judge.

For GAIF, at each outer loop iteration, 2,048 queries are randomly sampled from the training set. The current model and the teacher model each generate a ranked list, which goes through entity resolution to map to catalog items (via RapidFuzz). They are then scored by an LLM judge using a detailed relevance rubric[3]. Pairs where the NDCG scores differ by more than 0.1 are retained as preference pairs, with the higher-scoring output assigned as y^+. The inner loop trains on the sampled pairs for up to 10 epochs with an 80/20 train-validation split, using early stopping with patience 3. The adaptive weights are computed using rank-1 GN approximation as described in Equation 5. Learning rate (2e-5) and batch size (512) are selected via grid search; KL regularization is fixed at 10^{-3}. For the fixed-weight ablation, we searched $w_{\text{SFT}} \in \{0.1, 0.25, 0.5, 0.75, 0.9\}$ under the constraint $w_{\text{DPO}} + w_{\text{SFT}} = 1$, with equal weighting performing best. We run 20 outer loop iterations: data selection and inner-loop early stopping together stabilize training and performance plateaus after approximately 10-15 outer loop iterations, with further iterations yielding diminishing returns.

Evaluation. We evaluate on a human-curated set of 2,000 queries, disjoint from training and balanced across three types: title queries (e.g., a specific title), attribute-based queries (e.g., "Tom Cruise"), and complex intent queries (e.g., "relaxing movie for weekends"). The primary metric is NDCG@6 computed after fuzzy entity resolution against the catalog, with relevance scores provided by the aforementioned LLM judge. We also report the average number of unresolved items per query (titles not mappable to the catalog, e.g. hallucinations) and the average number of valid items per query (affected by output length, duplicates, and hallucinations), providing a more complete picture of output quality beyond ranking.

Candidates. We compare GAIF against: (1) Base Mistral-7B; (2) SFT only; (3) sequential SFT-then-DPO; (4) GAIF but instead of using the proposed adaptive weighting, we use GradNorm and PCGrad applied to the combined SFT+DPO loss; (5) GAIF but with fixed task weights throughout training, where $w_{SFT} = w_{DPO}$; and (6) Nova Pro, the independent large model baseline.

Table 1: NDCG@6, average unresolved titles, and average valid titles per query on the movie search assistant evaluation set. Confidence intervals obtained through bootstrapping.

Method	NDCG@6, CI95	Unres.	Valid
Base Mistral-7B	(0.4545, 0.4633)	2.234	**4.924**
SFT only	(0.4746, 0.4837)	2.703	3.167
Sequential SFT + DPO	(0.4539, 0.4634)	2.256	3.705
GradNorm + PCGrad	(0.2701, 0.2720)[†]	–	–
GAIF, fixed weights	(0.4761, 0.4878)	1.931	3.833
Nova Pro	(0.4729, 0.4822)	2.008	3.949
GAIF (ours)	**(0.4891, 0.4986)**	**1.7185**	4.290

[†] DPO dominates the training and training collapsed similar to Figure 1. One notable failure mode is that the model defaulted to generating only "assistant [EOS]" for many inputs.

Results. SFT alone improves NDCG substantially but at the cost of output validity. Its high unresolved title count and low valid title count would be unacceptable in a production system where ev-

[2] Amazon has not disclosed the parameter count. This figure is a community estimate (Thompson, 2024).

[3] The rubric, as well as the relevance-score post-processing, is calibrated against online search experiments to maximize correlation with online engagement metrics. This LLM-judge is developed independent of this experiment.

ery hallucinated or missing result directly degrades user experience. Sequential SFT-then-DPO recovers output validity but fails to improve NDCG over SFT or even the base model, demonstrating the structural tension between the two objectives. GradNorm, which assigns disproportionately high weight (>0.99) to DPO due to its much slower loss progression, collapses during training even when combined with PCGrad, demonstrating that reactive gradient correction cannot recover the training once task gradients begin to conflict. This further motivates prospective task weighting, which maximizes the likelihood of gradient alignment throughout training. GAIF with fixed task weights already outperforms all baselines on both NDCG and output validity, and full GAIF improves further. As shown in Figure 2, GAIF assigns high initial weight to DPO but dynamically balances with SFT as the gradient geometry evolves. Notably, despite aggressive DPO weighting, GAIF never collapsed across any of our hyperparameter search runs. This contrasts sharply with pure DPO training, which collapses readily under similar conditions due to reward hacking.

5.2 GSM8K

To evaluate whether GAIF generalizes beyond recommendation, we apply it to GSM8K (Cobbe et al., 2021) using Qwen2.5-1.5B-Instruct (Qwen et al., 2024) as the base model. The evaluation and training pair generation require no external evaluator: positive labels are ground-truth answers with CoT, and evaluation is exact match after parsing. Preference pairs are constructed from the model's incorrect output versus ground-truth solutions. This task requires the model to follow a specific output format in addition to producing correct answers. We use the following zero-shot system prompt:

> *You are a helpful assistant. Please think through the problem step by step before answering. Then provide only the final answer after the delimiter "####".*

Output length is restricted to 200 tokens. Answers are extracted from the number after the last occurrence of ####. This setup requires the model to simultaneously reason correctly, remain concise, and follow the output format. The base Qwen model struggles significantly with this joint requirement: despite having some mathematical capability, its verbosity and poor instruction following cause it to rarely produce a parseable answer within the token budget, resulting in a near-zero success rate in this task.

We compare SFT against two variants of GAIF that differ in the Hessian approximation used for adaptive weighting. The first uses the rank-1 Gauss-Newton estimate, which admits a closed-form solution for w^*_{SFT}. The second uses the diagonal empirical Fisher $H \approx \text{diag}\left(\frac{1}{N}\sum_{i=1}^{N} g_i \odot g_i\right)$, which better models gradient curvature but no longer admits an analytical solution; we instead perform a grid search over $w_{\text{SFT}} \in [0, 1]$ with 101 equally spaced grid points.

Table 2: GSM8K accuracy under zero-shot evaluation.

Method	**Accuracy**
Base Model	3.8e-3
SFT	0.4556
GAIF w/ rank-1 GN	0.4667
GAIF w/ diagonal empirical Fisher	**0.4776**

Results. Both GAIF variants outperform the SFT baseline, demonstrating the effectiveness of adaptive loss weighting across tasks beyond retrieval [4]. The diagonal empirical Fisher variant further improves over rank-1, suggesting that a more accurate Hessian approximation yields additional gains when computational budget permits. The rank-1 variant remains a practical default given its closed-form solution and lower memory cost.

6 Conclusion

In this paper, we presented the iterative GAIF algorithm, an adaptive and scalable framework for fine-tuning LLMs. While requiring a comparable level of hyperparameter optimization effort and training data as SFT, GAIF demonstrates consistent improvements over SFT across multiple tasks, both in terms of overall performance and output validity and instruction adherence. These gains are enabled by GAIF's ability to automatically adapt to the underlying data distribution, evaluation metrics, and training dynamics. Consequently, the proposed approach allows practitioners to place greater emphasis on data curation and selection when fine-tuning language models for downstream applications.

[4] Due to the constrained token budget, zero-shot prompting setup, and strict output parsing requirements, this evaluation setting is more challenging than commonly reported configurations, resulting in lower absolute accuracy.

7 Limitations

Task and evaluation scope. Our primary task (movie recommendation) relies on proprietary query data and LLM judges, which limits external reproducibility. We partially mitigate this by including GSM8K as a public benchmark, and we deliberately use models of different families and scales across the two tasks (Mistral-7B and Qwen2.5-1.5B-Instruct) to cover more ground. Validation on a broader range of tasks is left to future work.

Implementation complexity. The adaptive weighting requires custom training code that computes and accumulates per-task gradients across micro-batches (gradient accumulation), incurring additional time and memory cost beyond standard fine-tuning. For practitioners, we recommend first adopting the inner–outer loop with joint SFT+DPO training under fixed task weights: we observe that this already yields strong results with minimal added complexity, and the adaptive weighting can be introduced subsequently if further gains are desired.

Optimizer mismatch. Our adaptive weighting rule is derived under an SGD update, whereas we train with AdamW —a mismatch shared by related gradient-based multi-task methods (Désidéri, 2012; Yu et al., 2020; Liu et al., 2021; Chen et al., 2018), which are likewise motivated under plain gradient descent yet applied with adaptive optimizers. In preliminary experiments we implemented an Adam-aware variant of the weighting rule, but it required reconstructing Adam's internal preconditioning terms that the optimizer does not expose, which was substantially slower and more memory-intensive and yielded no improvement; we therefore retain the SGD-derived rule.

Abstract

Compressing a long multi-turn conversation requires choosing which earlier turns to keep, compress, or remove. We study a sparse keep/compress/drop (KCD) codec and vary the signal used to rank candidate turns: hidden-state geometry, semantic similarity, and query-conditioned geometry within a semantic shortlist. On saved MSC runs (1,000 conversations), LongLLMLingua has larger raw next-token logit ℓ_2 differences than recency baselines while its teacher-forced continuation loss is lower. In a separate KCD-variant run, query-conditioned geometry has the lowest reported raw logit ℓ_2 and teacher-forced loss at budget 0.50. On a fixed 100-instance LongMemEval-S artifact, semantic KCD has the lowest teacher-forced loss among the reported policies. These findings are descriptive: raw logit distance is a model-state diagnostic, not an answer-quality metric, and the LongMemEval experiment does not run the official generated-answer evaluator. We document the codec, run configuration, budget accounting, and artifacts needed to reproduce or extend the evaluation.

1 Introduction

Long conversations create a memory-allocation problem before they create a generation problem. Once the full dialogue no longer fits inside a practical inference budget, a system must decide which parts of the conversation to retain verbatim, which parts to compress into sparse surrogates, and which parts to evict. This is not only a capacity problem: even when the full context fits, language models fail to uniformly exploit information distributed across long histories—performance degrades substantially for content appearing in the middle of the context window (Liu et al., 2024).

Existing approaches include retrieval augmentation (Lewis et al., 2020), external or hierarchical memory management (Wang et al., 2023; Zhong et al., 2024; Packer et al., 2023; Wang et al., 2024), prompt compression (Jiang et al., 2023, 2024), and KV-cache compression or eviction (Liu et al., 2023; Zhang et al., 2023; Li et al., 2024; Cai et al., 2024; Kim et al., 2025). All are useful, but they motivate a central question for *in-context* conversational memory compression: *what signal should determine turn importance under a budget?* We focus on inference-time compression that operates within the context window without external indexes or model modification.

This paper studies that question through a sparse keep/compress/drop (KCD) codec for conversational memory. The codec is deliberately simple. Conversation segments can be kept in full, compressed into anchor-plus-support summaries, or evicted. The variable of interest is the *scoring signal* that drives those actions. We compare three regimes: geometry-based scoring from the conversation's hidden-state trajectory, semantic scoring from query similarity, and a hybrid policy that uses geometry only *inside* a semantic shortlist.

The paper's central claim is deliberately narrow. A turn-ranking signal can change the diagnostic and teacher-forced continuation metrics obtained by an otherwise fixed codec. We do not treat raw logit distance as task accuracy, claim a universally best signal, or infer a causal explanation for differences across models or benchmark lengths.

We first report a small exploratory stress-set pilot, then report saved MSC baseline and KCD-variant runs and a fixed LongMemEval-S diagnostic artifact. The paper distinguishes these runs rather than treating their point estimates as directly comparable across configurations.

This paper makes three main contributions:

- We specify a turn-structured KCD codec and three ranking signals with explicit state, cost, and tie-handling definitions.
- We report diagnostic raw-logit and teacher-

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 463–471
October 29, 2026 ©2026 Association for Computational Linguistics

forced continuation-loss results from separate saved MSC and LongMemEval-S runs, with their different evaluation limitations made explicit.

- We provide the implementation and source-backed hard-set artifacts in the accompanying repository, and record the configuration and provenance limits of the saved public-benchmark outputs.

2 Related Work

Memory architectures and compression. LongMem, MemoryBank, and MemGPT provide long-term or hierarchical memory mechanisms for language-model interaction (Wang et al., 2023; Zhong et al., 2024; Packer et al., 2023); MEMORYLLM instead incorporates a fixed-size, self-updatable latent memory pool (Wang et al., 2024). These systems expand or maintain memory capacity; our setting fixes the representation form and asks which signal allocates a limited turn budget. LLMLingua and LongLLMLingua perform prompt compression using token-level importance estimates (Jiang et al., 2023, 2024). COMEDY studies compressive memory for long-term conversations, R^{3}Mem uses reversible compression for memory retention and retrieval, and COMEM studies compressed context memory for online language-model interaction (Chen et al., 2025; Wang et al., 2025; Kim et al., 2024). Our main distinction is to hold the codec fixed and vary the ranking signal.

Budgeted inference and token-level retention. Scissorhands, H2O, SnapKV, PyramidKV, and EpiCache manage or compress KV caches using token- or head/layer-level retention rules (Liu et al., 2023; Zhang et al., 2023; Li et al., 2024; Cai et al., 2024; Kim et al., 2025). They target inference memory and are not directly token-budget-matched to our text-level turn actions. Our setting is turn-structured and evaluates raw next-token logit distance alongside teacher-forced continuation loss.

Benchmarks. MSC provides multi-session open-domain conversations where partners accumulate personal information (Xu et al., 2022). LongMemEval evaluates long-term interactive assistant memory, including retrieval and update demands (Wu et al., 2025). MemBench evaluates memory capability across factual and reflective settings, while TReMu focuses on temporal reasoning in multi-session dialogue agents (Tan et al., 2025; Ge et al., 2025). These benchmarks motivate a narrow question: how do alternative signals rank turns in the saved configurations studied here?

3 Setup

3.1 Conversation-State Geometry

For a conversation prefix $x_{1:T}$, let

$$z_t = f_\theta(x_{1:t}) \in \mathbb{R}^d \tag{1}$$

be the final-layer hidden state at the final token of turn t after applying the model chat template to the prefix. We normalize onto the unit sphere:

$$h_t = \frac{z_t}{\|z_t\|} \in \mathbb{S}^{d-1}. \tag{2}$$

Within a segment S_j, we move one-step increments into a common tangent space using the logarithm map and parallel transport:

$$u_t = \mathrm{PT}_{h_t \to q_j}\big(\log_{h_t}(h_{t+1})\big) \in T_{q_j}\mathbb{S}^{d-1}, \tag{3}$$

where q_j is a segment reference point taken as the Fréchet mean of the trajectory (Afsari, 2011). This allows local low-rank analysis and curvature-like instability scores to be measured in a common frame.

For a segment, q_j is computed by a fixed-iteration Fréchet-mean routine on its normalized states. The implementation clips the inverse-cosine argument to $[-1, 1]$, uses an $\epsilon = 10^{-8}$ norm guard, and treats a zero tangent vector as zero under transport. These operations provide a deterministic geometric feature construction; they do not establish that a raw geometric distance is shift-invariant or a proxy for answer correctness.

3.2 Query-Conditioned Geometry

For semantic-memory tasks, the geometry signal is not used directly. The semantic score is cosine similarity between normalized final-token states of the target and candidate turns. We retain the top $2k$ semantic candidates, where k is the number of turns that can be retained under the nominal budget, and compute geometry in the target turn's local frame. For target state h_q, let

$$v_q^{(j)} = \log_{q_j}(h_q) \tag{4}$$

be the query direction in the same tangent space as the segment motion. We then derive query-conditioned segment features including projected curvature, projected subspace energy, and query-alignment magnitude. These features are converted into turn-level refinement scores only *inside* the semantic shortlist.

This makes the hybrid policy a refinement method, not an independent retrieval method: a turn excluded by the semantic shortlist cannot be recovered by the geometric stage. Accordingly, comparisons involving the hybrid policy test whether local trajectory information changes the ranking of semantically plausible candidates; they do not test geometry as a replacement for semantic candidate generation.

3.3 The Sparse KCD Codec

For each segment j, the codec selects an action

$$a_j \in \{\text{keep}, \text{compress}, \text{evict}\} \tag{5}$$

under a fixed budget. A compressed segment retains its anchor and selected support turns; a kept segment retains all of its original turns; an evicted segment retains none. Turn-only policies rank candidates by score density and use stable original-turn order to break ties, then greedily fill the token budget. Segment KCD policies instead solve the discrete keep/compress/evict allocation by dynamic programming under the same nominal budget. The compression operator itself is fixed within each run. What changes is the scoring signal:

- `geometry_KCD`: geometric risk from transported motion.
- `semantic_KCD`: semantic similarity to the target turn.
- `budget_aware_semantic_KCD`: semantic scoring with budget-aware span control.
- `semantic_query_conditioned_geometry_KCD`: semantic shortlist first, then query-conditioned geometry within that shortlist.

3.4 Budgeted Objective and Distortion Metrics

Given a target turn $t^\star$ and a compression policy π, we evaluate a compressed history by comparing it with the full-history next-token logit vector. Let $\ell(x_{1:t^\star})$ denote that vector under the full history and $\ell(\widehat{x}_{1:t^\star})$ the vector under compression. We use

$$\Delta_{\ell_2} = \|\ell(\widehat{x}_{1:t^\star}) - \ell(x_{1:t^\star})\|_2 \tag{6}$$

as a raw model-state diagnostic. It is not invariant to logit shifts, and we do not interpret it as answer quality. The companion teacher-forced continuation metric is

$$\Delta_{\text{NLL}} = -\log p_\theta(y^\star \mid \widehat{x}_{1:t^\star}) + \log p_\theta(y^\star \mid x_{1:t^\star}) \tag{7}$$

as the change in negative log likelihood for the observed assistant continuation $y^\star$. Negative Δ_{NLL} means lower teacher-forced loss than the full-context reference. It is not a free-generation or official benchmark answer score.

The memory-control problem can be written as

$$\min_\pi \mathbb{E}[D(\pi)] \qquad \text{s.t.} \qquad \mathbb{E}[M(\pi)] \le B, \tag{8}$$

where $D(\pi)$ is a diagnostic, $M(\pi)$ is memory cost, and B is the nominal historical-turn budget. In the saved LongMemEval-S artifact, prompt formatting and an uncompressed recent window make mean realized full-prompt token fractions range from 0.932 to 0.978 despite mean nominal historical fractions ranging from 0.177 to 0.479. We therefore do not present those rows as token-matched comparisons.

3.5 Memory Regimes

The experiments distinguish two memory regimes.

- **Constraint-critical memory**: exact user instructions, retrieval packets, code constraints, or compact fact bundles whose loss directly breaks downstream answers.
- **Semantic continuity memory**: persona statements, preferences, identity, and episodic facts whose value is largely determined by their relation to the current query.

The paper's hypothesis is that these regimes favor different scoring signals inside the same codec.

4 Experimental Design

Benchmarks and models. We report: (1) a **nine-conversation exploratory hard-set policy pilot**, spanning three synthetic memory families and three compact models; (2) a separate **36-case Qwen2.5-0.5B support-retention analysis** over 12 cases per family; (3) two separate saved **MSC**

Table 1: Support-turn retention in the separate 36-case Qwen2.5-0.5B hard-set analysis at budget 0.35. Counts are descriptive case counts for geometry versus uniform.

Outcome	Cases
Geometry retains more support turns	14
Uniform retains more support turns	5
Tie on support-turn retention	17
Geometry retains the latest support turn when uniform drops it	13

valid runs over 1,000 conversations (Xu et al., 2022), one for external baselines and one for KCD variants; and (4) a fixed **LongMemEval-S** artifact of 100 full histories (Wu et al., 2025). Primary public-benchmark rows use Qwen2.5-1.5B-Instruct (`qwen25_15b`). The saved LongMemEval output contains 20 shard-ID files, partial rows, and a merge manifest; the fixed 100-instance subset is not claimed to be representative of the full benchmark.

Hard-set analyses. The nine-conversation pilot provides the three-model budget curves in Figure 1. Its separate 36-case analysis is restricted to Qwen2.5-0.5B and compares geometry with uniform support-turn retention at budget 0.35. Table 1 and the Figure 1 count panel report the same analysis. It is not the sample behind the nine-conversation curve summaries or a public-benchmark estimate.

Evaluation and statistics. We report raw next-token logit ℓ_2 and teacher-forced Δ_{NLL}, both averaged by conversation. The legacy reports include uncorrected Monte Carlo signflip values; we omit them because a finite 5,000-draw procedure cannot support an exact zero p-value and the planned comparisons were not multiplicity corrected. Thus, tables are descriptive point estimates, not confirmatory tests. New runs should use paired conversation-level bootstrap intervals, add-one Monte Carlo p-values, and Holm correction over pre-specified policy comparisons.

5 Constraint-Critical Memory: Why Signal Choice Matters

5.1 External Baselines on the Stress Set

The nine-conversation hard-set pilot also compares several non-KCD baselines. These point estimates are included as exploratory mechanism evidence, not as a public-benchmark or token-matched comparison.

Table 2: Exploratory external-baseline comparison in the nine-conversation hard-set pilot (`qwen25_15b`, 540 target-turn rows). Values are descriptive means of raw logit ℓ_2 and teacher-forced Δ_{NLL}; lower is better within each metric.

Policy	L2@.20	L2@.35	L2@.50	NLL@.20	NLL@.35	NLL@.50
Uniform	387.4	338.0	268.5	1.627	1.272	1.353
Recency	**348.4**	326.3	**274.6**	1.620	1.115	1.027
Recency-KCD	**348.4**	**311.8**	290.9	1.620	1.115	0.959
Lexical TF-IDF	381.9	323.1	276.9	1.553	1.004	**0.801**
LongLLMLingua	385.6	372.4	369.8	**1.252**	**0.758**	**0.697**

Table 3: Exploratory geometry-aware control versus uniform retention in the nine-conversation hard-set pilot. Negative deltas favor geometry-aware retention; no hypothesis-test claims are made.

Model	ΔLogit@0.20	ΔLogit@0.35	ΔNLL@0.35
qwen25_05b	-65.654	-99.503	-0.091
qwen25_15b	-33.647	-21.669	-0.181
smollm2_17b	-4.105	-11.329	-0.002

In this pilot, LongLLMLingua has the smallest teacher-forced loss at all three budgets, while Recency or Recency-KCD has the smallest raw logit distance. For example, at $B{=}0.50$, LongLLMLingua's raw logit distance is 369.8 versus 268.5 for uniform, while its teacher-forced loss is 0.697 versus 1.353 for uniform. The metrics therefore produce different orderings in this controlled set. This is a diagnostic observation rather than evidence about generated-answer accuracy.

5.2 Geometry-Aware Control Under Scarcity

We next compare geometry-aware retention with uniform retention in the same nine-conversation pilot. Negative deltas indicate smaller values under geometry-aware retention.

All three displayed model configurations have lower raw logit distance under geometry-aware retention at the two reported budgets. This limited pilot does not establish an architecture-wide effect or a generated-answer benefit, but it motivates examining the controlled signal swap below.

5.3 Signal-Swap Ablation

`geometry_KCD` and `semantic_KCD` use the same codec and differ only in their ranking signal. This is the pilot's direct signal-control comparison.

At 0.20 and 0.35, the semantic policy has larger values on both reported diagnostics. At 0.50, raw logit distance is effectively tied in this small pilot while the teacher-forced loss difference remains

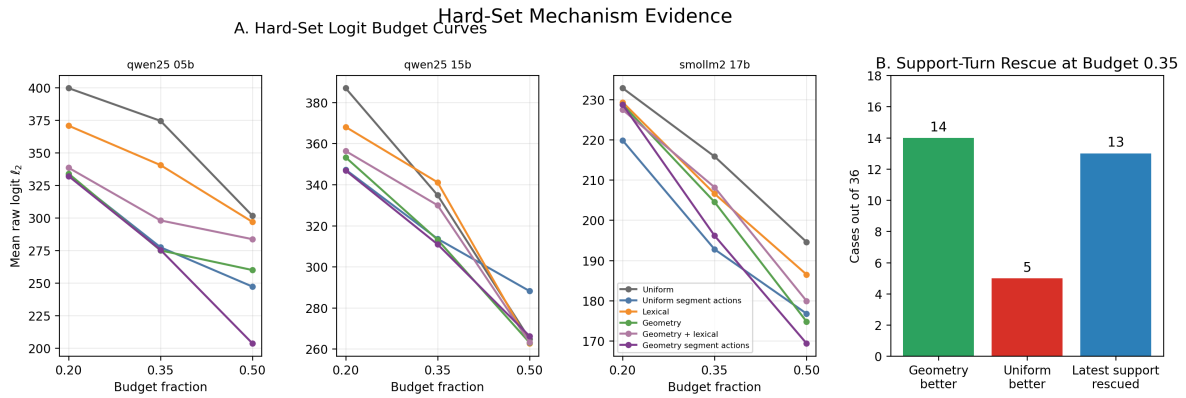

Figure 1: Hard-set diagnostic visualization from two distinct analyses. The left panel plots mean raw next-token logit ℓ_2 across budgets for the nine-conversation, three-model pilot. The right panel summarizes the separate 36-case Qwen2.5-0.5B support-retention analysis at budget 0.35: geometry retains more support turns in 14 cases, uniform in 5 cases, and geometry alone preserves the latest support turn in 13 cases. These are descriptive counts from the released per-case retention analysis.

Table 4: Exploratory signal-swap ablation in the nine-conversation hard-set pilot (`qwen25_15b`). Positive Δ means the semantic policy has a larger value than `geometry_KCD`.

Budget	$\Delta\Delta_{\ell_2}$	$\Delta\Delta_{\mathrm{NLL}}$
0.20	+37.8	+0.195
0.35	+38.5	+0.424
0.50	+0.1	+0.628

Table 5: Saved MSC external-baseline run (`qwen25_15b`, 1,000 conversations). Values are conversation-level means of raw logit ℓ_2 and teacher-forced Δ_{NLL}; they are descriptive and should not be compared with Table 6, which comes from a separate run configuration. Lower is better within each metric.

Policy	L2@.20	L2@.35	L2@.50	NLL@.20	NLL@.35	NLL@.50
Uniform	627.2	613.8	596.3	3.361	3.269	3.171
Recency	605.3	572.6	537.5	3.236	3.050	2.901
Recency-KCD	604.9	590.9	564.4	3.219	3.021	2.860
Lexical TF-IDF	617.4	610.5	594.0	3.249	3.074	2.930
LongLLMLingua	730.4	741.0	757.2	3.114	3.070	3.013

positive. The separate 36-case support-retention analysis in Table 1 and Figure 1 is the paper's mechanism evidence; it must not be numerically conflated with this nine-conversation signal-swap pilot.

6 Public Benchmarks: Diagnostic Results and Signal Variants

6.1 Geometry-Behavior Divergence: KCD vs. External Baselines

A central question for any compression method is whether behavioral quality metrics tell the full story. We compare KCD against LongLLMLingua (Jiang et al., 2024), recency-based, and lexical TF-IDF compression on MSC (1,000 conversations, 163,755 evaluation rows).

Within this saved run, LongLLMLingua has lower teacher-forced loss than the other listed policies at budgets 0.20 and 0.35, while its raw logit distance is 103–161 units above uniform. Relative to Recency-KCD, its raw-logit gaps are 125.5, 150.1, and 192.8; relative to ordinary Recency, they are 125.1, 168.4, and 219.7. The two diagnostics therefore rank policies differently. This observation motivates reporting both, but it does not establish an effect on generated-answer correctness.

Recency-KCD has the smallest raw logit distance at budget 0.20, while ordinary Recency is smallest at budgets 0.35 and 0.50. The results are not token-matched with LongLLMLingua, so they should not be read as a fairness-controlled superiority claim.

6.2 MSC: KCD-Variant Run

Table 6 reports a separate saved MSC KCD-variant run. The comparison fixes the KCD family but is descriptive: the legacy statistical outputs are not used for confirmation.

At B=0.50, `sem_query_cond_KCD` has the smallest reported raw logit distance (705.5) and teacher-forced loss (2.671) in this run. Table 7 records component-removal point estimates. Removing support-score weighting increases both reported diagnostics at B=0.50, whereas removing query projection changes the two diagnostics differently. These are hypotheses for a pre-registered rerun

Table 6: Saved MSC KCD-variant run (qwen25_15b, 1,000 conversations). Values are conversation-level means of raw logit ℓ_2 and teacher-forced Δ_{NLL}. Lower is better within each metric; no significance claims are made.

Policy	L2@.20	L2@.35	L2@.50	NLL@.20	NLL@.35	NLL@.50
Uniform	**799.6**	**783.0**	761.6	3.153	3.061	2.959
Geometry-KCD	804.9	814.5	812.8	3.105	2.973	2.811
Semantic-KCD	806.9	814.2	815.0	3.040	2.884	2.716
sem_query_cond_KCD	807.5	801.8	**705.5**	3.034	**2.850**	**2.671**

Table 7: Component ablation from the saved MSC KCD-variant run (qwen25_15b, 1,000 conversations). Values are descriptive conversation-level means; lower is better within each metric.

Policy	L2@.20	L2@.35	L2@.50	NLL@.20	NLL@.35	NLL@.50
sem_query_cond_KCD	807.5	**801.8**	**705.5**	3.034	**2.850**	2.671

rather than evidence for a causal mechanism.

6.3 LongMemEval-S: Fixed Teacher-Forced Diagnostic Artifact

LongMemEval-S rows come from a fixed artifact of 100 full histories. The experiment uses the observed assistant continuation for teacher forcing and does not run LongMemEval's official generated-answer evaluator. It is consequently not an answer-accuracy or behavioral-generalization test.

Semantic-KCD has the lowest reported teacher-forced loss at each listed budget in this artifact. The ordering differs from the MSC KCD-variant run, but the differing dataset, prompt construction, and non-binding realized token budget prevent a causal or length-based explanation. The artifact is retained to make this non-replication visible rather than to support a benchmark-wide claim.

7 Cross-Model Descriptive Check

The submitted study also contains a 50-conversation MSC check using Llama-3.2-3B-Instruct. It keeps the policy family fixed but changes both model family and scale relative to Qwen2.5-1.5B; it is therefore a descriptive scope check rather than an architecture ablation.

Semantic-KCD has the smaller displayed values in this saved Llama run. This differs from the Qwen MSC KCD-variant ordering at budget 0.50, but one Llama configuration cannot identify whether the difference is due to model family, scale, tokenizer, post-training, or another run-specific factor. The result limits any model-general claim; it does not establish an explanation for the reversal.

Table 8: Fixed LongMemEval-S teacher-forced diagnostic artifact (qwen25_15b, 100 full histories). Values are descriptive conversation-level means of raw logit ℓ_2 and teacher-forced Δ_{NLL}. The nominal budget is not equivalent to realized full-prompt token cost; no generated-answer or significance claim is made.

Policy	L2@.20	L2@.35	L2@.50	NLL@.20	NLL@.35	NLL@.50

Semantic-KCD	**671.9**	**633.5**	**586.1**	**3.526**	**3.317**	**3.139**

8 Discussion and Limitations

The saved runs show that raw next-token logit distance and teacher-forced continuation loss can order compression policies differently. This is a useful diagnostic observation, not evidence that either quantity measures user-visible answer quality. The two measures answer different questions: teacher-forced loss evaluates probability assigned to one observed continuation, whereas raw logit ℓ_2 compares the entire next-token vector and is sensitive to shifts in that vector. Their agreement or disagreement is therefore a property to measure, not a reason to treat either metric as a universal objective. Centered logit distance, Jensen–Shannon divergence, and top-k overlap are implemented for future runs but are not reported here because they were not available for all legacy artifacts.

The paper has four principal limitations. First, it does not include LongMemEval's official generated-answer evaluation, so it makes no LongMemEval answer-quality claim. Second, the 100-instance LongMemEval artifact is a fixed subset, not a documented random or representative sample. Third, its nominal historical-turn budgets do not match realized full-prompt token costs, precluding fair efficiency comparisons with external methods. Fourth, the reported point estimates come from separate saved configurations and legacy uncorrected significance reports; they should be reproduced with pre-specified compar-

isons, paired conversation-level confidence intervals, and multiplicity control. The primary model is Qwen2.5-1.5B-Instruct, a causal Transformer with RoPE, SwiGLU, RMSNorm, grouped-query attention, and tied word embeddings (Qwen Team, 2024). The reported results therefore support only this Qwen-family configuration; they do not identify an effect of any one architectural component.

8.1 Future Work

The next evaluation should run LongMemEval's official generated-answer protocol on all 500 questions, with a fixed dataset revision, seed, and task-family breakdown. It should compare policies at matched realized input-token counts and report compression latency, peak memory, and preprocessing cost alongside quality. To test the diagnostic interpretation, it should report centered-logit distances, distributional divergences, and top-k agreement in addition to raw logit ℓ_2. Finally, it should pre-specify primary contrasts, use paired conversation-level intervals with multiplicity correction, and evaluate several matched decoder-only model families. Such a study can test whether the observed Qwen result replicates across families or tracks tokenizer, post-training, scale, and architecture; the present experiments cannot distinguish those possibilities.

Acknowledgments

Experiments were conducted on cloud GPU infrastructure. This work received no external funding. The authors declare no conflicts of interest. The authors used Claude (Anthropic) to assist with manuscript drafting and editing; the authors reviewed and approved the final text.

A Implementation and Artifact Details

The implementation and source-backed figure-generation utilities are available in the accompanying repository: https://github.com/SteveMama/rt-geometry-memory. The main text specifies the state token and layer, semantic score, shortlist, cost unit, actions, allocation procedures, and tie handling. This appendix records the run lineages and limitations needed to interpret the displayed descriptive results. The extraction cache is keyed by model, conversation identifier, and extraction settings; queue jobs are durable across restarts and write per-conversation partial rows. Candidate prompts are deduplicated by retained-turn indices within a target turn before batched scoring. These optimizations change wall-clock cost, not the evaluated prompt or policy.

B Evaluation Provenance

The MSC baseline and KCD-variant tables are distinct saved runs and retain their own output directories. The LongMemEval-S artifact comprises 100 fixed identifiers, 20 shard-ID files, per-shard partial CSV files, and a merge manifest. Its rows use teacher forcing over observed continuations. The artifact does not contain official generated answers, generated-answer scores, or a token-matched comparison protocol. The hard-set pilot and Llama check are reported as descriptive evidence with their sample identities stated explicitly. The separate Qwen2.5-3B hard-set validation remains excluded because its source artifacts still need reconciliation before publication.

C Additional Exploratory Diagnostics

Geometry characterization. In the submitted characterization artifact, the estimated rank-95 summaries for the three compact-model trajectories were 1.049, 1.167, and 1.528; their turn-order-shuffled counterparts were 1.486, 1.458, and 1.799. The corresponding reported geometry–decoder-drift correlations were 0.989, 0.994, and 0.989. These values motivate testing transported geometry as a control feature, but they are not used as evidence that raw logit distance predicts user-visible answer quality.

Negative extensions. Several extensions did not improve the reported KCD policies. A two-head harm predictor ranked held-out turn-removal rows reasonably (held-out Kendall $\tau = 0.612$) but was poorly calibrated across conversations, so it was not used as a final policy. Marker-based object-level compression underused its target budget, realizing only 43–52% of the nominal budget in the failing policies. Finally, exploratory update-detection variants based on transported-increment sign structure did not reliably distinguish updates from controls. These negatives further bound the present claim: the evidence concerns turn ranking within the tested KCD codec, not a general-purpose memory-state detector or learned harm model.

Object-level checkpoint. The saved MSC checkpoint below makes the budget-underuse issue concrete. It is a diagnostic result from a separate configuration, not a token-matched comparison with the main tables.

Table 10: Exploratory object-level checkpoint on MSC valid (qwen25_15b, nominal budget 0.35). Lower is better for the two diagnostics. The object policies realize materially less than the target budget.

Policy	Raw logit ℓ_2	Teacher-forced Δ_{NLL}	Realized token fraction
Semantic	928.9	2.438	0.743
Budget-aware semantic KCD	931.2	2.487	0.736
Semantic object KCD	970.9	2.979	0.519
Object harm KCD	1023.0	3.251	0.431

The marker-based boundaries over-segmented the conversations and the within-object compressor then retained too little context. This is why these policies are treated as failed exploratory variants, rather than evidence about the value of object-level memory in general.

Faithfulness Is Not Free: Auditing Offline KV-Cache Quantization in Retrieval-Augmented Generation

Abstract

Retrieval-augmented generation systems can precompute and store key-value caches of retrieved documents to avoid re-encoding context at every query. Quantizing these caches further reduces storage, but no prior work asks whether compression damages *faithfulness*, whether responses remain grounded in the retrieved evidence. Faithfulness and accuracy are not equivalent: a model can produce a correct answer that is no longer supported by the context it was given. We evaluate Qwen2.5-7B-Instruct under INT8 and INT4 quantization on RGB and HotpotQA, measuring both accuracy and faithfulness with a hallucination detector, NLI entailment, and an LLM judge. INT8 is near-lossless across both metrics. INT4 reduces accuracy and, more critically, even among answers that remain factually correct, over 90% of faithfulness changes are negative, i.e., accuracy metrics are blind to this regression. The harm grows under noisy retrieval and with more retrieved chunks. Faithfulness must be audited before compressed caches are deployed.

1 Introduction

Retrieval-augmented generation (RAG) grounds model responses in external documents, but reprocessing the retrieved context for every query is expensive. Recent systems eliminate this cost by precomputing key-value (KV) caches for documents once and reusing them at inference time (Lu et al., 2025; Yao et al., 2025). As these offline caches scale with corpus size and retrieval depth, their storage footprint becomes a bottleneck, making low-bit quantization an attractive solution.

Prior work shows KV caches can be quantized to INT8 and INT4 with little *accuracy* degradation (Liu et al., 2024; Hooper et al., 2024), though aggressive compression can harm reasoning on complex tasks (Liu et al., 2025). However, all existing evaluations measure only task accuracy. They leave open a more subtle question: do quantized caches preserve **faithfulness**, whether generated responses remain *supported by the retrieved evidence*? This distinction matters. Exact Match and F1 measure agreement with a reference answer; they do not verify whether the answer is grounded in the provided context. A model can preserve the correct answer string while becoming less dependent on retrieved evidence, creating a hidden failure mode in compressed RAG systems (Yen et al., 2025; Tamber et al., 2025).

To our knowledge, this is the first audit of offline KV-cache quantization in RAG that evaluates faithfulness, showing that cache precision can affect grounding even when answer accuracy is preserved. Figure 1 shows our controlled protocol, which isolates cache precision as the sole variable and evaluates faithfulness with three independent signals. Our contributions are threefold. First, we introduce a faithfulness-centered audit protocol that avoids positional-stitching confounds by caching the full retrieved context in a single causal pass. Second, we show that INT8 is near-lossless, while INT4 silently degrades grounding even on accuracy-preserved examples (>90% of faithfulness flips are negative; McNemar $p < 10^{-20}$). Third, we show that this degradation is amplified by retrieval noise and larger retrieval depth, establishing faithfulness (not accuracy alone) as the necessary audit signal for compressed RAG.

2 Background and Related Work

2.1 KV-cache compression.

KIVI (Liu et al., 2024) achieves near-lossless 2-bit asymmetric quantization; KVQuant (Hooper et al., 2024) reaches sub-4-bit via per-channel key quantization; ZipCache (He et al., 2024) identifies token-level precision sensitivity; KVTuner (Li et al., 2025) sets 4-bit as the safe floor for Qwen2.5-7B

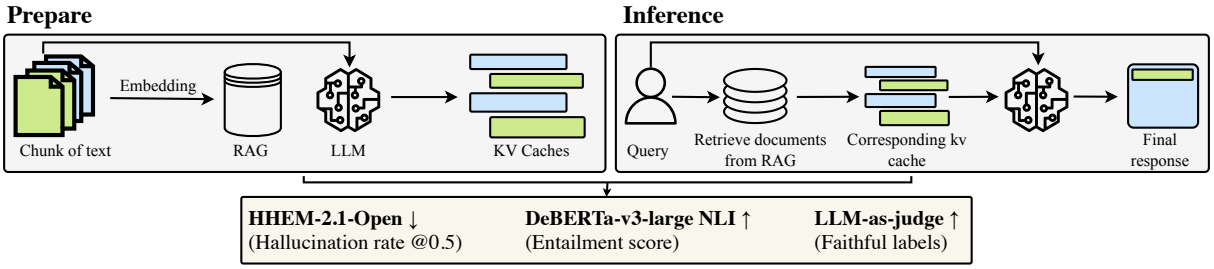

Figure 1: Audit pipeline. **Prepare**: retrieved documents are prefilled in one causal pass, and the resulting KV cache is quantized and stored. **Inference**: the stored cache is dequantized and reused for each query. **Evaluate**: three complementary faithfulness signals (HHEM hallucination rate ↓, DeBERTa-v3 NLI entailment ↑, LLM-as-judge ↑) are measured alongside standard accuracy metrics.

on reasoning tasks. Sub-4-bit can cause up to 59% accuracy loss on long-context tasks (Mekala et al., 2025), prompting variance-normalized quantization (Müller et al., 2026) and query-aware mixed-precision allocation (Zhang et al., 2025). **Gap**: all of these evaluate *online* cache compression via accuracy or perplexity; none audits faithfulness in retrieval-augmented settings.

2.2 RAG faithfulness.

RAGChecker (Ru et al., 2024) and RAGTruth (Niu et al., 2024) show that EM and F1 miss systematic faithfulness failures. HELMET (Yen et al., 2025) finds standard accuracy proxies correlate poorly with downstream RAG quality. LLM-as-judge outperforms detector-only methods for faithfulness evaluation (Tamber et al., 2025; Song et al., 2025). Distractor passages cause systematic grounding failures even without compression (Wu et al., 2025; Amiraz et al., 2025). **Gap**: none of these studies examines whether *cache compression* introduces faithfulness failures beyond those from retrieval noise alone.

2.3 Offline KV-cache RAG.

TurboRAG (Lu et al., 2025) stores chunk-level caches offline to eliminate repeated prefill; CacheBlend (Yao et al., 2025) addresses per-chunk positional mismatch via selective recomputation, reducing TTFT by 2.2–3.3×. **Gap**: neither examines whether compressing stored caches harms faithfulness.

3 Method

Our goal is to isolate the effect of KV-cache quantization in RAG. We keep the retrieved evidence, prompt, and decoding fixed, and vary only the stored cache precision. The method builds one position-consistent cache for the full retrieved context, quantizes it before storage, dequantizes it before decoding, and compares BF16, INT8, and INT4 under identical inference conditions.

Building a unified cache. For each query, we concatenate the system prompt with the top-K retrieved chunks and run one causal prefill pass. The resulting KV cache is a single unified cache for the full retrieved context, and this is the cache we compress. We avoid caching chunks independently and stitching them later, because independent chunk caches are created at local token positions but consumed at global positions during generation. This positional mismatch can degrade output quality by itself. Using a single prefill pass removes this confound and ensures that cache bit-width is the only variable changed across conditions.

Quantizing the cache. After prefill, we quantize the KV cache before storage and dequantize it back to bfloat16 before decoding. This matches an offline RAG deployment in which document caches are written to disk once and reused at inference time. INT8 uses per-token asymmetric quantization (Liu et al., 2024). INT4 uses group-wise quantization with groups of 64 channels, where each group stores its own scale and zero-point. This reduces the risk that large-magnitude channels dominate the quantization range and collapse smaller values under INT4's 16 levels (Liu et al., 2024; Hooper et al., 2024). The on-disk footprint of one KV cache is

$$M(b, g, o) = 2LHd_hN \cdot \frac{b}{8} + \frac{2LHd_hN}{g} \cdot \frac{o}{8}, \quad (1)$$

where L, H, d_h, and N denote the number of layers, KV heads, head dimension, and cached tokens. The quantization bit-width is b, the group size is g, and o is the scale/zero-point overhead per group. BF16 (b=16) has no overhead term. INT8 uses

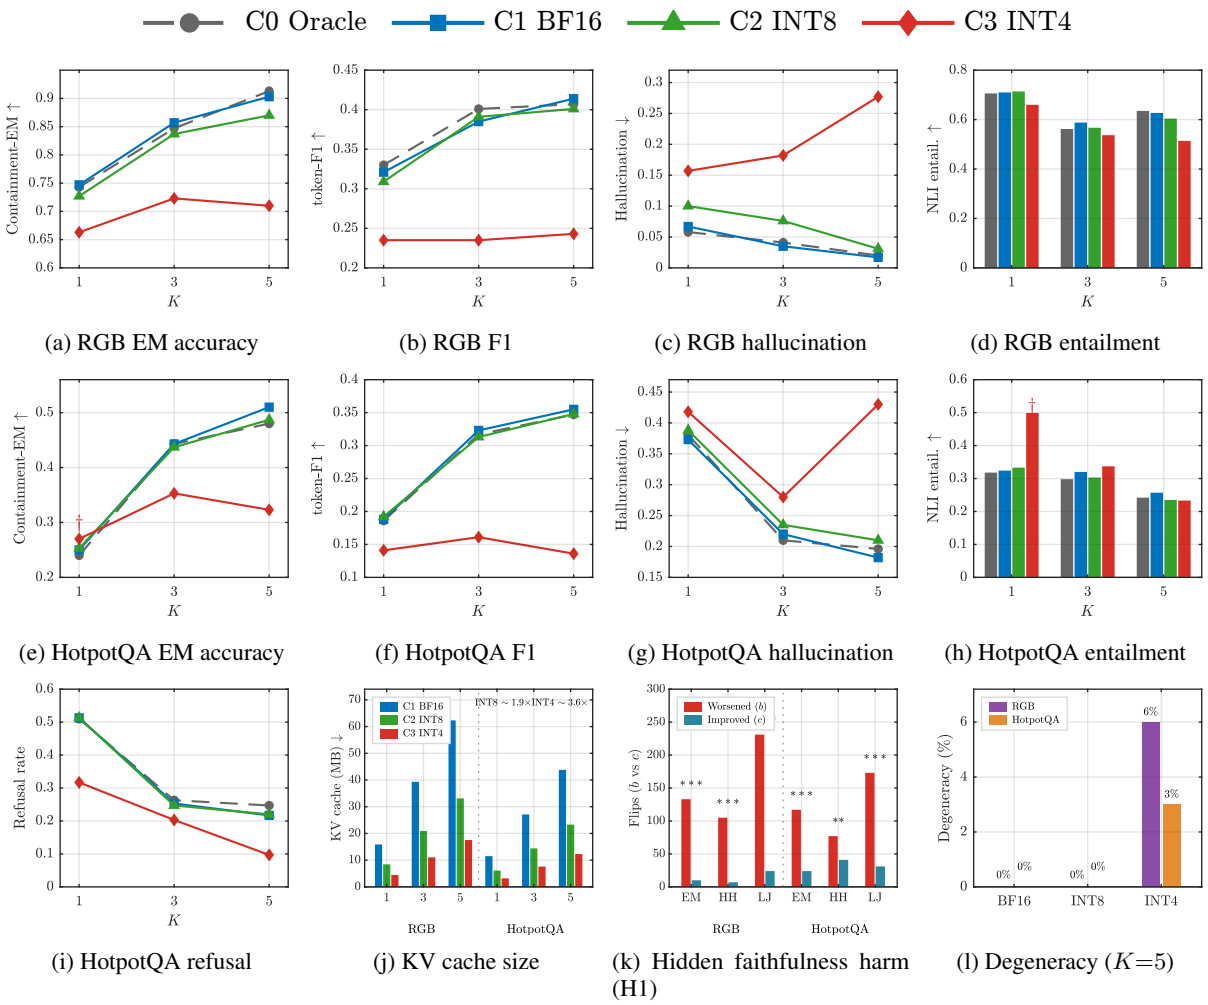
b=8 and g=d_h, while INT4 uses b=4 and g=64. Because INT8 and INT4 store metadata for each group, their realized compression ratios are lower than the nominal 2× and 4× limits.

Precision comparisons. Using the same retrieved chunks and greedy decoding, we compare four cache settings. **C0 (Oracle)** runs standard full-context generation without a cache round trip. **C1 (BF16)** stores and reloads the uncompressed cache, serving as the cache baseline. **C2 (INT8)** and **C3 (INT4)** store quantized caches and dequantize them before decoding. Thus, C1–C2 isolates the effect of INT8 compression, while C1–C3 isolates the effect of aggressive INT4 compression.

4 Experimental Setup

We evaluate Qwen2.5-7B-Instruct (Yang et al., 2024), a bfloat16-native 7B instruction-tuned decoder with a 32K-token context window. Its native bfloat16 precision avoids the float16 dynamic-range overflow that silently corrupts cached KV values on this architecture.

We use two complementary benchmarks. **RGB** (Chen et al., 2024) (300 examples) provides its own positive and distractor passages, keeping retrieval recall high and the noise structure controlled. **HotpotQA** (Yang et al., 2018) (300 examples, distractor split) requires combining evidence across at least two supporting passages mixed with distractors, testing multi-hop reasoning. Each example is evaluated at $K \in \{1, 3, 5\}$ retrieved chunks, giving $300 \times 3 \times 4 = 3{,}600$ generations per dataset. Retrieval uses a FAISS index (Johnson et al., 2021) over bge-small-en-v1.5 (BAAI, 2023) embeddings; we retrieve the top-10 chunks and slice to the first K.



We report both answer accuracy and evidence faithfulness. Accuracy is measured by containment exact match (EM), which marks a prediction correct if any normalized gold alias appears in the generated answer, and by token-level F1 as a secondary overlap metric. Faithfulness is measured with three independent signals: HHEM-2.1-Open (Vectara, 2024), reported as hallucination rate at threshold 0.5 (↓); DeBERTa-v3-large NLI entailment (He et al., 2023) (↑); and an LLM judge using Claude Haiku 4.5 (↑). Since HHEM and NLI agree only moderately on RGB (Pearson r=0.44), we treat them as complementary diagnostics. The LLM judge achieves 92% agreement on 50 hand-checked labels and serves as the primary faithfulness signal. We test three hypotheses using C1 BF16 as the uncompressed reference and C3 INT4 as the aggressive compression condition. For **H1**, we test whether faithfulness degrades even when accuracy is preserved. We restrict to examples whose containment-EM outcome is unchanged between C1 and C3, then apply a paired McNemar test to faithfulness label flips. For **H2**, we test whether harm increases with retrieval depth by fitting a linear slope over $K \in \{1, 3, 5\}$. Because only three retrieval depths are available, this test is underpowered (p=0.12) and is reported as directional. For **H3**, we test whether retrieval noise amplifies INT4 degradation by regressing the per-example INT4 faithfulness gap on distractor fraction within each K. H3 is evaluated only on RGB, where per-example noise ratios are available.

5 Results

Figure 2 reports the complete results across RGB and HotpotQA, and Table 1 summarizes the main effects.

Accuracy and hidden faithfulness harm. INT8 remains close to the BF16 cache baseline across accuracy and faithfulness metrics, whereas INT4 consistently degrades performance. INT4 reduces containment-EM (as shown in Figs. 2a, 2e) and token-F1 (as shown in Figs. 2b, 2f); correct→wrong flips greatly outnumber wrong→correct flips on both RGB (133 vs. 10) and HotpotQA (117 vs. 24; Fig. 2k). More importantly, INT4 also causes faithfulness loss that accuracy does not expose. On the accuracy-preserved subset, where containment-EM is unchanged between C1 and C3, faithfulness flips remain overwhelmingly negative: the LLM judge records 231 worsenings vs. 24 improvements on RGB ($p<10^{-38}$) and 173 vs. 31 on HotpotQA ($p<10^{-30}$; Fig. 2k). HHEM corroborates this trend on RGB for all K and on HotpotQA at K=5. Thus, INT4 does not merely make more answers wrong; it also makes some still-correct answers less grounded in the retrieved evidence. On HotpotQA at low K, INT4 additionally disrupts refusal calibration: the refusal rate drops from 0.513 to 0.317 at K=1 (Fig. 2i), which artificially inflates containment-EM and NLI entailment (the † markers in Figs. 2e, 2h). For this reason, the LLM judge is the primary H1 signal on HotpotQA.

Amplification, storage, and degeneration. The degradation becomes larger under harder retrieval

(e) HotpotQA EM accuracy (f) HotpotQA F1 (g) HotpotQA hallucination (h) HotpotQA entailment

(i) HotpotQA refusal (j) KV cache size (k) Hidden faithfulness harm (H1) (l) Degeneracy (K=5)

Figure 2: Benchmark results across RGB and HotpotQA under four precision conditions: C0–C3. † marks the HotpotQA K=1 refusal artifact: INT4 under-refuses, which *inflates* surface EM and NLI entailment—not a genuine gain. In (j), tick labels are *dataset,K* (R=RGB, H=HotpotQA); the inset shows on-disk shrinkage vs. C1 BF16: ∼1.9× (INT8) and ∼3.6× (INT4) at K=5, below the nominal 4× because INT4 stores per-block scale/zero-point pairs. In (k), columns group by dataset; within each, EM=containment exact-match, HH=HHEM, LJ=LLM-judge; bars are McNemar flip counts b (worsened) vs. c (improved). Significance: $***p<10^{-3}$, $**p<10^{-2}$, $*p<0.05$.

settings. The INT4–BF16 hallucination gap increases monotonically from K=1 to 5 on both benchmarks (Figs. 2c, 2g), although the slope test over only three retrieval depths is underpowered (p=0.12), so we treat H2 as suggestive. On RGB, where per-example noise ratios are available, the INT4 faithfulness gap also grows with distractor fraction independently of retrieval depth (β=0.22, significant within-K at K=3 and K=5), supporting H3. These failures occur despite substantial storage savings: at K=5, INT8 and INT4 reduce cache size by approximately 1.9× and 3.6×, respectively (Fig. 2j), with INT4 falling below the nominal 4× due to per-block scale and zero-point overhead in Eq. 1. INT4 is also the only condition that produces degenerate generations, i.e., empty outputs or repetition loops reaching 6% on RGB and 3% on HotpotQA at K=5 (as shown in Fig. 2l); BF16 and INT8 never degenerate.

6 Conclusion

KV-cache compression should be treated as a reliability decision, not only a storage optimization. In offline RAG, the cached KV forms the model's effective interface to retrieved evidence; when this representation is aggressively compressed, the model can preserve the surface answer while weakening its dependence on the supporting context. The central lesson is that compressed RAG systems cannot be validated by EM or F1 alone. Before deploying low-bit offline caches, systems should audit whether answers remain grounded in the retrieved documents. Faithfulness is therefore a

necessary evaluation target for practical KV-cache compression, especially when storage savings are obtained through aggressive quantization.

Limitations

This study isolates KV-cache precision under a controlled offline RAG setup, but its scope is limited to one model family, two QA-style benchmarks, and three retrieval depths. The magnitude of faithfulness loss may differ for larger models, other architectures, denser retrieval settings, or production retrievers. HotpotQA also introduces a refusal-calibration confound at low K, which limits the reliability of HHEM and NLI in that regime; we therefore rely on the LLM judge as the primary signal in that regime.

A Ablation Studies

A.1 Fidelity of the Cache Round-Trip (Stage-0 Gate)

Before any quantized run, we require C1 (BF16) to exactly reproduce C0 (Oracle) on 50 held-out examples. This gate confirms that the cache round-trip itself introduces no degradation; any difference in C2/C3 is attributable purely to quantization bit-width. C1 reproduced C0 within floating-point tolerance on all 50 examples, validating the baseline.

A.2 Numerical Stability

We monitored logits for NaN/Inf values across all 3,600 generations per dataset. No non-finite logits appeared under C0, C1, or C2. Under C3 (INT4), non-finite logits occurred in $< 0.1\%$ of examples and were aborted rather than allowed to emit corrupted tokens. This confirms that degeneracy (Fig. 2l) reflects semantic failure, not numerical explosion.

A.3 Faithfulness Signal Agreement

The three faithfulness signals are intentionally complementary. On RGB, HHEM and NLI entailment agree only moderately (Pearson r=0.44), confirming they capture distinct failure modes. The LLM judge achieves 92% agreement with human labels on RGB (76% on HotpotQA, where refusal artifacts add noise). Any single signal would undercount the faithfulness harm: H1 is supported by all three signals on RGB but only by the LLM judge on HotpotQA at low K, underscoring the need for a multi-signal faithfulness audit.

A.4 Effect of Per-Block Overhead on INT4 Storage

Equation 1 predicts that INT4 with g=64 achieves a $\sim$3.6$\times$ footprint reduction over BF16 at K=5, not the nominal $4\times$. We verified this empirically: the per-block scale/zero-point pairs consume $\approx$11% of the INT4 cache footprint, shrinking the effective compression ratio from $4\times$ to $3.6\times$. The INT8 footprint reduction of $\sim$1.9$\times$ (vs. nominal $2\times$) follows the same pattern, with per-token overhead consuming $\approx$5% of the INT8 cache.

A.5 H2 Power Analysis

The slope regression for H2 uses only three K values ($K \in \{1, 3, 5\}$), leaving it statistically underpowered (p=0.12). Nonetheless, the directional trend is consistent: on RGB, the INT4–BF16 hallucination gap increases from 0.09 at K=1 to 0.26 at K=5; on HotpotQA from 0.05 at K=1 to 0.25 at K=5. A denser sweep over $K \in \{1, 2, 3, 4, 5, 7, 10\}$ would likely yield a significant slope; we leave this to future work.

What we measured	What it means in plain terms	INT8	INT4	Does accuracy catch it?
Accuracy effects				
Containment-EM drops	More answers are simply wrong	✗ (safe)	✓ (drops)	Yes, EM detects this directly
Token-F1 drops	Even partial matches are worse	✗ (safe)	✓ (drops)	Yes, F1 detects this directly
Faithfulness effects (measured independently of accuracy)				
HHEM hallucination rate rises	Answers are flagged as not backed by the retrieved documents	✗ (safe)	✓ (rises)	No, EM/F1 miss this
NLI entailment score drops	Answers no longer logically follow from the retrieved context	✗ (safe)	✓ (drops)	No, EM/F1 miss this
LLM judge marks answer as unfaithful	A strong LLM judges the answer as unsupported by the evidence	✗ (safe)	✓ ($>90\%$ of flips negative)	No, EM/F1 miss this
The "hidden harm": faithfulness loss on accuracy-preserved examples (H1)				
Faithfulness drops even when the answer string stays correct	The model gives the right answer but for the wrong reason—it is no longer using the retrieved evidence	✗ (not observed)	✓ (McNemar $p<10^{-20}$, both datasets)	**No**, this is exactly what EM/F1 *cannot* see
Does the harm grow? (H2 and H3)				
Harm grows with more retrieved chunks (H2)	Longer context amplifies the quantization error in the cache	✗	✓ (directional, $K{=}1{\to}5$; $p{=}0.12$, underpowered)	No
Harm grows with more distractor passages (H3, RGB only)	Noisy retrieval makes INT4 even more likely to hallucinate	✗	✓ ($\beta{=}0.22$, significant at $K{=}3, 5$)	No
Failure modes unique to INT4				
Degenerate output (empty or repeated text)	The model collapses—produces nothing useful at all	✗	✓ (up to 6% of outputs at $K{=}5$)	Partially; EM is zero but the root cause is invisible
HotpotQA refusal confound	INT4 noise breaks the model's "I don't know" instinct; it guesses instead of refusing, inflating apparent accuracy	✗	✓ (refusal drops from 51% to 32% at $K{=}1$)	**No**, EM and NLI are *inflated*, masking harm
Storage efficiency				
Cache size reduction vs. BF16 baseline (C1)	How much disk space is saved	$\sim 1.9\times$ at $K{=}5$ (vs. nominal $2\times$)	$\sim 3.6\times$ at $K{=}5$ (vs. nominal $4\times$)	N/A

Table 1: Accuracy, faithfulness, and storage effects (✓ observed; ✗ not observed).

Cross-Modal Grounding for Calibrated Confidence in Vision Language Models

Abstract

We introduce a novel approach for calibrating uncertainty quantification (UQ) tailored for visual language models (VLMs). Existing state-of-the-art UQ methods rely on consistency among multiple responses, but often report higher confidence when the model is consistently incorrect, leading to poorly calibrated confidence. To address this, we leverage cross-modal consistency by grounding back the textual responses to visual inputs. The confidence from the grounding model (GM) is used to calibrate the overall confidence. Given that using a GM adds its own uncertainty, we apply temperature scaling to calibrate the GM's confidence in the accuracy of the generated responses. We comprehensively evaluate the proposed approach across diverse range of settings, including datasets with varying visuo-linguistic complexity, Q&A and caption generation tasks, general visual and specialized medical contexts, VLMs differing in scale, openness, and different categories of GMs. Experimental results show that our approach consistently improves confidence calibration, with expected calibration error (ECE) improvements ranging from 32.5% to 96.7% over both self and non-self consistency-based baselines. Code is available here https://github.com/trilokpadhi/Multimodal-Uncertainty-Quantification.

1 Introduction

Recent advancements in large language models (LLMs) have demonstrated their impressive performance across many domains, ranging from natural language processing (Devlin et al., 2019) and machine translation (Chitale et al., 2024) to creative writing (Gómez-Rodríguez and Williams, 2023) and code generation (Jiang et al., 2024). Despite their capabilities, these models are not infallible and are known to produce incorrect or misleading information, often referred to as hallucinations (Huang et al., 2025). Uncertainty Quantification (UQ) of LLMs has been proposed as a practical solution to assess trust in these models, particularly for their deployment in safety-critical areas such as healthcare (Shorinwa et al., 2024). UQ techniques aim to provide a quantitative measure of trust that a user can place in an LLM's response to the input query.

State-of-the-art (SOTA) approaches for quantifying the uncertainty of LLMs are motivated by self-consistency theory (Wang et al., 2022). This involves prompting the model multiple times for the same input under diverse settings, such as with a high temperature, and checking for similarity in the generated responses for assessing model's uncertainty on the input (Lin et al., 2023; Kuhn et al., 2023; Kadavath et al., 2022; Kaur et al., 2024). The underlying idea is that if the model generates semantically similar responses for the same input under diverse settings, then it is certain (or confident) about their input.

Consistency, however, does not imply accuracy. As shown in Fig. 1 (left), we observe that models can generate consistently incorrect responses. This observation is made on 25 inputs out of 75 manually verified test cases on Slake, a medical dataset (Liu et al., 2021). The goal of UQ is to provide a measure of confidence in the real-world performance of LLMs for their trustworthy deployment. The confidence in an LLM as reported by UQ approaches should, therefore, be aligned with the accuracy of the model. This alignment can be checked by plotting the expected accuracy of the model as a function of the reported confidence. These plots are known as *reliability diagrams* and have been used to report confidence-accuracy calibration (or alignment) of deep learn-

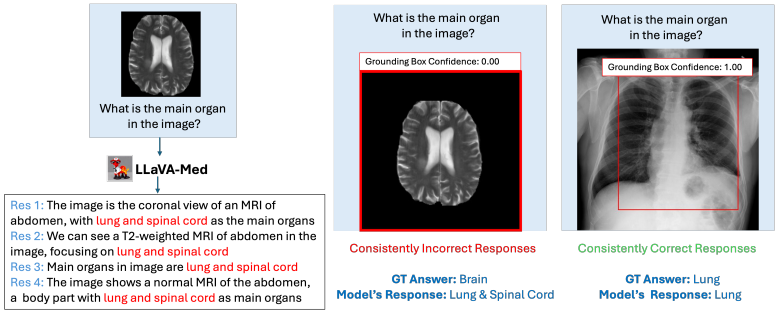

Figure 1: Consistently incorrect responses (Res 1..Res 4) by LLaVA-Med-v1.5-Mistral-7B (Li et al., 2023a) VLM on MRI image of brain from the Slake Medical dataset (left). BiomedParse (Zhao et al., 2024), a grounding model for medical images, is not able to locate 'lung and spinal cord' on the MRI image of brain, and therefore labels the entire image as lung with 0 confidence. It is, however, able to generate a bounding box for lung on the chest X-ray with 100% confidence (right).

ing models (Guo et al., 2017).

Fig. 4a and Fig. 4b in Appendix show reliability diagrams for two self-consistency-based UQ approaches for predicting confidence of Llama-2-13B (Touvron et al., 2023) on TriviaQA (Joshi et al., 2017) and COQA (Reddy et al., 2019) datasets respectively; a common test setting considered by these approaches (Lin et al., 2023; Kuhn et al., 2023; Kaur et al., 2024). High expected calibration error (ECE) shows poor calibration of the model's accuracy with its confidence predicted by these approaches We observe similar trends of high ECE by UQ approaches when applied to multi-modal input settings of text-image pairs for these models. These observations on visual language models (VLMs) are reported in the experimental section.

In this paper, we propose a cross-modal grounding approach for calibrating confidence in VLMs. The goal is to calibrate the confidence estimates produced by existing uncertainty quantification (UQ) methods by leveraging cross-modal consistency, specifically by grounding the VLM's textual responses back into the visual modality of the input image. For example, as shown in Fig. 1 (right), we ground the answers with bounding boxes on the image. A correct answer has a higher chance of being grounded as the evidence is likely to be present in the image. Thus, the ability (or inability) to ground the generated response to the input image provides evidence about the correctness (or incorrectness) of the response.

One consideration of relying on a grounding model (GM) to report the uncertainty of another model is that it introduces the GM's uncertainty into the pipeline. We apply temperature scaling to calibrate the GM's confidence in the accuracy of the VLM. Temperature scaling is a simple yet effective post-processing parametric calibration technique that has been widely used to align the confidence with the true likelihood of correctness (Jaynes, 1957; Hinton et al., 2015; Guo et al., 2017). Fig. 2 shows our proposed approach for calibrating confidence in predictions by VLMs. The contributions of this paper can be summarised as:

1. Miscalibration of UQ Approaches: We observe and report that existing UQ approaches for LLMs as well as VLMs exhibit poor calibration between the reported confidence and the model's accuracy.

2. Multi-modal Consistency: We propose a novel method to calibrate confidence in vision-language models (VLMs) by leveraging cross-modal consistency between the generated textual responses and the input image.

3. Significant Calibration Improvements: We show that our approach is generalizable by demonstrating significant calibration improvements in ECE (upto 96.7%) with experiments across *VLMs*: varying in size and type, *domains*: general, medical, reasoning, *datasets*: VQA, Slake, GQA, Whoops, *tasks*: Q&A, and caption generation, *grounding models*: semantic-based, segmentation-based, and foundation models, *UQ approaches*: SOTA self-consistency-based as well as non-self-consistency-based verbalized prompting approaches.

2 Background

2.1 Uncertainty Quantification

Uncertainty quantification (UQ) techniques aim to measure the uncertainty in the predictions of LLMs to assess their reliability. A prominent strategy for UQ is built on self-consistency theory (Wang et al., 2022), which focuses on generating multiple responses from the model for the same input and evaluating the consistency among these outputs.

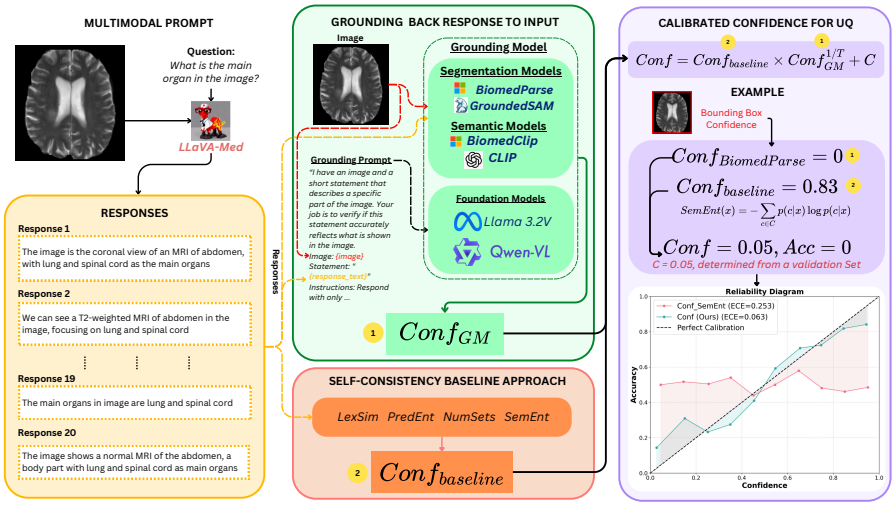

Figure 2: $Conf_{baseline}$: confidence from a self-consistency UQ baseline such as LexSim (Fomicheva et al., 2020), PredEnt (Malinin and Gales), NumSets (Kuhn et al., 2023), SemEnt (Kuhn et al., 2023), etc. on a VLM such as LLaVA-Med. $Conf_{GM}^{1/T}$: temperature-scaled calibrated confidence of grounding model on the accuracy of the generated responses. A grounding model can be as simple as the CLIP-based model, that provides its confidence in terms of a similarity score between embeddings of the generated response and the input image (e.g. BiomedCLIP), a detection model for response on the input image reporting its confidence on the detected bounding box (e.g. BiomedParse), or a foundation model that provides its verdict – a confidence score in $[0, 1]$ – on the relevance of the generated response to the input image (e.g. LLaMA 3.2V, Qwen VL, etc.). $Conf$ (2) is the proposed calibrated confidence score for UQ of VLMs resulting in substantially lower ECE than the baseline.

This strategy quantifies uncertainty by identifying discrepancies in the generated responses. Different approaches for UQ of LLMs differ in how they measure these discrepancies and the metrics they use to quantify the resulting uncertainty.

Predictive entropy over the probability distribution of responses is a popular uncertainty metric, and serves as a baseline in UQ for LLMs (Kadavath et al., 2022; Kuhn et al., 2023; Kaur et al., 2024; Lin et al., 2023). In the context of natural language processing, for an input query x the probability of a response r is calculated as the product of the conditional log probabilities for each token in the response: $p(\mathbf{r}|x) = \prod_i p(r_i|r_{<i}, x)$. *Lexical similarity* (Fomicheva et al., 2020) is another proposed approach that assigns a similarity score between each pair of responses (r_i, r_j) via RougeL (Lin, 2004)[1], and uses the average of this score over each pair as the confidence (1-UQ) metric in the LLM: $\frac{1}{P}\sum_{i=1}^{|R|}\sum_{j=1}^{|R|} \text{RougeL}(r_i, r_j)$. Here R is the set of responses, and $P = |R| \times (|R|-1)/2$. Kuhn et al. (2023) group the generated responses into semantically equivalent response clusters C, compute the probability of each cluster as the average probability of each response in the cluster, and use *semantic entropy* (SE) over these clusters as the uncertainty metric: $SE(x) = -\sum_{c \in C} p(c|x) \log p(c|x)$, Semantic equivalence between two responses for clustering them together is checked via bi-directional entailment between the two via Deberta (Natural Language Inference) model (He et al., 2020). Kaur et al. (2024) further enhances this approach by a new dynamic semantic clustering algorithm for deciding on the membership of a response. Another UQ metric as a baseline in (Kuhn et al., 2023; Kaur et al., 2024) is *NumSets*, that is the number of semantic clusters formed by the responses.

2.2 Confidence Calibration

Confidence in a model's predictions is known to be calibrated if it represents the true probability of those predictions to be correct (Guo et al., 2017). This means that for a set of predictions where the model's confidence estimate is c, the proportion of correct predictions by the model should be c.

Temperature Scaling (Guo et al., 2017) is a simple yet effective post-processing parametric method for calibrating the softmax confidence of classification models. It learns a single parameter (T) to scale the model's logits by a factor of $1/T$, with greater values of T softening the softmax distribution indicating high uncertainty, and lower values of T sharpening the distribution indicating low uncertainty.

Reliability diagrams (DeGroot and Fienberg, 1983), such as the ones shown in Fig. 4b, provide

[1]RougeL measures the similarity between two sentences based on the longest common subsequence between the two.

us with a way to visualize confidence calibration empirically. These diagrams plot the expected accuracy of the model as a function of confidence. The range of confidence in $[0, 1]$ is divided into equal-sized smaller bins, and accuracy for each bin is calculated as an average accuracy on the samples falling in that bin. A perfect calibration would result in average accuracy for each bin equal to the average confidence of the bin. Any deviation from this identity function indicates a miscalibration. *Expected Calibration Error* (ECE) (Naeini et al., 2015) provides us with a quantitative measure for this miscalibration. ECE is calculated as the weighted average over each bin's difference in accuracy and confidence (Guo et al., 2017):

$$\sum_{m=1}^{M} \frac{N_m}{n} |Acc_m - Conf_m|, \quad (1)$$

where M is the number of confidence bins, N_m is the number of samples in bin m, n is the total number of samples, and Acc_m, $Conf_m$ are the average accuracy and confidence of the mth bin.

2.3 Grounding

Grounding refers to the process of linking symbolic representations of knowledge (e.g. language) to the real world's sensory data (e.g., images, sounds). For example, visual grounding techniques (Yu et al., 2018; Acharya et al., 2019) have been proposed for mapping textual entities to bounding boxes on images. Grounding models (GM) such as object detection or localization models have been used to report interpretability of LLMs (Giulivi and Boracchi, 2024; Sahu et al., 2024). We propose the use of grounding models for calibrating the UQ of VLMs. Different types of GM can be utilized for linking back the generated response by an LLM to the input space. We consider three of those: *segmentation-based GM* that generates a segmentation mask relevant to the generated response on the input image, *semantic-based GM* that assigns a similarity score to the generated response and the input image, and a *foundation model* that can be instructed to verify the accuracy of the response as the description of the input image.

3 Related Work

There has been recent work on utilizing information from different modalities of multi-modal inputs to VLMs for their interpretability. Giulivi and Boracchi (2024) make use of a localization model (OWL-ViT) for projecting bounding box on the identified objects by the VLM. They do so by a joint training in the embedding space of the LLM and OWL-ViT. This approach is applicable to open-source models for joint training in the embedding space of vision modality. Sahu et al. (2024) run object detection model on an input image and make use of the detected objects to check the LLM's response for hallucinations. This is done by generating a claim from the query-response pair and then verifying the decomposed sub-claims against the detected objects.

There has been a recent focus on measuring uncertainty in VLMs via self-consistency theory. Zhang et al. (2024) apply perturbations in both text and image input modalities, and use entropy in the distribution of the generated responses for reporting uncertainty of the LLM on the input query. This can be used as the self-consistency UQ baseline in the proposed framework for calibrating the reported confidence (by the baseline) in VLMs. Li et al. (2024) propose to train a Graph Neural Network (GNN) on clusters of semantically equivalent responses to predict the probability of each response being correct, with the optimization goal of calibrating the predicted probabilities. This is, however, a supervised approach that requires a labeled training set for the GNN. Our approach does not require training any new model but involves calibrating the confidence of grounding models (GM) via temperature scaling on a small validation set to take into account the uncertainty of GM used in the pipeline. The use of a validation set is a common setting in uncertainty quantification literature such as conformal prediction (Balasubramanian et al., 2014), where the validation set is used to determine a threshold on the membership score (known as non-conformity score) of a generated response in the output set. The output is a set instead of a single prediction from the LLM to take into account uncertainty in the LLM with coverage guarantees on the set (Wang et al., 2025; Ye et al., 2024; Kaur et al., 2024; Quach et al., 2023).

Prompting LLMs to generate a confidence score along with its prediction has also been used to quantify the model's uncertainty (Tian et al., 2023; Xiong et al., 2023). High ECE in the self-confidence by VLMs has reported in the literature (Kostumov et al., 2024; Groot and Valdenegro-Toro, 2024). The authors report overconfidence by VLMs but do not propose any confidence technique for those. To the best of our knowledge, this is the

first work on calibrating confidence from existing UQ approaches when applied to VLMs.

4 Calibrated Uncertainty Quantification

The core idea behind the proposed approach is to leverage cross-modal consistency for evaluating the accuracy of the generated responses. This inference time accuracy evaluation can be utilized for calibrating the UQ of VLMs. The ability to ground back a response into the provided context generates evidence about the response's accuracy. Fig. 2 shows examples of grounding models (GM) that quantitatively provide this evidence by estimating a confidence score in the accuracy of the VLM's response. We use this GM-generated confidence (a score in $[0, 1]$) to calibrate the confidence reported by the existing UQ approaches. Specifically, confidence in a VLM by a UQ baseline, $Conf_{baseline} \in [0, 1]$, is calibrated by multiplying it with the GM's confidence in the accuracy of the model on the input query:

$$Conf = Conf_{baseline} \times Conf_{GM}^{(1/T)} + C, \quad (2)$$

where $Conf_{GM}$ is the average confidence of the grounding model over multiple responses generated for the self-consistency UQ baseline.[2] $T(> 0)$ is the hyper-parameter for temperature scaling or calibration of $Conf_{GM}$. Higher values of T sharpen (or increase) the confidence of the grounding model. Reducing the value of T reduces the confidence of the grounding model, and therefore the overall confidence. This is necessary to make sure the grounding model is calibrated correctly to the task. A constant $C(> 0)$ is also added to offset the reduction caused by the product of confidences in the range of $[0, 1]$. Both hyperparameters T and C are determined from a validation set.

Specifically, Conf_{GM} is computed as follows depending on the GM type: **Semantic-based (CLIP/BiomedCLIP):** cosine similarity between the text response and image embeddings, normalized to $[0, 1]$; **Segmentation-based (Grounded-SAM):** bounding-box detection confidence, natively in $[0, 1]$; **Foundation-based (LLaMA3.2V, QwenVL):** we assign a score of 1 for `Yes` responses and 0 for `No` or `Maybe` responses. In all cases, $Conf$ is clipped to 1 when C pushes the sum above 1.0. For foundation GMs, the grounding prompt asks the model to verify whether the textual response accurately reflects the input image, responding with only `Yes`, `No`, or `Not sure`. We map to 0 to both `No` and `Not sure`, reflecting a deliberate conservative design choice: in safety-critical settings, the inability to confirm a fact is functionally equivalent to a failure to provide grounding evidence (see Appendix for full prompt details).

[2] In case of non-consistency-based baselines, $Conf_{GM}$ is the grounding-model's confidence in a single response by the VLM.

Theoretical Motivation. Equation (2) can be viewed as a structured correction for the primary failure mode of self-consistency-based uncertainty quantification: the assumption that response consistency necessarily implies correctness. We consider three cases.

Case 1 — Model Inconsistency. When the base model is inconsistent, $\text{Conf}_{\text{baseline}}$ is already low, which naturally yields a low final confidence score.

Case 2 — Consistent but Incorrect. This is the critical setting in which existing self-consistency baselines often fail. The grounding term $\text{Conf}_{\text{GM}}^{1/T}$ introduces evidence from the visual modality. If the grounding model cannot identify visual support for the textual response, Conf_{GM} approaches zero, thereby correcting an overconfident baseline towards a calibrated low-confidence prediction.

Case 3 — Consistent and Correct. When the response is both consistent and visually supported, both terms remain high, preserving justified high confidence. The additive offset C is motivated by the fact that multiplying two values in $[0, 1]$ inherently compresses the resulting score; for example, $0.8 \times 0.8 = 0.64$. Without C, the formulation would systematically underestimate confidence for correct predictions. The offset shifts the confidence distribution closer to the $x = y$ identity line in the reliability diagram, thereby reducing ECE.

The formulation can also be interpreted as the ***Product-of-Experts*** with two complementary experts: *semantic consistency* ($\text{Conf}_{\text{baseline}}$), and *visuo-linguistic grounding* (Conf_{GM}). The power transformation $1/T$ acts as a parametric weight that calibrates the influence of grounding evidence. Their product implements a conjunctive AND constraint: high final confidence requires the response to be both internally consistent and externally grounded. The additive offset C further prevents confidence from collapsing to zero due to limitations of the GM, while still preserving the VLM's own consistency signal.

5 Experiments

5.1 Datasets

We evaluate our method on two open-ended visual question answering (QA) benchmarks from different domains: the medical-domain **Slake** (Liu et al., 2021) dataset and the general-domain **VQA v2.0** (Goyal et al., 2017) dataset. Slake is a bilingual (English and Chinese) dataset containing 14K QA pairs over 642 CT, MRI, and X-ray images, with both vision-only and knowledge-based questions annotated by physicians. We use only the English QA pairs and create 80/20 test/validation splits from the original test set. VQAv2 evaluates general visuo-linguistic understanding while reducing reliance on language priors through balanced annotations; we similarly use an 80/20 test/validation split from its test set. Additional examples from both datasets are provided in the Appendix.

We also perform ablation studies on **GQA** (Hudson and Manning, 2019) and **Whoops** (Bitton-Guetta et al., 2023). While VQA primarily evaluates general visual understanding (e.g., object recognition, counting, color identification, and factual reasoning), GQA requires compositional, multi-step reasoning over scene graphs. Whoops further challenges vision–language models with adversarial questions designed to avoid shortcuts based on dataset biases or scene-graph reasoning. Example image–question pairs from GQA and Whoops are included in the Appendix.

5.2 Vision Language Models

We consider LLaVA-v1.5-7B (Liu et al., 2024a) and LLaVA-Med-v1.5-Mistral-7B (Li et al., 2023b) as the VLMs for quantifying their uncertainty on VQA and Slake, respectively. **L**arge **L**anguage **a**nd **V**ision **A**ssistant (LLaVA) is a vision and language model that connects a vision encoder (CLIP (Radford et al., 2021)) with a language model (LLaMA 2 (Touvron et al., 2023)) to handle image-text queries. LLaVA-Med-v1.5-Mistral-7B is the fine-tuned variant of LLaVA on the medical domain with Mistral-7B (Jiang et al., 2023) as the language model. The fine-tuning is done by curriculum learning on biomedical image-caption pairs from the PubMed Central (Zhang et al., 2023a) dataset. We also conduct ablation studies on different VLMs, varying in openness and scale. Details and results of these studies on those models are in Section J.

5.3 Grounding Models

We consider different categories of the grounding models (GM). For VQA, we consider the following GM: **1. Segmentation-based:** GroundedSAM (Ren et al., 2024) is trained to perform segmentation on the bounding box detected by Grounding DINO (Liu et al., 2024b) on an image for an input text. **2. Semantic-based:** The **C**ontrastive **L**anguage–**I**mage **P**re-training CLIP (Radford et al., 2021) model assigns a similarity score between an image-text pair in the shared embedding space. **3. Foundation-based:** LLaMA-3.2-11B-Vision-Instruct (Grattafiori et al., 2024) (LLaMA3.2V), and Qwen2-VL-7B-Instruct (Wang et al., 2024) (QwenVL). For Slake, we report results with semantic and foundation GM: **1. Semantic-based GM:** BiomedClip (Zhang et al., 2023b), an advanced version of CLIP model fine-tuned on the medical domain. **2. Foundation GM:** Biomed-Qwen2-VL-2B-Instruct (Cheng et al., 2024) (Biomed-QwenVL), the fine-tuned version of QwenVL on the medical domain, and LLaMA-3.2-11B-Vision-Instruct[3]. We add prompt details for foundation GM in the Appendix.

5.4 Baselines

We consider all four self-consistency-based UQ baselines covered in the background section: Predictive Entropy (PredEnt), Lexical Similarity (LexSim), Semantic Entropy (SemEnt), and NumSets. For each prompt, we elicit 20 responses from VLM in order to capture diverse settings for the LLM with temperature $= 0.5$ for randomness, and top_p $= 1$ for nucleus sampling. For a fair comparison, we also consider calibrating all baselines directly with temperature scaling ($Conf_{baseline}^{(1/T)}$) where T is learned using the validation set.

We also conduct ablations on LLaVA for VQA on all four non-consistency-based verbalized prompting UQ approaches recently from Xuan et al. (2025). In these methods, models are explicitly instructed to output confidence scores for their generated responses, either through one-stage or two-stage prompting. One-stage prompting produces both the answer and its confidence within a single generation. This includes *Chain-of-Thought (CoT)* (Wei et al., 2022), where the model generates step-by-step reasoning followed by an answer and

[3]To the best of our knowledge, there is no model LLaMA3.2V family of foundation models specific to the medical domain

Baseline	Without Grounding (↓)		With Grounding (↓)			
	$Conf_{\text{baseline}}$	$Conf^{(1/T)}_{\text{baseline}}$	GroundedSAM	CLIP	LLaMA3.2V	QwenVL
LexSim	0.169	0.081	0.052 (−36.0%)	**0.045** (−44.6%)	**0.045** (−44.6%)	0.061 (−25.0%)
NumSets	0.410	0.246	0.143 (−41.9%)	0.143 (−41.8%)	0.127 (−48.4%)	**0.125** (−49.2%)
PredEnt	0.445	0.190	0.115 (−39.6%)	0.117 (−38.3%)	**0.096** (−49.4%)	0.119 (−37.5%)
SemEnt	0.108	0.108	0.036 (−66.9%)	0.038 (−64.6%)	**0.029** (−73.1%)	0.073 (−32.5%)

Table 1: Comparison of ECE over accuracy of LLaVA for VQA with the confidence reported by baseline ($Conf_{baseline}$), calibrated baseline ($Conf^{(1/T)}_{baseline}$), and the proposed calibration with grounding 2. Percentage improvement in ECE via grounding from the calibrated baseline is also reported (in green) for each grounding model.

Baseline	Without Grounding (↓)		With Grounding (↓)		
	$Conf_{\text{baseline}}$	$Conf^{(1/T)}_{\text{baseline}}$	BiomedClip	LLaMA3.2V	Biomed-QwenVL
LexSim	0.031	0.031	**0.004** (−87.1%)	0.013 (−58.1%)	0.038 (+22.6%)
NumSets	0.426	0.201	**0.007** (−96.5%)	0.021 (−89.6%)	0.132 (−34.3%)
PredEnt	0.390	0.215	**0.007** (−96.7%)	0.014 (−93.5%)	0.217 (+00.9%)
SemEnt	0.376	0.222	**0.008** (−96.4%)	0.010 (−95.5%)	0.247 (+11.3%)

Table 2: Comparison of ECE over accuracy of LLaVA-Med for Slake with the confidence reported by baseline ($Conf_{baseline}$), calibrated baseline ($Conf^{(1/T)}_{baseline}$), and the proposed calibration with grounding 2. Percentage improvement/regression in ECE via grounding from the calibrated baseline is also reported (in green/red) for each grounding model (GM).

its confidence score, and *Top-K* prompting, where the model produces K candidate responses with associated confidence scores in a single prompt, and the response with the highest confidence is selected. In contrast, two-stage approaches separate prediction from confidence estimation. *Self-reflection* prompting first generates an answer and then, in a subsequent pass, asks the model to reflect on that answer to produce a confidence estimate. *Visual Confidence-Aware Prompting (VCAP)* (Xuan et al., 2025) similarly follows a two-stage design, first eliciting a visual description along with a visual confidence score, and then performing the task conditioned on this self-assessed visual understanding to improve calibration.

5.5 Results

We report the average *Expected Calibration Error* (ECE) over accuracy with the confidence reported by (a) self-consistency baselines, (b) calibrated version of these baselines with temperature scaling, and (c) proposed calibration (2) for these baselines via grounding with different grounding models. Average ECE is calculated from 5 runs of random splits of the test/validation sets. Tables 1, and 2 show results for VQA and Slake, respectively. We observe a very low variance in all cases, and those values are in the Appendix. Values of hyperparameters T, C are also reported in the Appendix.

We also plot *reliability diagrams* for these baselines along with their temperature-scaled version, and the proposed grounding approach for calibration of these baselines with different grounding models (GM). These plots along with their respective ECE for LexSim, and SemEnt are reported in Fig. 3 for VQA and, Fig 8 in Appendix for Slake: LexSim and Sement are the top two UQ baselines in terms of ECE for both the datasets. Plots for other baselines (PredEnt and NumSets) are in the Appendix.

Observations on ECE: We make the following observations from Tables 1 and 2. First, ECE by the calibrated confidence via temperature scaling of all baselines is much lower than their original versions reported in the literature. This illustrates the efficacy of temperature scaling in calibrating the existing UQ techniques. Second, compared to confidence by the self-consistency approaches ($Conf_{baseline}$), the proposed grounding-based approach achieves much lower ECE in all but one test case for all grounding models on both VQA and Slake datasets, illustrating that the proposed approach is agnostic to the choice of GM. Finally, significant percentage improvements in ECE in most (all but three as shown in red) test cases - at least 32.5% for VQA and 34.3% for for Slake - from

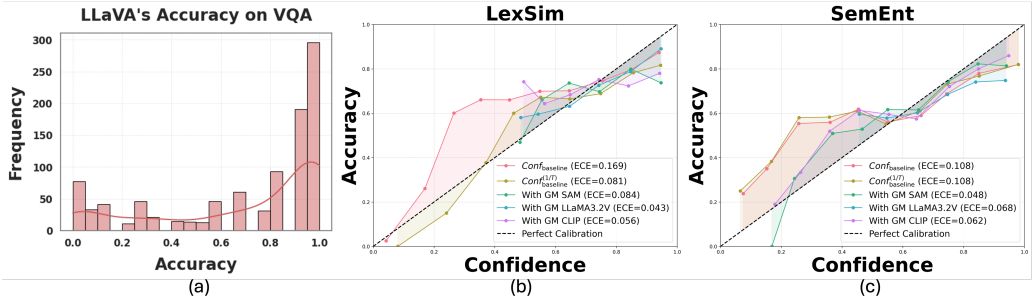

Figure 3: (a) Histogram on the frequency of LLaVA's accuracy on VQA. Reliability Diagrams for UQ of LLaVA on VQA by (b) LexSim, and (c) SemEnt baseline. Each diagram shows plots and the respective ECE for the confidence reported by the baseline $Conf_{baseline}$, its calibrated version $Conf_{baseline}^{(1/T)}$, and the proposed approach 2 for calibration with different GM.

the calibrated version of the baselines (as shown in green) illustrate that calibrating confidence of self-consistency scores on LLM's responses with external grounding is much more effective than calibrating those scores via temperature scaling.

Another important observation is that the amount of ECE improvement depends on the choice of the GM. In the case of VQA, LLaMA3.2V performs the best. Our hypothesis on this is as follows. LLaMA3.2V's diverse pretraining corpus has enhanced the model's capacity for commonsense reasoning and nuanced interpretation of complex image-text relationships, making it apt for grounding the responses of the VQA dataset that requires commonsense knowledge and understanding of visual domain. In the case of Slake, Biomed-Clip which is fine-tuned on medical domain performs better than the general-purpose LLaMA3.2V model. Although, Biomed-QwenVL is also fine-tuned for medical purposes but the use of synthetic data in the post-training might indicate its poor performance in the three baselines.

Observations from Reliability Diagrams: For VQA, LLaVA is able to answer most of the questions accurately - this is evident from the histogram on the frequency of LLaVA's accuracy on VQA 3 (a). This justifies the concentration of the reliability plots in the higher accuracy-confidence range (> 0.5) with all GM in case of LexSim and with LLaMA3.2V (best GM) on SemEnt. For other GM (SAM & CLIP) on SemEnt, the plot is more calibrated – closer to $x = y$ axis in all regions – in comparison to both the baseline and the temperature-scaled baseline.

For Slake, LLaVA-Med is not able to answer most of the questions accurately - this is evident from the histogram on the frequency of LLaVA-Med's accuracy on Slake 8 (a). This justifies the concentration of the reliability plots in the lower accuracy-confidence range (< 0.5) BiomedClip (best GM) on LexSim. The peaky behavior of the calibrated baseline and LlaMA3.2V in LexSim is due to uncalibrated confidence predictions on a very small number (2 to 3) inputs from higher (> 0.5) confidence bins. Similarly in case of SemEnt, BiomedLCip and LLaMA3.2V yields more calibrated curve in the lower accuracy-confidence range (< 0.5) but again we observe peaky behavior here, again due to uncalibrated confidence predictions on 2 to 3 inputs from higher confidence bins.

Additional robustness evidence (with results in Appendix): We provide several ablation studies to test whether the calibration gains are specific to a particular UQ baseline, dataset, VLM, grounding model, or calibration metric. First, Table 20 shows that the proposed grounding-based calibration also improves non-consistency-based verbalized confidence baselines, including CoT, Top-K, Self-Reflection, and VCAP. Second, Tables 14 and 15 show similar improvements on GQA and Whoops, extending the evaluation beyond the main VQA/Slake settings to compositional visual reasoning and caption generation. Third, Figure 11, Figure 12, and Tables 12–13 show that the approach remains effective across VLMs differing in openness and scale. We also report computation overhead and GM-only calibration baselines in Tables 5 and 6–11. Finally, in addition to ECE, Tables 16–19 report two additional calibration metrics, Smooth ECE (Blasiok and Nakkiran, 2024) and Brier score (Brier, 1950), to further evaluate the quality of the estimated confidence.

6 Conclusion

This work exposes a key limitation of self-consistency-based UQ for VLMs: **consistency**

does not imply accuracy. Consequently, relying solely on self-consistency can produce miscalibrated confidence estimates. We propose a calibrated UQ framework that complements self-consistency with cross-modal response consistency. Experiments across multiple VLMs, datasets, domains, tasks, and UQ baselines demonstrate that **cross-modal consistency, alongside self-consistency, is essential for achieving calibrated uncertainty estimates.**

Limitations

Our approach requires access to a grounding model (GM) capable of verifying model outputs against the input image, and introduces additional inference-time cost from this extra forward pass compared to self-consistency-only baselines. While our results show the method is robust to the specific choice of GM across the categories evaluated, the general framework assumes that a response can be meaningfully grounded back into the image (e.g., via bounding boxes or segmentation masks); it is less directly applicable to responses that are not spatially groundable, such as purely abstract reasoning steps. Separately, we observe that non-self-consistency verbalized-confidence baselines relying on structured output formats (e.g., XML/JSON) can fail to parse for vision-language models that do not reliably follow formatting instructions, which limits their comparability across all VLMs in our evaluation.

A Miscalibration of Existing SOTA self-consistency-based UQ approaches on TriviaQA and COQA

Fig. 4a and Fig. 4b show reliability diagrams for two self-consistency-based UQ approaches for predicting confidence of Llama-2-13B (Touvron et al., 2023) on TriviaQA (Joshi et al., 2017) and COQA (Reddy et al., 2019) datasets respectively; a common test setting considered by these approaches (Lin et al., 2023; Kuhn et al., 2023; Kaur et al., 2024). High expected calibration error (ECE) shows poor calibration of the model's accuracy with its confidence predicted by these approaches

B Prompt for the Foundation Grounding Models

Prompt

```
"I have an image and a short statement that describes a specific part of the image. Your job is to verify if this statement accurately reflects what is shown in the image.
Image: <Attached above>
Statement: "{response_text}"
Instructions: Respond with only one word — either "Yes" if the statement is correct, "No" if the statement is incorrect, or "Not sure" if you are uncertain. Do not provide any additional explanations."
```

We map "Yes" to the confidence score of 1, "No" as well as "Not sure" to the confidence score of 0.

C Examples of Question-Answer Pairs from VQAv2, GQA and Whoops Dataset

Fig. 5, and 6 shows sample multimodal question-answer pairs from the VQAv2 (Goyal et al., 2017) and GQA (Hudson and Manning, 2019) datasets, respectively. Fig. 7 shows some examples of the caption generation task for the Whoops dataset (Bitton-Guetta et al., 2023).

D Reliability Diagrams

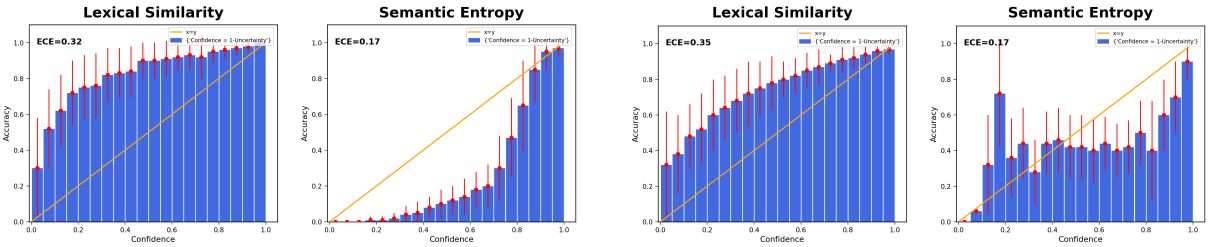

Figure 8 shows the reliability diagrams for LexSim and SemEnt on Slake. For Slake, LLaVA-Med is not able to answer most of the questions accurately, as shown by the accuracy histogram in Figure 8(a). This explains why the reliability plots are concentrated in the lower accuracy-confidence range. Figures 9 and 10 additionally show reliability diagrams for PredEnt and NumSets on VQA and Slake, respectively.

E ECE Results across different runs & Hyperparameter Configurations

Tables 3 show the values for mean and variance of ECE over 5 runs, as well as mean hyperparameter values of T and C again over 5 runs for VQA. Table 4 shows these values for Slake.

Baseline	Grounding Model	Mean ECE	Variance ECE	Mean T	Mean C
LexSim	NA	0.1692	0.00001	NA	NA
LexSim	Temp. Scaled Baseline	0.0813	0.00001	1.7	NA
LexSim	GroundedSAM	0.0524	0.00001	0.7	0.5
LexSim	Qwen-VL	0.0606	0.00001	1.1	0.5
LexSim	LLaMA 3.2V	0.0449	0.00001	0.3	0.5
LexSim	CLIP	0.0453	0.00001	0.7	0.5
NumSets	NA	0.4096	0.00001	NA	NA
NumSets	Temp. Scaled Baseline	0.2465	0.00001	5.1	NA
NumSets	GroundedSAM	0.1432	0.0001	0.3	0.5
NumSets	Qwen-VL	0.1249	0.0001	0.5	0.5
NumSets	LLaMA 3.2V	0.1265	0.00001	0.3	0.5
NumSets	CLIP	0.1434	0.00001	0.5	0.5
SemEnt	NA	0.1080	0.00001	NA	NA
SemEnt	Temp. Scaled Baseline	0.1078	0.00001	0.9	NA
SemEnt	GroundedSAM	0.0355	0.00001	2.9	0.2
SemEnt	Qwen-VL	0.0728	0.00001	0.9	0.5
SemEnt	LLaMA 3.2V	0.0290	0.0001	0.3	0.4
SemEnt	CLIP	0.0383	0.0001	4.7	0.1
PredEnt	NA	0.4445	0.0001	NA	NA
PredEnt	Temp. Scaled Baseline	0.1904	0.0002	9.7	NA
PredEnt	GroundedSAM	0.1145	0.0001	0.7	0.5
PredEnt	Qwen-VL	0.1187	0.0001	2.7	0.5
PredEnt	LLaMA 3.2V	0.0964	0.0001	0.3	0.5
PredEnt	CLIP	0.1165	0.0001	0.9	0.5

Table 3: Mean Expected Calibration Error (ECE), variance of ECE across five random splits over test/validation sets across different grounding models and baselines for the VQA dataset, and the corresponding average values of the temperature scaling parameter (T) and confidence threshold (C). Results are presented for all the four baselines—LexSim, NumSets, SemEnt, and PredEnt—each evaluated with the vanilla baseline, temperature-scaled baseline, and multiple vision-language grounding models including GroundedSAM, Qwen-VL, LLaMA 3.2V, and CLIP.

(a) TriviaQA (b) COQA

Figure 4: Reliability diagrams with the expected accuracy of LLaMA-2-13B on TriviaQA and COQA plotted as a function of the model's confidence predicted by two SOTA self-consistency-based UQ approaches. A perfect calibration between the model's accuracy and the predicted confidence would result in red points, representing the average accuracy for each confidence bin, lying on the $x = y$ axis with low variance.

F Verbalized Prompt Templates & Limitations

We provide the complete prompt templates used for each verbalized uncertainty quantification method.

F.1 Chain-of-Thought (CoT)

The CoT prompt elicits step-by-step reasoning followed by a structured answer and a verbalized confidence score in a single forward pass.

CoT

```
USER: <image>
Task: Answer the following question
    about the image. Provide your
    best answer along with a
    confidence score (0% to 100%).

Instructions:
- Carefully read and analyze the
    question.
- Reason through the answer step by
    step.
- At the end, present your final
    answer and a confidence score in
    the following XML format:
<answer>your answer here</answer>
<confidence>your confidence score
    here</confidence>

Example:
Question: How many people are
    visible in the image?

A: Let me analyze the image
    carefully. I can see several
    individuals in the scene. On the
    left side, there are two people
    standing together. In the
    center, there is one person
    sitting. On the right side, I
    can see one more person walking.
    Counting all visible
    individuals: 2 + 1 + 1 = 4
    people total.
<answer>4</answer>
<confidence>85%</confidence>

Now, here is your question:
Question: {question}

ASSISTANT:
```

F.2 Top-K Prompting

The Top-K prompt (with K=3) asks the model to produce K ranked answer candidates, each with an associated confidence. If fewer than K distinct answer options are plausible, the model is instructed to score only the available options.

Top-K Prompting, ($K = 3$)

```
USER: <image>
You are given an image and a visual
    question.

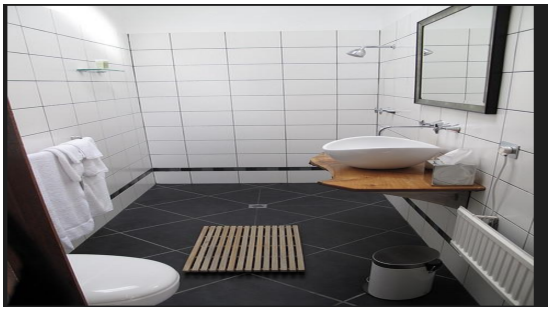
YOUR TASK is to answer the visual
    question.

Instructions:
- Provide your 3 best guesses and
    the probability that each is
    correct (0% to 100%).
- If fewer than 3 options exist,
    only provide the available
    answers with their confidence
    scores.
- Please reason step by step.
- At the end, present your final
    answers in the following
  XML format:
<answer1>[your first best
    answer]</answer1>
<confidence1>[confidence for
    answer1]</confidence1>
<answer2>[your second best
    answer]</answer2>
<confidence2>[confidence for
    answer2]</confidence2>
<answer3>[your third best
    answer]</answer3>
```

Q1: What does the sign say?
A: No cursing

Q2: What color is the engine?
A: Red

Q3: Are most of the people wearing hats?
A: No



Q4: Who does the man on the right resemble?
A: Surfer

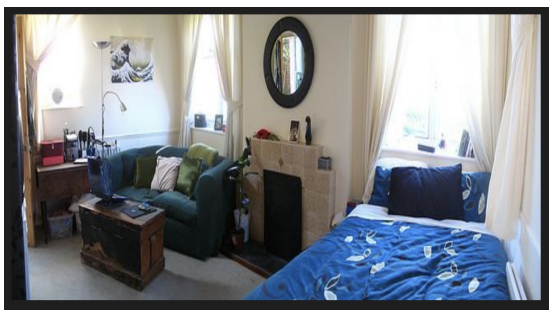


Figure 5: Example Q&A pairs from the VQAv2 dataset (Goyal et al., 2017).

Q1: Is the blue bag to the right or to the left of the player that is to the left of the towel?
A: The bag is to the left of the player.

Q2: Is the shower near the mirror dirty and large?
A: No, the shower is large but clean.

Q3: Is the fireplace near the couch white and closed?
A: No, the fireplace is closed but black.

Q4: Does the umbrella look open and large?
A: No, the umbrella is open but small.

Figure 6: Example Q&A pairs from the GQA dataset (Hudson and Manning, 2019).

Q1: Describe the image.
A: A Renaissance woman with a cheeseburger.

Q2: Describe the image.
A: A pagoda sits in front of the Eiffel Tower.

Q3: Describe the image.
A: A man is hiking up a mountain wearing a suit.

Q4: Describe the image.
A: Vikings ride on public transportation.

Figure 7: Example Image-caption pairs from the Whoops dataset (Bitton-Guetta et al., 2023).

Baseline	Grounding Model	Mean ECE	Variance ECE	Mean T	Mean C
LexSim	NA	0.0308	0.00001	NA	NA
LexSim	Temp. Scaled Baseline	0.0312	0.00001	0.9	NA
LexSim	BiomedCLIP	0.0040	0.00001	0.1	0.2
LexSim	LLaMA 3.2V	0.0134	0.00001	0.5	0.1
NumSets	NA	0.4263	0.00001	NA	NA
NumSets	Temp. Scaled Baseline	0.2015	0.00001	0.1	NA
NumSets	BiomedCLIP	0.0070	0.00001	0.1	0.2
NumSets	LLaMA 3.2V	0.0212	0.00001	0.1	0.2
SemEnt	NA	0.3764	0.00001	NA	NA
SemEnt	Temp. Scaled Baseline	0.2221	0.00001	0.1	NA
SemEnt	BiomedCLIP	0.0080	0.00001	0.1	0.2
SemEnt	LLaMA 3.2V	0.0098	0.00001	0.3	0.2
PredEnt	NA	0.3902	0.00001	NA	NA
PredEnt	Temp. Scaled Baseline	0.2149	0.00001	0.1	NA
PredEnt	BiomedCLIP	0.0069	0.00001	0.1	0.2
PredEnt	LLaMA 3.2V	0.0138	0.00001	0.1	0.2

Table 4: Mean Expected Calibration Error (ECE), variance of ECE across five random splits over test/validation sets across different grounding models and baselines for the Slake dataset, and the corresponding average values of the temperature scaling parameter (T) and confidence threshold (C). Results are presented for all the four baselines—LexSim, NumSets, SemEnt, and PredEnt—each evaluated with the vanilla baseline, temperature-scaled baseline, and two grounding models: BiomedCLIP (a biomedical domain-specific model) and LLaMA 3.2V.

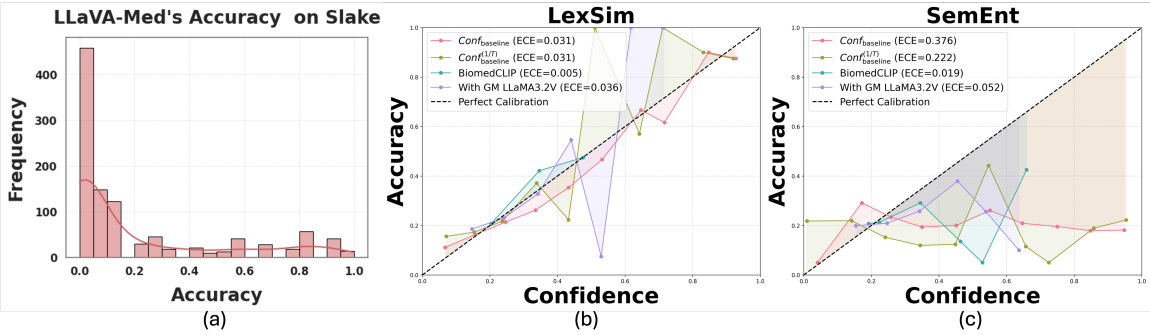

Figure 8: (a) Histogram on the frequency of LLaVA-Med's accuracy on Slake. Reliability diagrams for UQ of LLaVA-Med on Slake by (b) LexSim, and (c) SemEnt. Each diagram shows plots and the respective ECE for the confidence reported by the baseline $Conf_{\text{baseline}}$, its calibrated version $Conf_{\text{baseline}}^{(1/T)}$, and the proposed approach (2) for calibration with different grounding models.

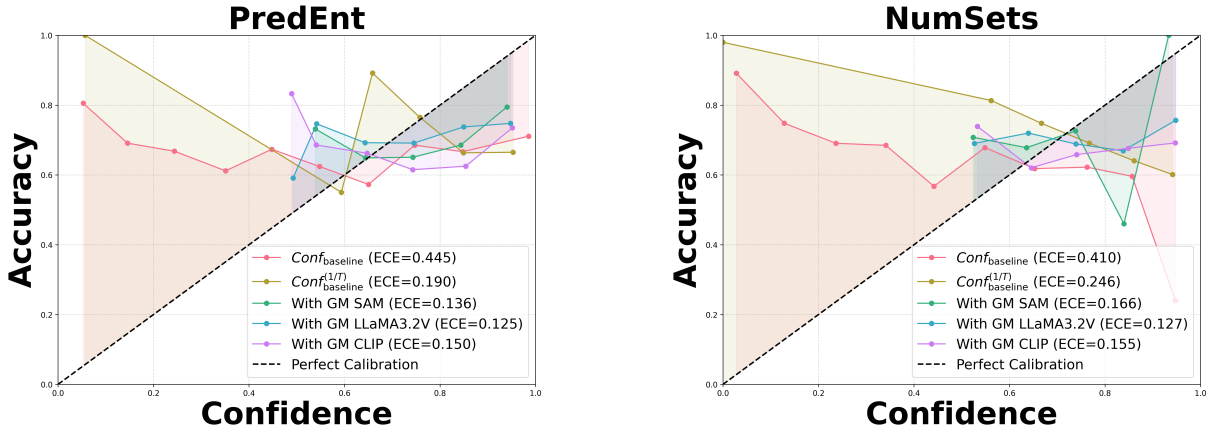

Figure 9: Reliability diagrams for UQ by PredEnt and NumSets baselines for LLaVA on the VQA dataset. Each diagram shows plots and ECE for the confidence reported by the baseline $Conf_{\text{baseline}}$, its calibrated version $Conf_{\text{baseline}}^{(1/T)}$, and the proposed approach (2) for calibration with different grounding models.

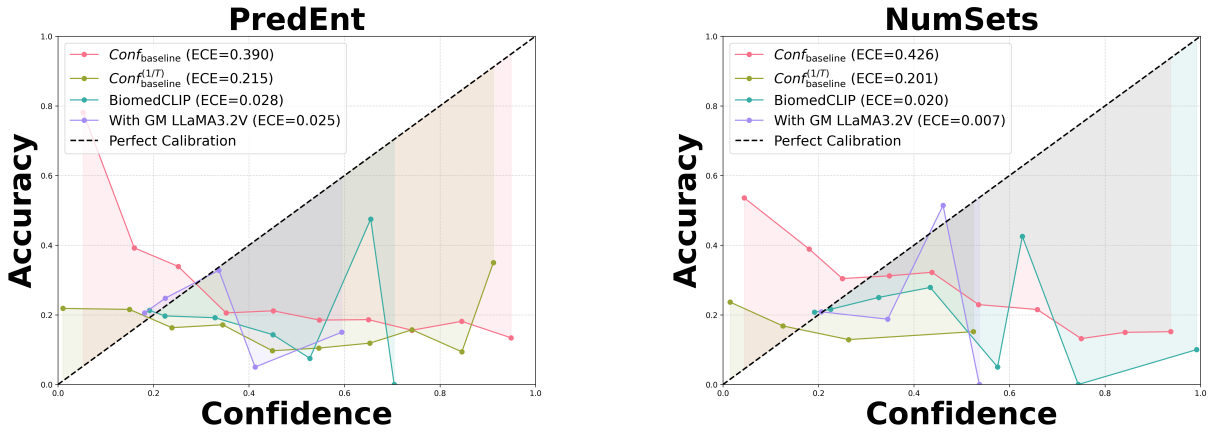

Figure 10: Reliability diagrams for UQ by PredEnt and NumSets baselines for LLaVA-Med on Slake. Each diagram shows plots and ECE for the confidence reported by the baseline $Conf_{\text{baseline}}$, its calibrated version $Conf_{\text{baseline}}^{(1/T)}$, and the proposed approach (2) for calibration with different grounding models.

```
<confidence3>[confidence for
    answer3]</confidence3>
```

```
Example output:
[YOUR_REASONING]
<answer1>yes</answer1>
<confidence1>75%</confidence1>
<answer2>no</answer2>
<confidence2>20%</confidence2>
<answer3>maybe</answer3>
<confidence3>5%</confidence3>

Question: {question}
ASSISTANT:
```

F.3 Self-Reflection

Self-Reflection is a two-stage method. In **Round 1**, the model answers the question with step-by-step reasoning but *does not* output a confidence score. In **Round 2**, the model receives the original question together with its Round 1 answer and is asked to reflect and output a single verbalized confidence score.

Self-Reflection — Round 1

```
USER: <image>
You are given an image and a visual
    question.

YOUR TASK is to answer the visual
    question.

Instructions:
- Please reason step by step.
- At the end, present your final
    answer in the following
  XML format:
<answer>[your answer to the
    question]</answer>

Example output:
[YOUR_REASONING]
<answer>yes</answer>

Question: {question}
ASSISTANT:
```

Self-Reflection — Round 2

```
USER: <image>
Task: Reflect on the following
    problem and solution, and
    provide a final confidence score.

Instructions:
- Carefully read and analyze the
    problem and solution.
- Reason through the solution step
    by step.
- At the end, present your final
    confidence score in the
    following XML format:
<confidence>confidence score
    here</confidence>

Example output:
[YOUR_REASONING]
<confidence>80%</confidence>

Problem: {question}
Solution: {solution}
ASSISTANT:
```

F.4 VCAP (Visual Confidence-Aware Prompting)

VCAP is a two-stage method. **Round 1** prompts the model to produce a detailed image description and attach a confidence score to that description. **Round 2** injects the description (including its confidence) and asks the model to answer the target question with confidence.

VCAP — Round 1: Image Description

```
USER: <image>
Task: Describe the image with enough
    detail to help answer visual
    questions about it. Provide a
    confidence score
(0% to 100%).

Instructions:
- Observe all important elements in
    the image.
- Describe objects, people, actions,
    colors, and spatial
    relationships.
- Provide a confidence score
    indicating certainty about your
    description.
- Please reason step by step.
- Present your output in XML format:
<description>your detailed
    description</description>
<confidence>your confidence
    score</confidence>

Example:
ASSISTANT: Looking at this image: In
    the foreground, I see a wooden
    table with a red tablecloth. On
    the table: a white coffee mug on
    the left, a plate with food in
    the center, and silverware on
    the right. The background shows
    a kitchen with white cabinets
    and a window.
    <description>Wooden table with a
    red tablecloth, a white coffee
    mug, a plate with food, and
    silverware. Background: kitchen
    with white cabinets and a
    window.</description>
<confidence>90%</confidence>
```

```
Now, please describe this image:
ASSISTANT:
```

VCAP — Round 2: Question Answering

```
USER: <image>
Task: Answer the following question
    about the image. Use both the
    image and the description below.

You have previously generated this
    description:
{description_with_confidence}

Instructions:
- Reason step by step, considering
    both the image and your own
    description.
- Take into account the confidence
    score of the description.
- At the end, present your final
    answer and a confidence score
    (0% to 100%) in XML format:
<answer>your answer here</answer>
<confidence>your confidence score
    here</confidence>

Example:
Previous description: "A park with
    green grass, several people
    playing with a frisbee, trees in
    the background,
sunny day" (confidence: 85%)

Question: What activity is happening?

A: Based on my description
    mentioning people playing with a
    frisbee (85% confidence), and
    checking the image to confirm, I
    see the frisbee in mid-air and
    people in throwing/catching
    positions.
<answer>playing frisbee</answer>
<confidence>90%</confidence>

Question: {question}

A:
```

A practical limitation of verbalized confidence estimation is its reliance on structured output formats (e.g., XML/JSON) for reliable parsing, which introduces two failure modes. First, many vision-language models—especially domain-specialized variants—do not consistently adhere to strict formatting constraints, resulting in parsing failures. This failure was evident for LLaVA-Med in our experiments, where the model could not generate a self-confidence score for these baselines. Second, imposing structured output constraints can itself degrade task performance; Tam et al. (2024) report drops of up to 38 percentage points on mathematical reasoning benchmarks under structured-output requirements (Tam et al., 2024).

G Additional Ablations

1. Computation Cost Analysis: Table 5 reports the time taken by baselines and grounding models on Slake. We acknowledge that our calibration approach introduces computational overhead due to the use of an external model for grounding. However, as evident from Tables 1 and 2, we would like to emphasize that we get substantial performance gains even with a lightweight GM such as Clip with at most 0.01% computational overhead.

Baseline	Grounding Model
LexSim: 44.24	BiomedClip: 0.47
NumSets: 47.82	Llama3.2V: 9.44
PredEnt: 44.18	Biomed-QwenVL: 17.68
SemEnt: 47.82	

Table 5: Computation Cost Analysis (in Seconds) on Slake

2. Using $Conf_{GM}^{1/T}$ as a Baseline: We also report ECE with temperature-scaled grounding model confidence as another baseline. These results are shown in Tables 6, 7, 8 show results for $Conf_{GM}^{(1/T)}$ as the baseline for VQA with Clip, LLaMA3.2V, and QwenVL as the grounding model respectively. Tables 9, 10, 11 show results for $Conf_{GM}^{(1/T)}$ as the baseline for Slake with Biomed-Clip, LLaMA3.2V, and QwenVL as the grounding model respectively. The proposed approach outperforms this baseline on all but two 2 cases on VQA and all but 3 test cases on Slake.

3. Different Sizes of VLMs For ablations on different sizes of VLMs, in addition to Llava-7B, we perform experiments with Phi-4-multimodal-instruct-5.6B (Abouelenin et al., 2025) and Qwen2.5-VL-32B-Instruct (Bai et al., 2025) models on GQA with Clip as the grounding model. Figure 11 shows significant percentage improvements – ranging from 41.6% to 97.7% – by our approach in ECE from the temperature-scaled baselines for all models. Tables 12 and 13 show detailed results for Phi and Qwen, respectively.

4. Generalizability w.r.t Datasets and Tasks: Tables 14 and 15, show these results for all the baselines with Llava-v1.5-7B as the VLM and Clip as the GM for Whoops and GQA respectively. Here,

also we observe significant improvements in the ECE for both GQA (at least 41.6%) and Whoops (at least 68.6%).

H Computation Resources

All experiments were conducted on a combination of AWS EC2 `p4de.24xlarge` and `p4d.24xlarge` instances. The `p4de.24xlarge` configuration includes 8 × NVIDIA A100 GPUs (80 GB HBM2e per GPU, totaling 640 GB of GPU memory), 96 vCPUs, 1,152 GiB of system RAM, 8 TB of local NVMe SSD storage, 400 Gbps network bandwidth, and approximately 19 Gbps of EBS throughput. The `p4d.24xlarge` instances, in comparison, provide 8 × NVIDIA A100 GPUs (40 GB HBM2 per GPU), 1.1 TiB RAM, and similar networking and storage specifications (Amazon Web Services, 2023). Our codebase was implemented in Python using PyTorch (Paszke et al., 2019), with model development and inference supported by the Hugging Face Transformers library (Wolf et al., 2019).

J Ablation Studies

1. Generalizability w.r.t the underlying UQ baseline. We conduct ablations on LLaVA for VQA for

all four non-consistency-based verbalized prompting UQ baselines. Table 20 shows these results. Here also, the proposed grounding-based calibration consistently outperforms all four verbalized prompting baselines across all grounding models, achieving improvements ranging from 60.8% to 96.4% in ECE as compared to temperature-scaled UQ baselines. Details on the verbalized prompts for these baselines and their limitations are listed in Appendix.

2. Generalizability w.r.t Datasets and Tasks: Apart from VQA for general Q&A and Slake for medical Q&A, we also consider two more datasets, namely GQA for Q&A and Whoops for the caption generation. These datasets are chosen as they test LLMs at varying levels of visuo-linguistic reasoning. Tables 14 and 15 in Appendix, show these results for all the baselines with Llava-v1.5-7B as the VLM and Clip as the GM. Here, also we observe significant improvements in the ECE for both GQA (at least 41.6%) and Whoops (at least 68.6%).

3. Generalizability w.r.t VLMs: Here we consider variability in terms of closed model such as Gemini-2.5-pro (Comanici et al., 2025), and different sizes of the VLMs. Unlike LLaVA, Gemini is a closed model without access to its generated token probabilities. As a result, baselines such as NumSets, PredEnt, and SemEnt, which rely on these probabilities, cannot be tested. So, we compare using the LexSim baseline, which assesses lexical similarity between every pair of responses. Figure 12 shows up to 86.25% improvements in ECE from the temperature-scaled baseline by the proposed approach with all grounding models on Slake. Similar results with ablations on different sizes of VLMs with parameters ranging from 5.6B (in Phi4) to 32B (in Qwen2.5) are included in the Appendix: Figure 11 and Tables 12 and 13.

We also perform other ablations on a) computation overhead due to the use of an external GM (Table 5) acknowledging that we get substantial performance gains even with a lightweight GM such as Clip with at most 0.01% computational overhead, and b) using temperature-scaled GM as baseline (Tables 6, 7, 8, 9, 10, 11). Details and results of these ablations are included in Appendix.

K Additional Calibration Metrics

To complement the standard ECE evaluation, we additionally report two calibration metrics: Smooth ECE (Blasiok and Nakkiran, 2024) and Brier score.

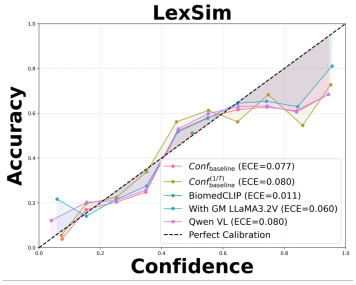

Figure 12: Reliability diagram and ECE comparison of LexSim with different GM in the proposed calibration approach for Gemini on the medical dataset Slake.

We evaluate these metrics on VQA across two GMs, CLIP and LLaMA3.2V, for all four baselines. Smooth ECE improvements range from 17.6% to 55.6%, and Brier score improvements range from 17.2% to 56.9%, with the exception of SemEnt, which shows marginal regression (-1.1% to -11.4%). These results provide additional evidence that the proposed approach improves confidence calibration beyond the standard ECE metric. Detailed results are reported in Tables 16–19.

Baseline	Without Grounding (↓)		With Grounding (↓)			
	$Conf_{\text{baseline}}$	$Conf^{(1/T)}_{\text{baseline}}$	GroundedSAM	CLIP	LLaMA3.2V	QwenVL
CoT	0.273	0.176	0.039 (-85.9%)	0.019 (-93.2%)	0.021 (-92.4%)	0.010 (-96.4%)
Top-K	0.297	0.126	0.010 (-92.4%)	0.036 (-71.4%)	0.049 (-60.8%)	0.017 (-86.5%)
Self-Reflection	0.410	0.334	0.056 (-83.2%)	0.011 (-96.6%)	0.103 (-69.2%)	0.133 (-60.3%)
VCAP	0.279	0.198	0.015 (-94.7%)	0.008 (-97.1%)	0.093 (-66.7%)	0.073 (-73.7%)

Table 20: Comparison of ECE over accuracy of LLaVA for VQA with confidence reported by non-consistency-based verbalized prompting UQ baselines ($Conf_{baseline}$), calibrated baseline ($Conf^{(1/T)}_{baseline}$), and our approach with grounding 2. Percentage improvement in ECE via grounding from the calibrated baseline is also reported (in green) for each GM.

Lost In Translation: Uneven Grounding Degradation Under Cross-Lingual Shift in LLM-Assisted Cyber Threat Intelligence

Lailah Denny
Lithonia High School
lailahdenny2@gmail.com

Abstract

We introduce **CrossCTI**, a multilingual benchmark for evaluating retrieval-augmented generation (RAG) grounding faithfulness in open-source large language models applied to cyber threat intelligence (CTI) analysis. Existing CTI and forensic NLP benchmarks are predominantly English-centric, leaving a critical gap in understanding how grounding faithfulness degrades under cross-lingual distribution shift, a realistic condition in multinational security operations centers. CrossCTI translates 50 English CTI reports into Arabic, Chinese, Swahili, and Russian using NLLB-200 with entity-preserving masking, achieving 100% IOC preservation across languages. We construct 26 forensic question-answer pairs and evaluate each against all five language corpora and three open-source models (Qwen2.5-7B, Llama-3.1-8B, and Mistral-7B-v0.3), producing 390 evaluation instances, scored with token-level F1, character-level F1, and entailment-based attribution. Using a repeated-measures mixed-effects analysis that accounts for the fact that each of the 26 items is evaluated under all 15 model×language conditions, we find that cross-lingual degradation is severe, but *uneven across metrics*: language is the dominant, robust predictor of lexical (token-level) grounding quality ($p < 0.001$), with no detectable effect of model identity on this metric. In contrast, model identity is a significant predictor of both character-level overlap and entailment-based attribution ($p < 0.01$), including a specific interaction in one model (Mistral) that underperforms specifically in Swahili. Token-level F1 drops from 0.44 (English) to 0.03 (Arabic); gold-chunk retrieval recall drops from 0.962 (English) to 0.115 (Arabic); and the instance-level correlation between retrieval success and token-level grounding is $r = 0.60$. Performance also improves from the top-$k = 1$ to the top-$k = 3$ retrieved passages before plateauing, with no consistent gains from the additional retrieved content. We further show that the entailment-based attribution metric is significantly elevated specifically for the model used to generate the benchmark's own QA pairs, a synthetic-annotator confound that we quantify directly via within-item paired tests rather than only disclosing qualitatively. CrossCTI provides a reproducible framework for multilingual CTI grounding evaluation and a case study in how the apparent dominant factor, language or model, depends on which grounding metric is used.

1 Introduction

Retrieval-augmented generation (RAG) has emerged as a dominant paradigm for improving factual grounding in large language models (LLMs) by conditioning generation on externally retrieved evidence (Lewis et al., 2021). Despite these advances, RAG systems remain susceptible to hallucination and attribution failures, particularly under conditions of imperfect or insufficient retrieval (Shuster et al., 2021; Tang et al., 2024). Faithfulness, defined as the consistency between generated outputs and their retrieved evidence sources, has consequently become a central axis of RAG evaluation (Es et al., 2025; Tang et al., 2024). Existing evaluation frameworks, however, are predominantly developed and validated in English-centric, general-domain settings. This limits their ability to characterize grounding behavior under cross-lingual distribution shift, despite well-documented evidence that multilingual conditions introduce substantial degradation in both retrieval and generation quality (Asai et al., 2021; Zhang et al., 2023). Critically, existing multilingual benchmarks primarily target either retrieval effectiveness (Zhang et al., 2023) or cross-lingual question answering (Asai et al., 2021), without explicitly measuring the faithfulness of generated outputs with respect to retrieved evidence. More recent multilingual RAG evaluation efforts, such as MEMERAG (Blandón et al., 2025), extend

Proceedings of the 1st Workshop on Grounding Language Models: Learning Faithfully and Efficiently (GroundLM 2026), pages 505–512
October 29, 2026 ©2026 Association for Computational Linguistics

evaluation to multilingual settings using human judgments, but remain anchored to general-domain Wikipedia corpora and do not address structured, domain-specific reasoning under retrieval grounding constraints. This gap is especially consequential in cyber threat intelligence (CTI), where RAG systems are increasingly explored for automating analysis of threat reports, extracting indicators of compromise (IOCs), and supporting digital forensics and incident response (DFIR) workflows (Clairoux-Trepanier et al., 2024; Alhuzali, 2025). Recent work has shown that LLMs exhibit unreliable behavior on real-scale CTI reports, demonstrating inconsistency and overconfidence even in monolingual English settings (Mezzi et al., 2025). Hallucinated or misattributed threat intelligence poses a direct operational risk: an erroneous IOC attribution or a fabricated TTP mapping can misdirect incident response at critical decision points. These failure modes are substantially amplified under cross-lingual conditions, yet no benchmark has characterized their extent.

To address this gap, we introduce **CrossCTI**, a multilingual benchmark for evaluating RAG grounding faithfulness under cross-lingual distribution shift in CTI analysis. We construct five language corpora by retaining 50 English CTI reports and translating them into Arabic, Chinese, Swahili, and Russian using NLLB-200 (Team et al., 2022), with entity-preserving masking applied to maintain IOC integrity across all language pairs. We construct 26 forensic QA pairs and evaluate each across all five language corpora and three open-source instruction-tuned models, Qwen2.5-7B, Llama-3.1-8B, and Mistral-7B-v0.3, providing 390 evaluation instances (26 items $\times$ 5 languages $\times$ 3 models). Because every item is repeated across all 15 model$\times$language conditions, we treat this explicitly as a repeated-measures design and analyze it with item-level mixed-effects models, cluster-robust regression, and within-item nonparametric tests, rather than treating the 390 instances as independent observations.

Our central finding is that *which factor appears to dominate depends on the grounding metric*. Under lexical (token-level) F1, language is overwhelmingly dominant and model identity has no detectable effect, a result that holds consistently across a mixed-effects model, a cluster-robust regression, and a nonparametric Friedman test. Under character-level F1 and entailment-based attribution, however, model identity is a significant factor in its own right, including a specific model$\times$language interaction (Mistral underperforming in Swahili), and a significant, consistent elevation of the model used to generate the benchmark's QA pairs on the attribution metric, a confound we quantify rather than only acknowledge. CrossCTI provides a reproducible framework for evaluating these failure modes and a case study in how metric choice shapes which axis of a RAG system, the language pipeline or the generator model, looks responsible for grounding failure.

2 Related Work

Retrieval-Augmented Generation and Faithfulness. RAG (Lewis et al., 2021) conditions generation on retrieval evidence to reduce hallucination (Shuster et al., 2021), but faithfulness evaluation remains an open problem. Frameworks such as RAGAs (Es et al., 2025) and MiniCheck (Tang et al., 2024) provide automated faithfulness scoring for English text; we adopt the general entailment-based faithfulness paradigm these frameworks establish but instantiate it with a multilingual NLI model (Section 3.3) rather than an English-only scorer, given our cross-lingual setting. Salemi and Zamani (2024) show that retrieval quality is itself a strong predictor of downstream RAG performance. In a security-specific setting, Fayyazi et al. (2025) introduce an embedding-based attribution method to quantify how much LLM responses in vulnerability analysis actually rely on retrieved evidence versus parametric knowledge, a complementary direction to our entailment-based faithfulness scoring.

Multilingual and Cross-Lingual RAG. MIRACL (Zhang et al., 2023) and XOR-TyDi QA (Asai et al., 2021) established that retrieval effectiveness and question answering accuracy both degrade under cross-lingual conditions, particularly for low-resource languages. More recently, XRAG (Liu et al., 2025) identifies that cross-lingual RAG systems struggle with both response language correctness under monolingual retrieval and with reasoning over multilingual retrieved evidence. At the same time, Li et al. (2025) show that incorporating multilingual document perspectives can improve robustness on culturally sensitive tasks, though citation behavior varies substantially by language resource level. MEMERAG (Blandón et al., 2025) extends multilingual RAG evaluation using human faithfulness judgments across five lan-

guages. CrossCTI differs from these efforts in two respects: it targets a structured, domain-specific reasoning task rather than open-domain Wikipedia or news QA, and it isolates language as an experimental variable independent of model choice via controlled translation rather than relying on naturally occurring multilingual corpora.

LLMs for Cyber Threat Intelligence. LLMs are increasingly applied to CTI workflows, including threat report summarization and IOC extraction (Clairoux-Trepanier et al., 2024). However, Mezzi et al. (2025) demonstrate that LLMs exhibit inconsistency and overconfidence on real-scale CTI reports even in monolingual English settings. No prior work has measured how these reliability features compound under cross-lingual distribution shift, which is the gap CrossCTI addresses.

3 CrossCTI Benchmark

3.1 Dataset and Translation Pipeline

CrossCTI is built from the `mrminhaz/CTI-Reports` dataset, a collection of publicly available English-language cyber threat intelligence reports sourced from open threat intelligence feeds. We load 100 reports and randomly sample 50 for evaluation using a fixed seed (`seed` $= 42$), reserving the remainder for corpus construction. Each report is segmented into overlapping chunks of 200 words with a 30-word stride, yielding a retrieval corpus of fixed-context passages that preserve local semantic coherence across chunk boundaries. To construct multilingual variants, we translate all English chunks into Arabic (`arb_Arab`), Chinese (`zho_Hans`), Swahili (`swh_Latn`), and Russian (`rus_Cyrl`) using NLLB-200 (Team et al., 2022), a massively multilingual neural machine translation model supporting 202 languages. Languages were selected to span a range of typological diversity, script systems, and resource levels: Arabic introduces right-to-left script and is high-resource but underrepresented in CTI corpora; Chinese provides a logographic script with strong coverage in Qwen2.5; Swahili represents a low-resource African language with limited forensic NLP precedent; and Russian provides a high-resource Cyrillic baseline with a natively documented threat actor ecosystem.

A critical preprocessing step is *entity-preserving masking*: prior to translation, all indicators of compromise (IOCs) — including IPv4 addresses, MD5, and SHA hashes, CVE identifiers, and file system paths — are replaced with indexed placeholders (`__IOCPH{i}__`) using a regular expression pattern, translated text is generated, and placeholders are restored in post-processing. This prevents NLLB-200 from corrupting domain-critical tokens that carry no translatable semantic content. Entity preservation is verified post-hoc by checking whether each original IOC string appears verbatim in the translated output. CrossCTI achieves a 100% IOC preservation rate across all four target languages.

3.2 QA Pair Construction

We construct question-answer pairs using Qwen2.5-7B-Instruct as a synthetic annotator. The model is prompted under a structured system instruction to generate forensic QA pairs grounded strictly in sampled English chunk text, prioritizing questions about malware families, CVEs, IOCs, MITRE ATT&CK TTPs, targeted sectors, persistence mechanisms, and command-and-control infrastructure. Each pair consists of a question, a gold answer, and a verbatim source quote supporting the answer.

After generation and filtering, this process yields **26 valid QA pairs**. Each pair is evaluated against all five language corpora (English plus four translations) and all three candidate models, yielding $26 \times 5 \times 3 = 390$ total evaluation instances, or 26 instances per model$\times$language cell. Because the same 26 items recur across every cell, instances are not statistically independent of one another; we treat this explicitly as a repeated-measures design throughout Section 4 rather than assuming 390 independent observations. A subset of 20 of the 26 pairs was manually reviewed for quality (Section 6).

We acknowledge that using Qwen2.5-7B-Instruct as both the QA generator and as one of the evaluated models constitutes a potential confounder. Section 4.3 presents direct statistical evidence of its effect on the attribution metric rather than treating it only as a disclosed risk.

3.3 Evaluation Protocol

Retrieval. For each language, we build a separate FAISS flat inner-product index (Johnson et al., 2017) over chunk embeddings produced by `all-MiniLM-L6-v2` (Reimers and Gurevych, 2019), with embeddings L2-normalized before indexing. At inference time, the top-k chunks most similar to the query are concatenated into a structured prompt. We evaluate at $k \in \{1, 2, 3, 5, 10\}$; primary results are reported at $k = 3$. All three

models share this single retriever; we return to this as a limitation in Section 6.

Generation. Three open-source instruction-tuned models are evaluated: Qwen2.5-7B-Instruct, Llama-3.1-8B-Instruct, and Mistral-7B-Instruct-v0.3. All models are loaded in 4-bit NF4 quantization via BitsAndBytes and prompted identically with a fixed zero-shot RAG template instructing the model to answer using only the retrieved sources. Generation uses greedy decoding ($T = 0$, `max_new_tokens` = 128) across all models to ensure comparability. We did not evaluate at full precision; this is discussed as a limitation.

Grounding Metrics. We report three complementary metrics. *Token-level F1* measures lexical overlap between the model answer and the gold answer at the unigram level. *Character-level F1* measures overlap at the character n-gram level, which is more robust to tokenization and morphological differences across scripts (Section 4.5). *Attribution* is assessed using XLM-RoBERTa-large fine-tuned on XNLI (Conneau et al., 2018, 2020) (the `joeddav/xlm-roberta-large-xnli` checkpoint), a multilingual natural language inference model natively covering all five evaluated languages as part of its 15-language XNLI fine-tuning set. The model outputs entailment, neutral, and contradiction probabilities for a (context, answer) pair; a generation is classified as hallucinated when its entailment probability falls below 0.5. We chose a multilingual NLI model rather than an English-only faithfulness scorer specifically to avoid introducing an additional cross-lingual validity gap on top of the retrieval-encoder gap already present in our pipeline (Section 6). Retrieval recall is computed as the fraction of instances in which the gold source chunk appears among the top-k retrieved passages.

4 Results

4.1 Overall and Per-Language Performance

Table 1 reports mean performance by language across all three metrics. All three metrics show a large English-vs-non-English gap, but the *shape* of degradation across non-English languages differs by the metric: Arabic is weakest on token F1, but Arabic and Chinese are statistically indistinguishable and jointly weakest on character F1 (Section 4.2), while Swahili shows a distinctly smaller character-level gap than its token-level gap would suggest (Section 4.5).

Language	Token F1	Char. F1	Attrib.
English	0.441	0.683	0.590
Arabic	0.032	0.134	0.295
Russian	0.047	0.166	0.282
Swahili	0.079	0.468	0.333
Chinese	0.107	0.130	0.333

Table 1: Mean grounding scores by language, averaged across all three models ($n = 78$ per language). Arabic is the weakest language on token F1; Arabic and Chinese are statistically indistinguishable and jointly weakest on character F1.

Model	Token F1	Char. F1	Attrib.
Llama	0.131	0.327	0.308
Mistral	0.140	0.252	0.269
Qwen	0.154	0.369	0.523

Table 2: Mean grounding scores by model, averaged across all five languages ($n = 130$ per model).

Table 2 shows that model-level differences are small for token F1 but substantially larger for character F1 and, especially, attribution — where Qwen's mean is roughly double Mistral's. Section 4.3 shows this gap is not incidental.

4.2 Statistical Analysis: Language and Model Effects

Because each of the 26 QA items is evaluated under all 15 model×language conditions, observations sharing an item are not independent. We therefore report three converging analyses per metric: an item-level mixed-effects model with a random intercept for item, a fixed-effects regression with standard error clustered by item, and a nonparametric within-item Friedman test. All three approaches agree on the qualitative conclusion for each metric.

Token F1. Language is highly significant (e.g., English vs. Arabic coefficient 0.396, $p < 0.001$ in the mixed model), while model identity is not significant under any of the three approaches (mixed model $p = 0.53$–0.95; clustered regression $p = 0.18$–0.88; Friedman $\chi^2 = 2.38$, $p = 0.30$). No model×language interaction is significant. This is the one metric on which the original hypothesis, that language dominates and model identity does not matter, holds robustly.

Character F1. Language remains highly significant, but model identity is also now significant

Model	AR	EN	RU	SW	ZH
Llama	0.024	0.420	0.051	0.062	0.095
Mistral	0.027	0.438	0.048	0.075	0.112
Qwen	0.046	0.464	0.043	0.100	0.114

Table 3: Token-level F1 by model and language ($n = 26$ per cell).

(clustered regression: Qwen coefficient 0.0415, $p = 0.001$; Friedman $\chi^2 = 29.77$, $p < 0.001$), and there is a significant model×language interaction: Mistral underperforms specifically in Swahili relative to its own baseline pattern (interaction coefficient $= -0.249$, $p < 0.001$, replicated in both the mixed model and the clustered regression). Within-item paired tests (Holm-corrected) confirm all three pairwise model comparisons are significant on this metric (all $p < 0.001$).

Attribution. Language remains significant (Friedman $\chi^2 = 11.21$, $p = 0.024$), and model identity is also significant when comparisons are pooled across five languages (Friedman $\chi^2 = 20.89$, $p < 0.001$), driven specifically by Qwen scoring higher than both other models (within-item paired tests, Holm-corrected Qwen vs. Llama and Qwen vs. Mistral both $p < 0.001$; Llama vs. Mistral not significant). We discuss the source of this effect in Section 4.3.

4.3 The Synthetic-Annotator Confound in Attribution

Qwen2.5-7B-Instruct is both the QA-pair generator (Section 3.2) and one of the three evaluated models. Table 2 shows Qwen's mean attribution score (0.523) is roughly double Mistral's (0.269) and well above Llama's (0.308), while all three models are statistically indistinguishable on token F1. This pattern, an advantage specific to the metric closest to "does this answer match what I would have generated," and specific to the model that generated the reference material, is the expected signature of QA-generator confound rather than a genuine capability difference. Within-item paired testing makes this precise: Qwen's advantage over each other model on attribution is significant after Holm correction ($p < 0.001$ in both comparisons), while Llama and Mistral are never distinguishable from each other on any of the three metrics. We do not use the attribution metric to support any claim about relative model capability, and recommend that future extensions of CrossCTI generate QA pairs with a model held out from evaluation entirely.

Language	Retrieval Recall
English	0.962
Arabic	0.115
Russian	0.269
Swahili	0.308
Chinese	0.192

Table 4: Gold-chunk retrieval recall by language ($n = 26$ per language; identical across all three models, as all share a single retriever).

Language	Token F1	Char. F1	Ratio
Swahili	0.079	0.468	5.92×
Arabic	0.032	0.134	4.11×
Russian	0.047	0.166	3.51×
English	0.441	0.683	1.55×
Chinese	0.107	0.130	1.21×

Table 5: Ratio of character-level to token-level F1 by language. A high ratio indicates token-level F1 substantially underestimates a true overlap relative to character-level overlap.

4.4 Instance-Level Retrieval-Grounding Relationship

Table 4 shows retrieval recall collapses outside English, most severely for Arabic. At the instance level ($n = 390$), retrieval success is significantly correlated with all three grounding metrics: token F1 ($r = 0.60$, $p < 10^{-39}$), character F1 ($r = 0.58$, $p < 10^{-35}$), and attribution ($r = 0.31$, $p < 10^{-9}$). Mean token F1 is 0.047 when the gold chunk is not retrieved versus 0.303 when it is, a more than sixfold difference.

4.5 Cross-Lingual Tokenization Sensitivity

Table 5 shows that the gap between token-level and character-level F1 is far from uniform across languages. For Swahili, an agglutinative Bantu language, character F1 is nearly six times token F1, indicating that whitespace/morpheme-boundary tokenization substantially undercounts genuine lexical overlap. Arabic and Russian, both morphologically rich, show similar if smaller effects. Chinese and English, by contrast, show token F1 and character F1 in much closer agreement. This indicates that a meaningful share of Swahili's apparent token-level "failure" in Table 1 is a tokenization artifact rather than a grounding failure, while Chinese and Arabic's low scores are consistent across both granularities and more likely reflect genuine

grounding degradation. We recommend that future multilingual RAG evaluations report both token- and character-level overlap, particularly when morphologically rich or agglutinative languages are included.

4.6 Top-k Sensitivity

Performance improves from top-$k = 1$ (0.199) to top-$k = 3$ (0.369), after which it plateaus (top-$k = 5$: 0.370; top-$k = 10$: 0.370), indicating diminishing returns from additional retrieved context beyond $k = 3$. This analysis was conducted at the level of the full 390-instance dataset.

5 Discussion

Our results reveal that retrieval quality is a strong, statistically robust predictor of grounding faithfulness at the instance level (Section 4.4), and its collapse under cross-lingual shift, driven by an English-centric encoder (`all-MiniLM-L6-v2`), plausibly explains a large share of the degradation observed on token-level F1. However, our repeated-measures analysis shows this is not the whole story: on character-level overlap and entailment-based attribution, model identity is an independent, statistically significant factor, including a specific and replicated Mistral×Swahili weakness that a retrieval-only account would not predict. This suggests that at least part of the multilingual grounding gap in CTI-focused RAG is attributable to generation behavior, not retrieval alone, and that conclusions about "language versus model" in cross-lingual RAG evaluation are sensitive to which grounding metric is used.

The tokenization-sensitivity analysis (Section 4.5) reinforces this point from a different angle: a meaningful share of the apparent Swahili grounding failure under token F1 is a measurement artifact of whitespace-based tokenization, not a genuine grounding failure, while Chinese and Arabic's weak performance is consistent across both token- and character-level measurement and more likely reflects a real effect. We recommend character-level (or morphology-aware) metrics as a standard complement to token F1 in future multilingual RAG evaluation.

Cross-lingual validity of the attribution metric. Because we use a multilingual NLI model fine-tuned on XNLI rather than an English-only faithfulness scorer, we are able to check the attribution metric's internal and external consistency separately in each evaluated language, rather than only in English. The derived binary attribution label is internally consistent with the underlying continuous entailment probability in every language (point-biserial $r = 0.86$–0.94, all $p < 10^{-23}$; Arabic $r = 0.896$, English $r = 0.941$, Russian $r = 0.907$, Swahili $r = 0.875$, Chinese $r = 0.859$), as expected since both are derived from the same model output; we treat this as a sanity check rather than independent validation. The more informative cross-lingual check is the model's relationship to a fully independent signal, token-level F1, which does not draw on the NLI model at all. Its relationship to lexical overlap is weaker and more variable, and breaks down specifically for Chinese: Spearman correlation between entailment score and token F1 is significant for Arabic, English, Russian, and Swahili ($\rho = 0.28$–0.37, $p < 0.012$) but not for Chinese ($\rho = 0.170$, $p = 0.136$). We read this as a real but narrow caveat rather than evidence against the metric generally: a multilingual NLI model can be internally consistent within a language while still disagreeing with a lexical-overlap metric for reasons specific to that language's tokenization or script (Section 4.5), and this is a difference we can only observe here because the underlying model was designed for multilingual use in the first place.

Finally, the attribution metric's elevation for Qwen, the model used to generate the benchmark's own QA pairs, is a caution about self-referential benchmark construction rather than a finding about Qwen's capability. We isolate it statistically here, so it cannot be mistaken for a genuine three-way model comparison; future extensions of CrossCTI should generate QA pairs with a model held out from the evaluated set entirely.

6 Limitations
