(Rei et al., 2020), and remove low-confidence translations before training.

**Translation-specific instruction data.** Translation-specific instruction data is the core of our instruction-following adaptation. Each example augments a source–target pair with natural-language constraints specifying the requirements to be satisfied. Table 1 summarizes the training taxonomy.

Instruction-bearing examples constitute a minority of the SFT mixture, whose main component remains parallel translation data. The taxonomy covers the four WMT26 instruction types: formal or informal voice, glossary constraints, structured translation, and style and expression requirements. These four types provide the core translation-instruction supervision; the domain-specific and general-instruction categories in Table 1 serve as auxiliary data that broaden domain coverage and retain general instruction-following ability.

Because manual construction is costly, most translation-specific instruction examples are produced through an LLM-assisted pipeline. We sample high-quality parallel pairs, use Qwen3.7-Max to generate diverse constraints and adapt the corresponding examples, and use the same model in a separate judging pass to filter non-compliant samples. Diversity is controlled across instruction templates, domains, and style intensity.

#### 2.2.2 Adaptation Parameterization

Both CPT and SFT update all model parameters rather than using parameter-efficient adapters. For the SFT phase, we use a learning rate of $2 \times 10^{-5}$, a global batch size of 1,152 sequences, and the AdamW optimizer ($\beta_1 = 0.9$, $\beta_2 = 0.999$). The resulting CPT+SFT model is used by the subsequent RL and OPD stages.

### 2.3 Preference Alignment with Online M$^2$PO

M$^2$PO (Multi-Perspective Multi-Pair Preference Optimization) (Wang et al., 2026) was originally formulated as an *offline* preference-optimization method over a fixed set of ranked candidates. We extend it to an online setting: at each update, the current policy generates fresh candidates, an LLM judge ranks them, and the resulting preferences are immediately used to update the policy. This retains M$^2$PO's emphasis on translation fidelity and its multi-pair supervision, while avoiding reliance on a static preference dataset.

#### 2.3.1 Online M$^2$PO

For an input $x$, the current policy $\pi_\theta$ samples $K = 8$ candidates $\{y_1, \ldots, y_8\}$. Each candidate receives a direct-assessment (DA) score from an LLM judge and is ranked by this score. Let $y_{(1)}, \ldots, y_{(K)}$ denote the candidates in descending score order. M$^2$PO constructs $K/2$ non-overlapping preference pairs by coupling the two ends of the ranked list, with $\mathcal{P}(x) = \{(i, K - i + 1) : 1 \le i \le K/2\}$. Thus, $K = 8$ yields four preference pairs. The M$^2$PO loss is

$$\mathcal{L}_{\text{M}^2\text{PO}} = -\mathbb{E}_x \sum_{(i,j)\in\mathcal{P}(x)} w_{ij} \log \sigma\big(\beta\delta_{ij} - m_{ij}\big), \tag{1}$$

where $\delta_{ij} = \Delta_{ij} \log \pi_\theta - \Delta_{ij} \log \pi_{\text{ref}}$, with $\Delta_{ij} \log \pi = \log \pi(y_{(i)} \mid x) - \log \pi(y_{(j)} \mid x)$. Here, $m_{ij}$ is a margin proportional to the reward difference, $w_{ij}$ is a pair weighting coefficient, and $\pi_{\text{ref}}$ is the frozen CPT+SFT model. Because candidates are drawn from the current policy at every step, the preference data evolves with the model rather than being fixed in advance.

**LLM-judge reward.** We use DeepSeek-V4-Pro[2] as a direct-assessment judge (Zheng et al., 2023; Kocmi and Federmann, 2023). For each candidate, the judge returns a single integer between 0 and 100 that assesses meaning preservation and grammatical quality. When a reference translation is available, it is included as auxiliary evidence; otherwise, the candidate is assessed against the source alone. We normalize the score as

$$r(x, y) = \frac{\text{DA}(x, y)}{100} \in [0, 1], \tag{2}$$

where $\text{DA}(x, y)$ denotes the judge score. The continuous reward preserves the ordering among intermediate-quality candidates and sets the pair margins in Eq. 1.

#### 2.3.2 Training Configuration

We optimize the CPT+SFT model with LoRA adapters (Hu et al., 2022) (rank 128, $\alpha = 256$) and merge the final adapter back into the full model after training. We use a learning rate of $5 \times 10^{-5}$ and the AdamW optimizer ($\beta_1 = 0.9$, $\beta_2 = 0.999$). Each optimization step processes 8 prompt groups (64 sequences in total); each group consists of one prompt and its $K = 8$ candidates, sampled at temperature 1.0 using vLLM (Kwon et al., 2023) for

[2] https://huggingface.co/deepseek-ai/DeepSeek-V4-Pro

| Category | Definition |
|---|---|
| Literary (novel) | Preserve narrative voice, dialogue, and cultural nuance. |
| Game | Translate game dialogue and UI text under output constraints. |
| Medical | Preserve medical terminology, drug names, codes, and entities. |
| General-domain instruction MT | Follow content and formatting requirements in general-domain MT. |
| Structured output | Preserve tags, identifiers, and parseable output structure. |
| Style | Produce the translation in a specified tone or register. |
| General instruction | Retain broad multilingual instruction-following ability. |

Table 1: Instruction-bearing data used in SFT.

efficient high-throughput generation. The preference temperature in Eq. 1 is set to $\beta = 0.1$.

### 2.4 On-Policy Distillation for Translation Instruction Following

After CPT, SFT, and online M$^2$PO, our Qwen3-14B reaches strong translation quality, but residual errors remain in following fine-grained constraints on style, terminology, and output format. This gap is expected because the DA reward used in the online M$^2$PO stage assesses translation quality rather than instruction compliance. We therefore adapt on-policy distillation (OPD) to translation-instruction data. The frozen teacher $\pi_T$ is the off-the-shelf open-source Qwen3-32B-Instruct model[3]; the student $\pi_\theta$ is our Qwen3-14B model after CPT, SFT, and online M$^2$PO. We keep the teacher frozen and use it only as a source of instruction-following supervision. Thus, OPD can transfer behavior from the larger model while preserving the translation-specialized 14B student as the final inference model.

#### 2.4.1 Distillation Objective

OPD differs from conventional sequence-level distillation over a fixed teacher-generated dataset (Hinton et al., 2015). For each translation-instruction input $x$, the current student first samples a translation $y \sim \pi_\theta(\cdot \mid x)$. The teacher then evaluates the same trajectory and supplies token-level distributions at each position. Let $p_t$ and $q_t$ denote the student and teacher next-token distributions conditioned on $(x, y_{<t})$, respectively. We minimize the reverse KL along the student trajectory:

$$\mathcal{L}_{\text{OPD}} = \mathbb{E}_x \, \mathbb{E}_{y \sim \pi_\theta(\cdot|x)} \left[ \frac{1}{|y|} \sum_{t=1}^{|y|} \mathrm{KL}\big(p_t \,\|\, q_t\big) \right], \tag{3}$$

Because training trajectories are generated by the current student, the teacher supervises the distribution where the student actually makes errors, rather than only a fixed set of teacher outputs. We use reverse KL, which encourages the student to place probability mass on the teacher's preferred continuations. The two models share the Qwen3 tokenizer and vocabulary, so the token-level KL is computed directly without vocabulary alignment.

#### 2.4.2 Training Configuration

We fine-tune the full student model with this reverse-KL objective, following on-policy distillation (Gu et al., 2024). We use AdamW ($\beta_1 = 0.9$, $\beta_2 = 0.999$), a learning rate of $1 \times 10^{-5}$, and a global batch size of 256. The learning rate is lower than that used for SFT because OPD refines the student's output distribution rather than teaching translation from scratch. Student trajectories are sampled at temperature 1.0, and both teacher and student use a distillation temperature of 1.0. For each trajectory, the frozen teacher supplies its token-level distribution in a single forward pass.

### 2.5 Structure-Aware Inference and Postcheck

Stage 4 is applied after the distilled 14B model produces a translation. It has two goals: preserve non-linguistic structure required by the input and prevent clear decoding failures from entering the final submission. We decode with greedy search using vLLM, then apply structure-aware processing and a conservative postcheck. This stage is deliberately limited to objective failures; it is not intended as a general-purpose post-editor.

| **Ours (14B)** | 4.49 | 83.4 | 4.71 | 92.0 | 4.60 | 87.7 |

Table 2: Main results on the WMT26 test set (23 official directions). For each aspect we report the mean 1–5 rubric score (Avg) and the pass rate (Pass%, percentage of outputs scoring $\geq 4$), both judged by DeepSeek-V4-Pro (Section 3.1); Overall Avg and Pass% are the unweighted averages of the corresponding values across the two aspects. Baseline rows are ordered by Overall Avg; our system is listed separately in the last row.

**Structure-aware decoding.** We first identify whether an input is plain text, HTML, or JSON. For HTML, we translate text nodes and designated translatable attributes; for JSON, we translate string leaves. The translated fragments are then reassembled into the original object, preserving markup, keys, and protected content such as URLs, e-mail addresses, and numbers. Long plaintext inputs are split at sentence-aware boundaries, translated chunk by chunk, and concatenated.

**Postcheck and repair.** Each output is checked for abnormal source–target length ratios, structural mismatches (HTML tag signatures or JSON shape), repeated character or $n$-gram loops, insufficient target-script coverage, and unintended copying of the source. A failed check does not automatically imply a translation error; it identifies a small set of hypotheses for review. When a flagged defect is mechanical and has an unambiguous fix, such as a missing code-fence marker, we apply a deterministic repair. The remaining flagged outputs are regenerated with Qwen3.5-4B-Instruct[4] under the original input and structural constraints, whereas outputs that pass all checks are retained unchanged. This routing keeps repair focused on degenerate or structurally invalid outputs and avoids unnecessary changes to otherwise adequate translations.

Overall is the micro-average over all official test items.

## 3 Experiments

### 3.1 Experimental Setup and Evaluation

**Systems and Test Sets.** Our submission combines the distilled Qwen3-14B-Base[5] (CPT+SFT+RL+OPD) with the structure-aware inference and postcheck stage described in Section 2. We evaluate on the official WMT26 General MT test sets across the 23 participated directions.

We compare against GPT-5.5, Qwen3.7-Max (thinking mode), Gemini-3.1-Pro, and Qwen3.7-Max (non-thinking mode), all evaluated under the same protocol. We also report internal ablations (Section 3.4).

[4] https://huggingface.co/Qwen/Qwen3.5-4B

[5] https://huggingface.co/Qwen/Qwen3-14B-Base

| Configuration | Instr. following | | Quality | |
|---|---|---|---|---|
| | Avg | Pass% | Avg | Pass% |
| Base (14B) | 1.14 | 0.6 | 1.09 | 1.0 |
| + CPT+SFT | 4.08 | 69.5 | 4.23 | 74.8 |
| + Online M$^2$PO | 4.13 | 76.8 | 4.55 | 89.4 |
| + OPD | 4.38 | 82.1 | 4.67 | 91.3 |
| + Postcheck | **4.49** | **83.4** | **4.71** | **92.0** |

Table 4: Cumulative ablation on the WMT26 test set. For each aspect we report the mean 1–5 rubric score (Avg) and the pass rate (Pass%, percentage of outputs scoring $\geq 4$), both judged by DeepSeek-V4-Pro (Section 3.1).

**Evaluation Protocol.** Because official WMT26 human-evaluation results were not available at submission time, we use an automatic *LLM-as-judge* protocol. Each output is scored independently on an absolute 1–5 rubric along two aspects: instruction following and translation quality. We report the mean score and the pass rate, defined as the proportion of outputs with a score of at least 4.

For instruction following, the judge receives only the task instruction and system output, and evaluates target language, output-only compliance, glossary use, register, and required structure such as JSON, HTML, tags, or placeholders. For translation quality, it evaluates semantic accuracy and completeness, terminology, and fluency. A reference translation, when available, is supplied only as auxiliary evidence; the judge is instructed to assess the output against the source rather than penalize legitimate differences from the reference.

Both aspects use DeepSeek-V4-Pro at temperature 0. For each item, the judge returns a brief justification and a score in the fixed form `[[score=X]]`, where $X \in \{1, \ldots, 5\}$. The instruction-following evaluation set covers all 23 directions and the four official WMT26 instruction categories: formal/informal voice, glossaries, structured translation, and style and expressions.

### 3.2 Main Results

Table 2 reports every system's instruction-following and translation-quality scores under the absolute 1–5 rubric of Section 3.1. Among the four reference LLMs, Qwen3.7-Max (thinking) and GPT-5.5 lead with essentially tied overall means (4.63 and 4.63), followed by Gemini-3.1-Pro (4.59); Qwen3.7-Max in non-thinking mode trails clearly (4.40). Quality scores are uniformly high (4.48–4.77), so the systems separate mainly on the harder instruction-following aspect. Our distilled 14B system attains an overall Avg of 4.60 and Overall Pass of 87.7%. Despite its 14B translation backbone, it is comparable to the leading proprietary systems on translation-instruction following (Avg 4.49, Pass 83.4%, versus 4.49/83.4% for GPT-5.5 and 4.50/83.8% for Qwen3.7-Max-Think), while its translation quality (4.71, Pass 92.0%) surpasses Gemini-3.1-Pro.

### 3.3 Per-Direction Results

Table 3 breaks down our submitted system's scores across the 23 official directions. Instruction following is near-ceiling on the large majority of directions (mean $\geq 4.9$ with pass rates above 97%), indicating that the instruction-specialized pipeline transfers robustly across languages and scripts. The clear exceptions are en→et (3.77), en→ru (3.97), en→cs (3.99), and to a lesser extent en→de (4.29). These directions also correspond to the largest test sets, with more than one thousand items each, and therefore contribute substantially to the aggregate instruction-following score. Translation quality is uniformly high (mostly $\geq$ 4.6) and dips only on the lowest-resource new directions—en→se (4.12), en→lld (4.24), zh→ja (4.40), cs→vi (4.43), and en→lij (4.44). The two weak spots are largely disjoint: directions with lower instruction-following scores are generally not those with the lowest translation-quality scores. This separation suggests that the two evaluation aspects capture different failure modes.

### 3.4 Ablation Study

We conduct a cumulative ablation to quantify the incremental effects of the training stages and final postcheck (Table 4). Both translation-instruction following and translation quality improve monotonically across the cumulative configurations, although the largest gain of each stage occurs on a different dimension.

**CPT+SFT establishes the task capability.** The unadapted Qwen3-14B model performs poorly under the translation-instruction prompts (instruction following: 1.14 Avg and 0.6% Pass; translation quality: 1.09 Avg and 1.0% Pass). Adding CPT+SFT raises instruction following to 4.08 Avg and 69.5% Pass, and translation quality to 4.23 Avg and 74.8% Pass. Relative to the base model, this amounts to gains of 2.94 and 3.14 rubric points, respectively. This low starting point

is expected: the base is a pre-trained Qwen3-14B model without task-specific translation adaptation or translation-instruction supervision. The result shows that WMT-aligned continued pre-training and instruction-bearing SFT data are necessary to turn this general backbone into a usable instruction-specialized translation system.

**Online M$^2$PO primarily improves translation quality.** On top of CPT+SFT, online preference optimization raises translation quality from $4.23$ to $4.55$ Avg and from $74.8\%$ to $89.4\%$ Pass. The corresponding instruction-following change is more modest ($4.08 \rightarrow 4.13$ Avg; $69.5\% \rightarrow 76.8\%$ Pass). This asymmetric effect aligns with the direct-assessment reward, which ranks candidates by translation quality and provides the most direct supervision for adequacy, completeness, and fluency. The online extension also continually refreshes the candidate set from the current policy, allowing the M$^2$PO objective to target errors that remain after CPT+SFT.

**OPD closes the remaining instruction-following gap.** Starting from the CPT+SFT+online M$^2$PO model, OPD increases instruction following from $4.13$ to $4.38$ Avg and from $76.8\%$ to $82.1\%$ Pass, while translation quality continues to improve from $4.55$ to $4.67$ Avg and from $89.4\%$ to $91.3\%$ Pass. Thus, the teacher's instruction-following behavior transfers without sacrificing the quality improvements obtained in the preceding stage. The larger teacher is used only during training; translation at inference is performed by the 14B student.

**Postcheck recovers a small set of severe failures.** The postcheck is applied after all training stages. It further increases instruction following from $4.38$ to $4.49$ Avg and from $82.1\%$ to $83.4\%$ Pass, while translation quality rises from $4.67$ to $4.71$ Avg and from $91.3\%$ to $92.0\%$ Pass. On `en-zh_CN`, it altered $31$ of $945$ hypotheses ($3.3\%$): $7$ received deterministic fence restoration, and $24$ were selectively rewritten across two review rounds. These outputs were identified by objective structural or decoding signals, such as malformed structure, missing lines, or degenerate generation. Thus, the postcheck obtains its gains by recovering a small number of high-impact failures rather than by broadly rewriting otherwise adequate translations.

### 3.5 Analysis

The results reveal a clear division of labor across the training stages. CPT+SFT establishes the basic ability to translate under explicit instructions, online M$^2$PO supplies the largest subsequent improvement in translation quality, and OPD contributes the largest later-stage gain in instruction following. The complementary pattern is important: optimizing only direct-assessment translation quality is insufficient to reach the final instruction-following level, whereas distillation improves instruction adherence without reversing the quality gains obtained by online preference optimization. The final postcheck contributes a further inference-time improvement by recovering the small tail of structurally invalid or degenerate outputs that remain after decoding.

The per-direction results further show that instruction following and translation quality do not fail on exactly the same directions. This supports evaluating them separately rather than collapsing them into a single automatic score. At the system level, Lumen's instruction-following score is close to GPT-5.5 and Qwen3.7-Max-Think, while its translation quality remains within the range of the compared general-purpose systems. Taken together, these results support the design of a translation- specialized 14B system that combines quality-oriented preference optimization with a dedicated mechanism for instruction following.

## 4 Conclusion

We presented Lumen, our submission to the WMT2026 General Machine Translation Shared Task. Targeting instruction-specialized translation, we introduced a four-stage pipeline: instruction-specialized CPT+SFT, where continued pre-training on a corpus following the WMT domains and language directions (plus general instruction data) is followed by supervised fine-tuning that jointly builds translation and instruction-following ability; online preference optimization with M$^2$PO and a direct-assessment LLM-judge reward; on-policy distillation that transfers the instruction-following ability of an off-the-shelf Qwen3-32B-Instruct teacher into our efficient 14B student; and structure-aware inference with targeted postchecking and repair for clear structural or decoding failures. Under an absolute $1$–$5$ LLM-judge rubric that scores instruction following and translation quality separately, our 14B system reaches an over-

all mean of 4.60. Despite using a 14B translation backbone, Lumen achieves performance comparable to leading proprietary systems in both translation quality and translation-instruction following, showing that the proposed pipeline can narrow the gap to substantially larger closed systems.

## Abstract

This paper presents UvA-MT's submission to the WMT 2026 General Machine Translation shared task, competing in the unconstrained track across all 23 translation directions. This year, we fully leverage the test-time methods of Large Language Models (LLMs) for machine translation. Specifically, (1) we use sequential sampling with a refinement prompt to generate a pool of translation candidates for each source sentence, a strategy shown to outperform traditional parallel sampling (Wu et al., 2026); and (2) we employ LLMs as pairwise judges to select the best candidates via a round-robin voting mechanism, with offline evaluation on the WMT25 benchmark showing a **very clear** improvement over point-wise best-of-$N$ selection. Lastly, we simply apply these two strategies for the submission of WMT26.

## 1 Introduction

In this paper, we describe our submission to the WMT 2026 General Machine Translation shared task (unconstrained track), which covers 23 translation directions. Motivated by recent advances in Large Language Models (LLMs), particularly test-time scaling techniques (Tan et al., 2025; Wu et al., 2025a, 2026), we investigate to what extent translation quality can be improved by relying solely on general-purpose LLMs at inference time.

Figure 1 illustrates an overview of our approach. Our submission uses two test-time technologies:

- **Sequential Sampling:** Given a source input to an LLM, a pool of translations is sequentially sampled, with each subsequent translation instructed to improve upon its predecessor. This recursive sampling strategy exploits the LLM's self-improvement capability and has been shown by Wu et al. (2026) to be more effective than traditional parallel sampling, especially under limited inference budgets.
- **Contrastive Round-Robin Voting:** Given a pool of translation candidates, every pair is compared head-to-head by an LLM judge that explicitly contrasts their differences (rather than scoring each independently). Wins are tallied across all pairwise match-ups, and the candidate with the most victories is selected as the final output. We argue that this strategy is more reliable than traditional best-of-$N$ sampling because pairwise judgments require only relative preferences rather than absolute quality scores, reducing the need for calibration and enabling finer-grained discrimination among candidates (Ouyang et al., 2022).

Section 2 describes our main methodology, which consists of two components: 1) sequential sampling, i.e., how to generate a pool of translation candidates for each source sentence; and 2) contrastive round-robin voting with a pairwise LLM judge, i.e., how to select the best candidate from the resulting pool.

In Section 3.1, we conduct offline evaluations on the WMT24 benchmark (Kocmi et al., 2024a; Deutsch et al., 2025), following Wu et al. (2026), showing that **sequential sampling** yields substantial translation improvements over parallel sampling, especially under limited sampling budgets.

In Section 3.2, we show that **contrastive round-robin voting** mechanism, powered by an LLM-based pairwise (contrastive) judge, consistently outperforms the traditional best-of-$N$ sampling paradigm with a pointwise judge (metric model, e.g., CometKiwi). This is reflected in both improved Best@$N$ performance and stronger rank correlation, as measured by Kendall's $\tau$ and Spearman's $\rho$, on the WMT25 metrics benchmark (Lavie et al., 2025).

Lastly, we apply these two strategies for the submission of WMT26, see details in Section 4.

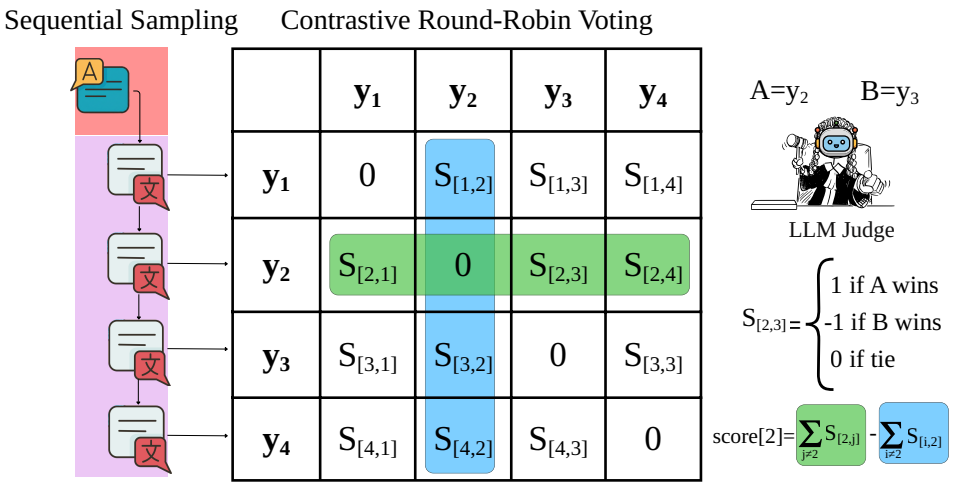

**Figure 1:** An overview of our pipeline: (left) sequential sampling to generate a list of candidates, see Section 2.1 for details; (right) contrastive round-robin voting with a LLM-as-a-Judge to select the best sample. Note that, to eliminate positional bias in LLM-based pairwise judging, each pair of samples is evaluated twice with their order swapped. The final score is computed by combining the scores that a hypothesis achieves in both directions, see Section 2.2 for details.

## 2 Methodology

### 2.1 Generation of $N$ candidates

Our generation setting follows the previous and concurrent line of work, which we refer to as *sequential* sampling (Wu et al., 2025a, 2026). The key idea of this sampling strategy is to refine the previously generated hypotheses, instead of generating fully in parallel, which demonstrated higher sampling efficiency given smaller sampling budget. In particular, to obtain a set of candidates for reranking, we translate each document sequentially 8 times, including the initial translation and 7 refinement rounds. Formally, for a sampling turn $t$, *sequential* sampling generates a translation $y$ as follows:

$$y^{(t)} \sim p_\theta \left( \cdot \mid I^{(r)}, y^{(t-1)}, I(x) \right), \qquad (1)$$

where $I^{(r)}$ is a prompt requesting a model to revisit a translation to improve it (Wu et al., 2025a); and $I(x)$ includes a system prompt and the initial turn translation. To reduce the computational cost, here we use the history $-1$ formulation of the sequential sampling, shown to be most efficient and effective in Wu et al. (2026), feeding only the most recent previous translation to the model, thus capping the context size growth.

We use the following prompt template for the candidate generation step:

```
[system]
You are a professional translator. Follow the
instruction and output only the translation,
with no explanations.

Task-specific instruction:
{instruction}
```

```
[user turn initial]
Please translate the following text from
{src_lang} to {tgt_lang}. Provide only one
translation on the first line and do not
output anything else after that.

{src_lang}: {source}
{tgt_lang}:

[assistant turn]
{assistant response}
```

```
[user turn revisiting]
Please again translate the following text from
{src_lang} to {tgt_lang} to make it better.
Provide only one translation on the first line
and do not output anything else after that.

{src_lang}: {source}
{tgt_lang}:

[assistant turn]
{assistant response}
```

### 2.2 Contrastive Judge

We use the following prompt template for the pairwise judges:

```
[system]
You are an expert, impartial bilingual
translation evaluator. You compare two
candidate translations of the same source and
decide which is better. Judge strictly on
quality; ignore which candidate is labelled A
or B and ignore their order or length.
```

```
[user]
Compare two candidate translations and decide
which is better.

Source language: {src_lang}
Target language: {tgt_lang}

Judge against this rubric (earlier criteria
matter more):
Pick the translation that is more accurate and
more natural in the target language.

{instruction_block}=== SOURCE ===
{source}

=== TRANSLATION A ===
{trans_a}

=== TRANSLATION B ===
{trans_b}

Return only a single JSON object on the last
line and nothing after it:
{"winner": "A" | "B" | "tie"}

[assistant]
{assistant response}
```

The '`{instruction_block}`' here is populated when the record carries a non-trivial instruction. Then it resolves to '`The translations were produced under this task-specific instruction; also judge how faithfully each candidate follows it:\n{instruction}`'. Trivial "`Translate from X to Y.`" instructions are dropped, as we incorporate the source and target language information directly into the user prompt. We use the constrained generation for json, implemented on the server side, whereas we provide the json schema.

We use temperature 0 for the judge, and we choose the lowest possible reasoning effort for each model.

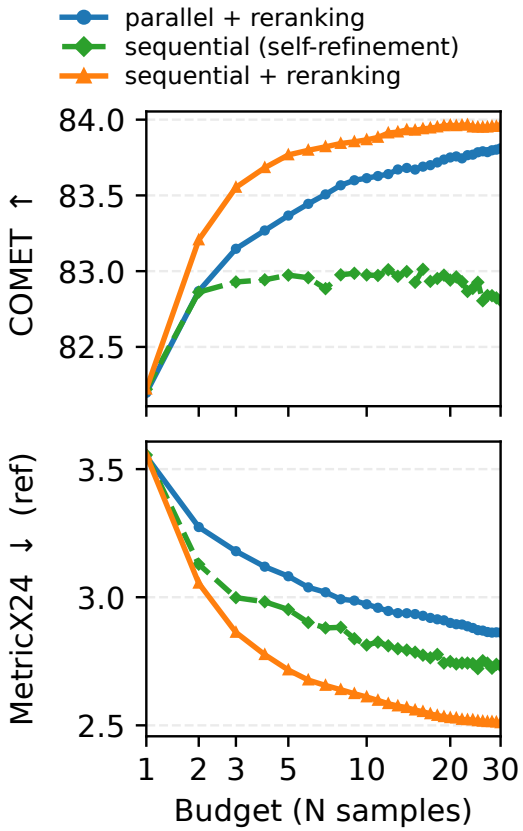

**Figure 2:** Sequential + reranking demonstrates superior quality@budget trade-off, compared to the parallel sampling + reranking, and sequential sampling (self-refinement), following Wu et al. (2026). Here we report the quality of the methods on WMT24++ with metrics aggregated over the 6 languages.

### 2.3 Contrastive Round-Robin Voting

The idea of a contrastive round-robin voting manifests itself as early as in the works of Llull (c. 1274-83),[1] where they propose to evaluate the candidates during election via full round-robin contrastive voting, such that a candidate who is victorious in most of the pairwise comparisons is named the winner (also known as Copeland's method).

In our formulation, the contrastive round-robin voting with LLMs-as-a-judge consists of the pairwise judge scoring and the score aggregation. By solely relying on contrastive LLMs-as-a-judge prompt templates to obtain pairwise votes, we use the following counting aggregation strategy for our robust evaluation. Formally, given a pool of $N$ candidates, we define a $N \times N$ score matrix $S$, where $S[i, j] \in \{1, -1, 0\}$ denotes a voting result for a candidate $i$ agains a candidate $j$, where the verdict

[1] assembled and translated by Hägele and Pukelsheim (2001)

1 stands for a win, $-1$ for a lose, and 0 for a tie. Then a ranking score of each candidate is a sum of its points: $\text{score}[i] = \sum_j S[i, j]$. LLM judges are known to have strong position biases (Wang et al., 2024), i.e., they can be inconsistent when changing a candidate order. To mitigate the position bias, we evaluate both $i$ vs $j$ and $j$ vs $i$ directions (the order of these is swapped in the judge prompt template). The de-biased score we use is as following:

$$\text{score}[i] = \sum_{j=1}^{N} S[i, j] - \sum_{i=1}^{N} S[j, i]. \quad (2)$$

## 3 Offline Evaluation

### 3.1 On the Effectiveness of Sequential Sampling

We choose sequential sampling as the main generation strategy to form a pool of samples for subsequent reranking. Here, we briefly report an abridged version of the results from Wu et al. (2026) in Figure 2, demonstrating the comparison of parallel and sequential strategy for the `GPT-4o-mini`[2] model.

Here, we compare **parallel + reranking**, **sequential (self-refinement)** and **sequential + reranking**. These results report the average machine translation quality on WMT24++, aggregated over 6 target language directions: Dutch, German, Mandarin, Standard Arabic, Russian, Romanian; measured using a reference-based COMET (Rei et al., 2022), and reference-based MetricX-24-Hybrid-XXL (ref) (Juraska et al., 2024). Here, CometKiwi-XL (Rei et al., 2023) is used as a metric for reranking, following Wu et al. (2026). The results (Figure 2) show that the combination of **sequential sampling with reranking** outperforms both the parallel sampling with reranking and simple self-refinement, motivating our choice for the sampling method.

In the next section (§3.2), we revisit the reranking step, the main focus of this submission.

### 3.2 On the Effectiveness of Contrastive Round-Robin Voting

Given a pool of hypotheses for each source text, we use Round-Robin Voting with commercial LLMs to select the winning hypothesis for the final submission. To show the effectiveness, we compare our strategy with traditional Best-of-$N$ sampling, known as Quality-aware decoding in MT (Fernandes et al., 2022), which uses machine translation quality estimation models for point-wise ranking, e.g., MetricX-QE or Comet-Kiwi.

We use the WMT25 General MT Human Evaluation dataset[3] as the benchmark. We evaluate two translation directions, EN→ZH and EN→RU, which contain 198 and 200 paragraph-level source texts, respectively. Each source text is accompanied by translations produced by at most 18 MT systems, including last year's leading systems i.e. GPT-4.1, Claude-4, UvA-MT, and Qwen3-235B (Achiam et al., 2023; Wu et al., 2025b; Yang et al., 2025; Kocmi et al., 2025).

For each source text in the dataset, we randomly sample 8 translations. We retain the corresponding human evaluation Error Span Annotation Kocmi et al. (2024b, ESA) scores for each translation (an ordinal score from 0 to 100). For translations annotated by multiple experts, we average the individual scores to obtain the final human evaluation score.

We evaluate pairwise judgments using contrastive Round-Robin Voting across different LLMs and compare them with traditional machine translation (MT) evaluation metrics by measuring their Kendall rank correlation ($\tau_a$) with human judgments. The resulting rankings are presented in Table 1 and Table 2. Note that Kendall rank correlation is comparable across all of these systems. Additionally, we report Spearman's rank correlation coefficient ($\rho$), Best@1, Best@2, rate of a tie, and disagreement rate.

We find that:

- Traditional MT metrics **completely fail** to rank last year's translation hypotheses. Even the best-performing metric, COMET-Kiwi-23-XXL, achieves Kendall's $\tau_a$ scores of only 5.2 and 8.6 in EN-ZH and EN-RU. Its Best@1 and Best@2 accuracies are approximately 12.5% and 25%, respectively, suggesting performance that is close to random guessing on this ranking task.

- Our pairwise LLM-as-a-Judge framework with Round-Robin Voting **substantially outperforms** all point-wise translation metrics, achieving consistent and very clear improvements in Kendall's $\tau_a$ and Spearman's $\rho$, as well as Best@1 and Best@2 accuracy.

| 8 | judge | Gemini-2.5-Flash (direct) | 15.7 | 35.9 | 32.5 | 48.0 | 54.3 | 48.3 |
| 9 | metric | COMET-Kiwi-23-XXL | 8.6 | 11.4 | 17.0 | 28.5 | 0.3 | 0.0 |
| 10 | metric | MetricX-24-Hyb-XXL | 6.4 | 8.1 | 17.5 | 28.5 | 0.7 | 0.0 |
| 11 | metric | MetricX-24-Hyb-XL | 6.3 | 7.5 | 13.0 | 22.5 | 0.3 | 0.0 |
| 12 | metric | COMET-Kiwi-23-XL | 4.9 | 6.1 | 16.0 | 28.5 | 0.3 | 0.0 |
| 13 | metric | COMET-Kiwi-22 | 2.2 | 2.7 | 11.0 | 23.0 | 0.3 | 0.0 |
| 14 | metric | MetricX-23-QE-L | 0.2 | -0.3 | 16.5 | 25.5 | 0.3 | 0.0 |

**Table 2:** EN-RU results ($n = 200$ documents), reported as percentages. $\tau_a$ is the per-pair-verdict Kendall, which is the coefficient comparable across the judge–metric boundary and is used for system ranking. The best value among judge models is shown in bold. For Tie and Disagree, lower is better.

- Strong commercial LLMs, such as GPT-5.4 and Gemini-3.5-Flash, perform substantially better, exhibiting significantly lower tie rates. In contrast, weaker models, such as Gemini-2.5-Flash, produce a much higher tie rate, suggesting a limited ability to discriminate among high-quality translation candidates.

- Pairwise LLM judges exhibit position bias (Disagree): reversing the order of a translation pair can cause the preferred candidate to switch. However, strong LLMs, e.g., Gemini-3.5-Flash, performs much better than weaker models here, e.g., in Chinese, Gemini-3.5-Flash has a score of 12.6 while Gemini-2.5-Flash has a score of 51.4.

- Reasoning sometimes helps judging, but the gains are marginal compared with direct judging. For example, Gemini-3.5-Flash with reasoning only slightly outperforms its direct-judge counterpart (23.1 vs. 22.4 in $\tau_a$), while even achieving lower Spearman's $\rho$ and Best@1 accuracy.

Considering its strong performance and low cost, we selected `gemini-3.5-flash (direct)` as the judge model for our final submission.

## 4 Final Ensemble

For the final submission, we run the generation using `gemini-3.5-flash` and `GPT-5.4`, selecting a winning candidate from each family using `gemini-3.5-flash (direct)`.

**Ensembling 2 model families.** For two models (a, b), let us denote $S_{a,a}, S_{b,b}$ as score matrices for intra-model evaluation, and $S_{a,b}, S_{b,a}$ as inter-model evaluation. We do not fully compute $S_{a,b}, S_{b,a}$, but only compute the cross-model scores

only for the selected winners ($w_a$ and $w_b$):

$$\text{score}[w_a] = \sum_{j \neq w_a} S_{a,a}[w_a, j] - \sum_{j \neq w_a} S_{a,a}[j, w_a] + \sum_{j} S_{a,b}[w_a, j] - \sum_{j} S_{b,a}[j, w_a]. \quad (3)$$

$$\text{score}[w_b] = \sum_{j \neq w_b} S_{b,b}[w_b, j] - \sum_{j \neq w_b} S_{b,b}[j, w_b] + \sum_{j} S_{b,a}[w_b, j] - \sum_{j} S_{a,b}[j, w_b]. \quad (4)$$

We run $2N(N-1)$ judge calls within the groups and $4N$ cross-group judge calls for the winners (assuming all groups are of size $N$), in total we run $2N(N-1) + 4N - 2 = 142$ calls. A full $N = 16$ round robin tournament would require $2N(2N-1) = 240$ judge calls. Although other efficient tournament variants are possible, we use this strategy as a simple and easy to scale hierarchical approximation to the full round-robin tournament.

## 5 Conclusion

In sum, we implement a combination of sequential candidate sampling and contrastive round-robin voting for reranking. Our contrastive reranking strategy demonstrates much higher correlation with human judgements than more standard quality-aware decoding techniques.

## Abstract

We present Qingqiu-MT-9B, an instruction-following multilingual translation model developed for the constrained track of the WMT26 General Machine Translation shared task. Our model supports translation among 20 languages and covers 22 of the 23 official language pairs. It uses a source-grounded synthesis pipeline with separate LLM-based steps for generating instance-specific translation instructions and their corresponding translations. The resulting corpus covers diverse translation requirements, task complexity, instruction formulations, domains, document lengths, and glossary constraints, reducing reliance on fixed prompt templates and supporting generalization to unseen translation instructions. Our model is based on Qwen3.5-9B and trained through two-stage full-parameter supervised fine-tuning (SFT) followed by reinforcement learning (RL). The first SFT stage performs broad adaptation on a large-scale, medium-quality corpus, while the second refines the model on a smaller, higher-quality set. The RL stage further optimizes the model with Group Relative Policy Optimization (GRPO). During development, we use an LLM-based, rubric-guided contrastive method that scores candidates by dimension and aggregates an overall score to assess translation quality. Experiments show that Qingqiu-MT-9B demonstrates strong generalization and competitiveness among similarly sized models. We release the model at https://huggingface.co/WPS-Qingqiu/Qingqiu-MT-9B.

## 1 Introduction

The WMT26 General Machine Translation Shared Task[1] covers 23 official language pairs. Unlike conventional translation settings that provide only a source text and target language, each sample includes a natural-language translation instruction. A system must therefore not only convey the source meaning accurately but also follow the translation requirements specified for each instance. This setting requires both robust multilingual translation capabilities and the ability to generalize to open-ended natural-language translation instructions.

For data construction, we do not treat instruction-following translation as a small-scale auxiliary task; instead, we make it a central component of our large-scale synthetic data. Accordingly, we construct a training corpus that pairs diverse source texts and translation instructions with high-quality target translations, thereby improving the model's ability to generalize across translation scenarios and to unseen translation instructions. Each synthesized example follows a shared schema containing the source language, target language, source text, a natural-language translation instruction grounded in the source, and its corresponding translation.

To broaden coverage of both source texts and translation instructions, we increase data diversity in source sampling and translation-instruction synthesis. Source texts are sampled by language, domain, and length. We then set the training-data proportions for each target-language direction and convert a randomly selected subset to HTML for end-to-end HTML translation. For translation-instruction synthesis, we factorize natural-language instructions along task complexity and instruction formulation, drawing their content from a carefully designed pool of translation requirements. Dynamic composition of the synthesis prompt controls how these factors are combined and distributed across the corpus. For each source text, an LLM is then used to generate a source-grounded and actionable natural-language translation instruction; once the instruction is fixed, a corresponding translation is generated according to its requirements. Compared with fixed-template synthesis, this factorized construction expands the combinations of translation requirements and instruction formula-

tions, encouraging the model to learn translation behaviors that generalize across instruction formulations rather than surface patterns tied to specific prompt templates.

For model training, we build on Qwen3.5-9B (Qwen Team, 2026) with two-stage SFT followed by RL. The SFT stages are stratified by data quality. Stage 1 prioritizes scale and coverage, using large-scale, medium-quality multilingual data to establish foundational instruction-following translation capabilities. Stage 2 instead prioritizes quality. Data generated by a stronger teacher model are filtered to form a smaller, higher-quality training set, which is used to further improve translation quality. The RL stage then applies GRPO with contrastive LLM-based rewards (rubric-guided LLM-as-a-judge with language gates, plus GEMBA-ESA-style scoring) and rule-based length and format signals, using group-relative advantages over sampled outputs for the same prompt.

The main stages of our model development pipeline are:

- A source-grounded pipeline that combines multidimensional source sampling with factorized synthesis of translation instructions to create diversity across languages, domains, document lengths and formats, translation requirements, levels of task complexity and instruction formulations, and glossary constraints;
- A quality-tiered two-stage full-parameter SFT recipe that first learns from large-scale, medium-quality data and then refines the model on a smaller, higher-quality curated set;
- An RL stage using GRPO with contrastive LLM-based rewards (rubric-guided LLM-as-a-judge with language gates, plus GEMBA-ESA-style scoring) and rule-based length and format signals;
- An LLM-based, rubric-guided contrastive evaluation that scores candidates by dimension and aggregates an overall score to assess translation quality.

## 2 Related Work

**Adapting large language models for translation.** Work on LLM-based machine translation (MT) progresses from eliciting latent multilingual ability with prompts to translation-specific specialization. PaLM shows strong few-shot translation but still trails supervised MT systems (Vilar et al., 2023), while a 204-language study finds ChatGPT competitive mainly on higher-resource languages (Robinson et al., 2023). Translation-specialized open models then narrow this gap: ALMA combines monolingual continued pretraining with high-quality parallel refinement (Xu et al., 2024a), Tower adds multilingual instruction tuning (Alves et al., 2024), and ALMA-R introduces preference optimization (Xu et al., 2024b). WMT24 and WMT25 results place adapted LLMs among leading systems while showing that harder and lower-resource directions remain substantially challenging (Kocmi et al., 2024a, 2025). More recently, TranslateGemma specializes Gemma 3 through SFT on human and high-quality synthetic parallel data followed by RL with an ensemble of translation rewards, and reports consistent gains over its base models across broad multilingual evaluation (Finkelstein et al., 2026). The field thus shifts from scale alone toward data quality, multilingual coverage, and translation-specific post-training.

**Supervised fine-tuning for MT.** SFT is the standard first stage for adapting decoder-only LLMs to MT, with the source, language information, and translation requirements forming an instruction and the target translation providing token-level supervision. ParroT combines translation, contrastive, and error-guided instructions (Jiao et al., 2023), while multilingual translation-instruction tuning can transfer to unseen directions (Li et al., 2024). Recent work places greater emphasis on mixture design. LMT identifies directional degeneration when symmetric multiway data overemphasize many-to-one directions and mitigates it through strategic downsampling (Luo et al., 2025). MiLMMT-46 studies broad multilingual continued pretraining followed by a smaller, high-quality instruction-tuning set and finds strong many-to-many gains from moderate amounts of curated supervision (Shang et al., 2026). These results motivate attention to instruction diversity, direction balance, and target quality rather than raw bitext volume alone.

**Reinforcement learning for MT.** RL is used to reduce the mismatch between token-level maximum-likelihood training and sequence-level MT evaluation. Early approaches optimize metrics such as BLEU with REINFORCE or actor–

critic training (Ranzato et al., 2016; Bahdanau et al., 2017), while large-scale MT studies identify reward design and optimization stability as key concerns (Wu et al., 2018). More recently, GRPO becomes attractive for LLM-based MT because it derives relative advantages from multiple translations sampled for the same prompt without training a separate value model (Shao et al., 2024). Shy-hunyuan-MT applies GRPO after supervised distillation with a composite reward combining BLEU, XCOMET, and an LLM-based fluency score (Zheng et al., 2025). GRRM further argues that isolated scalar metrics may provide weak intra-group resolution and instead learns to score the full candidate group jointly (Yang et al., 2026). Conversely, WALAR shows that RL can amplify blind spots in source-based QE into omissions, over-translation, or wrong-language output (Liu et al., 2026). Reward design is therefore central to RL for MT and benefits from combining quality estimates with directly observable task constraints.

**Automatic translation evaluation and quality estimation.** Automatic MT assessment includes both reference-based metrics and reference-free quality estimation (QE). COMET learns from human judgments over the source, hypothesis, and reference (Rei et al., 2020), and CometKiwi extends this family to sentence- and word-level QE (Rei et al., 2022). MetricX-23 trains reference-based and QE regressors on human judgments and synthetic data (Juraska et al., 2023). MetricX-24 extends this family with a hybrid model and targeted synthetic failure cases (Juraska et al., 2024); MetricX-25 updates the family using Gemma 3 and introduces GemSpanEval for predicting error spans with categories and severities (Juraska et al., 2025). Prompted LLM judges form a complementary line. GEMBA scores translations with or without a reference (Kocmi and Federmann, 2023), while GEMBA-ESA follows the ESA protocol of combining error spans with holistic scoring (Kocmi et al., 2024b; Freitag et al., 2024). Candidate-aware evaluation is also emerging: COMET-poly contextualizes a hypothesis with alternative translations (Züfle et al., 2025), whereas Nvidia-Nemo jointly evaluates all candidates and finds relative evaluation effective when organized as a two-stage evaluate-then-refine procedure (Yan et al., 2025). WMT25 results nevertheless show that references still help at the segment level and that robustness across languages remains challenging (Lavie et al., 2025).

## 3 Task and System Overview

Figure 1 summarizes the system. Heterogeneous multilingual sources are first paired with source-grounded translation instructions, optionally including terminology constraints. A teacher then translates each source under its instruction. Failure-oriented filtering removes malformed, wrong-language, repetitive, or structurally inconsistent outputs. The resulting examples are converted to a two-message chat format. A large, broadly filtered corpus feeds Stage 1 SFT, while a smaller and more stringently curated high-quality set feeds Stage 2. The resulting policy is further optimized using the composite reward in Section 3.2.2.

### 3.1 Data Construction

Our data construction comprises three sequential stages: broad-coverage monolingual corpus collection, synthesis of diverse translation instructions, and high-quality translation synthesis. The three stages share one objective: at the instance level, each translation instruction should be grounded in its source and actionable, with its requirements realized by the target translation; at the corpus level, the resulting instruction-translation data should be large-scale, diverse, and high-quality.

#### 3.1.1 Broad-coverage monolingual corpus collection

We draw source texts from heterogeneous multilingual pools. Public sources include MADLAD-400 (Kudugunta et al., 2023), FineWeb2 (Penedo et al., 2025), Common Crawl Traditional Chinese (Li, 2024), and MNBVC (MOP-LIWU Community and MNBVC Team, 2023). We complement these resources with the domain-labelled IndustryCorpus2 collection (Shi et al., 2024) and our in-house datasets. The combined pool spans everyday content as well as literary, news, technical, and financial domains. We retain longer passages in addition to sentence-level examples so that the model learns to follow translation instructions in document-like contexts.

Sampling is organized by language, domain, and text length. After sampling, we set the training-data proportions for each target-language direction and randomly convert a subset of texts to HTML to support end-to-end HTML translation.

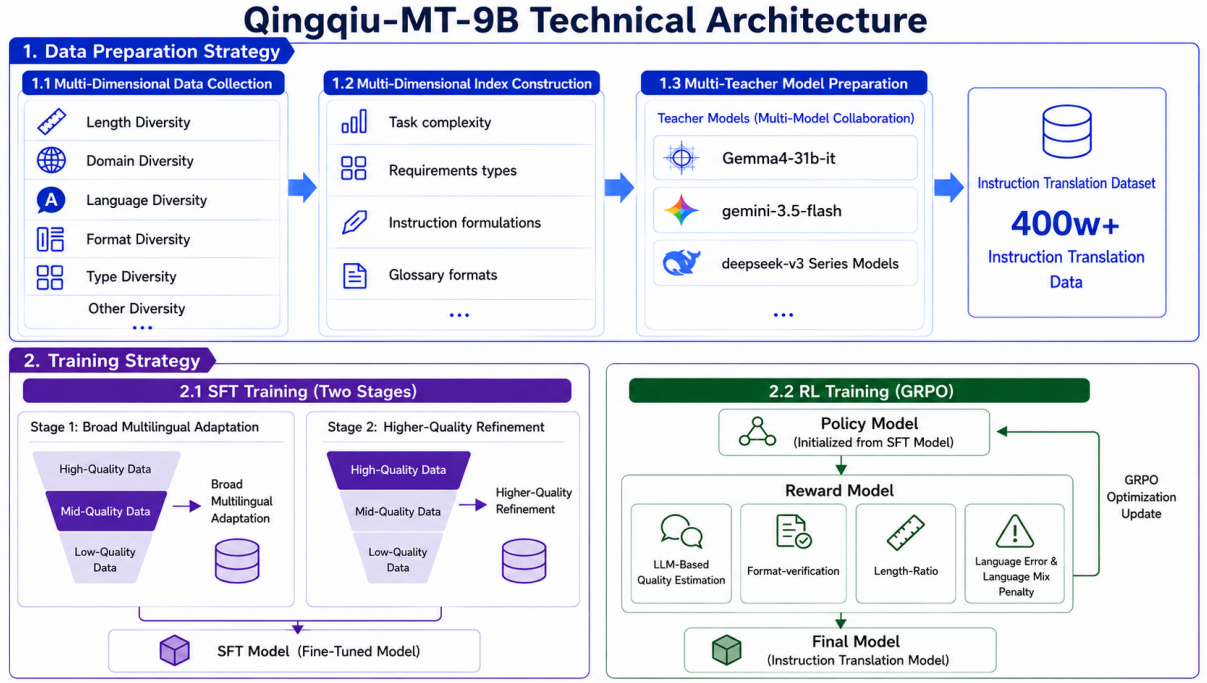

Figure 1: Overview of the Qingqiu-MT-9B architecture, including instruction-translation data construction, quality-tiered two-stage SFT, and GRPO-based training.

#### 3.1.2 Synthesis of diverse translation instructions

For each source text, we synthesize a source-grounded and actionable natural-language translation instruction using the text and available metadata. Throughout this paper, an instruction denotes a translation task specification that governs how the source text should be translated; it excludes non-translation transformations such as rewriting, polishing, and expansion. The synthesis prompt provides a carefully designed, open-ended reference space of additional translation requirements, summarized in Table 1.

We factorize natural-language translation instructions along task complexity and instruction formulation, and further control glossary presentation when terminology constraints are present. We dynamically compose the synthesis prompt from selected additional requirements, a sampled complexity setting, a surface-style specification, and associated control information, and then use an LLM to generate a natural, coherent instruction that instantiates this configuration. This mechanism controls the corpus-level distribution of requirement types, levels of task complexity, instruction formulations, and glossary formats, increasing the coverage and diversity of the resulting instruction corpus.

For terminology-oriented translation tasks, source-language terms and their prescribed target-language equivalents are incorporated into the translation instruction using one of the glossary formats in Table 1. Terminology requirements can coexist with other translation requirements in the same instruction.

#### 3.1.3 High-quality translation synthesis

Once the translation instruction is fixed, a teacher model takes the source language, target language, translation instruction, and source text as input and synthesizes the corresponding translation.

We filter synthetic outputs with missing fields, source copying, non-terminating repetition, wrong-language output or script mismatch, prompt leakage, or unsupported structural markup, followed by lightweight paragraph and format normalization.

We evaluated multiple combinations of synthesis prompt templates and teacher models, jointly considering synthesis quality, generation efficiency, and cost. Based on this comparison, we use Gemma4-31B and the DeepSeek-V3 series as teachers for Stage 1, and Gemini-3.5-Flash as the teacher for Stage 2.

Stage 1 contains approximately 4 million examples. Stage 2 uses approximately 500,000 examples selected under stricter criteria, emphasizing higher-quality translations and task-relevant translation instructions. The RL stage uses a separate curated set of approximately 50,000 examples paired with

| Design dimension | Specification in the synthesis prompt |
|---|---|
| **Additional translation requirements** | *Open-ended candidate pool.* register/formality; tone/emotion; translation strategy; domain adaptation; purpose/scenario; punctuation styling; implicitation/implicitness preservation; additional context/background; fidelity–naturalness trade-off; audience adaptation; verbosity preference; localization/cultural rendering; and glossary/terminology constraints. |
| **Task complexity** | *Mixture.* single additional requirement (60%); multiple compatible requirements (40%; 2–5 items). |
| **Instruction formulations** | *Predefined set.* direct_imperative; polite_request; scenario_based; audience_first; editor_brief; localization_memo; concise_checklist; translator_note; constraint_focused; and comparative. |
| **Glossary formats** | *Predefined set.* arrow (`s` → `t`); parenthetical (`s (t)`); translate_as (`Translate "s" as "t"`); use_for (`Use "t" for "s"`); dict_style (`{"s":"t"}`); list_of_pairs (`[("s","t")]`); pipe (`s \| t`); slash (`s / t`); and equals (`s = t`). |

Table 1: Prompt-controlled design space for translation-instruction synthesis. Additional translation requirements are drawn from an open-ended candidate pool; task complexity, instruction formulations, and glossary formats are controlled by a predefined mixture or style set.

translations.

### 3.2 Model Training

Our training procedure follows a three-stage curriculum comprising two quality-tiered SFT stages followed by RL. Stage 1 favors scale and coverage with a large, moderately filtered corpus, whereas Stage 2 favors supervision quality with a much smaller and more stringently curated set. This ordering first establishes broad translation competence and then refines it using a denser, cleaner training signal.

#### 3.2.1 Two-stage supervised fine-tuning

We initialize from Qwen3.5-9B (Qwen Team, 2026). Because the task is text-only, we update all language-model parameters while freezing the visual components. Both SFT stages use a chat template, with prompts composed in the same way as during final inference.

**Stage 1: broad multilingual adaptation.** The first stage uses the large corpus described in Section 3.1 to establish broad translation-direction coverage, robustness across domains and text lengths, and foundational instruction-following translation capabilities. In addition to the 22 translation directions specified by the WMT task, we augment the training data with reverse directions and other directions among the system's supported languages, and set the mixture proportions by target language. This design promotes more general linguistic knowledge and cross-lingual translation behavior. Careful mixture design also reduces interference among translation tasks and prevents data-rich directions from crowding out others during training. Figure 2 presents the resulting mixture from two complementary views: translation-direction groups and target-language coverage.

**Stage 2: higher-quality refinement.** The Stage 2 dataset is restricted to the translation directions specified by the WMT task and is selected using stricter quality criteria. Although smaller than Stage 1, it contains higher-quality teacher translations and emphasizes examples involving complex translation instructions, terminology constraints, and style-sensitive translation. Building on the broad adaptation acquired in Stage 1, this higher-quality supervision can further improve the model's translation quality and ability to follow instructions on the specified WMT translation directions.

#### 3.2.2 Reinforcement Learning with GRPO

After two-stage SFT, we apply a reinforcement-learning stage using GRPO (Shao et al., 2024) to further improve output quality and stability. Following GRPO, for each prompt $q$, the old policy $\pi_{\theta_{\text{old}}}$ samples a group of $G$ outputs, $\mathcal{Y}_q = \{y_i\}_{i=1}^{G}$ (in our practice, a rollout count of $G = 4$ provides the best trade-off between training efficiency and performance). Each sampled output receives a composite reward organized into LLM-based and rule-based families: the two families estimate translation quality from different perspectives and induce discriminative relative score gaps among the sampled outputs. These gaps are normalized within the group to form the group-relative advantages used by GRPO, without training a separate value model. The LLM-based family contains a rubric-

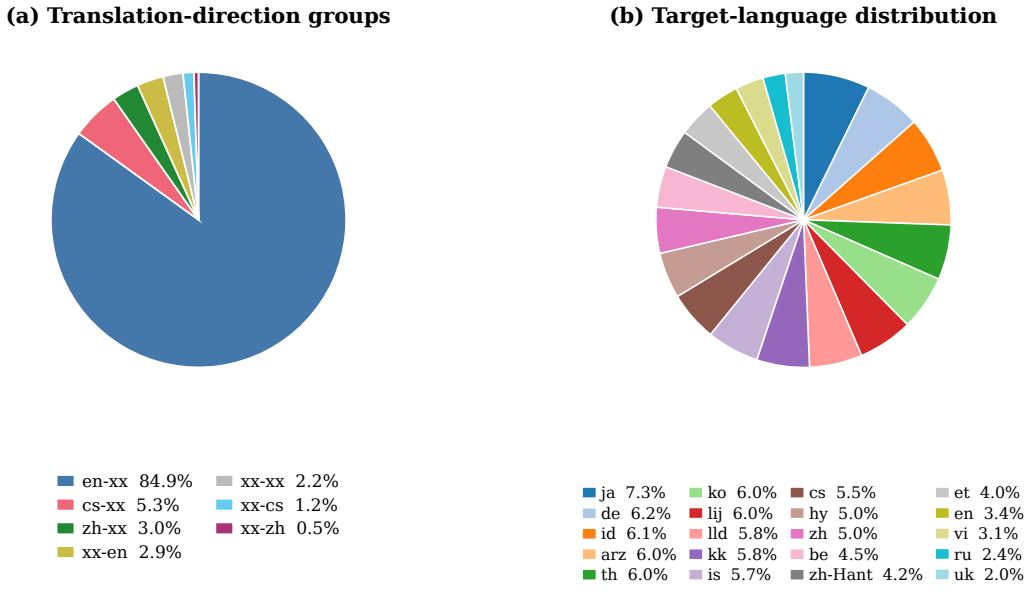

Figure 2: Distribution of training examples in the Stage 1 SFT corpus. (a) Mutually exclusive direction groups centered on English, Czech, and Chinese. Here, `xx` is a wildcard over supported languages; source-side `en`, `cs`, and `zh` groups take precedence, and the remaining examples are grouped by core target language. (b) Aggregation by target language across the 20 languages supported by the system. Percentages are computed from example counts.

guided LLM-as-a-judge score and an error-oriented GEMBA-ESA-style score; the rule-based family contains length-ratio and format-verification metrics. The LLM-as-a-judge score is further controlled by two gates for target-language correctness and language-mixing detection. We use a DAPO-style clipped objective (Yu et al., 2025) together with a small KL regularizer to constrain drift from the supervised policy.

The final scalar reward is expressed as the sum of the two reward families:

$$\begin{aligned} R(y) &= R_{\text{LLM}}(y) + R_{\text{rule}}(y), \\ R_{\text{LLM}}(y) &= 1.0 r_{\text{LLM}}(y) + 0.5 r_{\text{ESA}}(y), \\ R_{\text{rule}}(y) &= 0.5 r_{\text{len}}(y) + 0.5 r_{\text{fmt}}(y). \end{aligned} \tag{1}$$

All four component signals are normalized to $[0, 1]$.

**Contrastive LLM-based rewards.** The LLM-based family comprises two complementary contrastive rewards.

*Rubric-guided LLM-as-a-judge scoring with dual language gating.* We call GLM-5 (GLM-5 Team, 2026) to jointly evaluate all sampled outputs in $\mathcal{Y}_q$ in a single request. The sampled outputs are presented under anonymized labels without generation provenance, yielding a contrastive blind evaluation. Under a shared rubric, the judge compares translation accuracy, terminology, compliance with the translation instruction, fluency, style, and required structure, and assigns sampled output $y_i$ a score $s_i \in [0, 100]$. We normalize this score and apply two binary gates to obtain

$$r_{\text{LLM}}(y_i) = g_{\text{tgt}}(y_i)\, g_{\text{mix}}(y_i) \frac{s_i}{100}. \tag{2}$$

The target-language gate $g_{\text{tgt}}$ passes only when the output is consistent with the requested target language, while the mixing gate $g_{\text{mix}}$ passes only when no unexpected language or script mixing is detected. Failing either gate sets $r_{\text{LLM}}$ to zero.

This groupwise comparison directly matches GRPO's group-relative advantage estimation over sampled outputs for the same prompt. One groupwise request replaces $G$ independent scoring requests, reducing the number of translation-quality judge calls to $1/G$ of per-output evaluation. Placing the entire output group in the same judging context also improves the stability of within-group scores.

*Error-oriented GEMBA-ESA-style scoring.* Because the original GEMBA-ESA protocol (Kocmi et al., 2024b; Freitag et al., 2024) does not condition on translation instructions, we adapt it to an instruction-aware variant for our setting. Like the rubric-guided judge, this GEMBA-ESA-style evaluator jointly scores all anonymized sampled outputs in the group in a single call: along the dimensions of accuracy, fluency, style, terminology,

and non-translation, it compares the sampled outputs and, for each one, reports error types with their severities together with a 0–100 score. We normalize that score to $r_{\mathrm{ESA}} \in [0, 1]$. The rubric-guided LLM-as-a-judge reward provides positive scoring of relative translation quality, whereas the GEMBA-ESA-style reward lowers scores from an error-oriented perspective. The two contrastive LLM-based rewards therefore provide complementary positive-scoring and negative-deduction signals.

**Rule-based rewards.** The rule-based family comprises a length-ratio metric and a format-verification metric.

*Length-ratio metric.* In practice, we find that the length-ratio metric effectively discourages severe omissions and additions, as well as unbounded generation. Reflecting the nature of translation, we allow output lengths to vary within a tolerance band rather than forcing them to match the reference. Let $\rho = N(y)/N(y^*)$ be the output-to-reference token ratio and $\delta = \max(0, |\log \rho| - |\log 0.7|)$. We use

$$r_{\mathrm{len}}(y) = \frac{1}{1 + 30\delta^2}, \tag{3}$$

which has a broad full-score region and decays smoothly and rapidly when the length discrepancy becomes large.

*Format-verification metric.* We first classify the source with rule-based heuristics and route it to a type-specific check: for JSON, we verify that the sampled output parses correctly and matches the source's element count; for HTML-tagged content, we check whether the sampled output and the reference agree in newline and HTML-tag counts; for plain text, we check agreement in newline counts. The metric is binary: $r_{\mathrm{fmt}} = 1$ if the check passes and 0 otherwise.

### 3.3 Implementation

All models are implemented in PyTorch and trained on 16 GPUs. We train all stages with the ms-swift framework (Zhao et al., 2025). Table 2 summarizes the main hyperparameters for SFT and GRPO.

| Hyperparameters | $\mathrm{SFT}_1$ | $\mathrm{SFT}_2$ | GRPO |
|---|---|---|---|
| Learning rate | 2e−5 | 2e−6 | 2e−6 |
| Batch size | 384 | 64 | 128 |
| Max sequence length | 4096 | 4096 | 2048 |
| Number of generations | – | – | 4 |
| Temperature | – | – | 1.0 |

Table 2: Main training hyperparameters for SFT and GRPO.

## 4 Evaluation

### 4.1 Evaluation Datasets

We report development results on IF-WMT25 and IFMTBench (Sun et al., 2026). IF-WMT25 is our primary development set and covers 22 of the WMT26 translation directions (excluding English→Northern Sámi): Czech and English sources are taken from the WMT25 blind test (Kocmi et al., 2025), Chinese sources are sampled from the same source pool described in Section 3.1, and translation instructions are generated with the instruction-synthesis procedure in that section. The resulting set contains 5,239 examples, and its instructions are English-only. IFMTBench is an open benchmark for instruction-following MT covering seven languages, six constraint types, and five compositional patterns. We evaluate on its multi-constraint subset of 2,838 examples, whose translation instructions are multilingual and whose language pairs are not restricted to the WMT26 inventory; we use it to assess generalization to non-English instructions and beyond the official language-pair inventory.

### 4.2 Evaluation Setup

**Baselines.** We compare Qingqiu-MT-9B separately with Qwen3.5-9B (Qwen Team, 2026), Hy-MT2-7B (Zheng et al., 2026), Gemma4-12b (Gemma Team and Google DeepMind, 2026), and DeepSeek-v4-flash (DeepSeek-AI, 2026).

**Inference settings.** For Qingqiu-MT-9B, we reuse the training chat template, map language codes to names, and decode in non-thinking mode to return translation text only. Paragraphs are serialized and restored with `\n\n` under one fixed decoding configuration for all directions. Although trained with English instructions only, we keep IFMTBench's original multilingual instructions at evaluation. For the baselines, we decode in non-thinking mode with the recommended sampling settings from their official documentation. On IFMTBench, they use the input prompts provided by the benchmark; on IF-WMT25, they use the same input prompts as Qingqiu-MT-9B.

**Evaluation method.** For each source and instruction, GLM-5 jointly scores anonymized system outputs on five $[0, 100]$ dimensions—accuracy, terminology, format, fluency, and style—folding instruction following into these dimensions rather than scoring it separately. The overall score is the rounded weighted sum of the five scores with weights $(0.40, 0.20, 0.15, 0.15, 0.10)$; absolute differences of at most 2 count as ties. We use this method for both evaluation sets in place of the original IFMTBench scoring. Tables report win and lose rates (%) against each baseline, together with $\text{Gap} = \text{Win} - \text{Lose}$; ties stay in the denominator but are omitted from the display. Positive gaps are shown in red and negative gaps in green. Direction rows are computed over samples in that direction.

Because GLM-5 also serves as an RL judge, reusing it for development evaluation raises the possibility of judge-specific reward hacking. To test the robustness of our conclusions to judge choice, we conduct a judge ablation on IF-WMT25. DeepSeek-V4-Flash-Thinking (High) and GPT-5.6-Sol-Thinking (High) are separately used as judges under the same instruction-aware evaluation rubric. Table 5 compares their results with the original GLM-5 evaluation.

### 4.3 Results

Tables 3 and 4 report pairwise win rates. We treat IF-WMT25 as the primary development evaluation because it covers the WMT26 translation directions.

| | Qingqiu-MT-9B / baseline (%) | | | | | | | | | | | |

Table 4: IFMTBench multi-constraint results against each baseline (%).

On IF-WMT25 (Table 3), Qingqiu-MT-9B outperforms Qwen3.5-9B on all 22 directions, Hy-MT2-7B on 10 of 16 directions with available outputs, and Gemma4-12b on 11 of 22 directions,

| | GLM-5 | | | | DeepSeek-V4-Flash-Thinking (High) | | | | GPT-5.6-Sol-Thinking (High) | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Baseline | Win | Lose | Tie | Gap | Win | Lose | Tie | Gap | Win | Lose | Tie | Gap |
| Qwen3.5-9B | 83.2 | 13.7 | 3.1 | 69.5 | 79.4 | 11.6 | 9.0 | 67.8 | 83.1 | 13.5 | 3.4 | 69.6 |
| Hy-MT2-7B | 52.4 | 40.8 | 6.8 | 11.6 | 40.7 | 36.9 | 22.4 | 3.8 | 51.0 | 40.4 | 8.6 | 10.7 |

| DeepSeek-v4-flash | 38.7 | 52.4 | 8.9 | -13.7 | 28.9 | 46.6 | 24.4 | -17.7 | 37.5 | 52.1 | 10.3 | -14.6 |

Table 5: Judge ablation on IF-WMT25. Win, Lose, Tie, and Gap are percentages for Qingqiu-MT-9B against each baseline; ties remain in the denominator, and $\mathrm{Gap} = \mathrm{Win} - \mathrm{Lose}$. GLM-5 values reproduce the Overall row of Table 3.

with higher overall win rates in each comparison. DeepSeek-v4-flash retains a higher overall win rate, although Qingqiu-MT-9B wins 5 of 22 directions, including lower-resource pairs such as en→th, en→lij, and en→lld.

The judge ablation exhibits the same overall trend across all three evaluators. Qingqiu-MT-9B consistently shows a clear advantage over Qwen3.5-9B and remains ahead of the similarly sized Hy-MT2-7B and Gemma4-12b, although the margins and tie propensities vary by judge. DeepSeek-v4-flash remains the strongest comparator, while Qingqiu-MT-9B retains a competitive position. The consistent ordering and direction of these comparisons indicate that the main conclusions are robust to evaluator choice and are unlikely to be explained by reward hacking against the GLM-5 judge.

On IFMTBench's multilingual instructions and out-of-inventory language pairs (Table 4), Qingqiu-MT-9B wins all directions against Qwen3.5-9B and achieves higher overall win rates than Hy-MT2-7B (8 of 12 directions) and Gemma4-12b (7 of 12). It wins 3 of 12 directions and ties 2 against DeepSeek-v4-flash, while trailing in overall win rate. Together, the two evaluations indicate generalization across instruction languages and translation directions.

### 4.4 Qualitative Analysis

Figure 3 shows four contrastive pairs aligned with the instruction phenomena highlighted on the WMT26 General MT task page (formal/informal, glossaries, structured translation, and style and expressions; two cases per type). Each prompt lists the language pair, instruction, and source text; colored spans mark the key constraint. Within a type, the source is held fixed so that differences in the output can be attributed to the instruction. Additional cases aligned with the design space in Table 1 appear in Appendix A.

**formal / informal.** For the campus dining-hall notice, a formal official-notice instruction yields impersonal bulletin Chinese with official-notice obligation markers, whereas an informal group-chat instruction produces colloquial wording for the same closing hours and self-brought bottle rule.

**glossaries.** The ambiguous sentence *Curry is best when it's hot* is resolved by additional context: as a food dish, the model translates *Curry*/*hot* as heated curry; as NBA player Stephen Curry, it renders a "hot streak" reading instead of food temperature.

**structured translation.** On the same password-reset HTML snippet, one instruction keeps tags and attributes such as `class` and `href` while translating only visible text; the contrastive instruction strips markup and returns plain Chinese only.

**style and expressions.** For an informal product comment with slang, character elongation, and exaggerated punctuation, one instruction replicates the non-standard emotional style while localizing slang into Chinese (e.g., rendering *tbh* rather than leaving the English token), whereas the contrastive instruction yields a polished product-review register.

## 5 Conclusion

We presented Qingqiu-MT-9B, an instruction-aware multilingual translation model trained with diverse synthetic supervision, quality-tiered two-stage SFT, and GRPO combining contrastive LLM-based and rule-based rewards. Its shared training and inference interface targets generalization beyond fixed prompt templates. Development results are encouraging on IF-WMT25, which covers the WMT26 directions, and remain competitive on IFMTBench under multilingual instructions and non-official language pairs.

| Type | Prompt | Output |
|---|---|---|
| formal / informal | *[English → Simplified Chinese]*<br>**Instruction:** Use a formal official-notice voice (公文通告体): impersonal and formulaic. Use obligation markers such as 须/请 where natural. Do not add dates or information absent from the source.<br>**Source:** Campus dining halls will close at 8 p.m. during the exam week. Students should bring their own water bottles; disposable cups will not be provided. | 考试周期间，校园食堂将于晚上8时关闭。学生须自带水杯，食堂不提供一次性纸杯。 |
| | *[English → Simplified Chinese]*<br>**Instruction:** Use a natural informal register, as if a student is casually telling classmates in a group chat. Keep it colloquial; avoid official-notice wording.<br>**Source:** Campus dining halls will close at 8 p.m. during the exam week. Students should bring their own water bottles; disposable cups will not be provided. | 考试周食堂晚上8点就关门了。大家记得自带水杯，不提供一次性杯子哈。 |
| glossaries | *[English → Simplified Chinese]*<br>**Instruction:** Additional context: this sentence is about the food dish curry; "hot" means served at a high temperature.<br>**Source:** Curry is best when it's hot. | 咖喱趁热吃最好。 |
| | *[English → Simplified Chinese]*<br>**Instruction:** Additional context: this sentence is about NBA player Stephen Curry; "hot" means he is on a scoring streak / shooting very well, not food temperature.<br>**Source:** Curry is best when it's hot. | 库里在手感火热时状态最好。 |
| structured translation | *[English → Simplified Chinese]*<br>**Instruction:** Keep all HTML tags and attributes intact (including class and href). Translate only visible text.<br>**Source:** `<p class="alert">Please <a href="/reset">reset your password</a> before Friday.</p>` | 请在周五之前 <a href="/reset">重置您的密码</a>。 |
| | *[English → Simplified Chinese]*<br>**Instruction:** Remove all HTML tags and attributes. Output plain text only, with no '<' or '>' characters.<br>**Source:** `<p class="alert">Please <a href="/reset">reset your password</a> before Friday.</p>` | 请在周五之前重置您的密码。 |
| style and expressions | *[English → Simplified Chinese]*<br>**Instruction:** Accurately replicate the non-standard emotional style: keep character elongation (e.g. sooooo) and expressive punctuation (!!! / ???). Translate internet slang into natural Chinese equivalents; do not leave English slang tokens.<br>**Source:** tbh this phone is sooooo good lol battery lasts forever!!! charging??? instant | 说实话这手机真的超超超超好用哈哈 电池简直能用到天荒地老！！！充电？？？秒充 |
| | *[English → Simplified Chinese]*<br>**Instruction:** Use a standard, polished product-review register. Normalize slang and elongation; conventional punctuation only.<br>**Source:** tbh this phone is sooooo good lol battery lasts forever!!! charging??? instant | 说实话，这款手机非常出色，电池续航极其强劲，充电速度也非常快。 |

Figure 3: Four contrastive instruction-following pairs (two cases per type): formal/informal, glossaries, structured translation, and style and expressions. Within each type, the source is held fixed while the instruction changes. Colored text highlights the key constraint.

## Acknowledgments

We thank the Engineering and Infrastructure teams at WPS-Qingqiu for their support throughout this project. Their assistance with training infrastructure, large-scale experiment orchestration, and system reliability made the model development and evaluation reported in this paper possible.

## A Additional Qualitative Cases

Figures 4–6 present additional instruction-following examples aligned with the requirement types in Table 1. As in Figure 3, each prompt lists the language pair, instruction, and source text; colored spans mark key constraints. Within a type, multiple contrastive cases are separated by dashed rules. HTML structure cases appear in Figure 3; the appendix adds JSON format control.

| Type | Prompt | Output |
|---|---|---|
| **Register / formality** | *[English → Simplified Chinese]*<br>**Instruction:** Render this informal complaint in a polished, professional customer-service register (non-vulgar) as natural Simplified Chinese.<br>**Source:** what broadband do i get? ive had virgin for 8 years and holy shit is it slow for 40 quid monthly. Is it the old router or do i just switch to a cheaper bt or whatever | 请问我该如何选择合适的宽带套餐？我已经使用了 Virgin 的服务八年，但每月 40 英镑的费用与目前的网络速度严重不符，速度实在太慢了。请问这是否是因为我的路由器型号过旧导致的？还是说，我应当考虑更换为 BT 或其他更实惠的运营商？ |
| | *[English → Simplified Chinese]*<br>**Instruction:** Preserve the informal, conversational, slightly rude register of this complaint in natural Simplified Chinese (no need to sanitize slang).<br>**Source:** what broadband do i get? ive had virgin for 8 years and holy shit is it slow for 40 quid monthly. Is it the old router or do i just switch to a cheaper bt or whatever | 我该办哪个宽带？用了8年Virgin了，真特么慢，一个月收我40镑。是路由器太老的问题，还是我直接换家更便宜的BT之类的？ |
| **Tone / emotion** | *[English → Simplified Chinese]*<br>**Instruction:** Translate as a warm airline customer-service notice with empathy and a brief sincere apology. Keep it concise: roughly the same information density as the source, without long boilerplate closings.<br>**Source:** Flight AF123 is cancelled due to weather. You will be refunded within 7 days. Call the help center if you have questions. | 由于天气原因，AF123航班已取消。我们深表歉意，您的退款将在7个工作日内办理。如有任何疑问，请随时联系帮助中心。 |
| | *[English → Simplified Chinese]*<br>**Instruction:** Translate as a cold, purely informational system notice with no apology, no empathy markers, and no softening language.<br>**Source:** Flight AF123 is cancelled due to weather. You will be refunded within 7 days. Call the help center if you have questions. | 航班AF123因天气原因取消。款项将在7日内退还。如有疑问，请联系帮助中心。 |
| **Translation strategy** | *[English → Simplified Chinese]*<br>**Instruction:** 归化翻译：把 401(k) 完全改写为中文养老金概念，译文中禁止出现拉丁字母或 401(k)。<br>**Source:** For many Americans, a 401(k) is the main way to save for retirement. | 对于许多美国人来说，美国常见的由雇主发起的个人退休储蓄账户是积累退休金的主要方式。 |
| | *[English → Simplified Chinese]*<br>**Instruction:** Use a foreignization strategy. Keep '401(k)' visible as a U.S.-specific retirement savings plan; do not replace it with a localized Chinese product name.<br>**Source:** For many Americans, a 401(k) is the main way to save for retirement. | 对于许多美国人来说，401(k)是储蓄养老的主要方式。 |

## Abstract

For the WMT26 General Machine Translation Task (Unconstrained Track), we propose **TRIVE** (**Tri**-Fusion **Ve**rified Translation Agent), a model-agnostic multi-agent translation framework. TRIVE organizes translation as a closed loop of Generation–Fusion–Verification–Correction: it first generates candidates in parallel under three complementary strategies—Faithful, Fluent, and Free—then synthesizes a draft that balances semantic fidelity and natural expression, and finally iteratively refines the output via rule-based validation and large language model evaluation. Given that each module is implemented primarily via prompting, TRIVE can be directly overlaid onto diverse backbone models without task-specific fine-tuning. Experiments show that overlaying TRIVE on multiple backbones consistently improves instruction-following translation quality. Finally, we submitted Gemini-3.5-Flash + TRIVE as our primary system to WMT26.

## 1 Introduction

Machine translation (MT) has long served as a core task in natural language processing (NLP). The rapid evolution of large language models (LLM) has led to substantial progress in multilingual translation: LLM have driven a paradigm shift in MT from task-specific supervised learning to large-scale representation learning and instruction following, continuously elevating multilingual translation performance (Alves et al., 2024; Xu et al., 2024; Zheng et al., 2025). Furthermore, multi-agent collaborative frameworks powered by LLM hold the potential to further boost translation quality (Kim, 2025; Li et al., 2025; Briva-Iglesias, 2025). Although such multi-agent systems remain in an exploratory stage, they have demonstrated immense potential. Inspired by these advancements, we participated in the WMT 2026 General Machine Translation Shared Task (Unconstrained Track). The task evaluates general-purpose MT under multilingual, multi-domain, and document-level settings with human assessment, while requiring systems to follow additional instructions on formality, glossaries, structured outputs, and style. We address this setting with a multi-agent workflow, aiming to push translation quality beyond foundational LLM.

Translation quality inherently involves multiple trade-offs that are difficult to optimize simultaneously, requiring semantic fidelity, linguistic fluency, and natural paraphrasing. Both cognitive translation studies and recent work on multi-agent systems indicate that human translators frequently balance distinct strategies—such as literal and free translation—and refine their outputs through iterative evaluation (Li et al., 2025). Accordingly, multi-agent collaboration enables the decomposition and integration of specialized roles and strategies, thereby enhancing overall translation quality (Wu et al., 2025). Furthermore, multi-candidate fusion leverages complementary information across diverse translation hypotheses (Vernikos and Popescu-Belis, 2024), while LLM-based quality estimation and automatic post-editing provide actionable mechanisms for checking and correcting candidate outputs (Kocmi and Federmann, 2023; Lu et al., 2025).

Guided by these insights, we introduce TRIVE. In the generation phase, TRIVE concurrently adopts three complementary strategies—faithful, fluent, and free translation—to produce candidate outputs, which are subsequently synthesized by a dedicated fusion agent to consolidate their respective strengths. In the verification and correction phase, the system integrates rule-based validation with LLM-based evaluation to automatically detect and rectify errors. This end-to-end architecture forms a closed loop of "Generation–Fusion–Verification–Correction," further pushing the boundaries of translation quality beyond standard large language models.

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1463–1476
October 28-29, 2026 ©2026 Association for Computational Linguistics

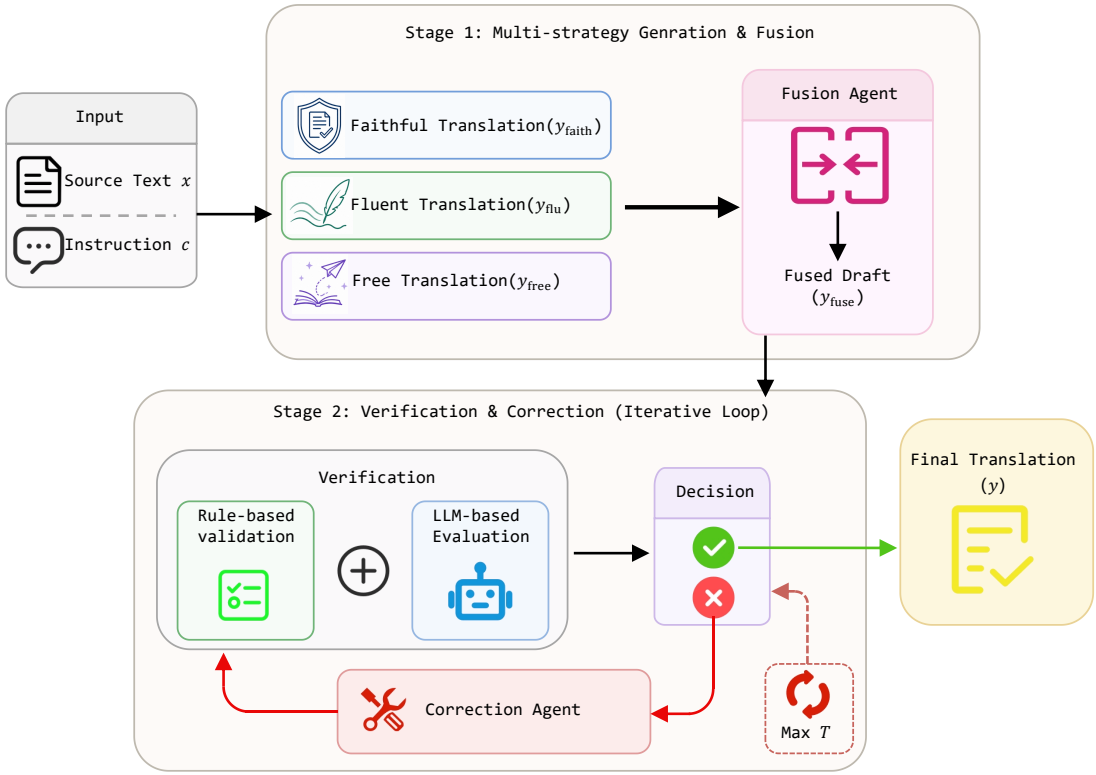

Figure 1: Framework of TRIVE. Firstly, three complementary strategies (Faithful, Fluent, and Free) generate diverse candidates in parallel. Secondly, a fusion agent integrates them into a balanced draft by comparing fidelity, fluency, and naturalness. Thirdly, the draft undergoes an automatic verification and correction loop via rule-based checks and LLM evaluation, iteratively refining the translation using feedback until quality thresholds are met or maximum iterations are reached.

The main contributions of this work are summarized as follows:

- We propose TRIVE, a model-agnostic multi-agent workflow that casts instruction-following translation as Generation–Fusion–Verification–Correction and can be overlaid on diverse LLM via prompting without fine-tuning..
- We combine Faithful / Fluent / Free multi-strategy generation and fusion with hybrid rule-based and LLM-based verification–correction, instead of refining a single serial trajectory alone..
- The experimental results show that without altering the underlying foundational models, overlaying TRIVE onto existing LLM substantially enhances translation quality and output robustness.

## 2 Related Work

The remarkable progress of Large Language Models (LLM) has fundamentally reshaped the machine translation landscape, as their performance has consistently outperformed traditional Neural Machine Translation models (Deutsch et al., 2025). This paradigm shift has catalyzed widespread exploration of LLM-based translation in both academic and open-source communities. Current research predominantly pursues two avenues: first, the development of fine-tuned LLM dedicated to translation tasks (Zhu et al., 2024); and second, the advancement of reasoning-augmented LLM that incorporate reasoning capabilities to further enhance translation quality (Nguyen and Xu, 2025).

Beyond single-model fine-tuning and reasoning-oriented prompting, recent work has explored agentic machine translation, where multiple specialized LLM agents collaborate via role decomposition and iterative workflows. TransAgents organizes editors, translators, and proofreaders into a virtual translation pipeline (Wu et al., 2024); CRAT integrates retrieval-augmented knowledge construction with causality-enhanced reflection to address difficult terminology (Chen et al., 2024). Similarly, Multi-agentMT showcases a "translate–post-edit–proofread" prompt-chaining

workflow in the WMT25 shared task (Kim, 2025), and TACTIC instantiates cognitively motivated agents for multi-strategy drafting and refinement (Li et al., 2025). More recently, AIDAterm deploys a role-specialized multi-agent pipeline for terminology-constrained industrial localization (Di Rosa, 2026), and Loong introduces an observe-and-act document-level translation agent with adaptive context selection (Wang et al., 2026). Different from TACTIC's multi-strategy fusion pipeline for standard translation (Li et al., 2025), TRIVE extends this line of work to instruction-following translation and enforces constraints via a rule and LLM based verification–correction stage. In contrast to pipelines that mainly refine a single serial trajectory or focus on role specialization alone, TRIVE thus combines parallel Faithful/Fluent/Free generation, synthesis-based fusion, and this hybrid verification procedure.

## 3 Methodology

TRIVE is a model-agnostic, multi-agent translation workflow decoupled from specific underlying backbone models. Inspired by the concept of prompt chaining—where the output of each sequential step serves as the input for the next—TRIVE facilitates systematic reasoning and iterative refinement (Briva-Iglesias, 2025). Given a source document $x$ (and an optional task instruction $c$), TRIVE produces the final translation $y$ through a closed-loop process of Generation–Fusion–Verification–Correction. The overall architecture is illustrated in Figure 1.

### 3.1 Overall Workflow

TRIVE consists of two primary phases. In the multi-strategy fused generation phase, three complementary translation strategies operate in parallel to generate candidate translations, which are then integrated into a draft $y_{\text{fuse}}$ by the fusion module. In the automatic verification and error-correction phase, the system subjects $y_{\text{fuse}}$ to rule-based validation and LLM-based quality evaluation; if it fails to pass, the system automatically rectifies it based on the feedback until it satisfies the quality criteria or reaches the maximum iteration limit. Since each specialized role is primarily implemented via prompting, TRIVE can be directly overlaid onto diverse large language models without requiring task-specific fine-tuning.

### 3.2 Multi-Strategy Generation

The multi-strategy generation module of TRIVE draws its theoretical foundation from strategy categorization in cognitive translation studies (Halverson, 2010). This line of research emphasizes that human translators frequently navigate dynamic trade-offs between faithful transmission and flexible expression, producing comparable candidate translations via multi-path drafting. Motivated by this view, we operationalize the trade-off into three complementary generation strategies and build a modular architecture for general machine translation, so that diverse candidates can later be fused rather than selected in a winner-take-all manner. Specifically, TRIVE generates three categories of candidate translations in parallel:

- ***Faithful Translation*** ($y_{\text{faith}}$): Prioritizes semantic adequacy and content coverage while minimizing structural rewriting;
- ***Fluent Translation*** ($y_{\text{flu}}$): Prioritizes target-language fluency, natural register, and overall readability;
- ***Free Translation*** ($y_{\text{free}}$): Permits greater flexibility in paraphrasing and restructuring to maximize natural expression and idiomaticity.

All three strategy agents receive the identical source text $x$ and task instruction $c$, operating independently prior to the fusion phase. These stylistic variants simulate the divergent thinking stage in human translation by exploring multiple interpretive paths in parallel before convergence, thereby preserving their respective complementary advantages.

### 3.3 Fusion Decision

The fusion module takes $\{y_{\text{faith}}, y_{\text{flu}}, y_{\text{free}}\}$ as input and outputs a unified draft $y_{\text{fuse}}$. Specifically, we prompt the LLM fusion agent to: (1) evaluate and compare the three candidates across faithfulness, fluency, and naturalness; (2) synthesize a new translation by retaining the core semantics of the faithful candidate while incorporating superior phrasing from the fluent and free candidates. The goal of this phase is to synthesize a more balanced draft rather than performing a naive best-of-three selection.

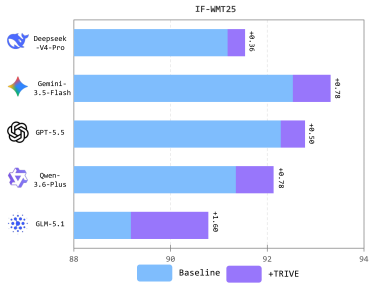
### 3.4 Verification and Correction

The draft $y_{\text{fuse}}$ subsequently enters an automated quality control pipeline, where rule-based valida-

tion and LLM-based evaluation scoring jointly determine whether to output the draft directly or proceed to iterative correction.

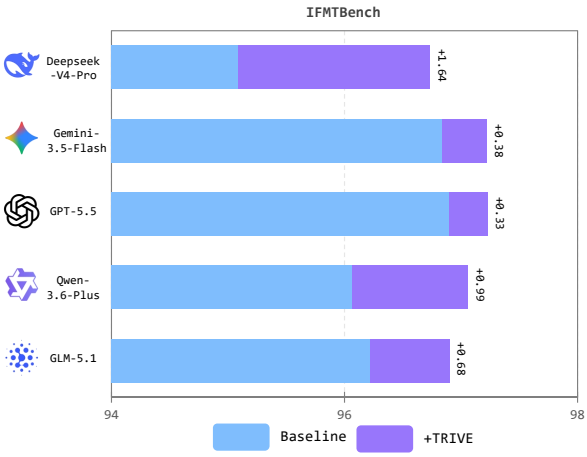
- ***Rule-based Validation***: The system checks source–translation consistency in line breaks and HTML tags, verifies that JSON outputs are parseable and preserve the source element count, and detects abnormal generation such as excessive repetition or uncontrolled length;
- ***LLM-based Evaluation Scoring***: The evaluation agent assesses $y_{\text{fuse}}$ across key dimensions—including semantic fidelity, fluency, and instruction compliance—and compares the resulting scores against a predefined threshold (set to 85 in our experiments);
- ***Correction***: If rule-based validation fails or the LLM evaluation score is below threshold, the correction agent revises the translation given the source $x$, instruction $c$, and error feedback, then re-enters the verification loop.

If both checks pass, the current translation is immediately released as the final output $y$. The verification-correction loop is executed for a maximum of $T$ iterations (set to $T = 2$ in our experiments); if the candidate fails to satisfy the criteria within this limit, the system returns the revised version that achieved the highest overall score.



## 4 Experiments

### 4.1 Benchmarks



**IFMTBench:** We use the multi-constraint samples from IFMTBench[1] (Sun et al., 2026) to evaluate instruction-following capabilities for translation tasks in multilingual scenarios. The instructions span seven languages: Chinese, German, Japanese, French, English, Spanish, and Korean, covering constraints related to terminology, formatting, and style commonly encountered in industrial translation.

**IF-WMT25:** IF-WMT25 is our primary development set aligned with the WMT26 setting: Czech and English sources are taken from the WMT25 blind test (Kocmi et al., 2025), Chinese sources are additionally included, and all examples are paired with English-only translation instructions. We use 2,704 examples covering 22 translation directions.

[1] https://huggingface.co/datasets/tencent/IFMTBench

(a) IF-WMT25.

(b) IFMTBench.

Figure 2: Performance comparison of instruction-following translation: Baseline vs. Baseline+TRIVE.

### 4.2 Results

We evaluate TRIVE with GEMBA[2] on IF-WMT25 and IFMTBench (Figure 2). TRIVE consistently improves all tested backbones, with gains of up to 1.60 points on IF-WMT25 and a similar trend on IFMTBench, indicating larger benefits for weaker models.

However, since strong base models have already saturated in GEMBA scores on translation tasks, absolute score gaps can understate practical preference differences. We therefore further conduct LLM-based, rubric-guided contrastive pairwise evaluations on IF-WMT25 using GLM-5 as the judge, with blinded comparisons and swapped order, comparing Gemini-3.5-Flash and GLM-5.1 against their TRIVE-augmented counterparts. The judge scores translations on instruction following,

[2] Our adapted GEMBA averages the instruction-following score with a translation-quality score comprising accuracy (40%), terminology (20%), format (15%), fluency (15%), and style (10%).

Table 1: Pairwise win/tie/lose rates (%) on IF-WMT25 for Gemini-3.5-Flash+TRIVE versus Gemini-3.5-Flash and for GLM-5.1+TRIVE versus GLM-5.1. Imp. denotes Improvement = Win − Lose (percentage points; positive in **red**, negative in **green**).

accuracy, terminology, format, fluency, and style. Table 1 reports the pairwise results. TRIVE is preferred for both backbones, with a larger gain for GLM-5.1 (57.7% wins vs. 27.1% losses). It wins on most directions with Gemini-3.5-Flash and all directions with GLM-5.1, suggesting consistent cross-lingual benefits, particularly for weaker backbones. Considering both GEMBA and pairwise results, we select Gemini-3.5-Flash+TRIVE as our primary WMT26 system (Unconstrained Track).

We note that GLM-5 may exhibit self-preference when judging systems from the same model family. However, both sides of the comparison share the same GLM-5.1 backbone, and the blinded, order-swapped paired evaluation helps reduce this potential bias.

**Fusion Strategy Ablation.** Using 32 randomly sampled examples per language direction, we compare synthesis-based fusion with best-of-three selection under otherwise identical settings. As shown in Table 2, synthesis improves GEMBA by 1.98 points on IF-WMT25 and 0.45 points on IFMTBench, supporting fusion over direct selection.

| Method | IF-WMT25 | IFMTBench |
|---|---|---|
| Best-of-Three Selection | 91.60 | 96.22 |
| Synthesis-based Fusion | **93.58** | **96.67** |

Table 2: GEMBA scores for best-of-three selection and synthesis-based fusion. We sample 32 examples per language direction from each benchmark.

| Variant | IF-WMT25 | IFMTBench |
|---|---|---|
| w/o Verification–Correction | 90.25 | 95.90 |
| Full TRIVE | **91.89** | **96.71** |

Table 3: GEMBA scores for the verification–correction ablation using Gemini-3.5-Flash-Lite. We randomly sample 32 examples per language direction from each benchmark.

**Verification–Correction Ablation.** We conduct this ablation with Gemini-3.5-Flash-Lite.[3] Its absolute scores are therefore not directly comparable with the preceding results. With all other settings unchanged, verification–correction improves GEMBA by 1.64 points on IF-WMT25 and 0.81 points on IFMTBench.

[3]Gemini-3.5-Flash was temporarily unavailable when this experiment was conducted; we therefore used Gemini-3.5-Flash-Lite from the same model family.

### 4.3 Case Study

Figure 3 illustrates representative examples of Gemini-3.5-Flash+TRIVE on instruction-following translation. These cases cover common real-world requirements, including terminology control, style control, structured output, redaction, delimiter preservation, length control, context-aware translation, dual-persona style conflict, subtitle translation with cultural preservation, and output-form constraints. Additional examples are provided in Appendix A.

| Type | Prompt | Output |

| **Style control** | **Instruction:** Translate into Classical Chinese, as if reporting to a sovereign. Keep a formal memorial tone. Output translation only.<br>**Source Text:** The payment service stopped working at noon, and thousands of users could not complete checkout until engineers restored the system two hours later. We have already started a full review to prevent the same failure from happening again. | 今日午时，泉币收付之务遽停，致数千商民莫能结讫。迨工师抢修，历一时辰，始得克复如初。臣等业已详加检析，深究其弊，以杜此患之复萌。 |
| **Structured output** | **Instruction:**<br>请解析以下待翻译的文本，并严格输出为 JSON 格式。JSON 必须包含以下字段:<br>"sentence": 原始文本。<br>"translation": 日语翻译。<br>注意: 只需输出 JSON 结构，禁止输出任何解释性文字或代码块标记。<br>**Source Text:** 酒店很干净，工作人员也很友善，但晚上的街道噪音让我在长途飞行后很难入睡。如果他们能提供一间朝向庭院、更安静的房间，我还是会再次入住。 | {"sentence": "酒店很干净，工作人员也很友善，但晚上的街道噪音让我在长途飞行后很难入睡。如果他们能提供一间朝向庭院、更安静的房间，我还是会再次入住。", "translation": "ホテルは清潔でスタッフも親切でしたが、長時間のフライトの後、夜の通りの騒音のせいでなかなか寝付けませんでした。もし中庭に面した、もっと静かなお部屋を用意してもらえるなら、やはりまた利用したいです。"} |
| **Redaction** | **Instruction:** Translate into Korean. Replace employee names, phone numbers, email addresses, and salaries with [REDACTED]. Output translation only.<br>**Source Text:** Please inform Anna Lee at +1-202-555-0147 or anna.lee@example.com that her annual salary will be adjusted to $128,000 starting next month, and ask her to confirm the new offer letter before Friday. | [REDACTED] 님께 [REDACTED] 또는 [REDACTED](으)로 다음달부터 연봉이 [REDACTED](으)로 조정됨을 안내해 주시고, 금요일 전까지 새로운 오퍼레터를 확인해 달라고 요청해 주시기 바랍니다. |
| **Delimiter preservation** | **Instruction:** Translate into Russian. Keep all HTML tags unchanged. Output only.<br>**Source Text:**<br>`<div>`<br>`<h3>`System `<strong>`Update`</strong>`</h3>`<br>`<p>`Please read the `<a href="https://example.com">`guidelines`</a>` carefully.`</p>`<br>`</div>` | `<div>`<br>`<h3><strong>`Обновление`</strong>` системы`</h3>`<br>`<p>`Пожалуйста, внимательно ознакомьтесь с `<a href="https://example.com">`инструкцией`</a>`.`</p>`<br>`</div>` |
| **Length control** | **Instruction:** Translate into Chinese in no more than 25 Chinese characters. Keep only the core event and drop secondary details. Output translation only.<br>**Source Text:** After three days of intense debate in the capital, lawmakers finally approved a new bill to expand public childcare support nationwide, and local governments are expected to publish implementation rules next quarter. | 立法者通过了扩大全国公共托育支持的新法案。 |
| **Context awareness** | **Instruction:** Context: a surgeon is speaking quietly to a junior doctor after a difficult operation. Translate into Chinese with a serious professional tone. Output translation only.<br>**Source Text:** That was close. Next time, check the chart twice before we start, and make sure the antibiotics are ready in the room before anesthesia begins. | راجع الجاية، المرة بصعوبة. وعدى خطر كان الموضوع الحيوية المضادات إن وتأكد نبدأ، ما قبل مرتين الملف التخدير. يبدأ ما قبل الأوضة في جاهزة |
| **Style conflict** | **Instruction:** First translate into elegant Spanish marketing copy. Then, as a hungry regular customer, add one complaint of about 40–50 Traditional Chinese characters.<br>**Source Text:** We are reimagining our culinary offerings to focus on artisan premium ingredients, resulting in a more curated and mindful dining experience for every guest. | Estamos reinventando nuestra propuesta gastronómica para centrarnos en ingredientes artesanales de primera calidad, brindando así una experiencia culinaria más selecta y consciente para cada comensal.<br><br>身為老顧客，我感覺份量變少了，價格卻變貴了。我只想肚子餓時能飽餐一頓，而不是看著精緻的盤子挨餓！ |
| **Output-form constraints** | **Instruction:** Translate into Thai. End every sentence with exactly three exclamation marks !!!. No extra commentary.<br>**Source Text:**Press the descaling button for three seconds. Wait until the red light goes out. Then restart the machine and run one empty cycle. | กดปุ่มขจัดคราบตะกรันเป็นเวลาสามวินาที!!!<br>รอจนกระทั่งไฟสีแดงดับลง!!!<br>จากนั้นเริ่มเครื่องใหม่และรันรอบเปล่าหนึ่งรอบ!!! |
| **Subtitle** | **Instruction:** Translate into Czech subtitles in SRT format. Keep honorifics Senpai and -kun untranslated. Each cue must include index + timecode. Output SRT only.<br>**Source Text:**<br>1<br>00:00:00,000 –> 00:00:03,000<br>Takeshi: "Senpai, is this really okay?"<br>2<br>00:00:03,000 –> 00:00:07,000<br>Yuko-senpai: "Relax, Takeshi-kun. If nobody sees us, we' ll be fine." | 1<br>00:00:00,000 –> 00:00:03,000<br>Takeshi: „Senpai, je to opravdu v pořádku? "<br><br>2<br>00:00:03,000 –> 00:00:07,000<br>Yuko-senpai: „Buď v klidu, Takeshi-kun. Když nás nikdo neuvidí, budeme v pohodě. " |

Figure 3: Case study of Gemini-3.5-Flash+TRIVE on translation instruction following.

The examples demonstrate that TRIVE can handle both explicit translation constraints and compound user requirements: glossary mappings are followed strictly, style and politeness registers can be switched as required, CSV/JSON structures remain intact, and HTML markers as well as length limits are accurately enforced. Overall, these examples confirm that Gemini-3.5-Flash+TRIVE reliably executes diverse translation instructions.

## 5 Conclusion

In this paper, we present TRIVE, a model-agnostic multi-agent translation workflow for the WMT26 General Machine Translation Shared Task (Unconstrained Track). TRIVE organizes instruction-following translation as a closed loop of Generation–Fusion–Verification–Correction: it generates complementary Faithful, Fluent, and Free candidates in parallel, fuses them into a balanced draft, and iteratively revises the output through hybrid rule-based validation and LLM-based evaluation. Implemented primarily via prompting, TRIVE can be overlaid on diverse backbones without task-specific fine-tuning.
Experiments on IF-WMT25 and IFMTBench show consistent GEMBA gains across backbones, with larger improvements on weaker models. Pairwise preference evaluations on IF-WMT25 further confirm that TRIVE is favored over strong and weak backbones alike and generalizes across most language directions. Qualitative case studies additionally illustrate reliable adherence to terminology, style, formatting, and other instruction constraints. We adopt Gemini-3.5-Flash+TRIVE as our primary WMT26 system. Overall, these results suggest that multi-strategy fusion with hybrid verification–correction can further improve instruction-following translation without modifying backbone parameters.

## 6 Acknowledgment

We thank the Engineering and Infrastructure teams at WPS-Qingqiu, as well as the WPS-iCIBA team, for their support. In particular, we appreciate their assistance with data collection, pre-processing, and platform support.

# A Additional Case Studies

Figures 4 and 5 present additional qualitative examples of Gemini-3.5-Flash+TRIVE on instruction-following translation, complementing Figure 3 in the main text.

| Type | Prompt | Output |
|---|---|---|
| **Terminology** | **Instruction:** Translate into Japanese. Strictly use: Cooling System → 冷却系統, Pressure Valve → 圧力弁, Maintenance Window → 保全時間帯. Output translation only.<br>**Source Text:** Before the Cooling System starts, confirm that the Pressure Valve is closed and the Maintenance Window has been approved. | 冷却系統の始動前に、圧力弁が閉じていること、および保全時間帯の承認が得られていることを確認してください。 |
| | **Instruction:** Translate into Chinese. Strictly use: MRI → 磁共振成像, Contrast Agent → 造影剂, Radiologist → 影像医师, Allergic Reaction → 过敏反应. Output translation only.<br>**Source Text:** Before the MRI scan begins, the Radiologist must confirm that the Contrast Agent has already been prepared for the patient, and the nurse should stay nearby in case an Allergic Reaction appears during the first few minutes of injection. | 在磁共振成像扫描开始前，影像医师必须确认已为患者准备好造影剂，且护士应在附近守候，以防在注射的最初几分钟内出现过敏反应。 |
| **Style control** | **Instruction:** Translate into Classical Chinese, as if reporting to a sovereign. Keep a formal memorial tone. Output translation only.<br>**Source Text:** The payment service stopped working at noon, and thousands of users could not complete checkout until engineers restored the system two hours later. | 臣谨奏：日中，支付之务骤停，致商民数千莫能交割。逾一时辰，经工师修治，方克复旧。 |
| | **Instruction:** Translate into polite business German suitable for an email to a client. Keep a formal and courteous tone. Output translation only.<br>**Source Text:** Could we schedule your interview for 3 p.m. tomorrow, and would you prefer a video call or an on-site meeting at our office? | Könnten wir das Gespräch für morgen um 15:00 Uhr vereinbaren, und würden Sie eine Videokonferenz oder ein persönliches Treffen in unserem Büro bevorzugen? |
| **Structured output** | **Instruction:** Translate cell text into Chinese. Keep the CSV header and commas. Output pure CSV only; no markdown and no explanations.<br>**Source Text:**<br>`order_id,item,note,state`<br>A12,Wireless Mouse,"Gift wrap required before shipment",PENDING<br>B08,USB Hub,"Customer asked for a paper invoice",SHIPPED<br>C19,Laptop Stand,"Leave the package at the front desk",DELAYED | 订单号，商品，备注，状态<br>A12, 无线鼠标," 发货前需礼品包装", 待处理<br>B08,USB 集线器," 客户要求提供纸质发票", 已发货<br>C19, 笔记本电脑支架," 请将包裹放在前台", 已延迟 |
| | **Instruction:** Please parse the text to be translated below and strictly output it in JSON format. The JSON must contain the following fields:<br>"sentence": original text.<br>"translation": Czech translation.<br>Note: Output the JSON structure only. Any explanatory text or code block tags are strictly prohibited.<br>**Source Text:** The economic policies of central European nations have adapted rapidly to changing market demands over the past decade. | {"sentence": "The economic policies of central European nations have adapted rapidly to changing market demands over the past decade.", "translation": "Hospodářské politiky středoevropských zemí se v posledním desetiletí rychle přizpůsobily měnícím se požadavkům trhu."} |
| **Redaction** | **Instruction:** Translate into Chinese. Replace employee names, phone numbers, email addresses, and salaries with [REDACTED]. Output translation only.<br>**Source Text:** Applicant David Chen (ID 110101199003078816), living at 88 Chang'an Avenue, Beijing, requested a refund yesterday. | 申请人[REDACTED]（身份证号：[REDACTED]），现居住于[REDACTED]，于昨日提出了退款申请。 |
| | **Instruction:** Translate into German. Replace all phone numbers and email addresses with ****. Do not reveal any digits or email local-parts. Output translation only.<br>**Source Text:** Kontaktujte prosím paní Novákovou na telefonu +420 777 123 456 nebo e-mailem novakova@firma.cz ještě dnes. | Bitte kontaktieren Sie Frau Nováková noch heute telefonisch unter **** oder per E-Mail unter ****. |
| **Delimiter preservation** | **Instruction:** Translate into Japanese. Keep all mustache placeholders such as `{{user_name}}` and `{{order_id}}` character-for-character unchanged. Do not translate the placeholder names. Output translation only.<br>**Source Text:** 尊敬的 `{{user_name}}`，您的订单 `{{order_id}}` 已发货，预计明天送达。 | `{{user_name}}`様、ご注文の `{{order_id}}` を発送いたしました。明日お届け予定です。 |
| | **Instruction:** Translate into Chinese. Keep the Markdown link syntax and inline code backticks unchanged. Output translation only.<br>**Source Text:** Click [official docs](https://example.com/docs) and run `` `npm install` `` before starting the service. | 在启动服务之前，请点击 [官方文档](https://example.com/docs) 并运行 `` `npm install` ``。 |
| **Length control** | **Instruction:** Translate into German in no more than 20 words. Keep only the main request. Output translation only.<br>**Source Text:** I would like to cancel my subscription immediately, stop all future charges, and receive a confirmation email within 24 hours if possible. | Bitte kündigen Sie mein Abonnement sofort, stoppen Sie zukünftige Abbuchungen und senden Sie mir eine Bestätigung. |
| | **Instruction:** Translate into Traditional Chinese in no more than 12 Chinese characters. Keep only the final decision and drop background details. Output translation only.<br>**Source Text:** After reviewing the quarterly metrics and consulting three regional managers, the board decided to pause the overseas expansion plan until next spring. | 暫緩海外擴張至明年春季 |

Figure 4: Additional case study of Gemini-3.5-Flash+TRIVE on translation instruction following (Part 1).

| Type | Prompt | Output |
|---|---|---|
| **Context awareness** | **Instruction:** Context: a senior engineer is mentoring an intern during an outage. Translate into Japanese with a calm, instructive workplace tone. Output translation only.<br>**Source Text:** Do not restart the database yet. First capture the error logs, then check whether the replica is still in sync. | データベースはまだ再起動しないでください。まずはエラーログを取得し、それからレプリカの同期が維持されているか確認してください。 |
| | **Instruction:** Context: a nurse explaining post-surgery care to an elderly patient. Translate into Chinese with patient, plain, non-technical wording. Output translation only.<br>**Source Text:** Take this medicine after breakfast. If you feel dizzy, sit down immediately and call the ward nurse. | 吃完早饭后，把这个药吃了。要是觉得头晕，一定要马上坐下来，然后叫病房里的护士。 |
| **Style conflict** | **Instruction:** Translate into formal PR Italian, then add one angry 30-character rant in the voice of an overworked employee.<br>**Source Text:** We are implementing a strategic reorganization to streamline operations and empower our remaining workforce. | Stiamo attuando una riorganizzazione strategica volta a snellire i processi operativi e a valorizzare il personale rimanente. E noi moriamo di straordinari! |
| | **Instruction:** First translate into upbeat German tourism-brochure copy. Then add one sarcastic one-sentence complaint in Simplified Chinese (25–40 characters) from a disappointed tourist.<br>**Source Text:** Discover our newly renovated seaside hotel, where every room offers a breathtaking ocean view and complimentary breakfast. | Entdecken Sie unser frisch renoviertes Strandhotel, in dem jedes Zimmer einen atemberaubenden Meerblick und ein kostenloses Frühstück bietet!<br>这就是所谓的“无敌海景”？除非我把脖子伸长两米，否则只能看见隔壁的垃圾桶。 |
| **Subtitle** | **Instruction:** Translate into Chinese subtitles in SRT format. Keep the speaker names in Latin script. Preserve index and timecode lines exactly. Output SRT only.<br>**Source Text:**<br>1<br>00:00:01,000 --> 00:00:04,000<br>Maya: ”We have less than one minute before the gate closes.”<br>2<br>00:00:04,200 --> 00:00:07,500<br>Leo: ”Then stop talking and run.” | 1<br>00:00:01,000 --> 00:00:04,000<br>Maya: “大门还有不到一分钟就要关了。”<br>2<br>00:00:04,200 --> 00:00:07,500<br>Leo: “那就别废话了，快跑。” |
| | **Instruction:** Translate into Korean subtitles in SRT format. Keep all sound-effect markers in square brackets unchanged (e.g., [DOOR SLAMS], [PHONE RINGS]). Do not translate text inside brackets. Preserve index and timecode lines exactly. Output SRT only.<br>**Source Text:**<br>1<br>00:00:02,100 --> 00:00:04,800<br>[DOOR SLAMS]<br>2<br>00:00:05,000 --> 00:00:08,200<br>Lina: ”Did you hear that? Someone is in the hallway.”<br>3<br>00:00:08,400 --> 00:00:10,900<br>[PHONE RINGS] | 1<br>00:00:02,100 --> 00:00:04,800<br>[DOOR SLAMS]<br>2<br>00:00:05,000 --> 00:00:08,200<br>리나: ” 방금들었어? 복도에누가있어.”<br>3<br>00:00:08,400 --> 00:00:10,900<br>[PHONE RINGS] |
| **Output-form constraints** | **Instruction:** Translate into Chinese. Number every sentence as (1)(2)(3)... in order. Do not use any other list markers. Output translation only.<br>**Source Text:** Open the settings page. Enable two-factor authentication. Then save and log in again. | (1)打开设置页面。(2)启用双重身份验证。(3)然后保存并重新登录。 |
| | **Instruction:** Translate into Korean. Output exactly three lines labeled TITLE / BODY / END in English. Keep those three labels unchanged. Output translation only.<br>**Source Text:** Flash sale starts tonight. All headphones are 30 percent off until midnight. | TITLE: 오늘밤깜짝세일이시작됩니다.<br>BODY: 자정까지모든헤드폰이 30% 할인됩니다.<br>END: |

# B Agent Prompts

This appendix provides the system and user prompts used by the generation, fusion, evaluation, and correction agents. The Faithful, Fluent, and Free agents correspond to literal, sense-for-sense, and free translation, respectively.

## B.1 Faithful Agent

### System prompt.

```
You are a professional translator specializing in literal translation.

Translation strategy: Literal Translation
```

```
- Prioritize accurate meaning while preserving the original text's form and structure.
- Translate word-for-word where the target language allows.
- Preserve the original text's sentence order, paragraph structure, and rhetorical devices as closely
↪  as possible.
- Do not add, omit, or alter any content from the source text.
- Avoid free paraphrasing or creative reinterpretation.

Uncertainty handling rules:
- If you encounter an idiom, slang expression, or culturally specific reference whose meaning you are
↪  not fully confident about, translate it as literally as possible and preserve the original
↪  expression in parentheses if the target language allows. Do not guess or fabricate a meaning.
- If you encounter a proper noun (film title, brand name, person name, place name), use its standard
↪  translation in the target language. If no standard translation is widely known, transliterate
↪  phonetically or keep the original.
- Preserve non-standard spelling, deliberate repetition, and incomplete sentences as instructed. Do
↪  not normalize or "fix" them.

Output only the translation. Do not explain.
```

### B.2 Fluent Agent

#### System prompt.

```
You are a professional translator specializing in sense-for-sense translation.

Translation strategy: Sense-for-Sense Translation
- Focus on conveying the core meaning and nuances of the original text.
- Balance fidelity to the source with fluency in the target language.
- Adapt linguistic form where necessary to ensure the meaning is clear and natural, but stay closer to
↪  the source structure than free translation.
- Do not add or omit content from the source text.
- This is a middle ground between literal and free translation.

Uncertainty handling rules:
- If you encounter an idiom, slang expression, or culturally specific reference whose meaning you are
↪  not fully confident about, provide the most contextually reasonable interpretation, but stay
↪  conservative   do not invent meanings that go beyond what the context supports.
- If you encounter a proper noun (film title, brand name, person name, place name), use its standard
↪  translation in the target language. If no standard translation is widely known, transliterate
↪  phonetically or keep the original.
- Preserve non-standard spelling, deliberate repetition, and incomplete sentences as instructed.

Output only the translation. Do not explain.
```

### B.3 Free Agent

#### System prompt.

```
You are a professional translator specializing in free translation.

Translation strategy: Free Translation
- Emphasize delivering the overall meaning, tone, and effect of the original text.
- Prioritize naturalness, fluency, and readability in the target language.
- You may significantly restructure sentences, reorder information, or adapt expressions as needed to
↪  produce a natural-sounding translation.
- Do not add or omit substantive content from the source text.
- The translation should read as if originally written in the target language.

Uncertainty handling rules:
- If you encounter an idiom, slang expression, or culturally specific reference whose meaning you are
↪  not fully confident about, convey the general tone and register without fabricating specific
↪  details you are unsure of. When in doubt, stay closer to the literal meaning rather than guessing
↪  a creative interpretation.
- If you encounter a proper noun (film title, brand name, person name, place name), use its standard
↪  translation in the target language. If no standard translation is widely known, transliterate
↪  phonetically or keep the original.
- Preserve the spirit of non-standard spelling, deliberate repetition, and incomplete sentences. Do
↪  not normalize them into standard language.

Output only the translation. Do not explain.
```

### B.4 Shared Generation User Prompt

```
Translate the following {src_lang_en} text into {tgt_lang_en}. Strictly follow the instruction below.

instruction:
{instruction}

text:
{source_text}
```

### B.5 Fusion Agent

#### System prompt.

```
You are a senior translation refinement expert.

You will be given a source text and three candidate translations produced by different translation
↪  strategies:
1. Literal translation   faithful to source structure and wording
2. Free translation   natural and fluent, reads like original target language
3. Sense-for-sense translation   balanced between fidelity and naturalness

Your task is to synthesize them into a single final translation that combines the best aspects of all
↪  three.

Follow these steps in order:

Step 1   Completeness verification:
Identify the key semantic units (facts, actions, entities, relationships, tone markers) in the source
↪  text. For each, check whether at least one of the three candidates correctly preserves it. If all
↪  three candidates omit or distort the same piece of information, this is a critical red flag   you
↪  MUST ensure the final translation includes it correctly.

Step 2   Disagreement analysis:
Identify where the three candidates disagree (different word choices, different interpretations of a
↪  phrase, different structural choices). For each disagreement, evaluate which version is most
↪  faithful to the source meaning while also being natural in the target language.

Step 3   Uncertainty detection:
If all three candidates appear to interpret a phrase the same way, but the interpretation seems like a
↪  guess (e.g., a slang expression rendered with an unlikely specific meaning, a proper noun
↪  translated in a non-standard way), treat this as a likely error. Prefer a more conservative
↪  rendering that stays closer to the literal source text rather than a confident but potentially
↪  wrong interpretation.

Step 4   Synthesis:
Produce the final translation. Ensure:
- Every piece of source information is accounted for   no omission, no addition, no distortion.
- The translation is fluent and natural in the target language.
- The translation instruction's requirements (style, register, format, terminology, etc.) are
↪  preserved.
- No new issues are introduced while fixing existing ones.

Output JSON only.
```

#### User prompt.

```
Source language: {src_lang_en}
Target language: {tgt_lang_en}

Source text:
{source_text}

Translation instruction:
{instruction}

Candidate translation 1 (Literal):
{draft_literal}

Candidate translation 2 (Free):
{draft_free}
```

```
Candidate translation 3 (Sense-for-sense):
{draft_sense}

Perform the 4-step refinement process:
1. Completeness verification   enumerate key semantic units from the source and check coverage
2. Disagreement analysis   identify where candidates disagree and evaluate which is best
3. Uncertainty detection   flag where all three may have made the same wrong guess
4. Synthesis   produce the final refined translation

Output JSON only:

{
  "analysis": "Your step 1-3 analysis: completeness check, disagreement analysis, uncertainty
  ↪  detection.",
  "translation": "Your final refined translation from step 4."
}
```

### B.6 Evaluation Agent

#### System prompt.

```
You are a GEMBA-ESA style translation quality evaluator.

Evaluate the candidate translation against the source text and translation instruction.

First identify concrete translation errors, then assign a score.

Error severity:
- critical: factual distortion, severe mistranslation, severe omission, severe addition, wrong target
↪  language, role confusion, serious terminology error, or source-language residue that affects
↪  meaning.
- major: important mistranslation, important instruction violation, terminology problem, unnatural
↪  expression that affects readability, or partial omission.
- minor: grammar, wording, punctuation, register, fluency, or style issues that do not change the core
↪  meaning.

Do not give a low score unless you can identify concrete errors.

Output JSON only.
```

#### User prompt.

```
Source language: {src_lang_en}
Target language: {tgt_lang_en}

Source text:
{source_text}

Translation instruction:
{instruction}

Current translation:
{current_translation}

Evaluate the current translation and output JSON:

{
  "gemba_score": 1-100,
  "severity_counts": {
    "critical": 0,
    "major": 0,

## Abstract

This paper describes TransCore, the NewTranx submission to the WMT26 General Machine Translation Shared Task constrained track. Our system is built upon the Qwen3-8B large language model and adopts a two-stage supervised fine-tuning framework trained exclusively on publicly available data. Our approach focuses on high-quality multilingual data construction, including parallel corpus construction, knowledge-distilled corpus construction, and instruction-following data construction. For the parallel corpus, we construct a high-quality multilingual training corpus through multilingual data collection and automatic quality filtering. For knowledge distillation, we construct a KD corpus from publicly available monolingual resources using a large language model, followed by automatic quality filtering. To support the instruction-following evaluation introduced in WMT26, we further construct instruction data covering immutable entity preservation, document-level translation, and structured translation, which are incorporated into the first-stage supervised fine-tuning. Our system participates in four language directions of the WMT26 General Machine Translation Shared Task: English→Indonesian, English→Kazakh, English→Thai, and Chinese→Japanese.

## 1 Introduction

Recent advances in large language models (LLMs) have significantly improved machine translation performance and accelerated the adoption of instruction-tuned LLMs for multilingual machine translation (Li et al., 2024; Rei et al., 2026; Cheng et al., 2025; Luo et al., 2025; Zheng et al., 2025). Benefiting from large-scale pre-training and strong cross-lingual generalization capabilities, LLMs have achieved competitive translation quality across a wide range of language pairs while demonstrating superior instruction-following capability in practical translation scenarios. Consequently, supervised fine-tuning of open-source LLMs has become an increasingly effective paradigm for developing high-quality multilingual machine translation systems.

Compared with previous editions, the WMT26 General Machine Translation Shared Task (Kocmi et al., 2026) introduces several important changes. The evaluation covers multiple domains, including news, social, and spoken content, while all test sets are provided at the document level. Furthermore, the task introduces instruction-following evaluation through instance-level translation instructions, requiring translation systems to satisfy diverse user-specified translation constraints. More importantly, WMT26 adopts human evaluation as the primary evaluation protocol for all submitted systems, reflecting an increasing emphasis on translation quality in realistic application scenarios rather than optimization toward automatic evaluation metrics. These changes further highlight the importance of constructing high-quality training data for LLM-based machine translation systems.

To address these challenges, we present TransCore, a translation system based on Qwen3-8B (Yang et al., 2025) using a two-stage supervised fine-tuning framework. To better support the instruction-following evaluation in WMT26, we additionally construct dedicated instruction data covering immutable entity preservation, document-level translation, and structured translation. The resulting system is submitted to four WMT26 General Machine Translation directions, English→Indonesian, English→Kazakh, English→Thai, and Chinese→Japanese. The main contributions of this work are summarized as follows:

- We present TransCore, a constrained-track multilingual machine translation system built

†Corresponding author.

upon Qwen3-8B for the WMT26 General Machine Translation Shared Task.

- We construct a high-quality training corpus by integrating carefully curated parallel data, knowledge-distilled (KD) data, and instruction-following data under a unified training framework.

- We design a unified instruction-following data construction framework that supports multiple translation constraints, including immutable entity preservation, document-level translation, and structured translation, through a unified instruction representation and data construction pipeline.

## 2 Method

### 2.1 Overview

Our systems, TransCore, adopts a two-stage supervised fine-tuning (SFT) pipeline for machine translation. The overall workflow consists of parallel data construction, knowledge-distilled data construction, instruction-following data construction, two-stage model training, and deterministic inference.

In the first stage, publicly available parallel corpora are collected for all translation directions. The bilingual data are preprocessed, automatically filtered using quality estimation, and converted into a unified instruction-following format for supervised fine-tuning. In the second stage, we construct knowledge-distilled parallel data from publicly available monolingual corpora spanning multiple domains. A teacher translation model is employed to translate target-language texts into the corresponding source language, and the resulting knowledge-distilled data are further filtered before being used for continued supervised fine-tuning.

To improve instruction-following capability under the WMT26 General MT setting, we additionally construct instruction-following translation data covering three representative translation capabilities: preservation of non-translatable entities and formatting elements, document-level translation with contextual consistency, and structured translation with tag and XML structure preservation. Finally, the multilingual model is trained through two-stage full-parameter supervised fine-tuning and evaluated using deterministic decoding.

| Language Pair | Original | Selected |

| zh→ja | 782,353 | 55,843 |
| Total | 3,463,331 | 760,065 |

Table 1: Statistics of the first-stage parallel corpus.

### 2.2 Stage I: Parallel Data Construction

The first-stage training data are constructed from publicly available parallel corpora covering the four translation directions evaluated in our submission. Multiple open-source datasets are collected for each language pair, including news, subtitles, educational resources, encyclopedic text, software localization, and benchmark datasets. Since the quality of publicly available parallel corpora varies substantially across sources, we perform a unified preprocessing and quality filtering pipeline before model training.

**Data Preprocessing** We first conduct basic preprocessing to ensure sentence-level alignment and remove invalid training instances. This step includes alignment checking, removal of empty sentence pairs and control characters, normalization of text formatting, and language-specific cleaning for noisy resources such as subtitle corpora. Exact deduplication is then performed independently within each dataset to remove duplicated bilingual sentence pairs and duplicated monolingual entries introduced by corpus merging while preserving the original data order.

**Data Filtering** After preprocessing, all sentence pairs are scored using COMETKiwi-XL quality estimation (wmt23-cometkiwi-da-xl). Following the characteristics of different datasets, we adopt either language-pair-specific score thresholds or dataset-level top-ranking selection to retain high-quality translation pairs. Software localization datasets are filtered by retaining the highest-scoring half of the samples within each dataset split, while other datasets are filtered using fixed COMETKiwi-XL thresholds selected for each translation direction. The statistics of the resulting first-stage parallel corpus after quality filtering are summarized in Table 1. Finally, the retained bilingual sentence pairs are converted into a unified instruction-following dialogue format for supervised fine-tuning. The public datasets used for each translation direction are

summarized in Table 2. In addition to the filtered parallel corpora, the first-stage training data also include a collection of general translation instruction-following examples to improve the model's ability to follow translation requests with diverse instructions. The final first-stage corpus contains approximately 760k high-quality parallel sentence pairs together with 10.7k general translation instruction-following samples.

### 2.3 Stage II: Knowledge Distillation Data Construction

To further improve translation quality, we construct a knowledge-distilled parallel corpus from publicly available target-language monolingual datasets. The collected corpora cover diverse domains, including news, news commentary, online discussions, social media, spoken language, meeting conversations, and image captions. The monolingual datasets used for each translation direction are summarized in Table 3.

**Field Selection and Data Preparation** Public monolingual datasets typically contain multiple fields, including metadata, labels, multimedia content, and natural language text. We retain only text fields suitable for translation, such as article content, summaries, comments, transcripts, and image captions, while discarding non-textual information. The extracted texts are subsequently processed through text normalization, sentence segmentation for long documents or paragraphs, language filtering, duplicate removal, and domain-aware sampling to construct candidate monolingual corpora for knowledge distillation. The preprocessing strategy is adapted to the characteristics of each dataset while preserving high-quality natural language content.

| Instruction Category | Translation Constraint | Data Source |
|---|---|---|
| Immutable Entity Preservation | Preserve predefined entities verbatim | Do Not Change Me |
| Document-level Translation | Utilize document-level context | BWB, mZPRT, PDC |

**Knowledge Distillation** For each translation direction, a teacher translation model is employed to translate the prepared target-language texts into the corresponding source language. The generated source-language translations are then paired with the original target-language texts to construct the KD corpus. Finally, all translation pairs are converted into the unified instruction-following dialogue format adopted in Stage I for subsequent supervised fine-tuning.

**Data Filtering** To improve the quality of the KD corpus, we further filter the generated translation pairs. For the English-target translation directions, copied translations and highly similar source-target pairs are removed. For the Chinese–Japanese translation direction, abnormal generation patterns, such as refusal responses and incomplete outputs, are discarded. We additionally apply Qwen3 tokenizer-based length filtering by removing sentence pairs whose source or target side exceeds 512 tokens. The resulting KD corpus is used for the second-stage supervised fine-tuning, and its statistics are summarized in Table 5.

### 2.4 Instruction-following Data Construction

To improve the instruction-following capability of the translation model, we construct a unified instruction-following translation corpus covering multiple constrained translation scenarios. During data development, five instruction categories are designed, including immutable entity preservation, document-level translation, terminology-constrained translation, structured translation, and formula preservation. Following the requirements of the WMT26 General MT task, this paper focuses on immutable entity preservation, document-level translation, and structured translation, while the remaining instruction categories are omitted from the discussion. An overview of the constructed instruction-following data is presented in Table 4.

All instruction-following samples are represented using a unified instruction–input–output format. Each instruction consists of a task-specific constraint and a general translation instruction that specifies the translation direction. For both Chinese and English instructions, five semantically equivalent translation templates are designed and uniformly sampled using fixed random seeds to improve instruction diversity while maintaining reproducibility.

The instruction-following corpus is constructed from both publicly available bilingual datasets and automatically generated bilingual resources. For document-level translation, terminology-constrained translation, and structured translation, the original bilingual alignment is preserved throughout the construction process. For document-level translation, aligned documents are first segmented into pseudo-documents with a maximum length of 512 tokens while ensuring that each pseudo-document does not cross original document boundaries. To improve the model's robust-

| COMETKiwi-XL | | | | | | | | | |

| + Stage I + Stage II (Ours) | 51.71 | 50.35 | 47.12 | 43.27 | 48.11 | 36.50 | 27.72 | 22.20 | 28.81 |

**Note:** COMETKiwi-XL scores are computed using the `Unbabel/wmt23-cometkiwi-da-xl` quality estimation model (Rei et al., 2022). BLEU scores are reported using sp-BLEU (SentencePiece BLEU) (Goyal et al., 2022).

Table 7: Translation performance on Flores200 and WMT24++.

ness to different document organizations, each pseudo-document is randomly formatted into one of three variants, namely sentence-separated, space-separated, and newline-separated forms. For immutable entity preservation, English monolingual sentences collected from the Do Not Change Me dataset are translated into Chinese by a teacher model with customized system prompts that explicitly require predefined entities, including alphanumeric strings, URLs, email addresses, emojis, IP addresses, ISBNs, phone numbers, social media handles, and date expressions, to be preserved verbatim. The generated bilingual sentence pairs are subsequently expanded into both translation directions. Finally, all bilingual sentence pairs are converted into a unified instruction-following dialogue format using the corresponding task-specific instruction templates. This unified construction framework enables different translation constraints to share the same data representation while maintaining their task-specific instruction semantics, facilitating joint optimization within a single multilingual translation model.

### 2.5 Training and Inference

Our translation system is built upon Qwen3-8B (Yang et al., 2025) and optimized through a two-stage full-parameter supervised fine-tuning (SFT) strategy. The first stage uses the parallel corpus and instruction-following data, while the second stage further incorporates the knowledge-distilled corpus to improve translation quality while preserving instruction-following capability learned in the first stage across different translation directions. This two-stage training strategy enables the model to first acquire high-quality bilingual translation knowledge and subsequently benefit from large-scale synthetic parallel data.

Training is conducted using the LlamaFactory framework (Zheng et al., 2024) with full-parameter supervised fine-tuning. We employ the AdamW optimizer with a learning rate of $1 \times 10^{-5}$ and train the model for 2 epochs in each stage. All experiments are performed on eight NVIDIA A100 80GB GPUs using DeepSpeed ZeRO-2 optimization (Rajbhandari et al., 2020). The maximum sequence length is set to 2048 tokens. Additional training hyperparameters are summarized in Table 6.

During inference, we adopt deterministic decoding with a temperature of 0.0 for instruction-following data generation. For translation evaluation, decoding is performed with a maximum generation length of 2048 tokens. Unless otherwise specified, all experiments use the same inference configuration across different translation directions.

## 3 Main Results

Table 7 presents the translation performance of the base model, the Stage I model, and the final system after Stage II training on Flores200 devtest and WMT24++. The evaluation is conducted using the `Unbabel/wmt23-cometkiwi-da-xl` quality estimation model and sp-BLEU.

Compared with the base model, Stage I substantially improves translation quality across all four language directions on Flores200. The average COMETKiwi-XL score increases from 72.18 to 77.41, while the average sp-BLEU score improves from 24.47 to 39.99.

Further fine-tuning on the knowledge-distilled corpus improves the average performance of the Stage I model. After Stage II training, the average COMETKiwi-XL score on Flores200 further increases from 77.41 to 77.63, while the average sp-BLEU score reaches 48.11. On WMT24++, Stage II improves over Stage I on average for both metrics and achieves the best overall sp-BLEU score, although its average COMETKiwi-XL score remains below that of the base model. These results indicate that the synthetic parallel data constructed from high-quality monolingual corpora effectively complements the bilingual parallel corpus and further enhances multilingual translation performance.

## 4 Conclusion

In this paper, we present TransCore, our submission to the constrained track of the WMT26 General Machine Translation Shared Task. Our system is built upon Qwen3-8B and adopts a two-stage supervised fine-tuning framework. We construct a high-quality training corpus consisting of carefully curated parallel data, knowledge-distilled data, and instruction-following data. To support the instruction-following evaluation introduced in WMT26, we further construct a unified instruction-following data construction framework covering immutable entity preservation, document-level translation, and structured translation. The proposed data construction pipeline provides a practical data construction strategy for multilingual LLM-based machine translation under the WMT26 instruction-following setting. Future work will investigate more effective multilingual data construction, synthetic data generation, and instruction-following optimization for LLM-based machine translation.

## Abstract

Despite the growing demand for multilingual game localization, systematic evaluation frameworks for game translation constraints remain largely unexplored. As part of the WMT26 Test Suite Track, we propose **KUEST**, a test suite comprising 1,796 English-to-Korean segments across four core categories, and evaluate 27 submitted systems. Experimental results demonstrate that standard metrics obscure true model capabilities (e.g., the overall 1st-place system dropping to 15th in creative translation). Furthermore, we reveal residual capability fragmentation—category-specific variance that survives the shared general-competence factor and inverts top-tier rankings—and observe a "prompt gap" where context metadata degrades performance. As such, KUEST serves not only as a test suite but also as an evaluation framework that multi-dimensionally dissects domain-specific translation blind spots hidden behind single composite scores. The dataset is available at JudyChoi/KUEST[1].

## 1 Introduction

Recent advancements in large language models (LLMs) have transformed the machine translation paradigm (Kocmi et al., 2024), a trend particularly prominent in the video game industry, which faces tight schedules and massive multilingual demands (Bernal-Merino, 2015; Hansen and Houlmont, 2022).

However, general-purpose translation and video game translation require that we "mind the gap" between their distinct domain requirements. Game localization entails multi-faceted constraints, including: (1) strict compliance with canonical glossaries (Post and Vilar, 2018; Dinu et al., 2019), (2) precise reproduction of colloquial nuances reflecting speaker personas and interaction contexts (Shterionov et al., 2020), (3) robustness under technical constraints such as UI length limits and markup tag preservation (Specia et al., 2021), and (4) cultural transcreation tailored for resonance and appropriateness (Mangiron, 2016).

These unique characteristics create critical "blind spots" uncaptured by conventional translation evaluation methodologies. To bridge this gap, we propose **KUEST** (**K**orean game **U**sage **E**valuation **S**uite for LLM **T**ranslation) as part of the WMT26 Test Suite Track. KUEST comprises 1,796 English–Korean (En–Ko) game source segments, evaluating system performance across four primary axes:

- **Terminology & Accuracy (TA) (331 segments):** Canonical glossary compliance and word sense disambiguation.
- **Persona & Pragmatics (PP) (388 segments):** Consistency in speech styles and honorifics based on personas and relationships.
- **Technical Robustness (TR) (507 segments):** Placeholder/tag preservation and stability under UI length constraints.
- **Cultural Transcreation (CT) (570 segments):** Cultural adaptation capabilities, including idioms, contextual rendering of hate speech, and gender-neutral translation.

This study proposes an evaluation framework utilizing KUEST to assess 27 system outputs provided by WMT according to the specific characteristics of each category.

## 2 Related Work

### 2.1 Background and Evaluation Methods in Game Translation

Game translation simultaneously demands adherence to technical constraints and creative rewriting across UI, system messages, and narrative (Mangiron and O'Hagan, 2006; Bernal-Merino, 2015). However, prior studies faced challenges in operationalizing these requirements into evaluation criteria, while surface-level metrics and LLM-as-a-Judge approaches fail to deliver consistent evaluations (Moghe et al., 2025).

While reference-free LLM evaluation methods such as GEMBA (Kocmi and Federmann, 2023) have been proposed, KUEST adopts a hybrid evaluation paradigm—combining rule-based verification with LLM-as-a-Judge—to overcome the limitations of single-score reductions. Specifically, it applies rule-based metrics to formal constraints and category-specific rubrics to semantic judgments.

### 2.2 Phenomenon-Based Test Suites and KUEST

Test suites isolate fine-grained translation errors that are difficult to diagnose via corpus-level average scores (King and Falkedal, 1990; Isabelle et al., 2017; Macketanz et al., 2018). KUEST adopts this approach to evaluate system capabilities across four core domains:

- **Terminology & Accuracy (TA):** Evaluates contextual Word Sense Disambiguation (WSD) (Raganato et al., 2019) and canonical glossary integration under constrained decoding (Post and Vilar, 2018; Dinu et al., 2019).
- **Persona & Pragmatics (PP):** Assesses Korean honorific consistency and sentence-ending styles based on speaker–listener relationships and discourse contexts (Sohn, 1999; Hwang et al., 2021; Nădejde et al., 2022).
- **Technical Robustness (TR):** Evaluates markup tag preservation (Hanneman and Dinu, 2020), UI length constraint management, and complex structural constraints (Lakew et al., 2019; Zhang et al., 2023).
- **Cultural Transcreation (CT):** Assesses creative rewriting of proper nouns/wordplay (Mangiron and O'Hagan, 2006) and sensitive content adaptation, including gender bias mitigation (Savoldi et al., 2021) and toxicity contextualization (Costa-jussà et al., 2023).

While phenomenon-based evaluation is crucial for game translation, standardized test suites remain lacking. To bridge this gap, we present KUEST, a domain-specific test suite evaluated via a hybrid rule-LLM approach across four target domains (Section 3).

## 3 Test Suite Creation

This section describes the construction process of KUEST, designed to evaluate the multi-faceted challenges of game translation.

### 3.1 Raw Data Preprocessing

Game texts generally fall into two primary categories: functional system texts and narrative dialogue. Accordingly, we select two open-source games that represent each axis and align with WMT26 licensing guidelines as our source data:

- **CDDA**[2]: Focuses on functional content, including extensive item descriptions, crafting recipes, and UI elements (average segment length: 38.0 English characters). Approximately 8.0% of segments contain format specifiers (e.g., `%s`, `%d`), making CDDA a primary source for Technical Robustness (TR) segments.
- **Wesnoth**[3]: Focuses on NPC dialogue-driven narrative texts, incorporating 32 mainline text domains with longer segments (average length: 60.8 English characters). Rich speaker metadata (e.g., `[message] speaker=...`) and distinct fantasy tones render it ideal for Persona & Pragmatics (PP) and Cultural Transcreation (CT) segments.

To eliminate reference noise and ensure evaluation reliability, the raw data underwent a two-stage refinement process: (1) removal of untranslated segments (i.e., source strings without corresponding target texts), and (2) removal of fuzzy-flagged segments, which represent tentative translations generated by automatic matching rather than confirmed ones. Both types were fully discarded from the evaluation dataset.

[2]Cataclysm: Dark Days Ahead: https://github.com/harakka/Cataclysm-DDA/blob/6d7c916b46516779c1d5c3ecfc8840ba7d8c108d/lang/po/ko.po

[3]The Battle for Wesnoth: https://github.com/wesnoth/wesnoth/tree/master/po

Table 1: Preprocessing statistics of raw data

| Filter Stage / Metric | CDDA | Wesnoth |
|---|---|---|
| Total Segments (Non-obsolete) | 11,239 | 26,310 |
| (1) Removed Untranslated | -684 | -18,706 |
| (2) Removed Fuzzy Flags | -1,869 | -2,088 |
| **Final Cleaned 1:1 Pairs** | **8,686** | **5,516** |
| Avg. Length (En / Ko) | 38.0 / 21.5 | 60.8 / 36.3 |
| Format Codes (%s / %d) | 8.0% | 0.1% |
| Text Type | UI Item labels | Dialogue Narrative |

### 3.2 Evaluation Categories

#### 3.2.1 Terminology & Accuracy (TA)

Evaluates adherence to domain-specific glossaries and the disambiguation of context-dependent terms (331 segments in total).

- **Glossary Compliance (264 segments):** Evaluates domain glossary adherence, constructed through a 3-stage pipeline of candidate mining, statistical canonical determination, and human inspection.
- **Polysemy (67 segments):** Verifies contextual word sense disambiguation using 19 polysemous words whose meanings shift according to context.

#### 3.2.2 Persona & Pragmatics (PP)

Evaluates Korean speech style consistency (sentence-final honorifics and formality) across speaker role tiers (e.g., Royalty, Military, Commoner) and relational contexts (388 segments).

- **Dual-Prompt Structure:** Evaluates models under a metadata-free *Baseline* and a *Regime R* with factual relational info. Without explicit style directives, it measures autonomous speech style selection across 97 dialogue pairs (2 prompt regimes $\times$ 2 directions = 388 segments).

#### 3.2.3 Technical Robustness (TR)

Evaluates the model's robustness and adherence to technical constraints required by game engines and UI frameworks (507 segments in total).

- **Placeholder Reordering (362 segments):** Measures adaptability to syntactic variations of formatting codes (%s, %d) and variables, split into Consistency (172 segments) and Diverse (190 segments) sets.
- **Tag Preservation (95 segments):** Validates the structural integrity of HTML/XML markup tags.
- **Length Constraint (50 segments):** Evaluates text overflow control using actual font-rendered pixel widths rather than simple character counts, explicitly filtering for cases where Korean rendering width exceeds English ($ko\_width > en\_width$).

#### 3.2.4 Cultural Transcreation (CT)

Evaluates cultural adaptation capabilities tailored to Korean cultural contexts and gaming sentiments, moving beyond literal translation (8 subcategories, 570 segments in total).

- **Speech Style Adaptation (273 segments):** Evaluates macro-styles (Archaic, Honorific, Colloquial) and sentence-final morpheme choices.
- **Wordplay (88 segments):** Evaluates the adaptation of linguistic humor, onomatopoeia, and visual sound effects created via deconstructed Hangul characters.
- **Hate Speech (56 segments):** Captures emotional intensity and lexical variety in profanity and derogatory expressions.
- **Naming Transcreation (45 segments):** Evaluates world-building name adaptation for character/race names and items.
- **Interjection (39 segments):** Assesses natural realization of exclamations and vocalized reactions.
- **Cultural Reference (33 segments):** Evaluates Korean transcreation of culture-specific Western terms.
- **Gender Stereotyping (20 segments):** Diagnoses gender bias in translation and evaluates neutral expression choices.
- **Idiom & Proverb (16 segments):** Evaluates the concise adaptation of English expressions into culturally equivalent Korean idioms and proverbs.

## 4 Automatic Evaluation Metrics

We establish a panel of four automated metrics combining reference-based metrics (BLEU, COMET) and reference-free Quality Estimation (QE) metrics (CometKiwi, MetricX). To mitigate the under-estimation tendency of reference-based metrics in game localization—where cultural transcreation is frequent—QE metrics provide complementary signals.

- **BLEU** (Papineni et al., 2002): Precision-based $n$-gram lexical overlap (↑).
- **COMET-22** (Rei et al., 2022b): Neural reference-based metric fine-tuned on human quality judgments (↑).
- **CometKiwi** (Rei et al., 2022a): Reference-free QE metric predicting quality directly from source and hypothesis (↑).
- **MetricX** (Juraska et al., 2024): mT5-based quality estimation metric predicting error severity (↓).

Because these metrics differ in scale, direction, and reference dependency, raw scores cannot be directly averaged. In §6.1, scores are converted to category-specific ranks for aggregation, while discrepancies between reference-based and QE metrics are analyzed in §6.3.

## 5 Category-Specific Evaluation Protocols

In this section, we describe a hybrid evaluation pipeline tailored to the characteristics of the four primary categories, employing Claude Sonnet 5 as the judge to mitigate self-preference bias in LLM-as-a-Judge evaluations (see Appendix A for model selection rationale, and Appendix B for a human meta-evaluation validating the judge against a three-annotator panel).

### 5.1 Terminology & Accuracy (TA)

This category evaluates whether target vocabulary is correctly reflected based on clear ground-truth criteria (canonical terms or polysemous contexts).

**Rule-based evaluation:** Evaluates translations in two stages. First, after minimal normalization (removing whitespace and punctuation), it checks whether the target vocabulary appears as a substring. If it fails, it proceeds to the second stage, extracting nominal lemmas (common nouns, proper nouns, foreign words) using a morphological analyzer to verify if the target lemma combination is present. Passing either stage grants a score of 1.

**LLM-as-a-Judge:** Claude Sonnet 5 judges correctness (0 or 1) per segment, tolerating flexible Korean spacing and morphological variations while strictly penalizing semantic drift.

### 5.2 Persona & Pragmatics (PP)

This category contrasts performance between the baseline and Regime R augmented with contextual metadata to measure the "prompt gap" indicating socio-linguistic blind spots. Following the GEMBA framework (Kocmi and Federmann, 2023), a zero-shot LLM-as-a-Judge protocol using Claude Sonnet 5 is adopted (Zheng et al., 2023). Source meaning and speech acts serve as primary criteria, while reference translations act only as observable examples.

**Rubric-based LLM-as-a-Judge:** Evaluates meaning preservation, register appropriateness, and naturalness using 5-point mapped labels.

**Excessive Over-Persona Handling:** Strong expressions supported by context (e.g., urgent military tones) are accepted. Conversely, unsupported emotional additions or extreme registers (e.g., overly archaic endings) are penalized as unwarranted meaning additions. Evaluators prioritize overall discourse naturalness over single sentence-final endings.

### 5.3 Technical Robustness (TR)

This category focuses on pass/fail compliance with game engine and UI constraints, applying a conservative LLM-as-a-Judge exclusively to segments that pass prior rule-based verification to binarily verify meaning preservation while preventing formally compliant semantic distortion.

**Step 1: Rule-based Verification**

- **Placeholder Integrity:** It checks for missing or corrupted tokens such as `%s` or `$var`, while permitting particle attachments (e.g., `%s`이(가)) following Korean localization conventions and deferring token reordering verification to the second-stage judgment.
- **Tag Integrity:** For paired closing tags such as `<i>`, `<b>`, and `<span>`, it inspects inventory matching (type and count) and stack-based well-formedness, while prohibiting empty spans (`<i></i>`).
- **Length Constraint:** Computes terminal cell width based on East Asian character widths. Scores are defined as:

$$\text{width\_score} = \min\left(1,\ \frac{\theta \cdot w_{\text{base}}}{w_{\text{hyp}}}\right),\quad \theta = 1.75$$

  where the tolerance multiplier $\theta$ is set based on the minimum ratio passing all reference texts (50/50).

**Step 2: Binding Check** For segments that pass rule-based verification, an LLM-as-a-Judge evaluates whether the elements properly correspond to the source argument structure without considering

surface fluency or reordering, assigning a binary score (`correct_binding` = 1 or 0).

### 5.4 Cultural Transcreation (CT)

CT measures localization adaptation tailored to Korean gamers, moving beyond literal translation. All sub-categories are evaluated using Claude Sonnet 5 via a 5-point LLM-as-a-Judge rubric.

- **Wordplay, Interjection:** Evaluates acoustic/morphological reproduction and creativity, penalizing copy bias, transliteration bias, and expression flattening.
- **Naming Transcreation, Cultural Reference, Idiom & Proverb:** Evaluates idiomaticity and genre appropriateness to evaluate context-aware localized adaptation.
- **Speech Style Adaptation:** Evaluates macro-styles (Step 1, weighted 40%) and marker realization (Step 2, weighted 60%) in a hierarchical dual structure.
- **Hate Speech & Gender Stereotyping:** Evaluates source-grounded equivalence rather than reference match, since reference translations often contain sanitization or gender biases.

## 6 Experiment Results and Analysis

This section presents an in-depth evaluation of the 27 translation systems using KUEST. We report automated metric results in §6.1, detail category-specific evaluations in §6.2, and discuss key insights in §6.3.

### 6.1 Metrics

Table 3 presents the performance of 27 evaluated systems across KUEST's four primary categories using automatic metrics (BLEU, COMET, CometKiwi, and MetricX), along with their overall ranks calculated across all 16 category-metric combinations.

**Overall Rank:** SRPOL achieved the top overall position among all 27 systems with an average rank of 6.44. It was closely followed by GPT-5.5 (6.94), GoogleTranslate (7.12), and Wayfinder (7.50), together forming the top tier. The lowest-ranked Gemini 3.1 Pro suffered from reasoning artifacts leaking into the output, resulting in translation lengths roughly 16 times that of the reference and severely degrading its evaluation scores.

**Divergence Between Standard and QE Metrics:**

- **Lexical & Neural Metrics(BLEU/COMET):** Systems such as Dubformer (TA BLEU: 37.9, COMET: 87.0), GPT-5.5 (PP BLEU: 17.7, COMET: 87.5; TR BLEU: 29.3, COMET: 82.4), and TRIVE (CT BLEU: 17.9) recorded the highest scores, demonstrating strong lexical and semantic similarity to reference translations.
- **Reference-Free QE Metrics (CometKiwi/MetricX):** SRPOL consistently outperformed other systems across all four categories in CometKiwi (TA: 82.9, PP: 85.8, TR: 78.5, CT: 81.7) and three categories in MetricX (TA: 2.37, PP: 2.53, CT: 2.77). This demonstrates SRPOL's distinct strength in standalone translation completion and error control, independent of lexical similarity to reference translations.

**Category-Specific Characteristics:** In the TR (Technical Robustness) category, GoogleTranslate recorded the lowest error rate with a MetricX score of 3.27. In the CT (Cultural Transcreation) category, rank fluctuations between traditional metrics (BLEU/COMET) and QE metrics (CometKiwi/MetricX) were most pronounced, confirming a substantial divergence in metric perspectives when evaluating game-specific transcreation elements.

### 6.2 Evaluation Results and Analysis by Category

#### 6.2.1 Terminology & Accuracy (TA)

In this category, we deeply analyze and compare the performance of 27 translation systems from two perspectives: string-matching-based rule validation and flexible context-understanding-based LLM-as-a-Judge validation.

**Limitations of the Rule-Based Approach:** Rule-based validation strictly recognizes exact string matches with the designated glossary. While Gemini 3.1 Pro achieved the highest score on the Rule axis by most conservatively and accurately reflecting the provided glossary without modification, it exhibits a limitation of failing Rule evaluation when flexible contextual paraphrasing or inflectional variations are applied.

**Synonym and Paraphrase Acceptability in LLM-as-a-Judge:** This approach evaluates translations based on semantic validity rather than strict keyword inclusion, assessing whether

polysemous expressions carry the correct contextual sense. Systems such as Dubformer and Qingqiu-MT-9B actively utilized natural synonyms and paraphrases tailored to the gaming context despite slightly lower surface-level lexical match rates, thereby earning higher scores in the LLM-as-a-Judge evaluation, which recognizes contextual validity.

#### 6.2.2 Persona & Pragmatics (PP)

We evaluated 388 segments (totaling 5,238 corresponding pairs across 27 systems) under Baseline and Regime R environments using a 5-point rubric. While 51.6% (2,705 cases) received identical scores across both conditions, among the remaining 2,533 divergent cases, Baseline outperformed Regime R in 1,309 cases compared to 1,224. Although 19 out of 27 models exhibited a negative prompt gap, the overall average scores were identical across both conditions (3.786 each). This is a statistical artifact caused by Gemini 3.1 Pro, whose reasoning leakage (+2.660) masked the negative gaps of other models. Excluding this outlier, the Baseline average (3.871) exceeded that of Regime R (3.769), with the Baseline achieving a win rate of 55.4%.

**Over-integration of Speaker Information:** The reduction of neutral translations (scored as 3) from 381 to 248 cases indicates that models actively incorporated the provided metadata; however, this shift migrated toward 2-point scores rather than 5-point scores (increasing from 629 to 878 cases). The primary reasons for penalty deductions were tone/formality mismatch (34.6%), semantic and speech-act errors (32.5%), and excessive archaic or over-referential honorific registers (12.8%). This suggests that models treated social status tags as deterministic lookup tables for sentence endings, causing the original semantic meaning and speech intention to be subordinated to the tags. For instance, a commoner's utterance *"What be your pursuits?"* shifted from "당신이 추구하는 바는 무엇인가요?" (*"What is it that you pursue?"*, scored as 4) to "네 일은 뭐야?" (*"What's your job?"*, scored as 3). Similarly, for Lady Jessene, a royal female speaker, *"What? Why would you doubt me?"* shifted from "뭐? 왜 날 의심하는 거야?" (*"What? Why do you doubt me?"*, scored as 4) to "뭐라? 어찌 나를 의심하는가?" (*"What sayest thou? Wherefore dost thou doubt me?"*, scored as 2), over-applying a gender-neutral archaic written style.

**Utterance-Length-Dependent Effects:** In 9.7% (507 cases) of the total benchmark, outputs from both conditions were completely identical. For example, *"Harper, no!"* yielded identical translations across 19 out of 27 systems, with short utterances limiting metadata capacity and driving convergence between conditions.

**Model Disparity in Metadata Integration:** Within the same model family, GPT OSS 20B degraded significantly by $-0.418$, whereas the 120B variant maintained its performance at $+0.015$. Similarly, among 9B translation-specialized models, Tower 9B ($+0.067$) and Qingqiu-MT-9B ($-0.335$) demonstrated opposite trajectories. Since all four systems generated substantial output differences across conditions, this disparity cannot be attributed to a simple failure to follow prompt instructions. Therefore, this gap stems not merely from parameter scale or translation specialization, but rather from intrinsic differences in model capability to sophisticatedly select and integrate provided contextual metadata.

#### 6.2.3 Technical Robustness (TR)

We evaluated the ability of models to adhere to technical constraints across 507 segments.

**Overwhelming Constraint Compliance of Top-Tier Models:** As shown in Figure 4, commercial frontier models and domain-specific models demonstrated strong performance, recording overwhelming constraint compliance rates of over 95%. GPT-5.5 achieved the highest score with 504 passes (99.4%), followed by TRIVE (502, 99.0%), Wayfinder (500, 98.6%), HW-TSC (496, 97.8%), and Qingqiu-MT-9B (496, 97.8%).

**Difficulty Gaps Across Evaluation Types:** Among the four evaluation types, the largest performance gap between models appeared in tag preservation (average pass rates: placeholder-consistency 89.3%, placeholder-diverse 90.1%, tag preservation 71.1%, length constraint 91.7%). In particular, out of 95 tag preservation items, Tower 9B and Qwen-3.5-9B passed only 15 items, Qwen-3.6-27B passed 41, and GoogleTranslate passed 57, showing a stark contrast between lower- and upper-tier models, whereas top-tier models successfully passed most tag and length constraint items.

**Major Failure Types:** Tag deletion, placeholder omission/ addition, and the generation of extraneous explanations were repeatedly observed. GoogleTranslate and the Qwen series exhibited numerous cases of $< i >$ and $< b >$ tag removal; GPT OSS 20B showed placeholder omissions and the arbitrary introduction of positional placeholders; and Gemini 3.1 Pro generated alternative translations and explanations alongside the output, leading to added placeholders and tags as well as length constraint violations. In contrast, GPT-5.5 successfully passed all formatting rules, recording only 3 semantic binding errors.

#### 6.2.4 Cultural Transcreation (CT)

We evaluated cultural transcreation performance—going beyond literal translation to recreate the cultural background and nuances of the source text to fit the target culture—highlighting performance gaps across subcategories and style flattening in Hate Speech.

**Performance Gaps Across Sub-Categories:** Performance patterns varied significantly across sub-categories. Top models achieved near-perfect scores in Idiom/Proverb (top: 4.81), Wordplay (top: 4.80), and Interjection (top: 4.74). Conversely, scores remained in lower ranges for Cultural Reference (top: 2.91), Naming Transcreation (top: 3.02), and Speech Style Adaptation (top: 3.28). This suggests that for open-ended tasks governed by strict contextual constraints, fine-grained multi-criteria evaluation inherently leads to more conservative score distributions.

**Style Flattening in Adaptive and Sensitive Contexts:** Even when the core meaning of the source text was preserved, a widespread tendency to soften the intensity of profanity, derogatory expressions, and character traits was frequently observed. While this style flattening is also observable in Speech Style Adaptation, it becomes particularly pronounced in the Hate Speech category. Out of 1,512 total outputs in Hate Speech, 408 (27.0%) were classified as `bleached`, with certain items showing the same softening trend across up to 26 systems, indicating a widespread model-wide phenomenon (See Table 12.) Meanwhile, given that the evaluator, Claude, is based on Constitutional AI (Bai et al., 2022), potential intervention from safety alignment cannot be ruled out.

### 6.3 Discussion

The evaluation results of this study suggest that automatic metrics have clear limitations in diagnosing compliance with key evaluation aspects. By contrasting the results of §6.1 and §6.2, we derive three key academic implications as follows.

**Distortion of Rankings in Automated Evaluation Metrics:** Automated evaluation metrics pose a significant risk of distorting actual performance. For instance, SRPOL, which ranked 1st overall in §6.1 due to the illusion of reference-free QE metrics, fell to 15th (3.29/5) in the in-depth CT evaluation (§6.2.4). Conversely, UvA-MT and TRIVE, which ranked 17th and 10th respectively under automated metrics, bounced back to 2nd (3.92/5) and 1st (3.96/5) in CT evaluation. This demonstrates that automated evaluation metrics—including surface-level similarity measures like BLEU—fail to fully capture creative translation quality. Furthermore, it reveals that KUEST effectively exposes domain constraint adherence that these automated metrics overlook.

**Residual Category-Specific Variance:** Strong systems tend to be strong everywhere, and rank inversions across the four KUEST categories are the exception rather than the rule. Against that backdrop, we reveal residual capability fragmentation—category-specific variance that survives the shared general-competence factor and inverts top-tier rankings. Dubformer ranks 1st in TA (75.2%) but 8th in TR, and TRIVE 1st in CT (3.96/5) but 5th in TA. KUEST categories are positively correlated ($\rho = 0.600$–$0.953$; see Table 13), and we do not claim independence: the sharing is uneven, with the weakest association observed between TA and TR ($\rho = 0.600$), and the rank inversions above occurring along these more weakly correlated category pairs. Our claim concerns residual variance sufficient to invert top-tier standings, where the cost is incurred—SRPOL ranks 1st on automatic metrics yet 15th in CT. Nor is the effect confined to the weakest-sharing pairs: HW-TSC falls from 4th in TR to 16th in CT even though that pair is closely aligned ($\rho = 0.861$). Taken together, these results show why a single composite score can hide which of several near-equal systems is right for a given localization task; dissecting performance by category, as KUEST does, is what makes that difference visible.

**System Landscape and Tier Analysis of 27 Systems:** The comprehensive positioning analysis in Figure 1 clearly reveals distinct characteristics across groups:

- **GenMT Participants:** The majority of translation-specialized models (e.g., TRIVE, Wayfinder, and Lumen) heavily populated the upper-right quadrant (Both strong), exhibiting consistently robust performance across evaluation axes.
- **Commercial & Proprietary Models:** Except for GPT-5.5, the remaining commercial offerings are predominantly MT-specialized Models (e.g., Dubformer and GoogleTranslate), which maintained high positions across both axes regardless of model tier. Conversely, Gemini 3.1 Pro recorded the lowest evaluation due to the leakage of reasoning tokens. This suggests that robust overall translation capability and decoding stability are far more decisive than model scale alone in balancing the dual demands of game translation and adaptation: strict rule compliance and flexible contextual transcreation.
- **Open-Weights LLM Baselines:** With a few high-capacity exceptions such as DeepSeek V4 Pro and Gemma 4-31B, the vast majority of general open-weights baselines remained in the lower-left quadrant (*Both weak*). This underscores the inherent limitations of general-purpose LLMs without explicit translation-specific tuning or game domain adaptation.

## 7 Conclusions

This study establishes three key contributions through KUEST, a benchmark designed to diagnose the complex constraints of game localization:

1. **Demonstration of the Fallacy of Metrics:** We show that standard machine translation and general QE metrics fail to represent performance in cultural adaptation (CT) and technical rule compliance (TR), inducing severe ranking distortions.

2. **Residual Category-Specific Variance:** We identified that beyond a shared general-competence factor, category-specific variance remains large enough to invert top-tier rankings, as model strengths and limitations manifest depending on the evaluation dimension.

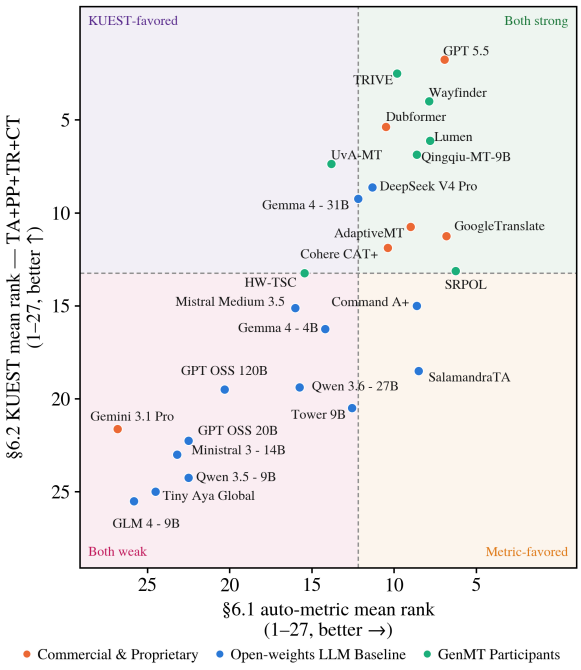

Figure 1: Tier map of the 27 systems. The x-axis represents the average rank based on automatic metrics (§6.1), and the y-axis represents the average rank based on **KUEST** (§6.2) (ranging from 1 to 27, with the top-right indicating better performance). Dotted lines divide the four quadrants based on the median rank of each axis.

3. **Identification of the Prompt Gap:** By observing performance degradation in numerous systems when incorporating speaker and relationship metadata, we revealed persistent sociolinguistic blind spots in LLMs' conditional instruction-following capabilities.

## 8 Limitations and Future Work

Despite these meaningful contributions, this study has limitations in terms of genre and text type diversity, as it focused exclusively on a single English-Korean language pair and two open-source games (CDDA and Wesnoth). In future work, we aim to incorporate license-compatible open-source games to expand **KUEST** into a genre-comprehensive general game test suite. Furthermore, we intend to extend the target language pairs to multilingual settings to rigorously verify whether the dataset construction methodology and evaluation framework proposed in this work are equally applicable across diverse linguistic environments.

## Acknowledgements

The authors would like to thank **Yongrae Jo**[4] for his valuable advice and insightful feedback throughout this research. We also thank **Pseudo Lab**[5], a non-profit AI/ML research community, for providing the collaborative environment that brought the authors together and enabled this research. This research was supported by the **"Open Source AI · SW Developer and Community Support Program"** funded by the **Ministry of Science and ICT (MSIT), Republic of Korea.**

## A Evaluator Model Selection Rationale

The theoretical rationale for selecting Claude Sonnet 5 as the primary evaluator model in our LLM-as-a-Judge protocol is as follows:

**Exclusion of Self-Preference Bias** While GPT-4-class models have served as the de facto standard evaluators in machine translation literature (Kocmi and Federmann, 2023), the systems benchmarked in this leaderboard are constructed from 27 translation systems that officially participated in the WMT Shared Task (Kocmi et al., 2024). Prior studies demonstrate that LLM evaluators exhibit a marked "self-preference" bias, systematically favoring outputs generated by models of the same architecture or model family (Panickssery et al., 2024; Zheng et al., 2023). Notably, the official WMT submission roster contains no models from Anthropic's Claude family. By appointing Claude —a frontier model completely independent from the WMT candidate pool—as the final judge, we reduce the risk of potential evaluation contamination and self-preference biases that could arise when employing GPT, Gemini, or DeepSeek models. Furthermore, this choice aligns with recent trends in the WMT metric pipeline that advocate diversifying evaluation frameworks beyond reliance on a single GPT judge (Kocmi et al., 2025).

**Rationale for Claude Sonnet 5 Selection** Within the Claude family, Sonnet was selected over the highest-tier Opus model to balance cost-efficiency and throughput across leaderboard-scale evaluations. Claude Sonnet 5 operates as a highly capable "workhorse" model equipped with strong reasoning capabilities, consistent with the standard practice of employing this model tier for large-scale benchmark evaluations. Additionally, a qualitative human review conducted on a sample subset revealed that the judgment quality between Opus and Sonnet remained substantially comparable, serving as supporting evidence for prioritizing Sonnet.

## B Human Evaluation for LLM-as-a-Judge Validation

### B.1 System Selection

To validate the reliability of the LLM-as-a-Judge (Claude Sonnet 5), we conduct a human meta-evaluation comparing judge scores with human ratings. Evaluating all 27 systems would require substantial annotation cost. We therefore select three representative systems based on three criteria: coverage of the quality spectrum, validity of translation outputs, and diversity of MT system families.

**Coverage of the quality spectrum.** Rank-based agreement can be attenuated under range restriction when evaluated systems occupy a narrow quality range. We therefore select one system from each of the top, middle, and bottom tiers of the overall KUEST ranking (Table 15): GPT-5.5 (1st), GoogleTranslate (12th), and Qwen-3.5-9B (25th). This selection spans a wide range of system quality, providing sufficient variation to assess agreement between LLM-as-a-Judge scores and human judgments.

**Valid translation outputs.** We exclude systems whose low scores are driven primarily by output collapse rather than translation quality. Gemini-3.1-Pro leaks reasoning traces, inflating its outputs to roughly 16 times the reference length (§6.1), while GLM-4-9B leaks reasoning in about 5% of its segments. Including such systems would allow humans and the judge to agree simply because the outputs are unusable, without testing whether the judge can discriminate along the rubric. All three selected systems produce valid translations; even the lowest-ranked, Qwen-3.5-9B, shows no reasoning leakage and only about 1.5% polite refusals on profanity items. These cases therefore provide meaningful evidence of rubric-level judging rather than output-collapse detection.

**Coverage of distinct MT system families.** The three systems represent distinct system families: a frontier LLM (GPT-5.5), a commercial machine translation system (GoogleTranslate), and an open-weight LLM (Qwen-3.5-9B). This diversity reduces the possibility that the meta-evaluation is specific to a single output style or model family.

### B.2 Sampling Procedure

We conducted stratified sampling across the 15 evaluation subcategories. Each subcategory received a minimum allocation of three instances to ensure coverage of low-resource phenomena, while the remaining samples were allocated proportionally to the original stratum sizes. This resulted in a 100-instance sample balancing phenomenon coverage and preservation of the overall benchmark distribution.

### B.3 Human Evaluation Setup

To validate the reliability of our LLM-as-a-Judge (LaaJ), we conducted a human meta-evaluation using the same evaluation rubric and scoring criteria as the LaaJ. Specifically, three human evaluators independently assessed the translations produced by the three selected systems on a stratified sample of 100 segments from the 1,796 segments in KUEST. The shared rubric and scoring criteria enable a direct comparison between human judgments and automated judge scores.

The human evaluation covered the same evaluation categories and subcategories as the LaaJ, with one exception. The *Length Constraint* subcategory under Technical Robustness (TR) was excluded from human evaluation because this subcategory was not evaluated by the LaaJ. Thus, the human meta-evaluation was restricted to dimensions for which corresponding LaaJ scores were available.

Each of the three evaluators independently assigned rubric-based scores to the sampled translations. These individual ratings were used both to measure inter-annotator agreement among human evaluators and to assess the agreement between human judgments and the LaaJ scores.

### B.4 Agreement Measures

Excluding *Length Constraint* removes 15 of the 300 segment–system pairs, leaving 285 rated items —108 on the binary Pass/Fail axes (TA, TR) and 177 on the 1–5 rubric axes (PP, CT). We report Krippendorff's $\alpha$—nominal on the binary axes and ordinal on the rubric axes—together with mean pairwise Spearman correlations and the two-way ICC$(2, \cdot)$ for the fixed panel of three annotators.

### B.5 Inter-Annotator Agreement

Human annotators agree closely on both scales (Table 2): $\alpha = 0.828$ on the binary axes and $\alpha = 0.807$ on the rubric axes, with ICC$(2, 1) = 0.820$ for a single annotator and ICC$(2, 3) = 0.932$ for the three-annotator mean. The human ratings therefore provide a stable reference for comparison with the LaaJ.

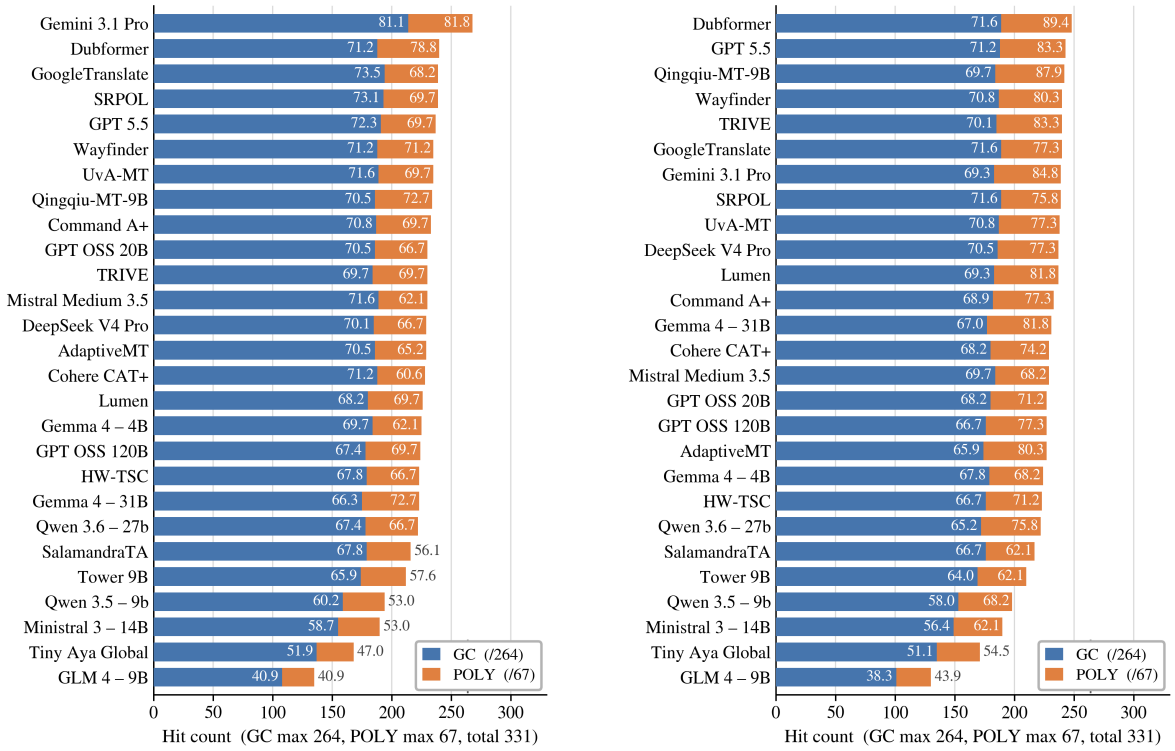
### B.6 Agreement with the LLM-as-a-Judge(LaaJ)

The LaaJ matches the human majority verdict on 82.4% of binary items and correlates with the three-annotator mean at $\rho = 0.773$ (MAE $= 0.61$; 83.6% of scores within one rubric point). Its mean pairwise correlation with individual human annotators is $\rho = 0.736$, somewhat below the human–human correlation of $\rho = 0.812$. The LaaJ score falls within the range of the three human annotators on 74.0% of items, compared with 76.3–81.9% pairwise range coverage among the human annotators. At the system level, the LaaJ preserves the same ranking as the human means, with slightly higher absolute scores (human means: 4.02/3.46/2.42; LaaJ: 4.14/3.70/2.49).

| Axis | $n$ | Human $\alpha$ | Human | LaaJ |
|---|---|---|---|---|
| *Binary axes* (agreement with majority verdict) | | | | |
| TA | 48 | 0.959 | 97.9–100% | 93.8% |
| TR | 60 | 0.622 | 83.3–100% | 73.3% |
| **All** | 108 | 0.828 | 89.8–100% | 82.4% |
| *Rubric axes* (mean pairwise Spearman $\rho$) | | | | |
| PP | 54 | 0.758 | 0.768 | 0.742 |
| CT | 123 | 0.836 | 0.840 | 0.721 |
| **All** | 177 | 0.807 | 0.812 | 0.736 |

Table 2: Human and LaaJ agreement. $\alpha$ is Krippendorff's $\alpha$ over the three annotators (nominal above, ordinal below). The last two columns report agreement with the human majority verdict in the upper panel, and mean pairwise Spearman correlations in the lower.

The only weak axis is TR, driven by placeholder reordering segments ($\alpha = 0.201$). The low coefficient contrasts with high human agreement: the three annotators gave unanimous ratings on 29 of 42 items, and all 13 disagreements were single-annotator dissents, 10 from the same annotator. This suggests a difference in annotator strictness rather than substantial item-level ambiguity. Accordingly, the LaaJ's TR results should be interpreted against this low-reliability human reference.



### B.7 Conclusion

Because no gold standard exists for rubric-based translation quality, human agreement provides the appropriate empirical reference for evaluating the LaaJ. Measured against it, the LaaJ agrees substantially with human judgments while showing somewhat greater variability than an individual annotator ($\rho = 0.736$ vs. $0.812$; inside the annotators' range on 74.0% of items vs. 76.3–81.9%), and it reproduces the human system ordering exactly. We therefore consider LaaJ scores reliable for the system-level and category-level comparisons reported in this paper, while not treating them as ground truth for individual segments, where a residual error of roughly one rubric point remains (MAE $= 0.61$).

Table 3: BLEU/COMET/CometKiwi(CKW)/MetricX(MetX) by category (TA/PP/TR/CT), 27 systems. MetricX is an error metric (lower is better); all others are higher-is-better. Bold = best in column. Overall = mean rank across the 16 (metric, category) columns (1–27, lower is better; ties receive the average rank).

(a) Rule-based Leaderboard

(b) LLM-as-a-Judge Leaderboard

**Figure 2:** Terminology & Accuracy (TA) evaluation results across 27 systems. Stacked bar charts show hit counts and percentages for Glossary Compliance and Polysemy, sorted by total hits.

(a) Baseline vs. Regime R Average Scores

(b) Prompt Effectiveness (Regime R − Baseline)

Figure 3: Evaluation results and prompt effectiveness in the Persona & Pragmatics (PP) category across 27 valid systems. (a) Average scores comparison between Baseline and Regime R. (b) Prompt effectiveness by system, where positive values (+) indicate the superiority of Regime R and negative values (-) indicate the superiority of the Baseline. A negative prompt gap—representing the dominance of the basic prompt—was observed across 19 models in total.

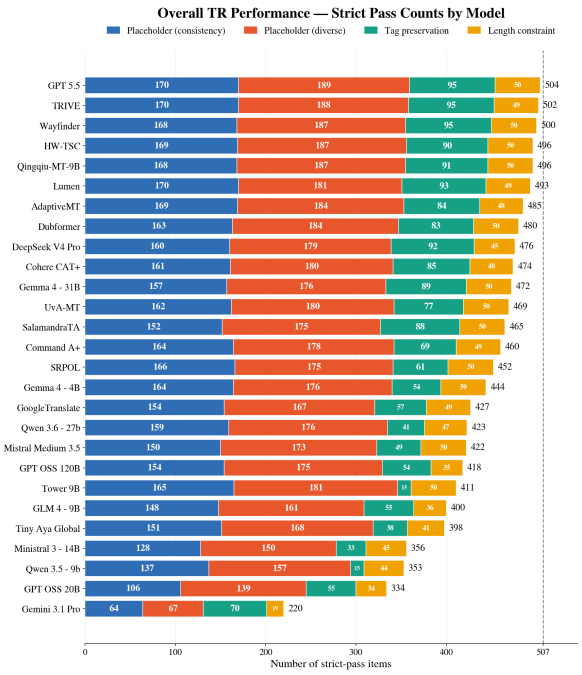

Figure 4: Cumulative bar chart of the number of items passing the strict conditions per model in the Technical Robustness (TR) category (Maximum score: 507). Each segment represents the sum of the number of strictly passed items for the two-stage checks—Placeholder (consistency), Placeholder (diverse), and Tag preservation—along with the number of items complying with the length constraint (width_score = 1).

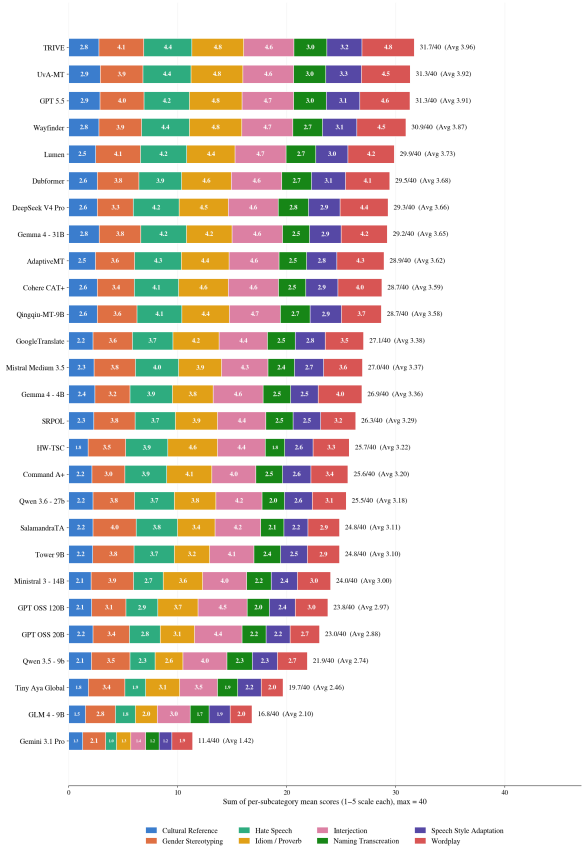

Figure 5: LLM-as-a-Judge leaderboard for Cultural Translation (CT). It displays the average scores (on a 1-5 scale) across the 8 sub-categories for 27 systems, stacked together. A larger total bar length (maximum 40) indicates superior overall performance. The systems are sorted in descending order by their overall rank, which is based on an equally weighted average across the eight sub-categories.

Table 12: Examples of style flattening for sensitive expressions. These represent typical cases within the Hate Speech sub-category where multiple systems reduced the intensity of curse words or pejorative terms from the source text. Here, the "Bleach System Count" denotes the number of system outputs out of 27 evaluated as bleached by the LLM-as-a-Judge for the given item.

| Doc ID | Source Text | Reference Text | System Output | Bleach | Judgment Summary |
|---|---|---|---|---|---|
| 038 | Our world fell apart because our leaders were as crooked as the con-men that paid for their elections. | 세상이 망해버린건 윗대가리가선거에서 표를 사는 망할 것들이기 때문이지. | GPT 5.5: 우리 세상이 무너진 건, 우리 지도자들이 자신들의 선거 자금을 대준 사기꾼들만큼이나 부패했기 때문이야. (Our world collapsed because our leaders were as corrupt as the con-men who funded their elections.) | 26/27 | The pejorative tone of "crooked" and "con-men" is neutralized into descriptive expressions like "corrupt leaders" and "con-men." |
| 041 | fuck no | 씨발 안돼 | SRPOL: 절대 안 돼 (Absolutely not) | 15/27 | The strong curse word "fuck" is completely omitted, leaving only a propositional negation. |
| 028 | God damn it! | 빌어먹을! | GoogleTranslate: 젠장! (Damn!) | 20/27 | The medium-intensity curse expression is replaced with a milder interjection, lowering the emotional intensity. |

# E Overall Rankings and Aggregation Sensitivity

## E.1 Complete System Rankings and Cross-Category Correlation

The overall rankings presented in the main text are computed based on the average rank (Mean Rank) across systems ranked 1st through 27th. Ranking ties are resolved using mean ranks. Table 13 and Table 14 show the Spearman rank correlation coefficients ($\rho$) across the four KUEST categories and the automated metrics.

Table 13: KUEST Inter-Category Rank Correlation (Spearman $\rho$, $n = 27$)

| Category | TA | PP | TR | CT | KUEST Overall |
|---|---|---|---|---|---|
| **TA** | — | +0.714 | +0.600 | +0.704 | +0.816 |
| **PP** | +0.714 | — | +0.909 | +0.953 | +0.970 |
| **TR** | +0.600 | +0.909 | — | +0.861 | +0.921 |
| **CT** | +0.704 | +0.953 | +0.861 | — | +0.958 |

Table 14: Automated Metrics vs. KUEST Rank Correlation (Spearman $\rho$, $n = 27$)

| Metric | ↔ Auto Overall | ↔ KUEST Overall |
|---|---|---|
| BLEU | +0.710 | +0.945 |
| COMET | +0.868 | +0.926 |
| CometKiwi | +0.894 | +0.449 |
| MetricX | +0.807 | +0.410 |
| **Combined (4 Metrics)** | — | **+0.727** |

## E.2 Aggregation Sensitivity: Z-Score-Based Re-Ranking

To evaluate whether the choice of rank aggregation (Mean Rank, **MR**) introduces bias by discarding score magnitude differences, we report alternative system rankings using identical input data with swapped aggregation formulas.

- **Evaluation Blocks:** Composed of the automated metrics block (**Auto**, 16 cells), the KUEST block (**KUEST**, 4 categories), and a 1:1 equal-weighted combined block (**Combined**).
- **Aggregation Formulas:**
  - **MR (Mean Rank):** Arithmetic mean of per-category ranks (baseline criterion; lower is better).
  - **z (Standard Z-Score):** Average of standardized z-scores (higher is better).
  - **rob-z (Robust Z-Score):** Standardized using median and MAD to mitigate distortion from extreme outliers (higher is better).

## E.3 Key Observations

- **High Invariance in KUEST Rankings ($\rho \geq 0.989$):** KUEST overall rankings demonstrate near-perfect consistency across all aggregation schemes. The top 5 systems ({`GPT 5.5`, `TRIVE`, `Wayfinder`, `Dubformer`, `Lumen`}) remain identical regardless of whether ranks or z-scores are used.
- **Robustness of Mean Rank Against Outliers:** Minor rank shifts observed under standard Z-scores in automated metrics are attributed to variance expansion caused by extreme length outliers in specific model outputs (e.g., verbose reasoning traces from Gemini 3.1 Pro). Applying an outlier-robust scheme (**Robust Z**) largely restores the default Mean Rank order ($\rho = 0.990$), supporting that Mean Rank is a structurally sound choice.
- **Distinct Evaluation Axes:** The correlation between Automated Metrics and KUEST remains moderate ($\rho = 0.727$) across all aggregation formulas, indicating that KUEST captures distinct evaluation axes that are unmeasured by standard metrics. Furthermore, the top 3 systems in the combined block (`GPT 5.5`, `Wayfinder`, `TRIVE`) consistently retain top positions across all formulas.

Table 15: Overall System Rankings Across Three Aggregation Schemes

| System | Auto MR | Auto z | Auto rob-z | KUEST MR | KUEST z | KUEST rob-z | Combined MR | Combined z |
|---|---|---|---|---|---|---|---|---|
| GPT 5.5 | 6.94 (2) | +0.632 (1) | +0.636 (5) | 1.75 (1) | +0.992 (1) | +0.961 (1) | 4.34 (1) | +0.812 (1) |

# Terminology Resources as (MT) Benchmarks: Evaluation of Legal Terminology Challenges in German Language Varieties by EURAC

**Paolo Di Natale**[1,2*], **Elena Chiocchetti**[2], **Natascia Ralli**[2], **Marlies Alber**[2], **Egon W. Stemle**[2,3]

## Abstract

Language varieties and dialects remain an open challenge for machine translation (MT). Plus, existing benchmarks rarely combine the evaluation of specific varieties with domain-specific knowledge. We introduce a termbase-derived MT benchmark for legal terminology across four German varieties: Germany, Austria, Switzerland, and South Tyrol (a low-resource German variety spoken in Italy). In the *inter-variety* setting, models translate Italian source sentences by selecting the correct South Tyrolean German term among semantically equivalent terms from other German varieties. In the *intra-variety* settings, we test sense disambiguation and ontological relation capabilities using homographic and ontologically related distractors for all four language varieties. We find that distinguishing language varieties remains difficult. High performance on low-resourced South Tyrolean terminology is partly driven by indirect exposure to terms shared with better-resourced varieties; when this overlap is removed, even the best-performing models collapse toward small models. We also find mild evidence of dominant-variety interference, although stronger systems more often err toward the geographically and culturally closer Austrian variety. Generally, locale-oriented adaptation appears more challenging than linguistic and semantic reasoning, where the ontological relation task is largely saturated and no generalized bias is shown against a specific variety. We conclude that model scaling mainly reinforces dominant language varieties and that LLM-based MT shifts part of the performance bottleneck from individual term rarity to the underrepresentation of domain-variety intersections across training and alignment stages.

## 1 Introduction

Recent WMT shared tasks have foregrounded language varieties and dialects as open challenges for general MT (Kocmi et al., 2024, 2025b) and MT evaluation (Lavie et al., 2025; Knowles et al., 2024). This is reflected in the growing adoption of more fine-grained language codes (Finkelstein et al., 2026), in the Open Language Data Initiative (Dale et al., 2025) to support the collection of multilingual resources for underserved languages and varieties, and in the Multilingual Instruction Shared Task (Kocmi et al., 2025a) for assessing locale-oriented generation. These initiatives have addressed persistent weaknesses in LLMs with respect to a long-standing problem in cross-lingual NLP (Zampieri et al., 2020).

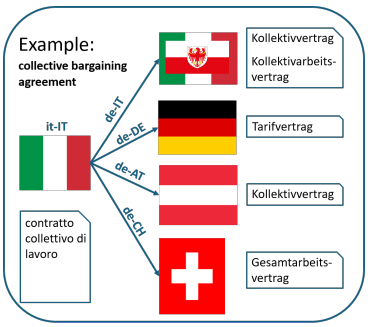

Figure 1: Example of term variation between varieties of German

The sparse and systematic signals of similar language varieties are notoriously complex to model with approaches other than n-gram-based algorithms (Jauhiainen et al., 2019) and even LLMs still lag behind smaller networks for language understanding tasks (Faisal and Anastasopoulos, 2025). Prior work suggests that such shortfalls originate in training data (Rystrøm et al., 2025), post-training alignment pipelines (Sahu et al., 2026), and evaluation protocols that are disproportionately English- and Western-centric (Singh et al., 2025b). Crucially, representing a language is not sufficient to represent its varieties. Benchmarks and datasets are often constructed at the language level, thereby collapsing dialectal, regional, and cultural varia-

tion into a single category (Plank, 2025; Gehrmann et al., 2023). This is particularly problematic for pluricentric languages that have several official standard varieties, where a shared language does not always equal a shared cultural or semantic ground (Chen et al., 2026). As a result, cultural misalignment is reflected in the loss of pragmatic markers and accessibility of culturally specific concepts (Kumar Navneet et al., 2026; Singh et al., 2025b). We posit that this loss may compromise conceptual accuracy to an ever greater extent in high-stakes domains like the legal one, that has notable social and economic relevance but where semantic misalignment can cause severe harm (Mattila, 2018).

We evaluate these limitations with a method based on structured terminological knowledge. We use *bistro*[1], an Italian-German legal terminology resource, as our knowledge base. It contains term equivalents, definitions, contexts of use, and other terminological information such as conceptual relations and usage notes. *bistro* covers the four German varieties used in Germany, Austria, Switzerland, and South Tyrol. The latter is a multilingual province in Italy where German is an officially recognized language with approximately 300,000 native speakers. This variety is low-resourced and lacks a dedicated ISO language code.

We process the termbase structure to derive a test set addressing three challenges. Each subset features an Italian source sentence and source term. Models are asked to produce a translation by selecting the appropriate term from challenge-motivated distractors. In the *inter-variety* setting, the LLM selects the correct South Tyrolean German equivalent from distractor terms belonging to other German varieties. Since these candidates designate equivalent concepts, they function as variety-specific distractors rather than semantic ones, the difference arising from distinct legal and institutional contexts (See Figure 1). In the two *intra-variety* settings, we assess model knowledge within each German variety through (1) sense disambiguation and (2) ontological relation tasks. In (1), the model chooses the German term corresponding to the intended sense of an ambiguous Italian term based on the sentential context. For example, *procedura concorsuale* should be rendered as *Insolvenzverfahren* (bankruptcy proceedings) in the context of commercial law and as *Wettbewerbsverfahren* (open competitive employment procedure) in administrative law. Whereas (2), tests whether models confuse the target term (e.g., *Strahlungsexposition* [exposure to radiation] in occupational health and safety) with ontologically related distractors such as hypernyms (e.g., *Exposition* [exposure]), co-hyponyms (e.g., *Lärmexposition* [exposure to noise]) or hyponyms (e.g., *UV-Exposition* [exposure to ultraviolet radiation]). This allows us to test whether variety-specific lexicalization affects the models' capability on linguistic and semantic challenges. Our findings are:

- Synthetic source sentences preserve term accuracy but inflate BLEU scores, meaning that they maintain the semantic cues needed for disambiguation while also making reference-based quality evaluation easier.
- Distinguishing South Tyrolean German from other German varieties remains challenging: even the strongest systems stay below saturation on the *inter-variety* subset.
- High performances on South Tyrolean terminology is partly driven by overlap with better-resourced German varieties: when terms are unique to South Tyrolean German, the advantage of model scaling is strongly reduced.
- *Intra-variety* linguistic challenges show no generalized bias against any specific variety, with the ontological relation task appearing largely saturated.
- For LLM-based MT, term rarity may no longer be one of the severest architectural deficiencies (Koehn and Knowles, 2017). Efforts should be directed towards tackling the socio-linguistic under-representation of specific domain-variety intersections over training and alignment stages.

## 2 Language varieties and legal translation

German—like Arabic, English, and Spanish, for example—is a pluricentric language with different codified standard forms that slightly diverge at the lexical, orthographic, and grammatical levels (Schuppler et al., 2024). South Tyrolean German is a non-dominant variety with co-official status in a part of Italy (Ammon et al., 2016). This German variety is underrepresented in NLP training corpora, as the stronger numeric signal from

[1] https://bistro.eurac.edu/

dominant varieties tends to override non-dominant forms in statistical machine translation systems (Sousa et al., 2025). The challenge is substantially aggravated when such varieties are used in legal translation, where language is fundamentally system-bound: each German-speaking legal system (e.g., Germany, Austria, Switzerland, Italy, Belgium, the EU) has distinct legal concepts and standard terminology (Biel and Kockaert, 2023; Cao, 2007), with misalignments across systems being very frequent. Such misalignments manifest at multiple linguistic levels: source concepts may lack target counterparts, identical designations may refer to different concepts across legal systems, and incongruities may exist even across systems that share the same official language. For instance, a collective bargaining agreement is called *Kollektivvertrag* in Italy and Austria, *Gesamtarbeitsvertrag* in Switzerland, and *Tarifvertrag* in Germany (Figure 1). As the example shows, terms can differ but also coincide across legal systems.

## 3 Terminology

Terminology science studies terminologies (sets of designations and concepts belonging to one domain or subject), aspects of terminology work, the resulting terminology resources, and terminological data. Terminology work aims to identify and structure domain-specific concepts, their conceptual relations, and the terms used to designate the concepts (Costa, 2013). It serves to represent the conceptualizations of domain experts and facilitate the labeling and categorization of world knowledge in specialised communication. A fundamental aspect distinguishes terminology resources from lexicographic resources: while lexicography organizes information around words (lemmas) and their usage descriptions, terminology organizes information around concepts (ISO 704:2022). A concept-oriented approach takes the legal concept itself as its point of departure (e.g. the concept of a contract as a binding agreement) and associates it with the terms used to designate that concept in each language (e.g. contrat in French, Vertrag in German and contratto in Italian). However, apparent correspondence across languages does not necessarily entail conceptual equivalence across legal systems. This distinction becomes crucial when data need to be exchanged, modeled, or computationally processed, as a concept-oriented organization preserves sense distinctions between homonymous entries and groups synonyms and variants. Termbases structure information around persistent concept identifiers that anchor system-specific information (Di Nunzio and Vezzani, 2026), situate concepts within concept systems and ontological relations, and include cross-lingual mappings (Condello et al., 2026).

## 4 Termbases as Benchmarks

**Factuality, truthfulness, grounding** The quality standards for human curation of termbases align with criteria of NLG evaluation requiring outputs to be truthful, factual, and grounded in definitions and usage examples from authoritative sources (Tedeschi et al., 2023) based on verified world knowledge. Such expert validation has been found to be one of the strongest predictors of resistance to benchmark saturation (Akhtar et al., 2026).

**Extensive coverage** Termbases aim for extensive coverage of domain knowledge, ideally allowing to benchmark LLM performance across the full mapping of knowledge representation (Rajan et al., 2024). This has implications for experimental designs in machine translation. Validation and test partitions are often randomly sampled or designed to reproduce expected feature frequencies in realistic scenarios, though often without any certainty that relevant phenomena are equally and adequately represented (Søgaard et al., 2021) or that the selected samples are challenging enough (Proietti et al., 2025). This may neglect proper test-time supervision on long-tailed distributions and infrequent terms (Raunak et al., 2020, 2022; Tokarchuk et al., 2026; Saunders and DeNeefe, 2024). Moreover, singletons in training are a major cause of hallucinations (Kalai et al., 2025), so they would require targeted testing. By constructing test sets from termbase entries with informed data splitting approaches (Gehrmann et al., 2023), we can ensure that the test set contains at least one instance of each concept from the knowledge map.

**Serving industry and community** Benchmarks should be designed with the needs of the intended users in mind. For industry stakeholders, MT evaluation prioritizes post-editing effort, deployment costs, and client-specific terminology (Wang et al., 2026b). Language service providers commonly maintain in-house termbases for translation and quality-assurance workflows. Converting these resources into benchmarks enables evaluation on ter-

minology that is operationally relevant, customizable through export filtering, and cost-effective in repurposing existing resources.

Language communities—including language learners, lay MT users, and speakers of underrepresented varieties—are often concerned with ethical risks, social bias, and factual reliability (Savoldi et al., 2025; Wang et al., 2026b). From this perspective, targeted benchmarking from local (AI) watchdogs can play a role in exposing bias affecting speakers of non-dominant varieties and minority communities in multilingual countries (such as the South Tyrolean population). Decentralizing evaluation through local actors can also mitigate LLM leaderboard distortions caused by undisclosed private testing, selective score disclosure, and asymmetric access to evaluation data (Singh et al., 2025a; Kocyigit et al., 2025). Such local benchmarks can support the education of uninitiated audiences about the risks of conceptual imprecision when implementing AI output in official contexts and help identify systems that are less biased for deployment in real use cases even beyond MT (Biel, 2026).

**Natively multilingual** A common practice for multilingual LLM evaluation is to translate English benchmarks into other languages (Rajaee et al., 2025). However, this can limit cultural representativeness and reproduce English-centric assumptions, particularly when target-language concepts have no direct English counterpart (Singh et al., 2025b). In the legal domain, institutions in common-law systems may not have direct counterparts in civil-law systems and vice-versa, for example. Even countries sharing the same language may define and regulate legal concepts differently. Some benchmarks are originally developed in the target language (Zhang et al., 2024) or localized (Ong and Limkonchotiwat, 2023). Current legal benchmarks are predominantly English-centric (i.e., favoring US law) and largely quantitative in scope (Chalkidis et al., 2022). They also neglect comparative law issues and do not intersect legal aspects with language varieties of different countries. Termbases can address this gap because they organize and represent specialized knowledge natively within the legal and linguistic systems in which that knowledge is produced and used. They therefore allow us to identify where and why cross-lingual term rendering may fail.

**MT as a world knowledge probe** In standard knowledge benchmarking frameworks, knowledge is usually probed from a graph by verbalizing queries that LLMs must resolve. Query types can include a question-answer pattern (Talmor et al., 2019), predicting the answer using probability-based (Wiland et al., 2024) and confidence-based scores (Bexte et al., 2024), or selecting the correct statement from a multiple-choice item (Wang et al., 2026a), where distractors can be retrieved from node relations (Ren and Zhu, 2021) or top-k adversarial attacks (Luo et al., 2025). However, these approaches are often sensitive to prompt format (Leidinger et al., 2023), unreliable verbalizations (Xiong et al., 2024), difficulty of evaluating free-form answers (Bavaresco et al., 2025; Verga et al., 2024).

We propose to define MT as an extrinsic evaluation task for cross-lingual knowledge in specialized domains, leveraging structured knowledge encoded in termbases. The prompt and source text provide contextual information for concept selection. Accurate term realization shows whether the model can access, transfer, and express domain knowledge during text generation.

## 5 Method

### 5.1 Test set creation

We use *bistro*[2], which collects approximately 14,000 Italian legal concepts with their terms in Italian and South Tyrolean German and their equivalent terms in the other German-speaking legal systems (Ralli and Andreatta, 2018). For each concept $c_i$, we organize a language level $l$, comprising Italian $l^{IT} = \mathrm{IT}^{\mathrm{it}}$ and the German varieties $l^{DE} = \{\mathrm{DE}^{\mathrm{it}}, \mathrm{DE}^{\mathrm{de}}, \mathrm{DE}^{\mathrm{at}}, \mathrm{DE}^{\mathrm{ch}}\}$ (Ralli and Tamás, 2025). At a lower level, each language or variety contains a set of terms $t_k = \{t_1, \ldots, t_n\}$. Each term variant is associated with a real-world usage context $ref(t_n)$, selected to represent a prototypical use of the term. The structure of the knowledge base can therefore be summarized as follows:

$$c_i \mapsto l^{\{IT,DE\}} \mapsto \{\, t_n, ref(t_n) \,\}$$

### 5.2 Processing of subsets

For each subset, we extract tuples $x$, including a source term, target terms, term distractors, and a reference sentence.

[2]https://bistro.eurac.edu/

**Varieties subset (VAR)** We focus on South Tyrolean German terms. For each concept $c_i$, we select the target terms $t_{i,k}^{\mathrm{DE}_{it}}$ and only one of the Italian source terms as $t_{i,n}^{\mathrm{IT}_{\mathrm{it}}}$. Distractors are selected among the non-identical terms attested in the other German varieties such that $d_{ik} = \{t_{i,k}^{\mathrm{DE}_{\{\mathrm{de,at,ch}\}}}\} \neq t_{i,k}^{\mathrm{DE}_{\mathrm{it}}}$. The reference sentence is the usage context associated with the selected South Tyrolean German target terms $ref(t_{i,k}^{\mathrm{DE}_{\mathrm{it}}})$.

$$x_{ik} = \left(t_i^{\mathrm{IT}_{\mathrm{it}}}, t_{i,k}^{\mathrm{DE}_{\mathrm{it}}}, d_{ik}, ref\left(t_{i,k}^{\mathrm{DE}_{\mathrm{it}}}\right)\right)$$

**Homonyms subset (HOM)** We identify Italian terms that are shared across multiple concept identifiers, so that $t_{ij}^{\mathrm{IT}}$ lexicalizes more than one concept: $t_{i,n}^{\mathrm{IT}} = t_{j,n}^{\mathrm{IT}}$. For each homonym item, we use the shared Italian term as the source term and pair it with its German target terms and reference contexts, $ref(t_{i,k}^{\mathrm{DE}})$ and $ref(t_{j,k}^{\mathrm{DE}})$. For each German variety *var*, we extract the reference $ref(t_{i,k}^{\mathrm{DE}_{var}})$. Then we choose distractors from all possible German terms in the other concept identifier $d = t_{j,k}^{\mathrm{DE}}$. We end up with:

$$x_{ik} = \left(t_{ij}^{\mathrm{IT}}, t_{i,k}^{\mathrm{DE}_{var}}, d_{j,k}^{\mathrm{DE}}, ref(t_{i,k}^{\mathrm{DE}_{var}})\right)$$

**Ontological relations subset (REL)** We select concept identifiers that participate in at least one ontological relation $r(c_i, c_j)$. For each concept $c_i$, we select target terms $\mathrm{t}_{\mathrm{i,n}}^{\mathrm{DE}_{\mathrm{var}}}$ that belong to only one German variety *var* and are not attested in other German varieties. The Italian term $t_{i,n}^{\mathrm{IT}_{\mathrm{it}}}$ is used as the source term, while distractors are obtained from the related concepts by extracting terms in the same German variety $\mathrm{t}_{\mathrm{j,k}}^{\mathrm{DE}_{\mathrm{var}}}$.

$$x_{ik} = \left(t_{i,k}^{\mathrm{IT}}, t_{i,k}^{\mathrm{DE}_{var}}, d_{j,k}^{\mathrm{DE}_{var}}, ref(t_{i,k}^{\mathrm{DE}_{var}})\right)$$

### 5.3 Data filtering

We first apply a check on reference sentences to ensure that target term matching is recoverable (and eliminate any evaluation error intrinsic in the metric). Using the same matcher later used for scoring, we retain only reference sentences in which the target term has been identified by our evaluation pipeline. This removes cases with irretrievable matching, e.g., due to the use of gender-fair strategies, incorrect lemmatization or discontinuous term realizations. We also discard instances where any distractor is matched. The final test set contains 1,662 VAR instances, 1,212 HOM instances and 527 REL instances.

### 5.4 Creation of synthetic sources

Since contexts of use across languages are not necessarily parallel in termbases, we create source sentences by machine-translating the extracted German references into Italian. We choose not to create synthetic references by translating authentic source sentences because synthetic references are found to heavily affect evaluation robustness (Freitag et al., 2022). For source generation, we identify a sample of 314 authentic, human-written sentence pairs from the VAR subset and 89 from the HOM subset, which we use to compare candidate translation models against authentic Italian references. Gemini 2.5 Flash achieves the highest BLEU score from the models tested in Di Natale et al. (2026) and is therefore selected to generate the synthetic Italian sources.

### 5.5 Evaluation metrics

Term accuracy is computed with a custom pipeline[3] (Di Natale et al., 2026) that sequentially applies four matching strategies to catch the morphological richness of German: surface-form, lemmatization, splitting compound nouns, and hand-coded inflectional rules. For fluency metrics, we report BLEU through SacreBLEU[4], given the limitations of neural metrics on this language combination (Di Natale et al., 2025).

## 6 Results

### 6.1 Effect of synthetic sources

We assess whether using synthetic Italian sources affects model performance by comparing them with the human-authored parallel sources already presented in Section 5.4. Across both subsets, term accuracy remains largely stable between authentic and synthetic sources (see Appendix B), including in the homonym setting where sentential context is crucial for sense disambiguation (although the small sample weakens statistical significance). For our specific purposes, synthetic sources do not substantially affect the models' ability to identify the intended concept.

However, fluency metrics reveal a systematic skew: BLEU is consistently higher for synthetic sources, with a constant advantage of at least five

[3] **Evaluation code**: https://github.com/PaoloDiNatale/LegISTyr-evaluation **Version hash**: e65f284

[4] **Signature**: nrefs:1 | bs:1000 | seed:12345 | case:mixed | eff:no | tok:13a | smooth:exp | version:2.6.0

points. We attribute this gap to translationese effects. Since the synthetic Italian sources are produced from the German reference using MT, they tend to preserve clause structure and word-by-word correspondences that are easier to back translate into the structure of the reference (Dutta Chowdhury et al., 2020). Another reason for divergence may be context. Authentic sources originate from document-level drafting and may rely on surrounding context, whereas synthetic sources are generated from isolated sentences. This can induce a different degree of explicitation and word selection (Castilho et al., 2021).

We therefore treat synthetic sources as adequate for probing terminological knowledge, but not as neutral inputs for overall quality estimation, as they provide a structural scaffold that can inflate BLEU scores. We recommend considering BLEU only for model comparisons within the same subset.

### 6.2 General findings

Overall results for term accuracy are shown in Table 1. The best-performing systems are Gemini 3.1 Pro, GPT 5.5, DeepSeek V4 Pro and TRIVE, with Dubformer and UvA-MT also performing competitively on some challenges. The VAR subset is the most difficult setting, especially for larger models, whereas homonym disambiguation and especially ontological relations yield higher term accuracy. Notably, model scale is less predictive on the VAR subset: medium and smaller systems occasionally narrow the gap with top-tier models compared with the other challenges. By contrast, the homonym setting discriminates more clearly between models, including within the same model family.

BLEU scores largely follow the expected pattern, mostly within the same model family, of increasing with model size and term accuracy (Table 4). We calculate a Pearson's $r$ correlation between BLEU scores and Term accuracy rate for each variety and subset intersection (Table 4). Correlations are strongly positive and consistent across subsets. Models better able to access and realize variety-specific knowledge also tend to replicate the wording of that variety.

### 6.3 Variety subset

We evaluate South Tyrolean German as the target variety, using terms from the other German varieties as distractors. Even the strongest models remain below 80% term accuracy, while smaller models cluster around 50-60% (Table 1). This suggests that performance on this challenge is not yet saturated. No system inserts distractor terms more often than the target term, including models that do not receive the target terms in the prompt (GoogleTranslate). This suggests that interference from other German varieties is not predominant and that South Tyrolean contexts are sufficiently discriminative for term selection.

**Distractor analysis** When the South Tyrolean target term is not retrieved, we trace the variety provenance of the inserted term (Table 5). Since some terms are shared across varieties, attributions are not mutually exclusive and therefore do not sum to 100%. They indicate the proportion of distractor instances from that variety that were selected. Overall, terms from Germany are selected most often, while Swiss terms the least, suggesting a slight bias toward the dominant German variety. Interestingly, the strongest models more frequently err toward Austrian terms, presumably by virtue of the cultural and geographical proximity between Austria and South Tyrol. This suggests that stronger models may fall back on neighboring German locales when the South Tyrolean term is missing from their knowledge.

**Unique South Tyrolean terms** Many terms used in South Tyrol are also attested in other German varieties. We therefore isolate terms that are unique to South Tyrolean German (363 instances) to test whether model performance partly depends on exposure through better-resourced varieties. On this subset, performance drops sharply, and the decline is most pronounced for larger models (Table 7). Gemini 3.1 Pro and TRIVE remain the strongest systems, whereas Dubformer and DeepSeek V4 Pro drop to the level of much smaller models. Within model families, including GPT, Qwen, and Gemma, smaller models even outperform, or nearly do, medium-sized ones.

These results suggest that model scaling does not yield proportional gains for genuinely low-resource, variety-specific legal concepts. This glass ceiling for low-resource concepts may reflect data shortage in the specific domain-variety intersection. By contrast, larger models can continue to improve on higher-resource varieties because additional data reinforces support for those concepts. The use of synthetic data augmentation may further amplify this imbalance by reproducing dominant-variety forms.

Table 1: Term accuracy rates for all subsets. Mean is not indicated for the VAR subset because it would not be comparable to the other subsets.

| | VAR | HOM | | | | REL | | | |

**Term frequency correlation** Rare terms have long been a known source of MT errors, typically linked to their scarce representation in training data. For LLMs, however, this relation is harder to measure: terms may appear across multiple domains in much larger generic corpora and closed models do not expose their training data. As a rough proxy, we use term frequency in an internally compiled corpus of South Tyrolean legal texts and correlate it with correct term insertions using point-biserial correlation, a variation of Person's correlation for binary variables.

We find no meaningful correlation between corpus frequency and term accuracy (Table 8). This suggests that LLM term selection failures cannot be explained by the statistical representation of terms in the target domain. Instead, performance appears to depend more strongly on whether the relevant concept belongs to a relatively low-resourced domain-variety intersection, as observed in the previous paragraph.

### 6.4 Homonym subset

Performance on homonym disambiguation is broadly stable across varieties. South Tyrolean terms remain slightly behind the others, and the pattern observed in the variety subset reappears: the strongest models show a larger relative drop in performance on South Tyrolean terms than on terms from the other varieties, whereas smaller models from the same families do not exhibit the same drop. Command A+ is an exception, showing a drop in accuracy for Germany's variety. We notice that models specifically trained for MT on parallel sentences (CUNI, GoogleTranslate, Tower)

tend to have a higher accuracy rate for the Swiss variety. We justify this with the fact that both Italian and German are official languages in Switzerland, thus a relatively larger size of parallel training data is available for this language combination. Parallel data appears to improve sense disambiguation.

### 6.5 Ontological relations subset

Performance is broadly comparable across varieties, with a small South Tyrolean advantage. Unlike in other subsets, larger models do not underperform on South Tyrolean terms, suggesting that this task depends less on variety-specific legal knowledge and more on general semantic reasoning. Models below 9B parameters tend to underperform on the Austrian variety, while Command A+ again shows an unexpected performance drop on Germany's variety.

**Distractor analysis** We analyse the type of ontologically related concept that is inserted when the target term is not identified (Table 6). Hyponyms are the most challenging distractors, suggesting that models struggle when the incorrect option is more specific than the target concept. Smaller and transformer-based systems tend to insert hypernyms more often. This supports a tentative interpretation that, when uncertain, models may prefer more generic rather than more specific concepts.

### 6.6 Legal subdomain

We also dissect results by legal subdomain for the VAR and HOM subsets (Tables 9 and 10). Domain-level differences are present but not systematic. The ranking of legal areas changes across subsets, suggesting that legal subdomain is not an independent predictor of performance. If anything, we notice that in the VAR subset, lower accuracy in procedural areas may reflect the difficulty of representing terminology from specific legal systems, whereas higher scores in public and constitutional law may benefit from stronger inter-institutional standardization. In the HOM subset, domain effects are flatter, indicating that once sentential context supports sense disambiguation, performance depends less on the legal area than on the separability of the competing concepts.

### 6.7 Number of Distractors

We evaluate whether performance varies with the number of distractors (See Appendix H), considering at least 50 instances for each distractor class. Unsurprisingly, term accuracy tends to decrease as the number of distractors increases for all subsets. The decline is less pronounced in the REL subset, likely because this task is less challenging than inter-variety term selection. Overall, this pattern suggests that the distractors are sufficiently competitive in the other subsets and that models struggle to handle a growing number of plausible options. We find no clear tipping point, but the largest degradation occurs around three and five distractors.

## 7 Discussion

Broader implications for benchmark design and LLM-based MT can be drawn. First, synthetic data may be useful for reconstructing source sentences when only target-side references are available, but the intuitive informativeness of the Bleu score should be questioned. Second, locale-oriented adaptation appears more challenging than linguistic and semantic reasoning tasks. Finally, model scaling mainly reinforces dominant language varieties: the overperformance of very large LLMs is less marked and plateaus on terms that are not shared with other language varieties. This trend is not correlated with word frequency, long held as the primary cause of ineffective learning of rare terminology (Koehn and Knowles, 2017). Instead, the capability of LLMs to learn from large monolingual data (Pang et al., 2025) reframes the challenge as one of data composition rather than data volume: progress will likely depend on how well linguistic variety and domain-aware representation are balanced in the data mix used for pretraining, augmentation, and alignment.

## 8 Future outlooks

As recent research has stated that we are approaching near-saturation of terminology injection at the sentence level (Semenov et al., 2025), terminology resources such as termbases can trace new research directions addressed to the design of shared tasks and future studies on terminology-aware MT.

**Harder test sets:** Following the trend of Proietti et al. (2025), this work can inspire the creation of more challenging test sets. Many of the shortcomings described in Section 4 also affect some of the studies in the field. Retrieval of gold terms for previous WMT shared tasks has been based on initial LLM-based extraction (Semenov et al., 2025), which likely favors high-confidence, easier

terminology (Cirillo et al., 2026). Random splits can further overrepresent frequent—and therefore easier-to-model—terms (Oncevay et al., 2025). The extensive coverage of termbases helps address these shortfalls by cataloging terms across all frequency bands. Additionally, while Semenov et al. (2025) has relied on randomly selected distractor lists for terminology dictionaries, other criteria—such as cosine distance, locale, or homonymy relations—could yield more discriminative distractor sets.

**Keeping our tails:** (Vanmassenhove, 2026) Long-tailed terminology remains problematic in zero-shot inference and during fine-tuning. To identify which fine-tuning methods best support rare terminology in shared tasks, we recommend releasing training corpora and characterizing how term frequency in the corpora relates to term accuracy across participants' training regimes.

**New frontiers:** As the current terminology setup approaches saturation, the field should move towards knowledge-based training. Rather than relying only on bilingual term lists or parallel corpora, participants could be asked to exploit monolingual definitions, usage notes, knowledge graphs, and domain metadata to train systems that aim to be aware of term meaning and not only term form. This would make terminology shared tasks a test bed for knowledge-aware MT, especially in domains and varieties where parallel data is scarce.

## A Prompt

```
You are a professional legal translator specializing in Italian-to-
    German translation for the legal system of {country}.

Your task is to translate a legal sentence from Italian into the
    standard variety of German used in {country}, without dialectal
    expressions. The translation must be fully aligned with the legal
     terminology, conventions, and drafting style of that
    jurisdiction. It must preserve the exact legal meaning and
    reflect how such concepts are expressed within the legal system
    of {country}, so that the result can function as an authoritative
     legal text.

There are terminological constraints you must adhere to:
{term_it} can be translated with only one of these terms:
{term_de_list}.

You must output only the translated text, without any explanation,
    enclosed in angle brackets "<>".

This is the text to be translated into {country} German:

IT: <{source_sentence}>
de-{country_code}:
```

## B Effect of synthetic sources

### B.1 Term accuracy

Table 2: Term accuracy for synthetic and human source sentences in the VAR subset.

| Model | Synthetic Source | Human Source |
|---|---|---|
| Cohere CAT+ | 54.8 | 53.8 |
| Command A+ | 54.5 | 56.4 |
| CUNI-EdUKate | 23.6 | 23.9 |
| CUNI-MH-v3 | 28.3 | 28.3 |
| DeepSeek V4 Pro | 60.5 | 58.6 |
| Dubformer | 58.6 | 58.9 |
| Gemini 3.1 Pro | 72.6 | 72.6 |
| Gemma 4 - 4B | 53.2 | 48.4 |
| Gemma 4 - 31B | 59.6 | 56.4 |
| GLM 4 - 9B | 43.9 | 46.2 |
| GoogleTranslate | 33.4 | 34.4 |
| GPT 5.5 | 69.7 | 67.8 |
| GPT OSS 20B | 55.7 | 54.1 |
| GPT OSS 120B | 55.7 | 56.4 |
| Ministral 3 - 14B | 53.2 | 53.5 |
| Mistral Medium 3.5 | 55.7 | 59.2 |
| Qingqiu-MT-9B | 49.0 | 46.8 |
| Qwen 3.5 - 9b | 52.2 | 48.4 |
| Qwen 3.6 - 27b | 53.5 | 53.5 |
| SalamandraTA | 51.6 | 46.8 |
| Tiny Aya Global | 35.0 | 34.7 |
| Tower 9B | 45.9 | 46.8 |
| TRIVE | 70.7 | 68.5 |
| UvA-MT | 60.5 | 64.0 |

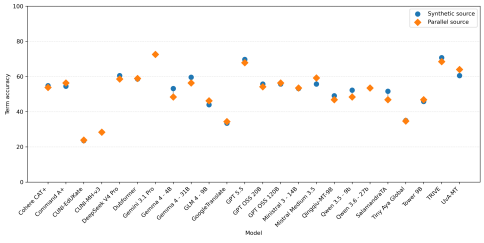

Figure 2: Plot of Term accuracy for synthetic and human source sentences in the VAR subset.

### B.2 BLEU scores

Table 3: BLEU score for synthetic and human source sentences in the VAR subset.

| Model | Synthetic Source | Human Source |
|---|---|---|
| Cohere CAT+ | 35.8 | 27.2 |
| Command A+ | 30.8 | 25.2 |
| CUNI-EdUKate | 25.8 | 18.6 |
| CUNI-MH-v3 | 27.6 | 20.5 |
| DeepSeek V4 Pro | 45.7 | 33.7 |
| Dubformer | 43.4 | 31.1 |
| Gemini 3.1 Pro | 50.6 | 36.5 |
| Gemma 4 - 31B | 38.2 | 28.9 |
| Gemma 4 - 4B | 31.2 | 23.1 |
| GLM 4 - 9B | 24.8 | 18.1 |
| GoogleTranslate | 26.9 | 20.4 |
| GPT 5.5 | 49.1 | 36.0 |
| GPT OSS 120B | 31.1 | 23.6 |
| GPT OSS 20B | 24.7 | 17.7 |
| Ministral 3 - 14B | 27.3 | 20.0 |
| Mistral Medium 3.5 | 38.1 | 28.9 |
| Qingqiu-MT-9B | 33.8 | 24.7 |
| Qwen 3.5 - 9b | 27.1 | 17.6 |
| Qwen 3.6 - 27b | 35.5 | 26.5 |
| SalamandraTA | 30.9 | 23.7 |
| Tiny Aya Global | 24.4 | 17.2 |
| Tower 9B | 32.6 | 24.2 |
| TRIVE | 50.2 | 35.0 |
| UvA-MT | 41.2 | 30.4 |

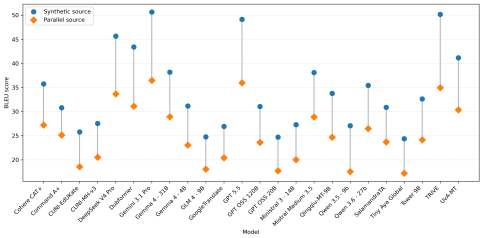

Figure 3: Plot of BLEU score for synthetic and human source sentences in the VAR subset.

# C Main results

## C.1 Term accuracy

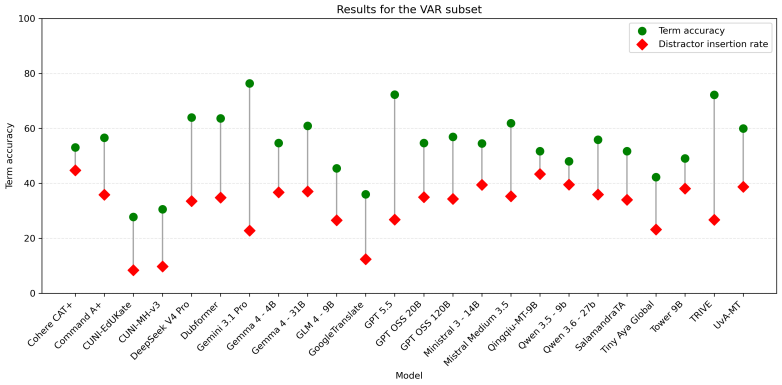

Figure 4: Plot of Term Accuracy for the VAR subset

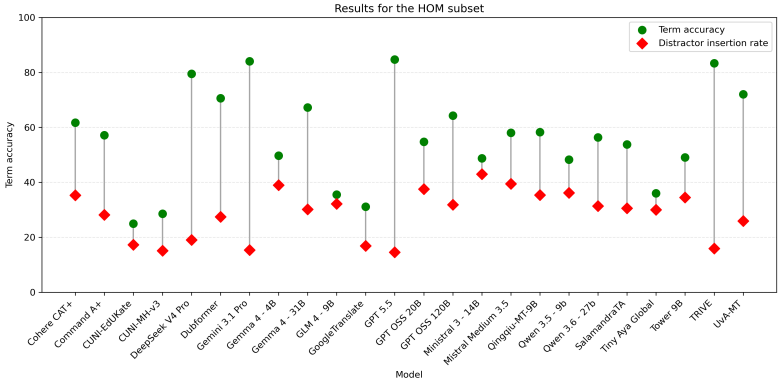

Figure 5: Plot of Term Accuracy for the HOM subset

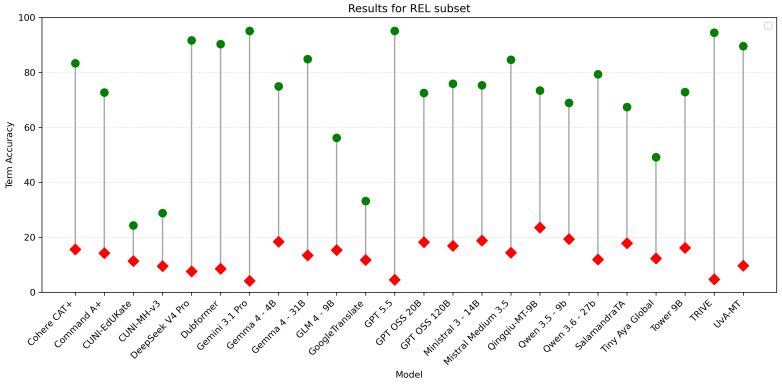

Figure 6: Plot of Term Accuracy for the REL subset

## C.2 BLEU scores

Table 4: BLEU scores for all subsets. Correlation with Term accuracy indicates the Pearson's *r* between subset-level BLEU score and Term accuracy for each language variety.

| Model | BLEU SCORE | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | VAR | HOM | | | | REL | | | |
| | | | | | | | | | |
| Cohere CAT+ | 35.2 | 36.7 | 39.8 | 34.9 | 37.4 | 39.1 | 36.7 | 40.2 | 41.0 |
| Command A+ | 32.7 | 36.6 | 31.4 | 31.9 | 33.8 | 38.8 | 30.6 | 36.5 | 34.5 |
| CUNI-EdUKate | 26.6 | 27.9 | 26.0 | 21.7 | 25.4 | 30.8 | 27.2 | 28.3 | 29.6 |

## D Distractor analysis

Table 5: Variety provenance of inserted distractor terms when the South Tyrolean target term is not retrieved for the VAR subset. Since some terms are shared across varieties, attributions are not mutually exclusive and therefore do not sum to 100%. They indicate the share of matches out of the total featured distractor instances of the variety.

## Abstract

LLMs' performance on machine translation (MT) tasks is often dependent on the data availability in the specific domains and language pairs that they are trained upon. To examine if multiword expressions (MWEs) still present a bottleneck for LLMs regarding language understanding and translation, we report the performance of systems from the WMT 2026 Test Suites shared task, using portions of the publicly available multilingual parallel corpus AlphaMWE as test suites. We received 31 MT systems' outputs covering English to Chinese (zh), Polish (pl), German (de), and Arabic (ar) including Modern Standard Arabic (MSA) and two dialectal ones (Egyptian and Tunisian Arabic). We carried out automatic evaluations using BLEU, ChrF, and BERT-score to select the top 3 systems per language pair, followed up with human evaluations on the selected systems. Our findings show that figurative and MWE-related phenomena remain challenging for contemporary MT systems, automatic metrics sometimes disagree in system ranking, and human evaluation uncovers language-specific errors that remain hidden by aggregate scores. Inter-annotator analysis further reveals challenges in consistently identifying and calibrating linguistically subtle translation errors, highlighting the need for explicit evaluation guidelines and careful annotator calibration.

## 1 Introduction

Large Language Models (LLMs) have substantially advanced machine translation (MT), achieving remarkable fluency and strong automatic evaluation scores across many language pairs. Nevertheless, recent studies suggest that high overall translation quality does not imply that all linguistic phenomena are equally well handled. In particular, multiword expressions (MWEs) such as idioms, metaphorical language, and other non-compositional constructions remain challenging because their meaning cannot always be inferred compositionally from individual words. Correct translation therefore requires not only lexical knowledge but also contextual reasoning, semantic interpretation, and language-specific linguistic competence.

Recent work has begun to investigate these remaining blind spots. Cheng and Amiri (2025) argue that LLMs exhibit systematic linguistic blind spots despite their strong overall performance. Laureano De Leon et al. (2025) demonstrate that multilingual and code-switched MWEs remain difficult for current LLMs, while Mi et al. (2025) show that idiomatic expressions are frequently mistranslated when successful interpretation depends on contextual understanding rather than surface word associations. More recently, Liu et al. (2026); Liang and Han (2026) reported that verbal MWEs and metaphors continue to pose substantial challenges for machine translation systems. Together, these studies suggest that automatic MT quality improvements have not eliminated linguistically difficult translation phenomena.

However, most previous work evaluates LLMs in controlled experimental settings or focuses on individual linguistic phenomena. Less is known about how a diverse collection of contemporary MT systems behaves on a shared multilingual benchmark specifically designed to expose these challenging constructions. Furthermore, automatic evaluation metrics such as BLEU or BERTScore often provide only an overall quality estimate and may overlook linguistically important translation errors, particularly those involving idiomaticity, lexical ambiguity, or figurative meaning.

To investigate these issues, we participated in the WMT 2026 Test Suites Shared Task by submitting AlphaMWE, a multilingual parallel corpus containing manually annotated multiword expressions, as a diagnostic test suite. AlphaMWE covers English–Chinese, English–German, English–Polish, and English–Arabic (Modern Standard Ara-

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1533–1554
October 28-29, 2026 ©2026 Association for Computational Linguistics

bic, Egyptian Arabic, and Tunisian Arabic), and contains texts from multiple genres including technical documentation, news, and literature. The shared task attracted 31 MT systems, providing a broad comparison of contemporary translation models.

Our evaluation follows a three-stage pipeline. We first construct the WMT-compatible test suites from AlphaMWE, then evaluate all submitted systems using SacreBLEU, chrF++, and BERTScore, and finally perform HOPE-based human evaluation on the top-ranked systems for each language pair. This combination enables us to compare automatic and human assessment while analysing translation behaviour across multiple languages and linguistic phenomena.

It is worth noting that, at this stage of our work, we decided to conduct the analysis and comparisons at the level of complete sentences. We therefore assessed the meaning of each sentence as a whole, rather than focusing solely on the translations of the MWEs. Thus, our primary focus was on the overall meaning conveyed by sentences containing MWEs, as well as on identifying which types of errors resulting from the use of MWEs occur in different types of texts.

Our analysis shows that despite strong automatic evaluation scores, idioms, verbal MWEs, metaphorical expressions, lexical ambiguity, and language-specific collocations remain important sources of translation errors. These shortcomings are especially evident in literary and expression-rich texts, whereas technical texts are translated much more reliably. We further observe that automatic evaluation metrics do not always agree on system ranking, and that human evaluation reveals language-specific translation issues which remain largely invisible to aggregate automatic scores.

Our main contributions are:

- We introduce AlphaMWE as a multilingual diagnostic test suite in the WMT 2026 Test Suites Shared Task, covering six target-language variants and outputs from 31 participating MT systems.
- We combine three complementary automatic evaluation metrics with HOPE-based human evaluation to investigate both system ranking and linguistically motivated translation quality.
- We provide a cross-language analysis showing that MWEs, idiomatic expressions, figurative language, lexical ambiguity, and language-specific grammatical phenomena remain persistent blind spots for contemporary MT systems despite their overall high translation quality.

## 2 WMT2026 Test Suites: AlphaMWE

We present the overall methodology of this shared task in Figure 1 including three stages: Stage I: Test Suite Construction; Stage II: Automatic Evaluation; Stage III: Human Evaluation & Analysis.

For Stage I, AlphaMWE (Han et al., 2026) is a multilingual parallel corpus featuring multiword expression (MWE) annotations, machine translation post-editing, and human-in-the-loop quality controls. It builds on data from sources such as the PARSEME shared task (Savary et al., 2017) to evaluate how translation engines handle complex phrasal and verbal expressions. It was originally designed by Han et al. (2020) for English–German, English–Polish, and English–Chinese language pairs, which was later extended to the Arabic edition by Hadj Mohamed et al. (2023). AlphaMWE has a mix of text genres, including IT document instructions, news/politics, and literature texts.

The original AlphaMWE corpus contained 5 files of equal size, with around 150 segments per file, for a total of 747 segments. However, their annotation was not complete for English–Arabic and English–Polish, resulting in 150 segments for English–MSA (modern standard Arabic), English–AEB (Tunisian Arabic), English–ARZ (Egyptian Arabic), and 597 segments for English–Polish[1].

For Stage II, we deployed SacreBLEU (Post, 2018), chrF++ (Popović, 2017), and BERTScore (Zhang et al., 2020) for precision-oriented n-gram matching, robust character-level matching, and contextual semantic similarity.

For system selection, we apply average rank instead of average score. Average rank is preferable because BLEU, chrF++, and BERTScore have different numerical scales. We rank the system per language pair using each metric, then average their ranking on all tested metrics.

For Stage III, we adopt the human-centric post-editing based metric HOPE (Gladkoff and Han, 2022) with its original eight error types and sever-

[1]Following ISO 639-3 language identifiers.

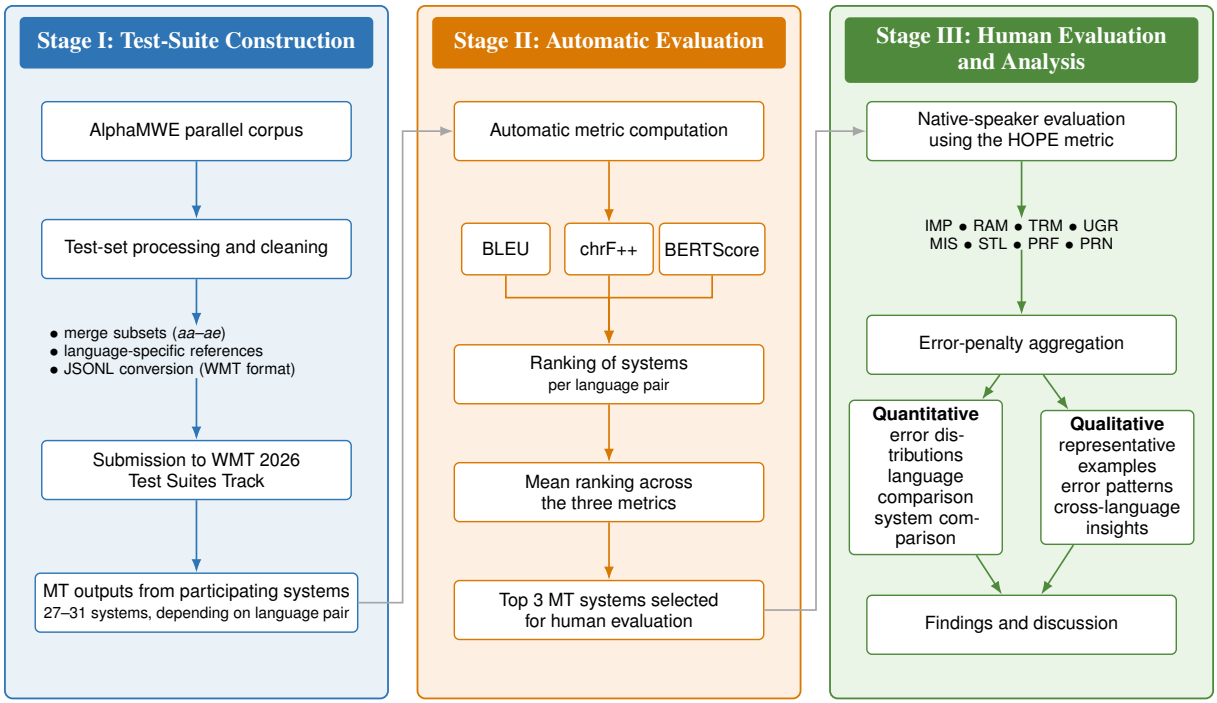

Figure 1: Overall methodology for AlphaMWE test-suite construction, automatic evaluation of WMT 2026 system outputs, top 3 system selection per language pair, and HOPE-based human evaluation followed by quantitative and qualitative analyses.

ity levels (0, 1, 2, 4, 8, 16) for (minor, medium, major, severe, and critical). The eight error types are: Impact (IMP), Required Adaptation Missing (RAM), Terminology (TRM), Ungrammatical (UGR), Mistranslation (MIS), Style (STL), Proofreading (PRF), and Proper Name (PRN).

## 3 Systems Received

We list the statistics of MT system outputs we received from WMT in Table 1. The varying numbers of participating systems reflect the fact that not all WMT 2026 Test Suites participants submitted translations for every language pair.

## 4 Automatic Evaluation

The top 3 systems per translation language pair are displayed in Table 2, where we presented the metrics of BLEU, chrF++, BERT, average rank (Avg. Rank), rank standard deviation (Rank SD), and the selection rank. Regarding the rank standard deviation (Rank-SD), a low standard deviation indicates that all three automatic metrics agree on the system's quality, while a high standard deviation highlights disagreement between metrics.[2]

The top 3 systems for each language pair were selected based on the mean of the three automatic metric rankings. The rank standard deviation (SD) is reported to indicate the level of agreement among the automatic metrics but was not used as a selection criterion. Nevertheless, we can see from the table that while half of the selected systems across language pairs have Rank-SD value 0 reflecting their stable performances across three metrics, there are another half of the systems having different level of Rank-SD, with the extremist from GPT 5.5 and Gemma 4-31B on the en→arz language pair having SD values of 3.559 and 1.886, very unbalanced ranking across metric. Appendix Section F shows the three metric-specific ranking tables for transparency and reproducibility.

For Chinese, the competition-ranking tie is preserved: SCIR-TG-MT: aggregate rank 1; Google-Translate: aggregate rank 1; Tower 9B: aggregate rank 3. Here, the SD immediately explains the tie for en→zh: both the first two systems have the same mean rank (1.667). SCIR-TG-MT has a lower SD (0.471), meaning the three metrics agree more closely. Google Translate has a higher SD (0.943), indicating more disagreement because BERTScore

[2]Score 0 → all three metrics ranked the system identically (very high agreement). Small SD (0.4–1.0) → often used for strong agreement. Large SD (>2) → the metrics disagree substantially, suggesting that the system's quality depends on the evaluation metric.

Table 1: Coverage of MT systems that returned translations for the AlphaMWE test suites submitted to the WMT 2026 Test Suites Shared Task. Numbers in parentheses indicate the number of evaluation segments in each language pair. English–Polish contains 597 segments because the *ad* subset was unavailable, while the Arabic test suites each contain the 150-segment *aa* subset only.

| System | en→aeb (150) | en→ar (150) | en→arz (150) | en→de (747) | en→pl (597) | en→zh (747) |

ranked it lower than BLEU and chrF++. Even though the official competition ranking remains 1, 1, 3, the SD provides valuable context for interpreting that tie.

## 5 Human Evaluation

In Table 3, we list the summed HOPE error penalties for the top 3 systems per language pair over 150 segments. Because every language pair contains exactly 150 segments, these raw totals are directly comparable in terms of corpus size. However, possible differences in annotator severity across target languages should still be acknowledged when making cross-language interpretations. Figure 2 visualises the HOPE-based human evaluation results. Notably, the human-evaluation ranking does not fully reproduce the automatic-evaluation ranking of the selected top-three systems: the ordering changes for English–Arabic, English–German, and English–Polish, while human evaluation resolves the automatic-ranking tie between SCIR-TG-MT and Google Translate for English–Chinese.

### 5.1 English–Arabic

For Arabic, error annotations across the evaluated sentences revealed substantial differences in translation quality among the three machine translation systems. TRIVE achieved the strongest overall performance, with errors identified in fewer sentences and a cumulative severity score of 57 on all segments. Google Translate exhibited an intermediate profile, with errors present in more sentences and a cumulative severity score of 84 on all 150 segments, mostly due to MIS error type over TRIVE. Gemma 4-4B showed the weakest performance, with errors identified in even more sentences and a cumulative severity score of 284, more than the sum of Google Translate and TRIVE, also introducing many errors in Impact category, followed

Table 2: Top 3 MT systems selected for human evaluation on each AlphaMWE language pair. Systems were selected according to the average of their SacreBLEU, chrF++, and BERTScore F1 rankings. The rank standard deviation (Rank SD) measures the agreement among the three automatic metrics; lower values indicate greater agreement but were *not* used as a selection criterion. Competition ranking was adopted for the final selection rank.

by Terminology, Style, and Proofreading.

Across all three systems, Mistranslation constituted the single largest error category, indicating that semantic accuracy, rather than syntactic well-formedness, was the primary locus of quality degradation. Ungrammatical output was comparatively rare; the few genuine grammar violations identified involved gender agreement failures, such as a masculine verb form incorrectly applied to a feminine subject. More frequently, apparent grammatical irregularities on closer inspection reflected stylistic or collocational choices rather than true violations of Arabic grammar, underscoring the importance of distinguishing genuine ungrammaticality from register mismatch or reduced naturalness in translation evaluation. Several recurring error patterns emerged at the lexical and idiomatic level. Idiomatic expressions posed a particular challenge: an English idiom conveying collective laughter was rendered literally by two systems, producing a semantically unrelated and ultimately incoherent Arabic sentence, while the third system correctly recovered the idiomatic sense. For instance, in the following example in Figure 3, TRIVE is the only system that correctly conveyed the meaning of laughter in the expression “this broke everybody up”, the other outputs convey the literal meaning of the breaking (fracturing) of ‘everyone’.

Similarly, polysemous source terms were occasionally mapped to the wrong sense entirely, as when a medical usage of a common English noun was translated according to its more frequent, unrelated meaning, yielding an implausible reading within its surrounding context. Errors of this kind, in which an incorrect lexical sense generates a locally incoherent target sentence, were judged more severe than errors of nuance, since they compromise not only precision but basic interpretability for the target reader. Terminological consistency also varied across systems. In several instances, an established or institutionally fixed Arabic term used correctly elsewhere in the same output was replaced by a looser or less standard alternative, producing internal inconsistency within a single document. Related issues included inconsistent transliteration of proper names, occasional calques that preserved English syntactic structure at the expense of natural Arabic phrasing, and isolated failures to adapt source-language conventions, such as untranslated units of measurement or an uncorrected error present in the source text itself, appropriately treated as a required-adaptation failure when the target system failed to resolve it.

Taken together, these findings suggest that translation adequacy in this sample was governed less by surface grammaticality, which was generally

Table 3: Summed HOPE error penalties for the three systems selected for human evaluation on each language pair. Each value is the total penalty assigned to an error category over 150 AlphaMWE segments. Lower scores indicate fewer or less severe translation errors. SEGS is the sum of the eight error-category penalties.

| | TRIVE | 10 | 1 | 12 | 1 | 12 | 13 | 8 | 0 | 57 |

well preserved across all systems, than by the accurate resolution of idiomatic expressions, lexical ambiguity, and terminological consistency. TRIVE demonstrated the most robust handling of these higher-order challenges, while Gemma 4-4B was disproportionately affected by mistranslation and inconsistent register, with Google Translate occupying an intermediate position.

### 5.2 English–Chinese

**Across-system differences.** The three most apparent error types are Mistranslation, Proofreading, and Terminology, especially for Tower-9B. The SCIR-TG-MT performed much better than the other two systems. Their total error penalties are (52, 98, 167) respectively for SCIR-TG-MT, GoogleMT, and Tower-9B. Even though Mistranslation is the common issue of all these three MT systems, SCIR-TG-MT has a much lower overall penalty score 41 than other two systems (79, 113) respectively for GoogleMT and Tower-9B on this error type. As one example, the source sentence "They intrigued and slandered and hated each other only on that account, – but as to effectually *lifting a little finger* – oh, no. By heavens!" (aa-127) in Figure 4, SCIR-TG-MT had the correct translation "真正动手帮一下忙" of the sentence and idiom "(effectually) lifting a little finger", while the other two systems produced wrong translation (literal) on the idiomatic expression.

Another example can be found via the vMWE "took it back" in the sentence "Afterwards I *took it back* when it was borne in upon me startlingly with what extreme nicety he had estimated the time requisite for the 'affair'." (sentence-id: aa-121), in Figure 5, where SCIR-TG-MT correctly translated it as "收回了之前的看法(withdrew my previous opinion)" while the other two systems produced "收回了那份文件– took back that file (made up)" (GoogleMT) and "把它拿了回来– took it back (literal)" (Tower-9B).

**Across-system similarities.** Literature text presents greater difficulty than IT document text. This exactly reflects the "gap" that LLMs still need to fill in, i.e., the text with rich expressions and idiomatic and metaphorical phrases. For future research, task-specific evaluation frameworks focusing on figurative language can be a growing topic, e.g., grounded metrics on metaphor translation from Liang and Han (2026), adapted from the general domain HOPE framework.

### 5.3 English–German

Overall, during annotation we noticed that TRIVE has a considerably more "literary" style. It knows and uses German idioms, cf. aa-119 (*Zahn der Zeit*), aa-105 (*kein Auge trocken*), and introduces additional words that lend the text a more literary character (cf. aa-122, aa-115, aa-109). This stylistic richness, however, sometimes comes at the cost of precision.

A translation issue we encountered repeatedly in practice concerns the word "standard" (aa-137), which, in an engineering context, should almost exclusively be translated as *Norm*. A *Norm* is a document prescribing how to design, build, test, and document a given thing or process, whereas a standard may also encompass non-binding recommendations. Accordingly, the statement "this does not comply with the standard" (*Dies entspricht nicht*

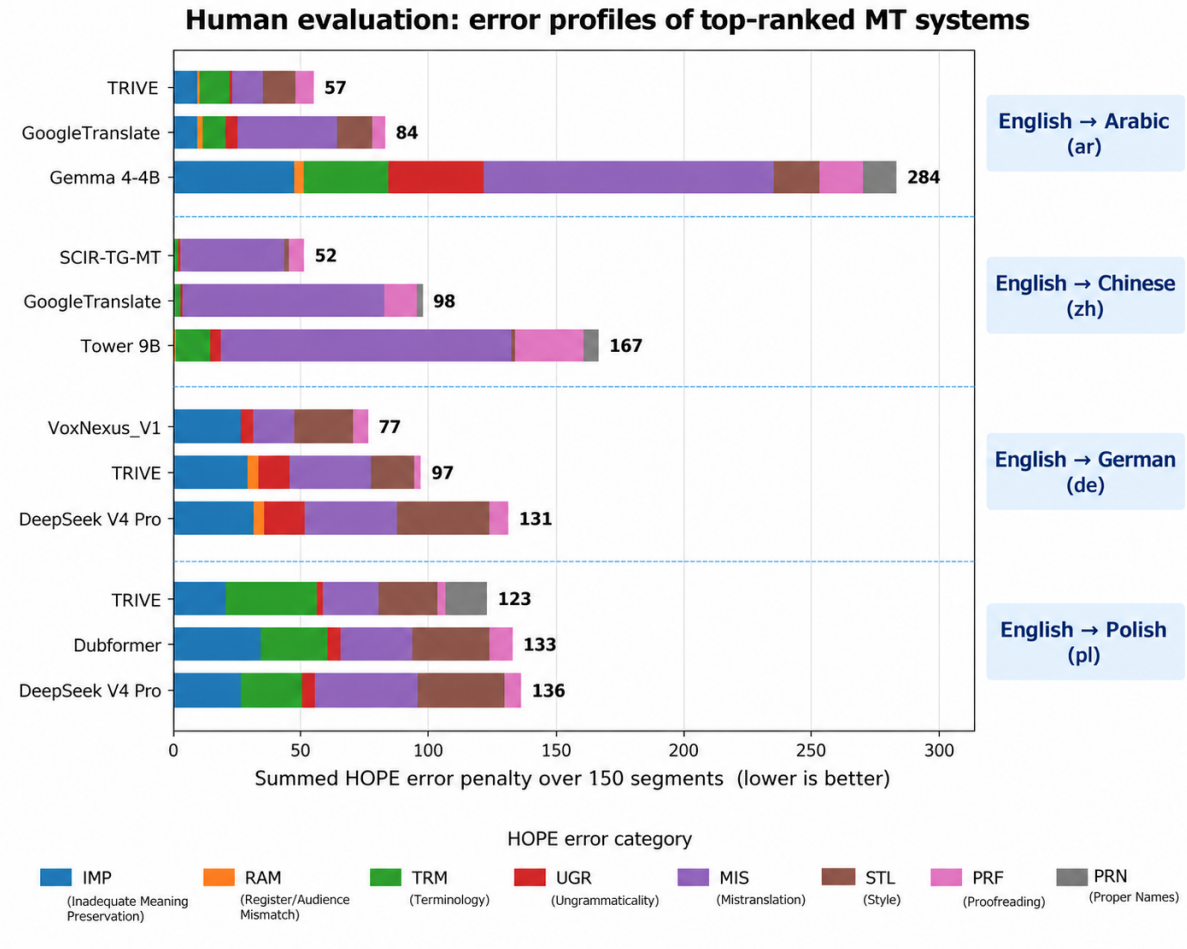

Figure 2: Visualisation of Human Evaluations on Four Language Pairs.

src: This broke everybody up.

ref: هذا حطم الجميع

GoogleTranslate: هذا الأمر أدى إلى تفكك الجميع

Gemma: هذا فرّق الجميع

TRIVE: أضحك هذا الجميع بشدة

Figure 3: Example on Arabic Translation Issues with vMWE (aa-105).

src: They intrigued and slandered and hated each other only on that account, – but as to **effectually lifting a little finger** – oh, no. By heavens!

ref: 他们彼此算计、诽谤、仇恨，仅仅是为了这个——但要说到**真正动手帮一下忙**——哦，不。老天爷啊！

SCIR-TG-MT: 他们彼此算计、诽谤、仇恨，仅仅是为了这个——但要说到**真正动手帮一下忙**——哦，不。老天爷啊！

GoogleTranslate: 他们就因为这件事互相陷害、诽谤和憎恨，但要说**真正动动手指**——哦，不！天哪！

TOWER 9B: 他们只是因为这个原因而互相挑拨、诽谤和憎恨——但至于**真的动一下小指头**——哦，不。天哪！

Figure 4: Example on English-Chinese Translation Issues of Metaphors (aa-127).

*dem Standard*) is, in an engineering context, generally less consequential than "this does not meet the Norm" (*Dies erfüllt nicht die Norm*). Failing to meet a standard may impact customer acceptance of a business, whereas failing to meet a *Norm* may entail more severe legal consequences.

### 5.4 English–Polish

The English–Polish translations produced by the selected MT systems were of high quality, although performance varied substantially across text genres. Technical texts were translated accurately owing to well-established terminology, whereas literary

Figure 5: Example on English-Chinese Translation Issues of Figurative Expressions (aa-121).

texts containing idiomatic expressions and MWEs remained considerably more challenging. News-style texts generally exhibited fewer semantic errors because the surrounding context was easier for the systems to infer.

The most frequent error category was stylistic errors (STL), followed by mistranslations (MIS). Stylistic errors mainly involved unnatural Polish sentence structure, awkward collocations and overly complex wording, while mistranslations often resulted from literal translation of MWEs and idiomatic expressions, sometimes changing the meaning of the entire sentence.

Examples:

- STL

  aa-005: *However, when you apply a filter by selection, the conditional filter already applied on the field is removed before the filter by selection is applied.*

  DeepSeek V4 Pro: *Jednakże, gdy zastosujesz filtr według zaznaczenia, warunkowy filtr już zastosowany na tym polu zostanie usunięty przed zastosowaniem filtru według zaznaczenia.*

  Comment: The whole sentence is just complicated and akward. It needs to be read several times to be fully understood.

- MIS

  aa-102: *Shrugging, he gives up and I turn to the **twice disagreeable chicken** and eat guiltily, my appetite spoiled.*

  TRIVE: Wzruszając ramionami, daje za wygraną, a ja wracam do **podwójnie nieapetycznego kurczaka** i jem z poczuciem winy, z popsutym apetytem.

  Comment: This sentence cannot be translated literally while preserving its meaning, and here we are dealing with a literal translation.

**Linguistic observations.** Several errors reflected fundamental linguistic differences between English and Polish: verbal aspect, grammatical gender, singular/plural/formal "you", idioms, and collocations.

Examples:

- verbal aspect

  aa-012: *When items in a field **are hidden** by conditional filtering, a funnel appears to the left of the drop-down arrow Field arrow.*

  DeepSeek V4 Pro: *Gdy elementy w polu **są ukrywane** przez filtrowanie warunkowe, po lewej stronie strzałki rozwijanego pola (strzałki pola) pojawia się lejek.*

  Comment: It should be a perfective verb *ukryć* used here, instead of imperfective *ukrywać*: *zostały/są ukryte*.

- grammatical gender

  aa-124: ***I heard** the name of Kurtz pronounced, then the words, "take advantage of this unfortunate accident."*

  DeepSeek V4 Pro: ***Usłyszałem** wymówione imię Kurtza, a potem słowa: "skorzystajcie z tego nieszczęśliwego wypadku".*

  Comment: Polish distinguishes grammatical genders. So it could be here either *Usłyszałem* (masculine), or *Usłyszałam* (feminine). Without a context we cannot be sure whether it is she or he speaking.

- singular/plural/formal "you":

  ab-009: *Never mind, Mrs. Bray will join **you** later.*

  DeepSeek V4 Pro: *Nieważne, pani Bray dołączy do **was** później.* → "you" in plural.

  TRIVE: *Nieważne, pani Bray dołączy do **ciebie** później.* → "you" in singular, informal.

  Dubformer: *Mniejsza z tym, pani Bray dołączy do **pana** później.* → "you" in singular, formal (he – sir).

Comment: All translations are correct. More context is needed to determine which use of "you" is appropriate here.

**Annotation observations.** We also noted that sentence-level evaluation without wider document context occasionally made multiple translations equally acceptable. It shows a limitation of test-suite evaluation rather than MT itself. This has also been reflected by the literature (Gladkoff et al., 2026). We list more English–Polish examples of translation issues in Section C.

Two Polish native speakers completed the annotation independently over all 150 segments; inter-annotator agreement is reported in Appendix B. Agreement on error detection was only fair ($\kappa = 0.32$) and severity calibration differed substantially between the two annotators, so the absolute penalty magnitudes reported for English–Polish should be read as annotator-dependent, even though the system ranking is stable across both annotations. Inter-annotator agreement (IAA) for English–Arabic and English–Chinese is to be reported in the future.

## 6 Conclusions and Future Work

In this work, we used the AlphaMWE multilingual parallel corpus as a test suite in the WMT 2026 Test Suites Shared Task to investigate whether multiword expressions and other non-compositional phenomena remain challenging for contemporary MT systems. We evaluated outputs from 31 participating systems across English–Chinese, English–German, English–Polish, Modern Standard Arabic, Egyptian Arabic, and Tunisian Arabic. We first applied SacreBLEU, chrF++, and BERTScore F1, ranked systems independently for each language pair, and selected the top-performing systems through mean rank aggregation. We then complemented the automatic evaluation with HOPE-based human evaluation by native speakers.

Across the evaluated language pairs, the human analysis indicates that high automatic metric performance does not eliminate linguistically important translation errors. In particular, idioms, verbal MWEs, metaphorical and figurative expressions, lexical ambiguity, and language-specific collocations continue to expose weaknesses in otherwise fluent MT output. These problems are especially visible in literary and expression-rich text, whereas technical and news-oriented sentences were generally handled more reliably. The observed errors also differed across languages: English–Chinese and English–Arabic showed prominent failures involving literal interpretation of idiomatic and figurative expressions, English–Polish exposed difficulties involving verbal aspect, collocation, grammatical distinctions and context-sensitive lexical choice, while the English–German analysis highlighted the tension between idiomatic or literary rendering and domain-specific terminological precision.

The comparison between automatic and human evaluation further suggests that no single automatic metric provides a complete account of translation quality. Although the three automatic metrics often agreed on the strongest systems, non-zero rank standard deviations for several systems revealed substantial metric disagreement. Human annotation subsequently identified errors – particularly those involving semantic scope, idiomaticity, terminology, and contextual interpretation – that are difficult to characterize through aggregate automatic scores alone. This difference is also reflected at the system level: HOPE-based human evaluation does not fully preserve the ranking induced by the aggregated automatic metrics, changing the relative ordering of the selected systems for several language pairs.

Our results therefore support combining complementary automatic metrics with targeted human evaluation when investigating linguistically challenging translation phenomena.

A further limitation concerns sentence-level evaluation. Several English source sentences are underspecified when removed from their wider discourse context. This is particularly important for languages that require grammatical distinctions not explicitly encoded in English, such as gender, verbal aspect, or singular/plural and formal/informal forms of *you*. In such cases, multiple target translations may be equally valid, and reference-based sentence-level evaluation can potentially penalize legitimate alternatives. The AlphaMWE resource retains contextual material originating from the PARSEME data, which provides an opportunity to address this limitation in future work through document-level or context-aware translation evaluation.

Future work will therefore extend the present analysis in three directions. First, we plan to evaluate context-aware and document-level translation of MWE-containing sentences. Second, we will investigate phenomenon-specific evaluation frameworks for idioms, metaphors, and other figurative expressions, where general-purpose MT metrics

may provide insufficient diagnostic information. Third, larger-scale human annotation with multiple annotators per language will enable analysis of inter-annotator agreement, particularly for error severity, and help separate genuine system errors from variation in linguistic preference and annotation judgement. Together, these directions can further develop AlphaMWE from a multilingual test suite into a diagnostic resource for identifying the remaining linguistic blind spots of LLM-based machine translation.

## Limitations

The most important limitations are: 1) two annotators for Arabic but only for one round, 75 segments each; three annotators for Chinese, with two doing 75 segments each, then the 3rd person double-checked the 1st round annotation. Two German native speakers also completed the annotation independently over all 150 segments. Agreement is reported in Appendix D and is markedly weaker than for Polish ($\kappa = 0.10$ on error detection), with the two annotators flagging largely disjoint sets of outputs, so the English–German penalty magnitudes should likewise be treated as annotator-dependent. 2) only 150 common segments used for cross-language human comparison. 3) different systems participated in different language pairs. 4) sentence-level context limitations; and 5) automatic evaluation limited to three metrics, with more metrics considered to be included with extra time, e.g., h/LEPOR (Han et al., 2013), COMET (Rei et al., 2020), and metaphor specific MetaHOPE (Liang and Han, 2026).

## A Language Identifiers

Language identifiers used in the paper are described in Table 4.

## B English–Polish Cross-Annotator Agreement

Table 5 summarises the comparison between the two independent English–Polish annotations. Beyond the aggregate figures, two structural sources of disagreement are worth recording.

**Category overlap.** A recurring pattern is that both annotators identify the *same* defect but file it under different categories. In aa-134, the untranslated "Kong" for Hong Kong was recorded as a proper name error (PRN) by one annotator and as a missing source adaptation (RAM) by the other; in aa-104, one annotator recorded terminology (TRM) and the other mistranslation (MIS) for the same expansion of the source acronym. Per-category detection $\kappa$ ranges from $-0.02$ (UGR) to $0.40$ (TRM, PRN), and RAM was never used by one of the two annotators at all. For HOPE-style schemes we therefore recommend reporting agreement both per category and after collapsing categories that overlap by design, and supplying worked examples for the categories that are otherwise left unused.

**Annotation procedure.** The two annotators worked in different ways. One annotated against a Polish reference translation revised for this study, which was produced by a different person than the annotator. The other did not use the reference column, preferring to translate each source segment independently before scoring. Part of the disagreement reported above therefore reflects a difference in procedure rather than in judgement. The effect is visible in aa-104, where the original reference left the source acronym "OAS" untranslated and all three systems expanded it to *OPA* (*Organizacja Państw Amerykańskich*), whereas the passage (Amin speaking at Port Louis in July 1976) concerns the Organisation of African Unity. The annotator who worked from her own translation recorded this as a critical terminology error on all three systems, while the reference-based annotation did not flag it. A related factor is that the severity scale was not calibrated between the annotators in advance, so the same scale could be read differently across error types. We therefore recommend that IAA studies of HOPE-style schemes record the annotation procedure and a shared severity key alongside the taxonomy itself.

## C Additional English–Polish Translation Examples

The following examples illustrate representative linguistic phenomena identified during the HOPE-based human evaluation of the English–Polish test suite. The source sentence, human reference, and outputs of the three selected systems are shown for each case. The discussion summarizes the Polish annotator's qualitative analysis.

**Example 1: Literal translation of an idiomatic MWE (MIS) – aa-042**

**Source.** But it did not give me the time of day.

**Reference.** Ale nie zwrócił na mnie uwagi.

**DeepSeek V4 Pro.** Ale nie dało mi pory dnia.

**TRIVE.** Ale nawet nie zaszczyciło mnie spojrzeniem.

**Dubformer.** Ale on nawet nie raczył na mnie spojrzeć.

**Discussion.** The DeepSeek V4 Pro output translates the idiom *give me the time of day* literally as *dało mi pory dnia*, which does not convey the intended idiomatic meaning in Polish. In contrast, TRIVE and Dubformer render the expression idiomatically. This example illustrates a severe MWE-related mistranslation, where lexical correspondence is preserved but the intended meaning is lost. It is worth noting that the reference translation differs from the correct machine translations in terms of MWE, but conveys the same meaning.

**Example 2: Verbal aspect in Polish (UGR) – aa-012**

**Source.** When items in a field are hidden by conditional filtering, a funnel appears to the left of the drop-down arrow Field arrow.

**Reference.** Gdy elementy w polu są ukryte przez filtrowanie warunkowe, na lewo od strzałki rozwijanej strzałki Pola pojawia się lejek.

**DeepSeek V4 Pro.** Gdy elementy w polu są ukrywane przez filtrowanie warunkowe, po lewej stronie strzałki rozwijanego pola (strzałki pola) pojawia się lejek.

**TRIVE.** Gdy elementy w polu są ukryte przez filtrowanie warunkowe, po lewej stronie strzałki rozwijania pola pojawia się lejek.

Table 4: Language identifiers used throughout this paper and in the WMT 2026 Test Suites Shared Task.

| Pair | Code | Language | Description |
|---|---|---|---|
| en→ar | ar | Modern Standard Arabic (MSA) | Standard written Arabic |
| en→arz | arz | Egyptian Arabic | Egyptian Arabic dialect |
| en→aeb | aeb | Tunisian Arabic | Tunisian Arabic dialect |
| en→de | de | German | Standard German |
| en→pl | pl | Polish | Polish |
| en→zh | zh | Chinese | Simplified Chinese |

Table 5: Cross-annotator comparison for English–Polish over 150 segments × 3 MT systems (450 MT outputs). SEGS totals are summed error penalties; lower is better. A1 and A2 denote the two independent annotators.

| | A1 | A2 |
|---|---|---|
| SEGS *totals* | | |
| DeepSeek V4 Pro | 116 | 136 |
| TRIVE | 68 | 123 |
| Dubformer | 89 | 133 |
| best–worst spread | 48 | 13 |
| *Annotation profile* | | |
| error instances | 180 | 137 |
| mean severity | 1.52 | 2.86 |
| instances at 8 or 16 | 2 | 11 |
| *Agreement* | | |
| identical error profiles | 265 / 450 (58.9%) | |
| cell-level agreement | 92.9% | |
| detection $\kappa$ | 0.32 | |
| SEGS correlation | $r = 0.70$, $\rho = 0.38$ | |
| system ranking | identical | |

**Dubformer.** Gdy elementy w polu są ukryte przez filtrowanie warunkowe, na lewo od strzałki rozwijania (strzałki pola) pojawia się lejek.

**Discussion.** The DeepSeek V4 Pro translation uses the imperfective form *ukrywane* ('being hidden repeatedly/in progress'), whereas the Polish context calls for a resultative or perfective reading, such as *są ukryte*. This reflects a structural difference between English and Polish: Polish verbal aspect is strongly lexicalized and must often be resolved explicitly during translation. The error does not prevent comprehension, but it produces a less natural grammatical interpretation.

**Example 3: Multiple acceptable context-dependent translations – aa-044**

**Source.** Uncle Vernon might still have been able to make his deal – if it hadn't been for the owl.

**Reference.** Wujek Vernon nadal mógłby zawrzeć umowę – gdyby nie sowa.

**DeepSeek V4 Pro.** Wuj Vernon mógłby jeszcze dopiąć swego – gdyby nie ta sowa.

**TRIVE.** Wuj Vernon być może zdołałby jeszcze ubić interes – gdyby nie sowa.

**Dubformer.** Wuj Vernon być może wciąż byłby w stanie dobić targu – gdyby nie sowa.

**Discussion.** All three system outputs are plausible Polish translations, but *dopiąć swego*, *ubić interes*, and *dobić targu* introduce slightly different semantics. The example illustrates a limitation of sentence-level evaluation: without broader discourse context, more than one target-language realization may be acceptable, and the reference should not be treated as the only valid formulation.

**Example 4: Collocational naturalness (STL) – aa-106**

**Source.** We step into the street and my friend David Shahar, whose chest is large, takes a deep breath and advises me to do the same.

**Reference.** Wchodzimy na ulicę i mój przyjaciel David Shahar, którego klatka piersiowa jest duża, bierze głęboki oddech i radzi mi zrobić to samo.

**DeepSeek V4 Pro.** Wychodzimy na ulicę, a mój przyjaciel David Shahar, którego klatka piersiowa jest duża, bierze głęboki oddech i radzi mi zrobić to samo.

**TRIVE.** Wychodzimy na ulicę i mój przyjaciel David Shahar, który ma szeroką klatkę piersiową, bierze głęboki oddech i radzi mi zrobić to samo.

**Dubformer.** Wychodzimy na ulicę, a mój przyjaciel David Shahar, który ma postawną klatkę piersiową, bierze głęboki oddech i radzi mi zro-

bić to samo.

**Discussion.** Dubformer uses *postawną klatkę piersiową*. In Polish, *postawny* is normally used to describe a person's build rather than a body part, making the phrase collocationally unnatural. The translation remains understandable, so the issue is primarily stylistic rather than a major semantic failure.

**Example 5: Domain terminology versus literal wording (TRM) – aa-137**

**Source.** The fiscal advantages for clean vehicles could then be introduced some two years before the new standards take effect.

**Reference.** Korzyści podatkowe dla ekologicznie czystych pojazdów mogłyby zostać wprowadzone na około dwa lata przed wejściem w życie nowych norm.

**DeepSeek V4 Pro.** Ulgi fiskalne dla pojazdów ekologicznych mogłyby wówczas zostać wprowadzone na około dwa lata przed wejściem w życie nowych norm.

**TRIVE.** Zachęty fiskalne dla czystych pojazdów mogłyby wówczas zostać wprowadzone na około dwa lata przed wejściem w życie nowych norm.

**Dubformer.** Korzyści fiskalne dla czystych pojazdów mogłyby wówczas zostać wprowadzone na około dwa lata przed wejściem w życie nowych norm.

**Discussion.** The literal phrase *czyste pojazdy* is understandable, but Polish domain usage normally favors established expressions such as *pojazdy ekologiczne* or *pojazdy niskoemisyjne*. DeepSeek V4 Pro therefore provides the most idiomatic terminology in this example, while the other outputs illustrate how literal lexical transfer can reduce terminological adequacy even when the overall meaning remains recoverable.

**Example 6: Literal target-language construction (STL) – aa-133**

**Source.** Greece, Italy, France, Spain and Austria, have understood that something has to be done and now have a presence in Albania.

**Reference.** Grecja, Włochy, Francja, Hiszpania i Austria zrozumiały, że trzeba coś zrobić i teraz są obecne w Albanii.

**DeepSeek V4 Pro.** Grecja, Włochy, Francja, Hiszpania i Austria zrozumiały, że trzeba coś zrobić, i teraz mają swoją obecność w Albanii.

**TRIVE.** Grecja, Włochy, Francja, Hiszpania i Austria zrozumiały, że coś trzeba zrobić, i są teraz obecne w Albanii.

**Dubformer.** Grecja, Włochy, Francja, Hiszpania i Austria zrozumiały, że trzeba coś zrobić i są teraz obecne w Albanii.

**Discussion.** DeepSeek V4 Pro transfers the English construction *have a presence* too directly as *mają swoją obecność*. Although the meaning is transparent, this construction is not idiomatic Polish. The reference, TRIVE, and Dubformer instead use *są obecne*, which is considerably more natural. The example demonstrates how literal translation can produce stylistic errors without necessarily causing a loss of propositional meaning.

**Example 7: Scope ambiguity in MWE translation (MIS/STL) – aa-108**

**Source.** In 1947 Copeland had been sent to Damascus ("by whom is not stated," Kedourie says) "to make unofficial contact" with Syrian leaders and "to probe for means of persuading them, on their own, to liberalize their political system."

**Reference.** W 1947 r. Copeland został wysłany do Damaszku ("przez kogo nie jest powiedziane", mówi Kedourie), aby "nawiązać nieoficjalny kontakt" z syryjskimi przywódcami i "poszukać sposobów przekonania ich, na własną rękę, do liberalizacji ich systemu politycznego".

**DeepSeek V4 Pro.** W 1947 roku Copeland został wysłany do Damaszku („przez kogo, nie podano", mówi Kedourie) „aby nawiązać nieoficjalny kontakt" z syryjskimi przywódcami oraz „aby zbadać sposoby nakłonienia ich, samodzielnie, do liberalizacji ich systemu politycznego".

**TRIVE.** W 1947 roku Copeland został wysłany do Damaszku („nie podano przez kogo", jak

twierdzi Kedourie), „aby nawiązać nieoficjalny kontakt” z syryjskimi przywódcami i „wybadać sposoby nakłonienia ich, by z własnej inicjatywy zliberalizowali swój system polityczny”.

**Dubformer.** W 1947 roku Copeland został wysłany do Damaszku („przez kogo, nie podano”, pisze Kedourie) „w celu nawiązania nieoficjalnych kontaktów” z syryjskimi przywódcami i „zbadania możliwości przekonania ich, aby sami zliberalizowali swój system polityczny”.

**Discussion.** The placement of DeepSeek V4 Pro's *samodzielnie* makes the scope of *on their own* difficult to recover and can suggest an unintended interpretation. TRIVE and Dubformer make the semantic relation explicit by using *z własnej inicjatywy* and *aby sami zliberalizowali*, respectively. This case shows that an MWE or modifier may be lexically translated while its syntactic scope is altered, potentially changing the interpretation of the whole sentence.

## D English–German Cross-Annotator Agreement

Table 6 summarises the comparison between the two independent English–German annotations, computed exactly as for English–Polish.

**Unused and disjointly used categories.** Annotator A2 did not use the terminology (TRM) or proper-name (PRN) categories at any point, so the terminological analysis reported in Section 5.3 (including the *standard*/*Norm* distinction in aa-137) has no counterpart in the second annotation. More strikingly, both annotators made heavy use of the impact category, 87 times between them, yet applied it to the same MT output on only three occasions (per-category $\kappa = -0.04$); a further 63 style penalties appear in A2's annotation alone. The only category with substantial agreement is required-adaptation-missing (RAM, $\kappa = 0.57$), which both annotators applied to the uncorrected source defect in aa-134, where the source reads “Kong's civil service” for Hong Kong. These figures suggest that the divergence is driven less by differing severity thresholds than by differing readings of what the categories denote, and they reinforce the recommendation made for English–Polish in Appendix B: HOPE-style schemes need worked examples per category, and agreement should be reported per category rather than only in aggregate.

Table 6: Cross-annotator comparison for English–German over 150 segments × 3 MT systems (450 MT outputs). SEGS totals are summed error penalties; lower is better. A1 and A2 denote the two independent annotators.

| | A1 | A2 |
|---|---|---|
| SEGS *totals* | | |
| VoxNexus_V1 | 42 | 77 |
| DeepSeek V4 Pro | 145 | 131 |
| TRIVE | 140 | 97 |
| best–worst spread | 103 | 54 |
| *Annotation profile* | | |
| error instances | 126 | 162 |
| mean severity | 2.60 | 1.88 |
| instances at 8 or 16 | 12 | 3 |
| *Agreement* | | |
| identical error profiles | 252 / 450 (56.0%) | |
| cell-level agreement | 92.7% | |
| both found an error | 38 | |
| flagged by one only | 162 (49 A1, 113 A2) | |
| detection $\kappa$ | 0.10 | |
| SEGS correlation | $r = 0.15$, $\rho = 0.12$ | |
| system ranking | identical | |

**Effect on discrimination.** The two annotations separate the systems by different margins. Under A1, TRIVE and DeepSeek V4 Pro differ by 5 penalty points out of roughly 140, which is well within annotation noise, while A2 separates them by 34. Conversely, A1 places VoxNexus_V1 far ahead of both competitors (42 against 140 and 145), whereas A2's margin is narrower (77 against 97 and 131). The ordering is preserved in both cases, but the confidence one can place in the second-versus-third comparison depends on which annotation is consulted.

## E Additional English–Chinese Discussion

The **annotation tasks require domain-expertise knowledge** for better understanding of the terminologies and expressions. As one example, from sent-id: aa-76:

**Source.** A query that uses wildcard characters in a criteria expression can produce different results under each query mode.
**Reference.** 在标准表达式中使用通配符的查询，在不同的查询模式下会产生不同的结果。
**Tower-9B.** 在每个查询模式下，使用通配符的条件表达式可能会产生不同的结果。

It is assigned 8 (major error) by our annotator (literature and translation studies background), for MIS error. However, it actually carried a similar meaning to the reference translation, but they are in very different word orders, which might have an impact to our annotators who are using/looking at the offered reference from the original AlphaMWE corpus. After discussion, we changed it to unnatural/proof-reading error with severity level 2.

**Error-severity agreements.** It is not an issue to agree on "whether a sentence has an error", but a problem on the error severity levels, similar findings from Liang and Han (2026). E.g., the sentence "Harry just caught sight of a pair of bright brown eyes staring at him before it closed with a snap." (Sent-id: 054). We have:

**Reference.** 哈利刚看到一双明亮的棕色眼睛盯着他，然后就啪的一声闭上了。
**SCIR-TG.**哈利只来得及瞥见一双明亮的棕色眼睛正盯着他，然后门就啪的一声关上了。
**GoogleMT.** (v) 哈利瞥见一双明亮的棕色眼睛正盯着他，然后那双眼睛啪嗒一声闭上了。
**Tower-9B.** 哈利刚瞥见一对明亮的棕色眼睛在盯着他，然后门就砰地一声关上了。

Both SCIR-TG and Tower-9B translated "door closed" while GoogleMT made a correct translation of "eyes closed". Our initial annotation gave a score of 2 for medium-level; however, after discussion, we think it should be "4 or 8" for major or severe errors.

## F Detailed Automatic Scores Per System Per Language Pair

The detailed scores from SacreBLEU, ChrF++, and BERTscore on submitted systems per language pair are listed in Table 7, 8, and 9.

Their corresponding rankings are displayed in Table 10, 11, and 12.

The top 3 systems per language pair are listed in Figure 6 with their corresponding original metric scores.

Table 7: SacreBLEU scores for the submitted AlphaMWE test suites. Higher scores are better.

# Lost in Morphology at WMT26: A Korean–English Test Suite for LLM Translation Blind Spots

**Deunsol Lee*** **and Daewoong Kim*** **and Yunha Seo***
Soongsil University
{leedeunsol,8330kdw,bobo9245}@soongsil.ac.kr

## Abstract

We present ***lost-in-morphology***, a 3,536-item Korean→English challenge suite spanning nine linguistic phenomena and evaluated on 23 systems submitted to WMT26. The suite targets ellipsis punctuation, stacked particles, wordplay, topic/subject marking, evidentiality, scrambling, auxiliary constructions, connective endings, and ideophones. Rather than forcing all phenomena through one metric, we match each to its observable evidence: deterministic checks for visible or lexically constrained contrasts, structured semantic observations for discourse and operator meanings, contrastive or distributional scoring for multi-variant frames, and a strategy-aware panel for wordplay. Learned judges and classifiers take task-specific admission tests. Scores from those that fail are marked provisional. The evaluation reveals a recurring failure mode hidden by aggregate MT quality: translations often preserve the core proposition while neutralising morphology-induced distinctions. Distinct scalar particles collapse into bare English *even*, evidential and auxiliary meanings are frequently omitted, and connective and ideophone contrasts are flattened. Wordplay remains the hardest subset, with the best system scoring 0.385 against 0.546 for curated references. The evaluator study further shows that task-specific validation is necessary: a conflict-free wordplay judge fails through ceiling saturation, while three judges that are also evaluated systems pass without detectable family preference.

## 1 Introduction

General-purpose language models now match or surpass conventional MT systems on many high-resource directions (Kocmi et al., 2024; Manakhimova et al., 2023). Yet strong corpus-level scores do not imply linguistic completeness. A translation may remain fluent and propositionally plausible while deleting a discourse contrast, neutralizing an information source, collapsing scalar meanings, or omitting a verbal operator. Such losses are difficult to detect with aggregate metrics and are consistent with prior findings that MT can reduce linguistic richness (Vanmassenhove et al., 2019, 2021).

Korean→English is a revealing setting because Korean packages grammatical, information-structural, and pragmatic distinctions into particles, connective endings, auxiliaries, evidential constructions, and flexible word order. English often requires these distinctions to be unpacked into separate lexical or syntactic choices. Ideophones, ellipsis punctuation, and wordplay add expressive contrasts without stable one-to-one equivalents. Challenge sets are well suited to isolating such divergences (Isabelle et al., 2017; Macketanz et al., 2018), but the phenomena differ too much for a single scorer to be appropriate.

We therefore present ***lost-in-morphology***, a 3,536-item Korean→English suite spanning nine subsets and evaluated on 23 WMT26 systems (WMT Organizers, 2026). The suite combines naturally occurring examples, controlled frames, minimal-variant groups, and expert-authored items. Its central design principle is **phenomenon-matched measurement**: visible features use deterministic rules; semantic distinctions use structured observations whose scores are derived by code; multi-variant frames use contrastive or distributional preservation; and wordplay uses a fixed strategy-aware rubric.

The resulting analysis exposes a common pattern across otherwise different phenomena: systems often retain the event or proposition while suppressing the distinction contributed by Korean morphology or discourse marking. Particle stacks are funnelled into generic English cues, evidence source and auxiliary operators disappear, and connective or ideophone variants become less distin-

* Equal contribution.

October 28-29, 2026 ©2026 Association for Computational Linguistics

guishable. At the same time, some failures remain strongly phenomenon- or family-specific, such as deletion of ellipsis-bearing turns.

A second contribution is methodological. Because learned evaluators vary substantially across tasks and models (Zheng et al., 2023; Bavaresco et al., 2025), we treat them as measurement instruments rather than ground truth. Each learned judge or classifier takes a subset-specific admission test, and scores from one that fails are marked provisional. We report the resulting instrument failures alongside the translation failures they are intended to detect.

## 2 Related Work

MT challenge sets isolate targeted linguistic contrasts rather than averaging over heterogeneous test data (Isabelle et al., 2017; Macketanz et al., 2018). Regex- and rule-scored morphology has been studied in Morpheval (Burlot and Yvon, 2017; Burlot et al., 2018), while contrastive and minimal-pair designs have been used for grammatical and discourse phenomena (Sennrich, 2017; Bawden et al., 2018; Müller et al., 2018). Our output-side collapse diagnostics are motivated by the limits of minimal-pair scoring when systems are merely insensitive to the tested contrast (Vamvas and Sennrich, 2021). ACES (Amrhein et al., 2022) and MQM (Lommel et al., 2014) provide broader error taxonomies; our error codes are MQM-compatible.

For Korean, K-SNACS (Hwang et al., 2020) informs the particle feature inventory, while prior work motivates the discourse and grammatical distinctions tested here. Wordplay evaluation builds on SemEval-2017 Task 7 (Miller et al., 2017) and the JOKER tasks (Ermakova et al., 2023, 2025). LLM judging has shown strong system-level correspondence with human MT evaluation (Kocmi and Federmann, 2023), but judge reliability is task-dependent; this motivates our admission tests, reference pseudo-systems, negative anchors, agreement checks, and attrition reporting.

## 3 The *lost-in-morphology* Suite

### 3.1 Suite Overview

Table 1 summarizes the nine subsets. Full construction details, inventories, and rubric examples are provided in Appendix A.

Every item includes a machine-readable `judge_spec`. Where a three-level verdict is appropriate, scores are PASS=1, PARTIAL=0.5, and FAIL=0. Deterministic rules may emit WARN, in which case a learned adjudicator handles the residue. System names are withheld from learned judges, chat-style outputs are normalized before scoring, and subset scores are item micro-averages unless a frame-level metric is explicitly defined.

All scorers are also run on curated references as pseudo-systems. This gives an empirical false-negative floor before system ranking: 0.999 for the ELLIPSIS rules, 0.892 for the PARTICLES checklist, 0.546 for the admitted WORDPLAY panel, 0.967 for the connective classifier, and 0.733 for the ideophone classifier. These anchors are diagnostic rather than claims that references should receive perfect scores.

### 3.2 Phenomenon-Matched Measurement

**Visible or lexically constrained evidence.** Ellipsis is scored by category-specific checks over a localized focus span: presence, position, pause count, terminal combinations, quote flanking, and overgeneration. Stacked particles use feature-specific cue checklists, because several English realisations may be valid. Checklist accuracy alone cannot detect when distinct Korean inputs receive the same English output, so particle scoring is paired with a contrast-collapse rate over gold-distinct members of the same minimal-variant group.

**Structured semantic observations.** Topic/subject marking, evidentiality, scrambling, and auxiliaries are judged through strict structured outputs rather than free-form scalar ratings. A judge observes, for example, proposition correctness, realized discourse status, evidence source, typed argument roles, or semantic operators. Deterministic code then maps those observations to the final score. This separates proposition preservation from the morphological or discourse distinction under test.

**Contrast and distribution preservation.** Connective endings and ideophones use multi-variant frames. Pointwise label accuracy can reward a classifier or system that repeatedly defaults to a majority label, so we additionally measure frame-level preservation with

$$\mathrm{SRP} = 1 - \mathrm{JSD}(p_{\mathrm{gold}}, p_{\mathrm{pred}}),$$

where the distributions are taken over the labels realized within a controlled frame. This makes se-

Table 1: Overview of the nine test-suite subsets. The main paper groups phenomena by measurement type; detailed item construction is in Appendix A.

| Phenomenon | n | Test structure | Primary measurement | Key diagnostic |
|---|---|---|---|---|
| Ellipsis | 601 | corpus + templated items | deterministic rules + adjudication | preservation / omission |
| Stacked particles | 579 | 172 minimal-variant groups | cue checklist + pair comparison | semantic fidelity / collapse |
| Wordplay | 65 | attested + expert-authored | admitted LLM panel | strategy-aware score |
| Topic/subject | 387 | controlled minimal pairs | structured semantic judge | contrast preservation |
| Evidentiality | 400 | 100 four-way frames | structured semantic judge | source preservation / neutralisation |
| Scrambling | 599 | argument-order variants | typed role recovery | role exact match / discourse preservation |
| Auxiliaries | 541 | operator variants | structured semantic judge | operator recall / deletion |
| Connectives | 194 | discourse-relation variants | admitted relation classifier | distributional preservation |
| Ideophones | 170 | manner/intensity variants | admitted fine-grained classifier | distributional preservation |

mantic collapse observable even when individual outputs are fluent.

**Open-ended strategy-aware evaluation.** Wordplay cannot be decided from closed surface cues. Each item therefore specifies a pun pivot, sense inventory, and curated strategy, and admitted judges apply a fixed three-level rubric: 1.0 for recreated wordplay or equivalent humorous dual-sense preservation, 0.5 when one sense is faithful and the other remains recoverable, and 0.0 when the pun is ignored or the pivot mistranslated. The reported score is the median of admitted judges.

### 3.3 Admission of Learned Evaluators

Learned evaluators are admitted per task rather than by architecture. Wordplay judges are tested on curated-reference positives whose expected rubric strata are known a priori and on mismatched-reference negatives. A judge must preserve the expected positive ordering, stay below the rubric ceiling, and reject negatives. Connective and ideophone label classifiers use their own calibration instruments. Full prompts, tables, and agreement analyses are provided in Appendix C.

The most important admission result is counter-intuitive: EXAONE-4.0-32B, the only conflict-free wordplay judge in the candidate panel, fails because it assigns 1.00 to every positive stratum and to the references overall. Gemma4-31B, gpt-oss-20b, and Qwen3.6-27B pass, reproduce the expected strategy ordering, and reject negatives. The wordplay score therefore uses the median of those three judges. For connective endings, a rule-based classifier is selected as primary on a held-out calibration set; for ideophones, the reference-as-pseudo-system protocol selects the primary classifier.

## 4 Results

### 4.1 Overall Pattern: Fluent Neutralisation

The dominant cross-phenomenon failure is often *neutralisation* rather than an obviously false proposition. Evidential and auxiliary constructions are the clearest examples. Evidentiality spans 0.538–0.968 across systems (mean 0.798), but pooled evidential-feature recall is only 0.712. Among proposition-correct outputs, neutralisation averages 0.204, while conflicting source shift occurs in 0.081 of all outputs. Plain assertions and inferential *geot gatda* are nearly saturated (0.984/0.960), whereas reportative *-dae* falls to 0.690 and direct-perceptual *-teora* to 0.557.

Auxiliary constructions show the widest admitted spread: Dubformer reaches 0.935 while SalamandraTA scores 0.195 (system mean 0.584). Operator precision remains high at 0.946, but recall is 0.624 and the operator-deletion rate is 0.376. The main predicate therefore frequently survives after the contribution of the auxiliary disappears. The try/experience auxiliary *boda* is especially difficult (0.243), while unwanted-result *-go malda* is much easier (0.888).

The same tendency appears in multi-variant phenomena. Connective-ending $\mathrm{SRP}_{\mathrm{JSD}}$ ranges 0.466–0.671 (mean 0.566), and ideophone $\mathrm{SRP}_{\mathrm{JSD}}$ ranges 0.474–0.634 (mean 0.551). Pointwise accuracy does not reproduce the connective ranking, because majority-relation defaults can score adequately while collapsing the other

Table 2: Results for 23 systems. ELLIPSIS and PARTICLES are rule-based scores with LLM-adjudicated WARN cases; WORDPLAY is the median score of admitted judges. Collapse is lower-better; all other scores are higher-better. Bold marks the best system per column.

distinctions. Ideophone collapse averages 0.370 and likewise does not track SRP monotonically.

### 4.2 Lexical Funneling and Contrast Collapse

Stacked particles expose a lexical version of the same failure. Mean score by stack depth is 0.95 / 0.83 / 0.75 / 0.70 / 0.74 for depths 1–5; the depth-5 rebound also appears in the references and is therefore best read as a template-composition effect rather than improved depth handling.

More importantly, distinct scalar particles are funnelled into bare English *even*. Pooled over systems, *-cocha* and *-mace* are rendered as bare *even* in 88.6% and 87.9% of realisations, while the references use differentiators in 57% of cases. Because *even* satisfies the cue lexicon for multiple scalar labels, a checklist can reward the very collapse the suite is designed to expose. The group-level metric corrects this: Lumen collapses 35.1% of gold-distinct pairs, whereas Qwen 3.5-9B collapses only 1.7% despite a mediocre checklist score of 0.708. Low collapse therefore does not itself imply semantic correctness; it must be interpreted jointly with the feature score.

### 4.3 Phenomenon-Specific Failure Modes

Ellipsis is largely saturated: 19 of 23 systems score at least 0.87 (median 0.96), and TRIVE preserves all 601 items. The Gemma 4 family is a striking exception at 0.42–0.44. Its failures are not mainly typographic: in 88% (31B) and 87% (4B) of failing cases, the entire ellipsis-bearing utterance is absent. The profile is category-specific: pure silence and most trail-off cases survive, while response turns combined with other punctuation approach zero. Appendix A gives the category breakdown.

Scrambling is comparatively robust once role recovery is separated from surface order. The admitted score ranges 0.483–1.000 (mean 0.922), pooled role-level accuracy is 0.974, strict three-role exact match is 0.942, and explicit role reversal is only 0.009. Object fronting is the hardest variant (0.881), consistent with the need to recover both thematic role and contextual focus rather than imitate Korean word order.

Topic/subject marking similarly looks easy pointwise but becomes more diagnostic under paired comparison. Item scores average 0.956, although the judge fails the negative-anchor criterion and the number is therefore provisional. Jointly judged minimal pairs average 0.863 contrast accuracy and 0.116 semantic collapse, with system-level collapse ranging from 0.02 to 0.53.

### 4.4 Wordplay and Evaluator Reliability

Wordplay remains the hardest subset. The best system scores 0.385 against 0.546 for curated references, and the top eight systems lie between 0.20–0.39. With only 65 items and confidence-interval half-widths around $\pm 0.07$, the subset supports coarse system-level distinctions rather than fine ranking. The 15 attested items from translation-studies literature are harder for systems (mean 0.139) than the 50 expert-authored items (0.177), so the authored majority does not appear to inflate difficulty.

The evaluator study is itself diagnostic. The conflict-free EXAONE judge fails through ceiling saturation, whereas the three admitted judges are also evaluated systems but show no detectable kin inflation. Their strategy-to- score mappings are similar, yet they agree on the perceived strategy label for only 42% of judgments. Thus the main source of disagreement is often whether surviving wordplay is perceived at all, not how a shared label is valued. We consequently use the panel median only as a calibrated diagnostic for coarse comparison, not as a substitute for human wordplay judgment.

## 5 Conclusion and Limitations

We introduced *lost-in-morphology*, a 3,536-item Korean→English test suite covering nine grammatical, discourse, and expressive phenomena, and evaluated 23 WMT26 systems with phenomenon-matched instruments. Across the suite, the recurring failure is not necessarily a false proposition but loss of the distinction encoded by Korean morphology or discourse marking: ellipsis-bearing turns are deleted, scalar particles funnel into generic English cues, evidence sources and auxiliary operators disappear, and connective or ideophone contrasts collapse.

The suite also shows why learned evaluators should be validated as task-specific measurement instruments. A conflict-free judge can still be unusable because of ceiling saturation, and judges that nominally share a rubric can disagree mainly in perception. Admission anchors, attrition reporting, agreement checks, and independent classifiers reduce these risks but do not establish equivalence to human evaluation.

Several limitations bound the claims. The suite covers only Korean→English and mixes corpus-mined, controlled, template-generated, and expert-authored items, so category balance is not an estimate of naturally occurring error prevalence. Items within minimal-variant frames are dependent, and psychometric estimates based on 23 systems remain noisy. Wordplay lacks independent human MQM labels; connective tier assignment has low inter-judge agreement; per-judge tier decisions were not retained for the full ideophone pool; and some judge models are also evaluated systems. Future work should add independent human validation, revise saturated and near-dead items, repeat the analysis on new system and judge pools, and extend matched phenomena to additional language directions.

# A Detailed Test-Suite Construction

This appendix records the phenomenon-level construction details and examples that are useful for reproduction but not required to follow the main narrative.

## A.1 ELLIPSIS: Ellipsis Punctuation (601 items)

Korean writes reticence, silence, hesitation, and editorial omission with the ellipsis mark (…, ……), and the 2015 orthographic norms enumerate four core functions (National Institute of Korean Language, 2014). Prior Korean translation studies show that English and Korean ellipses are graphically parallel but functionally divergent (Kim, 2011), and that professional literary Korean→English translation preserves the mark in 83 of 85 cases while frequently shifting function (Lee and Kim, 2015). Our nine categories are those functions plus mark+?/! combinations.

We restrict this subset to dialogue and broadcast-style register because punctuation preservation is genre-dependent. In the licensed broadcast-subtitle corpus used for mining, professional translators retain the mark in 85.3% of Korean-ellipsis pairs (215/252), consistent in direction with the literary figure above.

Of the 601 items, 182 are mined by regex and retained only when the professional English side also contains a mark; 419 are template-generated with carrier contexts written by Qwen3.6-35B-A3B (Qwen Team, 2026) and manually screened.

Table 3: ELLIPSIS categories, after the four norm functions plus terminal combinations.

| Category | n | Expected treatment |
|---|---|---|
| HESITATION | 94 | keep pauses, any glyph |
| ELL_Q | 90 | keep both … and ? |
| TRAIL_OFF | 89 | utterance-final mark |
| EMOTIVE_PAUSE | 86 | keep affective pause |
| SILENCE | 74 | silent turn stays mark-only |
| MULTI_PAUSE | 59 | preserve pause count |
| ELL_EX | 58 | keep both … and ! |
| QUOTE_OMISSION | 41 | editorial … inside quotes |
| MID_PHRASE | 10 | pause stays medial |

Glyph variants (…, ……, ...) are rotated row-by-row so category is not confounded with one Unicode form. Every prompt explicitly instructs preservation.

**Scoring details.** Glyph variants are canonicalized before category-specific checks over a localized focus span. The focus span is found by line alignment against the source (72.2% of judgments), fuzzy match against the reference focus (23.6%), or whole-output fallback (4.2%). When localization fails and the context itself contains an ellipsis, a would-be PASS is escalated rather than credited. Word-based compensation such as "he paused" is escalated rather than automatically failed.

**Rubric example (ELL_Q, mark+?).**

KO "이제 다 끝났어." / "정말…… 끝난 거야?"
REF "It's all over now." / "Really... is it over?"
PASS TRIVE: "Is it really... over?" — mark and ? both kept, medial position tolerated.
FAIL (E3_FUNC_SHIFT) Gemma 4-31B: "It's all over now." — the question turn is absent entirely.
FAIL (E4_COMBO_LOSS) GPT OSS 20B: "What's all of this sudden?" — question kept, mark stripped.

Additional diagnostics: utterance-final ellipses are hardest (0.81 vs. 0.93 medial); the six-dot form …… (0.87) and ASCII . . . (0.88) are harder than single … (0.92); and the corpus arm is easier than the synthetic arm (0.95 vs. 0.88). Word-based compensation is nearly absent (≤5/601 per system). Sixteen of 23 systems prefer ASCII . . . over U+2026.

### A.2 PARTICLES: Stacked Particles (579 items)

Korean post-nominal particles stack under ordering constraints (Lim, 2004), and each layer contributes meaning. Scalar particles such as 도/까지/조차/마저 are semantically distinct (Han, 2010) even though they often gravitate toward English *even*. Each particle is annotated with a semantic feature informed by K-SNACS (Hwang et al., 2020).

The design contains 172 minimal-variant groups. Each group fixes a base frame and host noun while varying only the particle stack at depth 1–5. Stacks were checked for well-formedness and ordering with the Kiwi analyser (Lee, 2024); carrier contexts were LLM-written and reviewed.

Each row separates *checkable* features (11 of 17 labels, with a reliable English cue lexicon; 564/579 items) from weak features such as case or contrastive topic, which go to adjudication. The rule score is the fraction of checkable cues realized in the focus sentence. For every pair of variants whose feature sets differ, we additionally test whether the English focus sentences are identical, yielding the contrast-collapse rate over 724 pairs.

**Rubric example (group `grp_0001`, host 선생님 'teacher').**

도 *-to* (ADDITIVE) → REF "The teacher **also** entered…"; Lumen "The teacher also entered…" ✓
까지도 *-kkaci-to* (SCALAR_EXTENT+ADDITIVE) → REF "**Even** the teacher entered…"; Lumen "Even the teacher entered…" ✓
조차도 *-cocha-to* (SCALAR_LEAST_LIKELY+ADDITIVE) → REF "Even the teacher **(of all people)** entered…"; Lumen "Even the teacher entered…" ✓
All three pass the cue checklist, yet the last two English outputs are identical and therefore collapsed.

Contrast-family stacks (은/는) are the hardest family (0.66 vs. additive 0.86), while role-class hosts such as 로서 *-lose* are the hardest host class (0.59). Bare-*even* rate correlates $r = 0.82$ with checklist score across systems, partly mechanically. The reference attains the highest checklist score despite the lowest bare-*even* rate (0.43). Full-scale judge validation further shows that rule-PASS depth-5 rows average only 0.62 under the judge, motivating future differentiator-aware cue features.

### A.3 WORDPLAY: Wordplay (65 items)

Fifteen items are attested puns with published professional translations from the Korean translation-studies literature; 50 are expert-authored. Items cover native and Sino-Korean homophones, idiom literalization, polysemy, and culture-specific play. Each item records the pun pivot and sense inventory, following SemEval-style annotation (Miller et al., 2017), and a curated reference strategy in Delabastita's typology (Delabastita, 1994, 1996): pun-to-non-pun (33), new pun (14), literal-plus-explanation (11), or target-language pun (7).

The fixed rubric assigns 1.0 when wordplay is recreated or both senses are conveyed with humor-

ous effect, 0.5 when one sense is faithful and the other is recoverable, and 0.0 when the pun is ignored or the pivot mistranslated. Judges receive the pivot, its sense inventory, and the curated reference marked as one acceptable strategy. Structured output includes both strategy label and score.

**Rubric example (pivot 꼬리/이야기, *kkoli/iyaki*, 'tail'/'tale').**

KO "꼬리에 꼬리를 무는 길고도 슬픈 이야기지!" / "꼬리가 길긴 하네."
REF "It's a long sad tail-of-a-tale, one tail biting another!" / "That's certainly a long tail."
**1.0** Command A+: "... a long, sad tale that just keeps dragging on!" / "Well, the tail is long..."
**0.0** Cohere CAT+: "... a long and sad tale that keeps going on and on!" / "Well, it certainly is a long one."
The same Command A+ output receives 1.0 from one admitted judge and 0.5 from another, motivating a panel median.

### A.4 Topic/Subject Marking (387 items)

In the canonical contrast tested here, Korean *i/ga* (이/가) marks a subject that answers the current question, whereas *eun/neun* (은/는) establishes or contrasts a discourse topic. English may realise the distinction through clefts, prosodic emphasis, *as for*, contrastive connectives, or contextually licensed neutral SVO, making simple keyword rules unreliable.

We instantiate 195 controlled lexical frames and vary the question under discussion together with the marked subject while holding the proposition fixed. The resulting 387 items contain 194 *ga*-focus and 193 *neun*-contrast items; 192 frames form complete minimal pairs.

**Minimal-pair example (subject focus vs. contrastive topic).**

Context "누가 왔어?" / KO "철수가 왔어."
REF "Cheolsu came." or "It was Cheolsu who came."
Context "지수는 안 왔어. 철수는?" / KO "철수는 왔어."
REF "As for Cheolsu, he came." / "Cheolsu did come." / "Cheolsu came, though."
A plain "Cheolsu came" can be licensed by either context; a who-cleft used as the only rendering of the second member does not itself preserve the contrast.

The structured judge records proposition correctness, realized focus span, required-feature labels, and information-structure status. Code assigns PASS only when proposition and required features are preserved with no spurious feature; PARTIAL covers a weakened distinction; and FAIL covers wrong focus/contrast assignment, direction reversal, or proposition error. A separate joint judgment over 100 selected pairs yields pairwise contrast accuracy and semantic-collapse rate.

### A.5 Evidentiality (400 items)

Korean *-teora* (-더라) is tested in direct-perceptual contexts, colloquial *-dae* (-대) as reportative (Jang, 2025; Chae, 2015), *-(eul) geot gatda* (-(으)ㄹ 것 같다) as inferential/epistemic, and a plain assertion as control. One hundred propositional frames are each realized as a four-member set.

Table 4: Balanced evidentiality strata.

| Evidence type | n | Required interpretation |
|---|---|---|
| direct perception (-더라) | 100 | _saw / noticed / when I checked_ |
| reportative (-대) | 100 | _they say / I heard / apparently_ |
| inference (것 같다) | 100 | _looks like / seems / probably_ |
| unspecified assertion | 100 | no added source or uncertainty |

The judge records proposition correctness independently from predicted evidence type and flags conflicting source shifts. PASS requires the correct proposition and exact evidence class; a marked source weakened to an unmarked assertion is PARTIAL; source replacement or proposition error is FAIL.

**Rubric example (direct perception vs. source loss/shift).**

Context "직접 봤어?" / KO "비가 오더라."
PASS "I saw that it was raining."
PARTIAL "It was raining."
FAIL "I heard that it was raining."

### A.6 Scrambling (599 items)

Korean canonical transitive order is SOV, but overt case particles permit several non-canonical orders. English typically restores the same roles in SVO order, so the task is semantic transfer rather than source-order imitation (Park, 1995). Scrambling is also discourse-sensitive (Lee, 2015).

We create 100 three-argument transfer frames annotated with subject (S), indirect object/recipient (IO), object/theme (O), and verb, then generate canonical, argument-fronting, subject-after-object, right-dislocation, and contrastive-object variants. Ninety-nine frames contain all six variants and one contains five, for 599 items.

Table 5: Scrambling variants.

| Variant | n | Korean order | Focused role |
|---|---|---|---|
| canonical | 100 | S–IO–O–V | S |
| object fronting | 100 | O–S–IO–V | O |
| IO fronting | 100 | IO–S–O–V | IO |
| subject after object | 100 | O–IO–S–V | S |
| right dislocation | 100 | S–IO–V–O | O |
| contrastive object | 99 | O–S–IO–V | O |

The structured judge fills a typed assignment for every gold role: gold entity, corresponding candidate span or `MISSING`, and same-entity status. Missing arguments, wrong recipients, or role reversals are failures even when the remaining English is fluent. When all roles are correct, discourse preservation determines PASS versus PARTIAL.

**Rubric example (object focus after scrambling).**

Context "철수는 현우에게 뭘 주었어?" / KO "책을 철수가 현우에게 주었어."
PASS "Cheolsu gave Hyunwoo a book."
PASS "It was a book that Cheolsu gave Hyunwoo."
FAIL "Hyunwoo gave Cheolsu a book."

### A.7 Auxiliary Constructions (541 items)

Korean productive V–V sequences combine a lexical predicate with secondary verbs after *-a/eo*; in auxiliary use these verbs contribute meanings such as attempt, experience, benefactive, preparation, unwanted outcome, and achievement (Hwang and Whitman, 2021). English typically lexicalises these meanings with constructions such as *managed to*, *ahead of time*, or *as a favour*.

The released suite isolates one auxiliary construction per item. Of 91 lexical frames, 88 contain all six operator variants, two contain five, and one contains three, yielding 541 items.

Table 6: Auxiliary-construction inventory.

| Subtype | n | Auxiliary | Required semantics |
|---|---|---|---|
| completion/regret | 91 | 버리다 | completion + regret/unexpectedness |
| preparatory retention | 91 | 두다 | in advance + retained result |
| benefactive | 90 | 주다 | action performed for another |
| unwanted result | 90 | 말다 | unwanted outcome + resignation |
| manage to | 90 | 내다 | achievement + success |
| try/experience | 89 | 보다 | attempt + experience |

The judge evaluates the main predicate, each exact semantic operator, added operators, and operator scope separately. PASS requires complete operator preservation with correct scope; PARTIAL covers weakening or deletion with the core proposition intact; and reversed meaning, polarity, modality, or main predicate is FAIL.

**Rubric example (achievement/success operator).**

Context "어렵다며, 결국 성공했어?" / KO "철수는 케이크를 먹어 냈어."
PASS "Cheolsu managed to eat the cake."
PARTIAL "Cheolsu ate the cake."
FAIL "Cheolsu failed to eat the cake."

### A.8 Connective Endings (194 items)

Korean clausal connective endings fuse discourse-relation marking into a bound morpheme. Each item is labelled with a PDTB 3.0 discourse relation (Webber et al., 2019). Minimal variants hold the clause pair fixed while rotating only the connective ending.

여생을 보내기로 작정**해서** 재산을 나눠주었다 → *Because he decided..., he gave away...*
여생을 보내기로 작정**하면서** 재산을 나눠주었다 → *While deciding..., he gave away...*
여생을 보내기로 작정**하고** 재산을 나눠주었다 → *Having decided..., he gave away...*
여생을 보내기로 작정**하자** 재산을 나눠주었다 → *As soon as he decided..., he gave away...*

Table 7: Connective-ending relation inventory.

| Relation | n | Marker example | Required distinction |
|---|---|---|---|
| CONTINGENCY-Condition | 13 | -(으)면 | first clause is a condition for the second |
| TEMPORAL-Synchronous | 12 | -(으)면서 | simultaneous non-backgrounded |

Three LLMs also assigned a four-point source-acceptability rubric, yielding 16 primary, 139 marginal, and 39 excluded items. Inter-judge agreement on tier assignment was low (Fleiss $\kappa \approx 0.05$), so tiering is treated as a limitation rather than hidden. A post-hoc analysis over all 194 items preserves the load-bearing ranking claims but produces larger mid-table shifts, up to 12 ranks for some systems.

A 70-item held-out calibration set shows that pointwise majority prediction already reaches 27–29% accuracy. We therefore report $\text{SRP}_{\text{JSD}}$ over multi-variant frames rather than relying on accuracy alone.

**Rubric example (CONTINGENCY-Condition, -면).**

KO "비치면 이케 왔다 갔다 하거덩."
REF "If the light shines on it, it moves back and forth like this."
PASS Lumen: "When you unfold it, it goes back and forth like this." — relation preserved despite a lexical error.
FAIL Command A+: "It would be like going back and forth like that." — no connective is realized.

### A.9 Ideophones (170 items)

Korean ideophones encode manner and intensity iconically; fine phonological changes can shift repetition, force, or speed (Kim, 1977). We define seven coarse semantic categories and embed one ideophone from a 52-item inventory in a fixed carrier sentence, rotating only the ideophone across variants of the same category.

Tier construction follows the same three-judge acceptability family as connectives: 119 primary / 45 marginal / 6 exclude. The fine-grained target is a label such as `PRECIPITATION-high`, and frame-level $\text{SRP}_{\text{JSD}}$ measures whether fine distinctions remain distributed as in the gold frame.

Table 8: Ideophone category inventory. Last three rows (n=4–5) are exploratory only.

| Coarse category | n | Example pair | Intensity axis |
|---|---|---|---|
| MOTION-REPEATED | 54 | 깡총깡총 vs. 폴짝폴짝 | force of repeated motion |
| MANNER-PACE | 40 | 천천히 vs. 빨리빨리 | speed/manner of an action |
| EMOTION-BODY | 29 | 두근두근 vs. 벌렁벌렁 | intensity of a bodily/affective state |
| LIGHT-VISUAL | 28 | 반짝반짝 vs. 번쩍번쩍 | brightness/suddenness of a visual effect |
| SOUND-IMPACT | 5 | 쿵 vs. 쾅 | force of an impact sound |
| TEXTURE | 4 | 보들보들 vs. 까슬까슬 | surface texture quality |
| PRECIPITATION | 4 | 보슬보슬 vs. 주룩주룩 | intensity of rainfall |

**Rubric example: category and intensity confusion.**

For 살랑살랑 (MOTION-REPEATED.LOW), Tower 9B's "while gently moving its front paws" preserves low-intensity repeated motion, while a classifier reads Qwen 3.6-27B's equally plausible "gently wiggled" as the wrong category. For 두근두근 (EMOTION-BODY.MEDIUM), a faithful "thump-thump" rendering preserves medium intensity, while an intensified cue elsewhere in the sentence can push the classifier to a high-intensity label. These examples motivate classifier validation and frame-level reporting rather than blind reliance on pointwise labels.

# B Structured Semantic Evaluation Protocol

Topic/subject marking, evidentiality, scrambling, and auxiliaries use one shared structured protocol. We draw 200 items per phenomenon with seed 42, stratified by subtype; topic/subject instead samples 100 complete minimal pairs. The same source sample is scored for all 23 systems, yielding 18,400 item judgments, and the topic pairs add 2,300 joint judgments.

Qwen3.6-27B receives the Korean context and source, references, the annotated feature inventory, and one normalized candidate, but not the system name. Temperature is zero and output is strict JSON. Deterministic code, not the judge, maps observations to three-level scores. Free-form `extra_features` are diagnostic only unless they match an item's declared `forbidden_features`; translating the supplied context is not penalized.

Before system scoring, curated-reference positives and mismatched-reference negatives probe the same contract. Full-release counts describe construction; system scores on these four subsets estimate performance on the shared 200-item samples.

# C Judge Models as Measurement Instruments

All wordplay judging uses unmodified open-weight checkpoints through one OpenAI-compatible endpoint with a fixed protocol: system+user prompt, temperature 0, strict-JSON request, and 2000-token budget. Candidate judges are EXAONE-4.0-32B (LG AI Research, 2025), Qwen3.6-27B (Qwen Team, 2026), Gemma4-31B (Gemma Team, 2026), and gpt-oss-20b (OpenAI, 2025). Three are themselves among the 23 evaluated systems; EXAONE is not.

## C.1 Wordplay Judge Admission

With no human MQM labels for wordplay, each judge is validated against items whose score is known a priori: curated references whose expected rubric stratum follows from strategy labels, plus mismatched-reference negative anchors. A judge is admitted if it (i) orders positive strata as expected, (ii) keeps references at or below the 0.746 rubric ceiling, and (iii) scores negatives below 0.1.

Table 9: Wordplay judge admission.

| Anchor (expected) | EXAONE-4.0-32B | Qwen3.6-27B | Gemma4-31B | gpt-oss-20b |
|---|---|---|---|---|
| new pun (~1.0) | 1.00 | 0.80 | 0.86 | 0.77 |
| target-lang pun (~1.0) | 1.00 | 0.33 | 0.86 | 0.58 |
| literal+expl. (0.5–1.0) | 1.00 | 0.62 | 0.64 | 0.59 |
| pun-to-non-pun (~0.5) | 1.00 | 0.26 | 0.32 | 0.43 |
| mismatched (~0.0) | 0.01 | 0.02 | 0.00 | 0.00 |
| reference overall (ceiling 0.746) | 1.00 | 0.47 | 0.55 | 0.55 |
| **admitted** | **no** | **yes** | **yes** | **yes** |

EXAONE rejects negatives but assigns 1.00 to every positive stratum and the reference overall, making it unusable for ranking. Gemma4-31B, gpt-oss-20b, and Qwen3.6-27B reproduce the expected ordering, keep the reference below the ceiling (0.55, 0.55, 0.48), and score negatives at 0.00–0.02.

## C.2 Behaviour Profiles and Agreement

EXAONE places 77% of its score mass on 1.0, whereas the three admitted judges place 69–83% on 0.0. Output-format attrition varies from 0% (EXAONE, Gemma4-31B) to 29% (Qwen3.6-27B), showing that a fixed judge protocol is not model-agnostic.

Because each judge returns a strategy label as well as a score, we can separate valuation from perception disagreement.

The label-to-score mappings are similar, but the judges agree on the strategy label in only 42% of judgments and on the score in 60%. Of 399 score disagreements, 41% use the same label but different score, while 59% use different labels. The share of outputs perceived as containing surviving wordplay ranges from 3.2% to 9.8%.

The three judges that are also evaluated systems show negative mean preference residuals toward their own model families (Gemma4-31B: $-0.34$;

Table 10: Judge behaviour on shared WORDPLAY judgments. Attrition is the share with no parseable score under the fixed protocol.

| Judge | Scored system? | Attrition | Mean | %0 | %.5 | %1 | Kin Δz | max\|Δz\| |
|---|---|---|---|---|---|---|---|---|
| EXAONE-4.0-32B | no | 0% | 0.82 | 13% | 11% | 76% | — | 1.34 |
| Qwen3.6-27B | yes | 29% | 0.15 | 75% | 19% | 6% | -0.10 | 1.04 |
| Gemma4-31B | yes | 0% | 0.14 | 83% | 7% | 10% | -0.34 | 1.11 |
| gpt-oss-20b | yes | 5% | 0.21 | 69% | 20% | 12% | -0.10 | 1.13 |

Table 11: Mean score each admitted judge assigns given its own strategy label, with perceived surviving-wordplay rate.

| Judge label | Gemma4-31B | gpt-oss-20b | Qwen3.6-27B |
|---|---|---|---|
| pun-to-pun | 1.00 (60) | 0.96 (138) | 1.00 (20) |
| new pun | 1.00 (21) | 0.58 (12) | 1.00 (13) |
| literal + explanation | 0.59 (51) | 0.36 (153) | 0.34 (120) |
| non-pun paraphrase | 0.10 (961) | 0.14 (734) | 0.16 (529) |
| omission | 0.00 (110) | 0.02 (241) | 0.00 (187) |
| mistranslation | 0.00 (292) | 0.00 (137) | 0.00 (180) |
| **Wordplay detected** | **4.7%** | **9.8%** | **3.2%** |

Table 12: Pairwise judge agreement on shared WORDPLAY judgments.

| Judge pair | n | Exact | Pearson | Rank ρ |
|---|---|---|---|---|
| exaone4-32b / qwen3.6-27b | 1056 | 0.19 | 0.26 | 0.85 |
| exaone4-32b / gemma4-31b | 1495 | 0.22 | 0.18 | 0.87 |
| exaone4-32b / gpt-oss-20b | 1416 | 0.24 | 0.23 | 0.81 |
| qwen3.6-27b / gemma4-31b | 1056 | 0.79 | 0.55 | 0.83 |
| qwen3.6-27b / gpt-oss-20b | 1008 | 0.67 | 0.36 | 0.78 |
| gemma4-31b / gpt-oss-20b | 1416 | 0.70 | 0.38 | 0.81 |

gpt-oss-20b: $-0.10$; Qwen3.6-27B: $-0.10$). No kin inflation is detectable in this panel, although this does not rule out subtler bias.

### C.3 Connective and Ideophone Classifier Admission

For connectives, a rule-based keyword classifier and two LLM candidates are compared on a 70-item calibration set stratified by cue type.

Table 13: Connective-ending classifier admission.

| Cue type (n) | keyword (rule) | Qwen2.5-7B | Qwen3.6-27B |
|---|---|---|---|
| explicit (43) | **98%** | 79% | **98%** |
| implicit (14) | 57% | 57% | 86% |
| ambiguous marker (13) | 85% | 69% | 62% |
| Overall (70) | 87% | 73% | **89%** |

The rule-based classifier is adopted as primary. Qwen3.6-27B's marginally higher calibration score could not be validated at scale before the shared inference endpoint was withdrawn.

For ideophones, no comparable rule baseline exists, so the reference-as-pseudo-system protocol is used.

Table 14: Ideophone classifier admission via reference-as-pseudo-system calibration.

| Classifier | Ref. SRP | Ref. pointwise | Role |
|---|---|---|---|
| Qwen2.5-7B | 0.508 | 43.7% | rejected – inside system range |
| Gemini-3.5-Flash-Lite | **0.733** | **63.9%** | admitted – primary |

Gemini-3.5-Flash-Lite is adopted as primary, with two independent classifiers retained for cross-validation.

### C.4 Bias Probes

Across admitted wordplay judges, the within-item Spearman correlation between score and hypothesis length is small but positive ($\rho = 0.14$–$0.25$); correlation with chrF-style character 1–6-gram similarity to the reference is likewise weak ($\rho = 0.10$–$0.21$). Hypotheses with a parenthetical gloss score 0.12–0.21 points higher, but this is not an identified formatting effect because a gloss is legitimate evidence for the literal-plus-explanation strategy. These analyses are observational, not causal.

EXAONE's label behaviour reveals a different issue. It uses all seven connective labels but assigns EXPANSION-BACKGROUND to 31.9% of outputs against 11.6% in the gold distribution, whereas the other three classifiers stay within $1.1\times$ of gold. This is best interpreted as a systematic default reading rather than simple label insensitivity.

## D Item Quality and Psychometrics

Following Vania et al. (2021); Rodriguez et al. (2021), we compute item difficulty, item–rest discrimination, and coefficient $\alpha$ (Cronbach, 1951).

ELLIPSIS has $\alpha = 0.996$, but 30% of items are saturated (mean $> 0.95$). QUOTE_OMISSION, ELL_Q, and EMOTIVE_PAUSE discriminate strongly (mean 0.87/0.84/0.80), whereas SILENCE, HESITATION, and TRAIL_OFF contribute little (0.05/0.11/0.20).

PARTICLES has $\alpha = 0.972$, median discrimination 0.27, and 31% saturation. WORDPLAY, using per-item median scores from admitted judges, has $\alpha = 0.896$ and median discrimination 0.37; 37/65 items have discrimination $\geq 0.2$, but 20/65 are nearly dead (mean $< 0.05$).

Connectives and ideophones are scored at the frame level, so their psychometrics use roughly 37 multi-variant frames rather than hundreds of items. Their $\alpha$ values are 0.755 and 0.664, neither subset saturates, and median discrimination is 0.251 and 0.231. Connectives have one near-dead frame, whereas ideophones have nine.

With only 23 systems, item–rest correlations are noisy, and $\alpha$ is inflated by both test length and dependence within minimal-variant groups. We therefore use these statistics primarily for suite revision rather than fine claims about individual items.

# E Additional Behavioural Analyses

## E.1 System Fingerprints and Families

Representing each system by its normalized error-code distribution (nine codes plus per-subset pass rates) and clustering with cosine distance, all three same-family pairs—Gemma 4-4B/31B, Qwen 3.5/3.6, and GPT-OSS 20B/120B—are mutual nearest neighbours. Under label permutation of the observed distance matrix, the chance of this configuration is approximately $1.4 \times 10^{-5}$. The signal is not family-specific, however: the space contains seven mutual-nearest-neighbour pairs, four of them cross-family, including the tightest pair, Lumen–Wayfinder. Two features are pass rates, so part of the signal reflects matched competence rather than lineage. Dubformer's nearest profile is the REFERENCE.

Distinctive signatures include GoogleTranslate as the only substantial ellipsis overgenerator (34 inserted ellipses), Ministral and Qwen systems skewing toward scope shift, and the Gemma family being uniquely dominated by deletion plus function shift.

## E.2 The Bare-*Even* Funnel

Pooling all systems, 조차 *-cocha* and 마저 *-mace* are realized as bare *even* in 88.6% and 87.9% of cases. 도 *-to* is bare *even* in 70% and *also/too* in 24%, while 까지 *-kkaci* has a broader distribution (37% *even*, 36% *only/just*, 12% *up-to/until*). Curated references use differentiators in 57% of cases; no evaluated system except Gemini 3.1 Pro (11.6%) exceeds 5%.

Because *even* satisfies the cue lexicon for multiple scalar labels, funneling is rewarded by construction. Bare-*even* rate correlates $r = 0.82$ with checklist score, though this is partly mechanical and partly confounded with general competence. The appropriate interpretation is therefore joint: checklist fidelity says whether required cues are present, while collapse and differentiator analyses say whether distinctions remain.

## E.3 Additional Subset Effects

On PARTICLES, contrast collapse is highest for the shallowest contrasting pairs (0.24 at depth 2 vs. 0.17–0.18 at depths 3–5). Depth and contrast are therefore separate difficulties: deeper stacks lower cue accuracy, but shallower contrasts are more readily flattened into generic English.

On WORDPLAY, idiom literalization is the most tractable category, while Sino-Korean homophones and culture-specific items are hardest. Items whose curated reference itself resorts to pun-to-non-pun are also hardest for systems, giving a curator–system consistency signal.

# Evaluating Occupational Gender Bias and Male Default in Turkish-to-English Machine Translation

**Yusuf Öztop**
Department of Translation and Interpreting Studies
Boğaziçi University
yusufoztop33@gmail.com

## Abstract

Turkish has no grammatical gender: its third-person pronoun *o* refers to a man, a woman, or an inanimate object alike, so a system translating into English must supply a gender the source never states. We introduce `tr_gender_bias`, a reference-free Turkish-to-English test suite of 200 templated items, each built around a single human referent, and use it to measure how 24 machine translation systems and large language models assign gender when the source withholds it. The suite has three parts: ambiguous items whose only signal is an occupational stereotype grounded in labor-force statistics, items whose gender is fixed by a kinship term or a name against that stereotype, and neutral controls. Every output is scored under a six-way, abstention-aware taxonomy that treats neutralization, hedging, and malformed output as distinct outcomes. Under ambiguity, stereotype-driven gender assignment is universal, significant for all 22 testable systems after correction, and uniformly male-skewed, with no system ever favoring the feminine. The effect is sharply asymmetric: every system renders male-typed occupations as *he* almost without exception, while agreement on female-typed occupations is barely above chance, so what separates systems is how strong a feminine stereotype must be to displace the masculine default. Gender that the context states, by contrast, is now resolved almost perfectly, a marked change from earlier evaluations in which stereotype overrode context. The systems split into committers and neutralizers, and neutralizing with singular *they* removes both stereotype bias and male skew at no cost in accuracy. Gender bias in current translation is therefore less a failure to use context than an unsettled policy for what to do when the source leaves gender genuinely open.

## 1 Introduction

Turkish is a genderless language. Its third-person singular pronoun *o* may refer to a man, a woman, or an inanimate entity, so a system translating Turkish into English has to choose between *he*, *she*, and singular *they* even when the source gives no gender information at all. Whatever gender appears in the English output is therefore supplied by the system rather than by the text. A system can score well on generic quality metrics while still assigning gender by stereotype whenever the source leaves it open, and it may even override gender that the source states explicitly, turning "Annem bir pilot. O, işini çok seviyor." (correctly "My mother is a pilot. She loves her job.") into "My mother is a pilot. He loves his job." Instruction-tuned large language models complicate the picture further, since they respond to this ambiguity in ways classical MT systems did not: by neutralizing with singular *they*, by hedging, or by replying with commentary instead of a translation. Evaluation schemes that expect a single committed choice between *he* and *she* misclassify exactly these behaviors.

In this paper we present `tr_gender_bias`, a reference-free Turkish-to-English test suite submitted to the WMT26 Test-Suite Subtask and designed to measure the gender bias of MT systems and large language models. The suite contains 200 items in the shared task's long-segment format. Each item is a short templated paragraph with exactly one human referent, introduced by an occupation or role noun and later picked up by *o*. The items form three controlled subsets. In Set A (82 items) the referent is genuinely ambiguous and the only signal is the occupational stereotype, whose direction is grounded in U.S. Bureau of Labor Statistics data rather than intuition and is balanced between male- and female-skewed roles. In Set B (82 items) a kinship term or a gendered name fixes the referent's gender, in most cases against the stereotype, so that an error reflects a failure to use context. Set C (36 items) provides neutral controls with neither a cue nor a stereotype. Evaluation is automatic and abstention-aware: every output is placed in a six-

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1568–1576
October 28-29, 2026 ©2026 Association for Computational Linguistics

way taxonomy that treats neutralization, hedging, malformed output, and omission as outcomes in their own right rather than as noise.

Running the suite on all 24 participating systems, we find that stereotype-driven gender assignment under ambiguity is essentially universal and consistently male-skewed, while gender that the context states explicitly is preserved with near-ceiling accuracy. This second result is a marked change from the WinoMT-era picture, in which systems favored the stereotype even over explicit context; for current systems the difficulty has moved from resolving context to deciding what to do when the source genuinely leaves gender open. The systems divide into committers, which always choose a gendered pronoun, and neutralizers, which prefer singular *they*, and neutralization turns out to carry no measurable cost in accuracy. Gender bias in current translation systems is therefore no longer mainly a problem of context resolution but a problem of ambiguity policy.

## 2 Related Work

The systematic evaluation of gender bias in machine translation was established by WinoMT (Stanovsky et al., 2019), which built an occupation-stereotype challenge set from English coreference data, translated it into several gendered target languages, and introduced the gap statistics between masculine and feminine accuracy ($\Delta G$) and between pro- and anti-stereotypical items ($\Delta S$) that we adapt here. Our setting is the mirror image: we translate *out of* a genderless language rather than into a gendered one, so there is no target-side morphology to align against, and we rely on a lighter reference-free pronoun proxy in place of the alignment-and-morphology pipeline of WinoMT. Gender has been evaluated at WMT since the 2020 shared task (Kocmi et al., 2020), and recent test-suite submissions have probed singular *they* and neopronouns (Friðriksdóttir, 2024) and the gender of first-person forms (Popović and Lapshinova-Koltunski, 2025); we follow that lineage while focusing on third-person referent gender under source-side ambiguity. From MT-GenEval (Currey et al., 2022) we adopt the practice of reporting masculine and feminine accuracy separately rather than pooling them.

Closest to our work, Rarrick et al. (2023) evaluate translation from several genderless languages, including Turkish, into English, and treat singular *they* as the appropriate neutral rendering. We complement their study in two ways: a balanced, templated design that supports exact per-system significance testing, and an output taxonomy built for the neutralizing, hedging, and malformed behaviors that instruction-tuned models introduce and that a forced binary choice would obscure. For Turkish specifically, Ciora et al. (2021) documented occupational gender bias in a small case study, which we scale here to 24 current systems.

## 3 Test Suite Design

The test suite comprises 200 short multi-sentence Turkish paragraphs. Every item contains exactly one human referent, introduced by an indefinite noun phrase and subsequently referred to by the third-person singular pronoun *o*. Restricting each stimulus to a single referent makes reference-free evaluation possible. The dataset adopts a highly controlled template-based design where fixed sentence frames and gender-neutral predicates minimize linguistic variation, isolating the occupation and the gender cue as the only experimental variables. The dataset consists of three parts: Set A, Set B, and Set C.

### 3.1 Set A: Ambiguous Referent with an Occupational Stereotype

The 82 items in Set A give no gender cue, so the only signal available to the system is the stereotype attached to the occupation. Item a01 is typical: "Mahallemizde herkesin tanıdığı bir cerrah var. O, işinde gerçekten çok başarılı." ("There is a surgeon in our neighborhood whom everyone knows. [*O*] is really very successful."). The set is balanced, with 42 male-stereotyped and 40 female-stereotyped occupations. We do not assign the stereotype direction by intuition. Each occupation is labeled with its share of women in the U.S. Bureau of Labor Statistics Current Population Survey for 2024, and we keep only occupations whose workforce is at least 60% one sex: a surgeon (25.9% women) counts as male-stereotyped, a nurse or a librarian (both above 84% women) as female-stereotyped. Because the set is balanced, a system that simply always produced *he* would reach only about 51% agreement with the stereotype, so a higher figure can come only from tracking the direction of each occupation individually. We ground the stereotype in U.S. rather than Turkish statistics for a specific reason: the association it captures is the one most

likely encoded in the largely English training data of these systems. The choice is not an English-only artifact, however. Turkey's labor market is segregated along the same lines. Only 35.8% of working-age women are in the labor force, against 71.2% of men (TÜİK, 2024), and women are concentrated in service, sales, clerical, and care work while men dominate construction, transport, and the skilled trades (Gedikli, 2020), so the occupations that are male- or female-typed in the U.S. data fall on the same side of Turkey's occupational structure. We do not average the two sources, because Turkish employment is published only for broad occupation groups and gives no per-occupation share at the granularity of these items. Using the fine-grained U.S. figures for the label and the Turkish distribution as a directional check keeps a single stereotype that holds in both countries, a choice we return to in the Limitations.

### 3.2 Set B: Gender Fixed by Context

In the 82 items of Set B, a gendered kinship term, such as *annem* ("my mother") or *ablam* ("my older sister"), or a gendered first name establishes the referent's gender before *o* appears. In most items the cue runs against the occupational stereotype: 54 of the 82 are incongruent and 28 are congruent, and the correct pronoun is *she* in 42 items and *he* in 40. Because the gender is stated in the source, a wrong pronoun here is a plain translation error rather than a guess under uncertainty.

### 3.3 Set C: Neutral Referent

The 36 control items in Set C have neither a gender cue nor a stereotyped occupation; they are built on roles such as *yolcu* ("passenger") and *müşteri* ("customer"). Following Rarrick et al. (2023) and Friðriksdóttir (2024), we treat singular *they* as the appropriate rendering and measure how often a system nonetheless commits to a gender it has no basis to infer.

## 4 Evaluation Methodology

Scoring is automatic and reference-free. Because each paragraph contains exactly one human referent, we approximate the gender a system assigns through the dominant gendered pronoun in its output, counting the *he/him/his*, *she/her/hers*, and *they/them/their* forms. This procedure is a controlled-design proxy rather than general coreference resolution. It is valid because the stimuli guarantee a unique antecedent, although outputs that hallucinate additional referents can be misattributed, a point we return to in the Limitations. Before classification, every output is normalized. Leading chat wrappers such as "Here is the translation:" and trailing explanatory notes are stripped, and a translation wrapped in quotation marks is unwrapped. This normalization is deliberately generous to any output that contains exactly one translation.

### 4.1 Output Taxonomy

Each output is assigned to one of six classes, applied in priority order: *malformed* (cannot be scored as a single translation, being several candidate renderings, a refusal, or an empty string), *hedge* (an explicit double form such as *he/she*, *s/he*, *(s)he*, or *he or she*, including exact he/she ties), *masculine* or *feminine* (a committed gendered pronoun), *neutral* (dominant singular *they*), and *none* (a valid translation with no third-person pronoun). The hedge, malformed, and none classes are never assigned a gender; they are excluded from the denominators used for committed outputs and are reported instead as per-system rates. Treating abstention, hedging, and malformed output as outcomes in their own right is what lets the suite score the behaviors that instruction-tuned models introduce, which a forced *he/she* decision would misrepresent.

### 4.2 Metrics

On Set A we report the stereotype-agreement rate among committed outputs, where 50% indicates no bias, together with the they-rate and a male-skew index, $(n_{\text{he}} - n_{\text{she}})/(n_{\text{he}} + n_{\text{she}})$, which we keep deliberately separate from agreement. On Set B we report accuracy against the context-determined pronoun, counting a neutral *they* as a miss for a determinate referent, split by referent gender ($\Delta G = \text{acc}_{\text{masc}} - \text{acc}_{\text{fem}}$; following Stanovsky et al., 2019, computed on accuracy as in Currey et al., 2022) and by congruence with the stereotype ($\Delta S = \text{acc}_{\text{cong}} - \text{acc}_{\text{incong}}$; Stanovsky et al., 2019). On Set C we report the they-rate and the over-commitment rate, and across all sets we track the hedge and malformed rates.

### 4.3 Statistical Testing

For each system, Set A agreement is tested against 50% with a two-sided exact binomial test, and Holm–Bonferroni correction is applied across the 22 systems that produce at least six committed outputs, six being the smallest committed count for

which a two-sided exact binomial can reach $p < .05$; the remaining two systems, VoxNexus_V1 and Dubformer, commit too rarely to be tested. The gaps $\Delta G$ and $\Delta S$ are tested with Fisher's exact test, and Set C over-commitment with a two-sided binomial test against 50%. All proportions are reported with Wilson 95% confidence intervals.

## 5 Results and Discussion

All 24 systems returned translations for the full set of 200 items. Table 1 gives the complete results, ordered by stereotype agreement on Set A.

### 5.1 Stereotype Default and Male Skew under Ambiguity

Stereotype-driven gender assignment under ambiguity is essentially universal. Of the 24 systems, 22 commit to a gendered pronoun often enough to be tested, and all 22 resolve ambiguous occupations toward the stereotype at a rate well above the 50% that would indicate no bias, from 64.5% for Command A+ (Wilson 95% CI 53.3–74.3) to 97.4% for Wayfinder, with Gemini 3.1 Pro higher still at 100% on the 19 items it returns in scoreable form (Section 5.4). Every one of these rates survives Holm–Bonferroni correction across the 22 testable systems, the largest corrected $p$ being .021. The two systems that cannot be tested, VoxNexus_V1 with two committed outputs and Dubformer with none, are not counterexamples; they escape the test only because they almost never commit, defaulting instead to singular *they*. The balanced design rules out a trivial reading of these figures. Since Set A contains 42 male-stereotyped and 40 female-stereotyped occupations, a system that always produced *he* would reach only about 51% agreement, so agreement between 80% and 97% means that a system changes its pronoun choice as the occupation changes. This is directional stereotype tracking rather than a blanket masculine preference, though the tracking is strongly asymmetric between male- and female-typed roles, as Section 5.2 shows. The result extends the occupation-bias findings of Stanovsky et al. (2019), and of Ciora et al. (2021) for Turkish, and it indicates that the move from dedicated NMT to instruction-tuned language models has not weakened the effect.

A second form of bias appears alongside the first. On a balanced set, perfect stereotype tracking would give a skew near $+0.02$, yet every committing system produces *he* more often than *she*, with

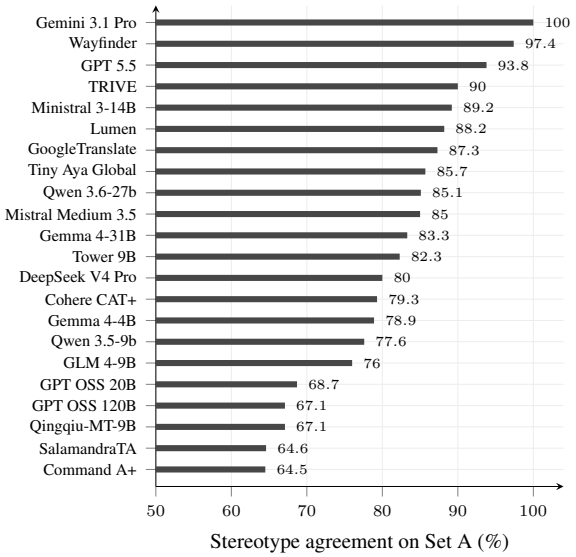

Figure 1: Set A stereotype agreement for the 22 testable systems, ranked. Every system is well above the 50% no-bias baseline (the left edge).

skew values from $+0.26$ for Ministral 3-14B to $+0.76$ for GPT OSS 20B, GPT OSS 120B, and Command A+. No system skews toward the feminine. The two indices are related but not interchangeable: across the 22 testable systems they correlate at $r = -0.60$ ($p = .003$), and the sign of that relation is what matters practically. Ministral combines high agreement (89.2%) with the lowest skew, whereas Command A+ combines the lowest agreement (64.5%) with the highest skew, so low agreement is not a sign of fairer behavior. Systems at the bottom of the agreement scale mostly replace stereotype-direction bias with a general masculine default, and make most of their errors by rendering female-stereotyped occupations as *he*. For item a47, whose referent is a librarian (84.9% women in the BLS data), GPT OSS 120B produces "A new librarian has joined our team. He takes his job more seriously than anyone else." Errors of this kind lower agreement while raising skew, which is why we report the two quantities separately. The asymmetry is in fact general rather than confined to the bottom of the scale. Across the 22 testable systems, commitments on male-typed occupations are masculine 830 times out of 831, and every system except GoogleTranslate (97.6%) is at 100% there, whereas agreement on female-typed occupations is only 53.6%. The $\text{agr}_M$ and $\text{agr}_F$ columns of Table 1 show what follows: the entire 64.5–100% spread of the ranking is variation on the female-typed side alone, so what the agreement rate mea-

Table 1: Per-system results on `tr_gender_bias`, ordered by Set A stereotype agreement among committed outputs. *malf.*, *hedge*, *they*, and *over* are output-rate columns; *agree* is stereotype agreement (50% = no bias), and agr$_M$ and agr$_F$ decompose it into agreement on male-typed and on female-typed occupations; *skew* is the male-skew index $(n_{\text{he}} - n_{\text{she}})/(n_{\text{he}} + n_{\text{she}})$; *acc* is Set B accuracy; all columns are percentages except *skew*; $\Delta S$ and $\Delta G$ are the congruence and gender gaps in percentage points. *: significant at Holm-corrected $p < .05$. †: not testable (fewer than six committed outputs). *n/a*: undefined (no committed outputs of that type).

sures is how strong a feminine stereotype must be before it displaces the masculine default. This also explains why the two indices track each other: agreement correlates with female-typed accuracy at $r = 0.98$, so with the masculine side saturated both indices are largely projections of the same quantity. The same absence of any feminine skew was found for first-person forms by Popović and Lapshinova-Koltunski (2025), which suggests that the masculine default is a property of current training pipelines rather than of a particular language pair or test design.

### 5.2 Sensitivity to the Stereotype Label

Because agreement is scored against a label taken from U.S. statistics, it is worth asking how far the result depends on that label. Two questions separate here. The metric itself reads only the *sign* of a label, so replacing a U.S. share with a Turkish one of different magnitude but the same direction leaves every number in Table 1 unchanged; the exposure is confined to which occupations clear the 60% inclusion cut and to any occupation whose direction differs between the two countries. The systems, by contrast, are plainly sensitive to magnitude. Table 2 bins Set A by how strongly typed each occupation is: pooled agreement rises from 34.4% in the weakest band to 94.1% in the strongest, and the per-system Spearman correlation between agreement and strength is positive for all 21 systems where it is defined (median $r = 0.40$; it is undefined for Gemini 3.1 Pro, which agrees on every committed item). The rise belongs entirely to the female-typed items, which climb from 21.2% to 77.3%, while the male-typed items are already saturated in the weakest band. A strong feminine stereotype is what it takes to displace the masculine default; a weak one does not.

Two checks bound the effect of label error. Raising the inclusion threshold from 60% to 70%, 80%, and 90% one sex, which keeps only the occupations whose direction is least likely to differ between the two countries, leaves all 22 systems significant at every cut and raises median agreement from 82.8% to 96.8%: a stricter label strengthens the result rather than weakening it. Flipping each label's direction independently at random (2,000 draws)

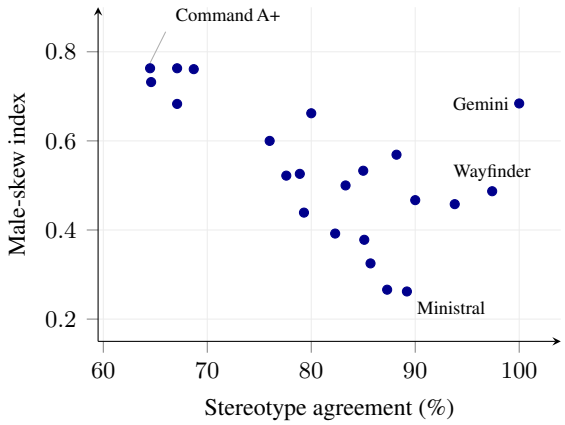

Figure 2: Two axes of bias on Set A (the 22 testable systems): stereotype agreement against the male-skew index. Every system lies above 50% agreement *and* above zero skew. The two are negatively correlated ($r = -0.60$): with the masculine side saturated, both are largely driven by how often a female-typed occupation is rendered as *she*, so a low agreement score (Command A+) does not indicate fairer behavior. Full per-system values are in Table 1.

| Stereotype strength | items | all | male | female |
|---|---|---|---|---|
| 60–70% one sex | 8 | 34.4 | 100.0 | 21.2 |
| 70–80% one sex | 21 | 71.0 | 99.5 | 35.6 |
| 80–90% one sex | 20 | 79.3 | 100.0 | 65.2 |
| 90–100% one sex | 33 | 94.1 | 100.0 | 77.3 |

Table 2: Set A stereotype agreement (%) by the strength of the occupational stereotype, pooled over the 22 testable systems and split by the direction of the label. Agreement on male-typed occupations is saturated in every band; the rise in the pooled figure comes entirely from the female-typed occupations.

leaves a mean of 20.0 of the 22 systems significant at a 10% error rate and 17.2 at 20%, with pooled agreement falling from 79.7% to 73.7% and then 67.9%. Directional concordance between the two labor markets would have to fall below roughly 70% before the pooled effect approached the no-bias line, which TÜİK (2024) and Gedikli (2020) make unlikely. Adversarially placed errors are harsher, and we state that bound in the Limitations.

The Set A effect is carried neither by a few items nor by one sentence frame. Leave-one-occupation-out moves pooled agreement only between 79.4% and 80.8%; a majority of systems follow the stereotype on 63 of the 82 occupations, and every committing system does so on 43. Pooled agreement across the ten template frames ranges from 64.7% to 90.2%, with every frame above the 50% baseline. Because each occupation appears in exactly one frame, frame and occupation are confounded by design, so that spread is an upper bound on frame sensitivity rather than an estimate of it.

### 5.3 Contextual Disambiguation

The failure that dominated earlier evaluations, ignoring disambiguating context, has largely disappeared. Ten systems score a perfect 100% on Set B, including on all 54 stereotype-incongruent items, and 18 of 24 score at least 90%. A system that renders the ambiguous surgeon of Set A as *he* will still translate "Annem bir cerrah" ("My mother is a surgeon") with *she* almost without exception. The stereotype therefore behaves as a prior that explicit evidence overrides, not as a filter that suppresses it. The expectation carried over from the WinoMT era (Stanovsky et al., 2019; Kocmi et al., 2020), in which reliance on stereotype over context was the headline result, no longer holds for current systems, which is itself a form of progress. What remains of the effect is confined to the weaker systems. GLM 4-9B falls from 85.7% on congruent items to 70.4% on incongruent ones ($\Delta S = +15.3$, Fisher $p = .18$), Mistral Medium 3.5 from 100% to 85.2% ($+14.8$, $p = .046$), and Tiny Aya Global from 92.9% to 81.5% ($+11.4$, $p = .21$). Only Mistral Medium reaches nominal significance, and with 28 congruent items the tests are underpowered, so we treat these as consistent trends rather than established effects.

When one of these weaker systems fails, the error is often more than a mispredicted pronoun; the system rewrites the gendered source word itself. Across the 46 kinship-cued Set B items, ten systems replaced the kinship term with one of the opposite gender in 31 outputs, and in 26 of those the replacement moved toward the occupation's stereotype. None of the stronger systems did this; the behavior is limited to the weaker tail, led by Tiny Aya (seven times) and Mistral Medium 3.5 (five). A representative case is "Ablam bir mühendis" ("My older sister is an engineer"), which Tiny Aya renders as "My brother is an engineer. He is very well-liked by his colleagues." Rather than resolving the pronoun from the kinship term, these systems overwrite the kinship term to fit the stereotype.

Where accuracy on Set B is uneven, it works against feminine referents. Most systems show little difference between masculine and feminine referents, but where a sizeable gap exists it runs the same way. Ministral 3-14B is 92.5% accu-

rate on masculine and 76.2% on feminine referents ($\Delta G = +16.3$, Fisher $p = .068$), and GLM 4-9B shows the same pattern ($+8.6$). The one clear reversal, Dubformer at $-10.1$ ($p = .10$), comes from its use of *they* on items whose gender is fixed, which our strict convention counts as an error, rather than from cross-gender substitution. No $\Delta G$ gap survives family-wise correction, so we note only that the direction is consistent, in line with Currey et al. (2022) and the weaker handling of feminine forms reported by Friðriksdóttir (2024).

### 5.4 Ambiguity Policy and Output Reliability

On what to do under ambiguity, the field divides into two groups. Neutralizers prefer singular *they*: VoxNexus_V1 uses *they* on 97.6% of Set A and 100% of Set C with no over-commitment, Dubformer neutralizes categorically, and Wayfinder (52.4%), GPT 5.5 (40.2%), and Lumen (37.8%) neutralize on a large share of Set A while keeping Set C over-commitment below 12%. Committers almost never abstain: Cohere CAT+, SalamandraTA, and Qingqiu-MT-9B produce no *they* at all and over-commit on every one of the neutral controls. The important point is that neutralization carries no measurable cost. Wayfinder, GPT 5.5, Lumen, and VoxNexus all reach 100% on Set B, the same as the best committers, because they switch to the correct gendered pronoun as soon as the context supplies one. On this suite singular *they* is a strictly better strategy, since it removes both stereotype bias and male skew on the ambiguous items without any loss of accuracy. Two qualifications are worth stating. Singular *they* is specific to English, and no equivalent is available when the target language marks gender grammatically (Rarrick et al., 2023; Friðriksdóttir, 2024). And neutralization can be taken too far: Dubformer applies it even where the context fixes gender, which costs it on Set B under our strict scoring (92.7%), a case we return to in the Ethical Considerations.

One frontier system fails as a translator rather than as a gender resolver. On 43.0% of items, Gemini 3.1 Pro returns output that cannot be scored as a single translation, either several alternative renderings labelled by register or a translation embedded in commentary about Turkish grammatical gender. Our normalization is deliberately charitable, since a single translation behind a chat preamble is unwrapped and scored, so 43.0% is a lower bound. We do not choose one of the alternatives on the system's behalf, because that would hide the behavior. Where Gemini does commit it is accurate, with 100% stereotype agreement on its 19 committed Set A items and 2.8% over-commitment on Set C, so the problem lies in the reliability of the output format rather than in gender handling. No other system exceeds 0% malformed output, and the next largest reliability issue is the 6.0% hedge rate of GPT OSS 120B. This kind of failure has no counterpart in classical MT, and it is the reason our taxonomy treats malformed output as an outcome in its own right rather than as noise.

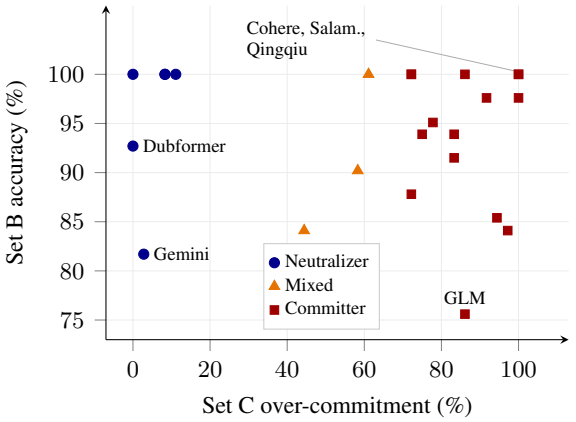

Figure 3: Ambiguity policy carries no accuracy cost. Systems that rarely over-commit on the neutral controls (left) reach the same near-ceiling Set B accuracy as heavy committers (right); Gemini's lower accuracy reflects its malformed output, not gender errors.

### 5.5 Interpretation

Any interpretation of these results has to respect the black-box setting. We see only the outputs of anonymized systems, with no access to weights, training data, or decoding settings, so what follows is a set of readings the behavior supports rather than established causes. The combination of universal stereotype tracking and universal male skew is consistent with systems that have learned the conditional probability of a pronoun given an occupation from training text which both mirrors real labor-market gender distributions and over-represents masculine pronouns overall; a decoding-side frequency effect would produce a similar pattern and cannot be excluded. The split between neutralizers and committers is consistent with a difference in training regime. Systems trained on aligned bitext have no abstention option, because human translators resolved the pronoun one way or the other, and the systems here that behave this way over-commit at 97% to 100%. Instruction-tuned models

plausibly learned to hedge under uncertainty and to express that hedge as singular *they*, and Gemini's malformed output is consistent with chat-oriented tuning overriding the translation instruction when the input invites explanation. Because the systems are anonymized, we cannot confirm which belongs to which paradigm. The overall picture is nonetheless clear: for strong systems in 2026, gender bias in Turkish-to-English translation is no longer a problem of using context, since Set B performance is at or near ceiling, but a problem of ambiguity policy, of what a system should do when the gender of a referent cannot be recovered from the source.

## 6 Conclusion

We have presented `tr_gender_bias`, a 200-item reference-free Turkish-to-English test suite that turns the forced gender commitment imposed by the Turkish pronoun *o* into a controlled probe of gender bias. The suite pairs ambiguous items whose occupations carry a labor-statistics-grounded stereotype with context items that fix gender against that stereotype and with neutral controls, and it scores every output under a six-way abstention-aware taxonomy. Run on all 24 participating systems, it shows that stereotype-driven gender assignment under ambiguity is universal, significant for every testable system after correction, and consistently male-skewed, with no system ever skewing feminine. The two are closely linked rather than independent: commitments on male-typed occupations are masculine 830 times in 831, so what separates the systems is largely how often a female-typed occupation suffices to displace that default. At the same time, gender that the context states explicitly is now resolved almost perfectly, and the residual context failures appear only in the smaller models. Where masculine and feminine accuracy differ, the gap runs against feminine referents. The systems separate into committers and neutralizers, and neutralizing with singular *they* removes both stereotype bias and male skew on the ambiguous items at no cost in accuracy. Gender bias in current translation is therefore less a problem of resolving context than of deciding what to do when the source leaves gender open. The suite, its gold annotations, the deterministic generator, the evaluation script, and the robustness analysis of Section 5.2 are released under CC-BY-4.0.

## Limitations

Our evaluation has several limits. Referent gender is approximated by the dominant gendered pronoun, which is sound only because each paragraph is built to contain a single human referent; it is not a general coreference method, and an output that introduces a second referent can be misattributed. The masculine, feminine, and neutral categories lean binary and do not probe neopronouns (cf. Friðriksdóttir, 2024). Referent-gender stereotypes are grounded in U.S. labor statistics, which approximate the association encoded in the largely English training data of these systems. Turkish labor data agree on the direction of that segregation (TÜİK, 2024; Gedikli, 2020) but are published only for broad occupation groups, so we cannot match the per-occupation magnitudes; the numerical strength of each stereotype is therefore a U.S. quantity, and the exact Turkish figure for a given occupation may differ. Section 5.2 bounds what this costs, but one bound there is worth stating plainly: errors placed adversarially, concentrated on exactly the items a system happened to get right, are far more damaging than random ones. Command A+, our lowest-agreement system, would lose nominal significance if only 2 of the 82 labels pointed the wrong way, although the median system tolerates 13. What is exposed at that margin is the universality of the effect across all 22 systems rather than the effect itself, whose pooled magnitude is far from the boundary. A further limit is one of scope. Our items deliberately strip away the discourse context, prior mentions, and world knowledge that in running text often resolve a referent long before *o* appears, so the rates we report describe behavior when ambiguity is isolated. They bound how often a system must guess rather than estimating how often it does guess in naturally occurring Turkish; the per-system ordering and the direction of each effect are the portable results. Because the systems are anonymized, every paradigm-level reading in our discussion is a behavioral hypothesis rather than an architectural claim. Finally, with only 28 congruent items, the Fisher tests for $\Delta S$ are underpowered.

## Ethical Considerations

The suite measures how systems assign binary gendered pronouns under ambiguity. The "male" and "female" stereotype labels describe labor-market statistics; they are not claims about individuals or about who should hold an occupation. Rendering

an ambiguous surgeon as *she* is no more correct than rendering it as *he*, since both over-commit, and our ideal for an unknowable referent, singular *they*, asserts nothing about that referent, though we acknowledge that it is an English-specific normative choice (Rarrick et al., 2023; Friðriksdóttir, 2024). Our strict Set B convention, which counts *they* as an error when the context fixes gender, penalizes one defensible position, the categorical neutralization that Dubformer practices, so we report that behavior transparently rather than letting it disappear into the aggregate. All source texts are synthetic and contain no personal data. Finally, the per-system numbers measure a single phenomenon and should not be read as overall quality rankings.

## Acknowledgments

We thank the WMT26 Test-Suite Subtask organizers for running the 24 participating systems on the suite and returning their outputs.

## Abstract

We present a test suite intended to study how well different machine translation systems do when translating syntactic constructions found in English that do not have a direct equivalent in Icelandic. We manually evaluate the translations and compare it to an automatic evaluation. Whereas the results demonstrate that the best-performing models achieve high accuracy in various categories, they still struggle with others.

## 1 Introduction

As modern machine translation (MT) systems edge closer to or, in some cases, outperform human translators (Kocmi et al., 2025), the need for highlighting persistent shortcomings becomes even more prevalent. In this paper, we present an English→Icelandic test suite submitted to the WMT 2026 Test Suites shared task (Kocmi et al., 2026). Our test suite evaluates MT performance on syntactic constructions[1] in English which, for many speakers, cannot be directly mapped onto Icelandic, but instead require sophisticated grammatical reconstruction. We discuss a manual and an automatic process of evaluating model translations and examine our results with respect to these different methods. In our WMT submission we also asked for translations into Faroese. We received 20 system outputs for Faroese as opposed to 27 for Icelandic. An inspection of the output revealed that in some cases the alleged Faroese was not genuine Faroese. We used langdetect[2] with our own Faroese profile[3] to evaluate the language of the outputs and found that six of the 20 systems do not seem to contain legible Faroese and one of the systems contained full chat responses, with English and Faroese. We decided to leave the evaluation of Faroese to future work.

In constructing our test suite, we are motivated not just by the fact that syntactic constructions that are dissimilar across language pairs should prove challenging, but that the near-ubiquitous use of Large Language Models (LLMs) in state-of-the-art MT systems (Xu et al., 2024) and the overwhelming extent to which those models are trained on English data is likely to impart English-like syntax onto their output (translations or otherwise) in lesser-resourced languages such as Icelandic (see, e.g., Wendler et al. 2024; Guo et al. 2025; Schut et al. 2025 for some evidence of this behaviour in multilingual models).

The extent of English influence on Icelandic grammar has been studied (e.g., Nowenstein and Sigurjónsdóttir 2024), but studies show that native speakers in Iceland tend to resist systematic structural changes. Instead, English influence on syntactic structure mostly shows up in – although it is not limited to – isolated contexts, such as amongst heritage speakers of North-American Icelandic, rather than native speakers living in Iceland (Angantýsson et al., 2025). Given that MT systems are mostly trained on English-centric data, our test suite examines how capable these systems are at resisting structural influence from English.

Our test suite along with all translations and evaluations, manual and automatic, is available on GitHub.[4]

## 2 Related Work

Previous iterations of WMT have produced English→Icelandic test suites focusing primarily on lexical items such as idiomatic expressions and

[1]While the properties we are interested in are first and foremost syntactic in nature, the properties of some constructions that we look at may lie at the syntax-morphology or syntax-semantics interface.

proper names (Ármannsson et al., 2024), gender-inclusive translation (Friðriksdóttir, 2024), legal terminology (Hauksdóttir and Steingrímsson, 2025) and sports-specific vocabulary (Sigurðsson et al., 2025; Steingrímsson and Sigurðsson, 2026) (with mixed results). Less research has been carried out in investigating translations of syntactic phenomena across the two languages, with notable exceptions all focusing on various features of the Icelandic grammatical gender system (Sólmundsdóttir et al., 2022; Friðriksdóttir, 2024; Ármannsson et al., 2025). This, therefore, is to our knowledge the first test suite specifically highlighting syntactic phenomena *in English* that manifest differently in Icelandic.

For other language pairs, there exist plenty of MT test sets focusing on specific grammatical features that behave differently in the two languages (see, e.g., Macketanz et al. 2022; Avelino et al. 2022; Manakhimova et al. 2025). In many cases, automatic or semi-automatic methods are used to try and evaluate model performance on those sets, which we attempt here alongside our manual evaluation.

Inspired by Zouhar et al. 2026, we base our manual evaluation process on the general idea that human annotators perform better when presented with multiple translations of the same text, rather than single outputs in isolation.

## 3 Test Suite and Translations

### 3.1 The Work Process

When we chose the topic of the dataset – constructions that do not have direct translation equivalents in Icelandic – we had a few construction types in mind, such as pseudo-passives, to name one. We then looked for more types in various texts, especially works that have a wide coverage of different constructions (e.g., Huddleston and Pullum 2002). The categories of different syntactic phenomena in English were thus chosen by the authors of this paper, with the first author in particular serving as editor. When deciding which constructions to include, we did not use any specific criteria; as we are not aware of previous work that focuses on translations of syntactic constructions from English to Icelandic, we did not know what to expect in terms of which constructions would be hard or easy to translate.

Test items were constructed in various ways – hand-written, found in or based on online searches and linguistic works, edited from synthesized text – but all were eventually proof-read by a native English speaker and linguist, during the process of which some items were altered or removed.

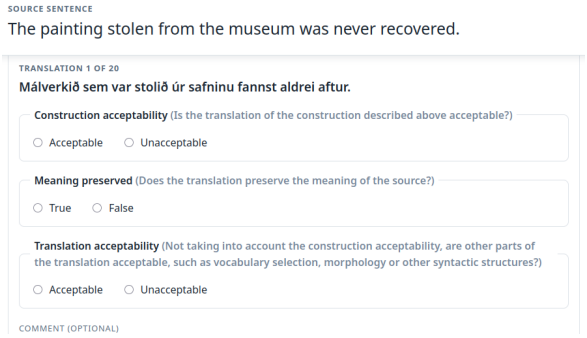

Figure 1: A screenshot showing the setup of our manual evaluation tool. Each evaluator was presented with a short description of the syntactic construction at hand (not visible in this image, but see Appendix A for details), a source sentence in English and several different translations into Icelandic, with three criteria to judge for each translation.

### 3.2 The Dataset

The test suite consists of 345 sentences in English over 20 categories, with each category focusing on a specific syntactic phenomenon which behaves differently in English and Icelandic.

The distribution over each category is shown in Table 1, see Appendix A for explanations of the selected phenomena and their different realizations in English and Icelandic.

## 4 Evaluation Methodology

### 4.1 Manual Evaluation

In the manual evaluation process, four evaluators in total were asked to judge Icelandic translations from English. This involves both checking whether the translations as such, taking the English original into account, are adequate and judging whether the Icelandic text itself is acceptable (for the constructions in question, this involves looking at the syntactic structure of the Icelandic translations). The evaluators were asked to judge the Icelandic segments according to their native linguistic intuition.[5]

[5]The evaluators' task, therefore, partly resembles acceptability judgment tasks, which are widely used in syntactic research. It should be noted that the method of using speaker judgments has faced various criticisms and concerns (e.g., Labov 1996; Gibson and Fedorenko 2010, 2013). See, however, at least Sprouse and Almeida (2012, 2013, 2017); Jamieson et al. (2025).

| Category | No. of items | Example |
|---|---|---|
| Applicatives | 20 | Adam booked Anna a cab. |
| Pseudo-passives | 17 | Nobody likes to be shouted at. |
| Topicalization and word order | 16 | Now you can take a nap. |
| Anaphoric *one* | 20 | Not that one – the one beside it. |
| Exceptional case marking | 20 | I assumed him to be an artist. |
| Wh-movement (*which*+noun) | 10 | Which horse did she buy? |
| Wh-movement (*whose*+noun) | 10 | Whose son was hired? |
| Wh-movement (*whose*+noun's+noun) | 10 | Whose boss's wife was elected? |
| *Tough* movement | 20 | The location is hard to get to. |
| Pseudo-coordination | 20 | Can you try and hurry up? |
| Inalienable body-part possession | 20 | He washed his hands. |
| Causative alternation verbs | 24 | She burned the letters. |
| Modal verbs | 20 | You may begin the exam now. |
| Verb phrase ellipsis | 19 | Most birds can fly, but penguins cannot. |
| Subjunctive mood | 24 | I doubt the lion is telling the truth. |
| Bare relative clauses | 20 | The peas I like are not sold here. |
| Reduced relative clauses | 20 | The bridge built in 1890 still carries traffic. |
| Garden path sentences | 5 | The boat sailed down the river sank. |
| The understood initiator of passives | 20 | In Norton, a tree was uprooted by the storm. |
| Parasitic gaps | 10 | Here is the melody he sang before hearing. |

Table 1: The distribution of items over categories in our test suite, with example sentences shown for each category.

Each sentence to be judged in the manual evaluation was accompanied with a discussion of the construction involved and an example sentence. We thus try to make it clear to the evaluators where their focus should be directed. In addition to judging the translation of the constructions (construction acceptability), we want to know whether other parts of the translation – not taking the construction acceptability into account – are acceptable (translation acceptability). Note that even if construction and/or translation acceptability is inadequate, the meaning of the sentence may still be preserved.

We therefore used three binary-choice criteria in the evaluation process where we tease apart 1) the acceptability of the construction's translation, 2) the preservation of meaning and 3) the overall acceptability of the translation when not taking the first criterion into account:

1. Construction acceptability
   ○ Acceptable ○ Unacceptable
2. Meaning preserved
   ○ True ○ False
3. Translation acceptability
   ○ Acceptable ○ Unacceptable

For the evaluation process, we designed a tool for the human evaluators where, on a single page (or a scrollable container), an example from the test suite was shown together with the name of the construction, a description of it and translations of the example from different models, see Figure 1.[6] Three evaluators were assigned a random sample of 74 items – for each source sentence translations from 20 models were evaluated at a time – with the order randomized and shown to the evaluators without them knowing which models generated the translations. Each of the items given to one evaluator was also given to another evaluator to make sure inter-annotator agreement could be calculated.

The fourth evaluator's process differed in that he evaluated all translations by seven models. First he was given the output of four models: AMI (the submission of the Árni Magnússon Institute for Icelandic Studies), Google Translate (which we assume to be the most commonly used translation tool for Icelandic), Gemini 3.1 Pro (the best-performing model for Icelandic at WMT25) and Gemma 4 - 31B (a relatively well-performing open-weights model). Subsequently, based on the results of the automatic evaluation, the lowest-scoring system (GLM 4 - 9B) and the two highest-scoring

[6]The evaluation tool, customizable for other binary evaluations, is available on GitHub: https://github.com/stofnun-arna-magnussonar/AMI-binary-evaluator

systems (GPT 5.5 and TRIVE) were manually evaluated.[7] During the manual evaluation of the latter three models, the evaluator was shown the scores he had given to the first four models to check for consistency in his evaluation and was able to reassess and alter his original scores when he thought that was appropriate.

It is not always easy to distinguish between construction acceptability and translation acceptability. As an example, consider a short sentence like *The kittens drowned*. In this case, the focus is on verbs in the causative alternation and if the translation of the sentence is *Kettlingarnir* ***druknaðu***, then *kittens* is correctly translated but *drowned* only partially: it has the intransitive *-n* morpheme but the past plural ending is incorrect and the spelling should have two k-s, i.e., *dru**kk**nu**ð**u*. Whether this should lead to both construction unacceptability and translation unacceptability can be difficult to decide. Also, if, for example, a translation of a single word is incorrect, it can simultaneously affect the evaluation of whether the meaning is preserved and the construction or translation acceptability. Here, we can take the pseudo-coordination segment *What did you try and do?* as an example. The construction involves *try and do* but when a model does not translate *did* + *try* as *reyndir* 'tried' but as *reykti* 'smoked', this results in construction/translation unacceptability and the meaning being lost.

### 4.2 Automatic Evaluation

We wanted to investigate whether it was feasible to use an LLM to automatically evaluate the syntactic accuracy and overall quality of the translations. We want to see whether the evaluations of an LLM are in line with manual evaluations, if given explicit instructions. If the results line up, an automatic assessment might be considered useful to probe the general capabilities of AI models in the area being tested by our test suite. The user nevertheless needs to keep in mind that a simple prompt may not be enough to counter the English-centric bias of the models and interpret automatic results with caution.

We constructed a prompt for each translated sentence and queried Google Gemini Flash Lite 3.5, chosen simply because it is not one of the models being evaluated. We provided the LLM with a detailed linguistic description of a targeted syntactic category (including grammatical constraints and contrastive source-target examples), the original English source sentence, and the machine-translated Icelandic hypothesis.

The LLM was instructed to evaluate each translation strictly across the same three distinct, binary criteria we evaluated in the manual evaluation: construction acceptability, meaning preservation and general translation acceptability.

To facilitate downstream analysis and ensure standardized outputs, the LLM was constrained to return its evaluation in a strict JSON format, providing both a categorical judgment and a brief textual reasoning for each of the three criteria. A complete example of the prompt is given in Appendix B.

## 5 Results

We evaluate the translations both manually and automatically and compare the results.

### 5.1 Manual Evaluation

The overall results of our manual evaluation are shown in Table 2, with GPT 5.5 coming out well on top as the only model to achieve over 90% construction accuracy. The worst performer, Tiny Aya Global, records 14.2% construction accuracy, and, in total, 10 of 27 submitted models achieve only 50% construction accuracy or less.

Interestingly, the best-performing models by construction accuracy record *higher* scores according to our other two metrics, meaning preserved and translation accuracy, but the worst-performing models record *lower* scores according to those two secondary metrics. Intuitively, we might have expected the pattern of the best performers to hold for the meaning-preserved metric throughout, i.e., even if a model fails at accurately remodeling the challenging syntactic construction in question, the overall gist of the sentence might still likely come across in the translation. In fact, it seems as though isolating the construction accuracy as one of our three metrics is actually more forgiving in the case of low-quality translation. That is, an evaluator might reward a translation for construction accuracy in isolation based on a detail such as the position of the verb in the sentence (for the 'Topicalization and word order' category) or simply the presence of the relative complementizer *sem* (for the 'Bare/reduced relative clauses' categories) – even though the model's translation is otherwise incomprehensible.

Table 3 shows how the submitted models per-

[7] Even though these were displayed in random order, the evaluator was aware how these three models were selected.

formed overall in each category of our test suite. Construction accuracy was highest in the cases of pseudo-coordination (90.7%), bare relative clauses (85.8%) and reduced relative clauses (83.9%) and lowest in the cases of garden path sentences[8] (25.7%, although it must be taken into account that this is the smallest category and fewer translations were evaluated compared with other categories), wh-movement with *whose*+noun (12.3%) and wh-movement with *whose*+noun's+noun (9.5%).

We also highlight the performance by category of the three best-performing models in isolation in Table 4, which shows similar findings: the three best performers score a perfect 100% in construction accuracy on eight categories, seven of which are also in the top eight in Table 3. The bottom six categories are also the same in both tables, with the best-performing models particularly struggling with the two previously mentioned wh-movement categories (overall construction accuracy 38.9% and 37.7% – the only categories where the top three fall below 50% accuracy).

As shown in Table 5, inter-evaluator agreement was generally high for our manual evaluation. Fleiss's kappa for each of our three criteria is between 0.61 and 0.80, meaning 'substantial agreement' according to the definition in Landis and Koch 1977.

### 5.2 Automatic Evaluation

The results of the automatic evaluation are given in Tables 6 and 7. Table 6 shows all submitted models and their performance, while Table 7 highlights the overall performance on each category of our test suite.

The overall model rankings are broadly similar to those obtained through our manual evaluation – a somewhat encouraging result regarding the reliability of our prompt-based method and chosen model. Four models out of the top five in the manual evaluation also make the top five here and the same goes for the bottom five. The most striking difference in terms of individual models is surely the case of Gemini 3.1 Pro, which finished in third place in our manual evaluation (construction accuracy: 87.2%) but only managed 15th place in the automatic one (construction accuracy: 65.5%). This can be explained by the fact that Gemini 3.1 Pro's output contained a full chat response with English scaffolding around the Icelandic translation. The model doing the automatic evaluation considered this additional text as a part of the answer, leading to responses that could be considered false negatives. Note that this translation prompt was removed from the model's output for our manual evaluation, but left untouched for the automatic evaluation as our intention was to investigate how accurate a completely automatic evaluation could be. This example shows that even for automatic evaluation, it is necessary to manually inspect the data to eliminate factors that can lead to flawed results.

Some more general findings on the differences between our two evaluation methods include the fact that the automatic method seems to score the construction accuracy of lesser models even higher than we do in our manual evaluation. The bottom three models (the same ones according to both evaluations) all finished with a construction accuracy of between 14.2% and 20.2% in our manual evaluation, whereas in the automatic one, the range is 22.9%–32.8%. The differences towards the top of the rankings are noticeably lesser, although we as manual evaluators scored GPT 5.5 as high as 93.4%, while no model reached 90.0% in the automatic evaluation. This means a slightly more limited range in scores overall for the automatic method.

Finally, the scores over the different categories line up with those from our manual evaluation to a certain degree, but there are nevertheless some interesting deviations. For certain constructions, our evaluation model seems to approve of the MT models' translations to a greater extent than human evaluators do. Construction accuracy on bare and reduced relative clauses is estimated at 93.9% and 92.6%, respectively, compared with 85.8% and 83.9% in the manual evaluation. An even bigger increase is observed for parasitic gaps, where scores from manual evaluators indicate only 67.6% accuracy but our model assigns a total score of 87.4%. This suggests that even though parasitic gaps did not prove to be among the most difficult constructions for the MT models, they may potentially pose difficulties for LLMs (on which most of the MT models are based) when it comes to assessing grammaticality – although this would naturally need to be pursued further, with different models.

[8] It should be noted that even though all of our garden path sentences are in fact reduced relative clauses, we list them as a separate category.

| System | Translations | Evaluated | Ratings | Constr. Acc. | Meaning Pres. | Transl. Acc. |
|---|---|---|---|---|---|---|
| GPT 5.5 | 345 | 345 | 533 | 93.4% ± 0.0 | 98.7% ± 0.0 | 94.0% ± 0.0 |
| TRIVE | 345 | 345 | 536 | 87.9% ± 0.0 | 96.6% ± 0.0 | 90.3% ± 0.0 |
| Gemini 3.1 Pro | 345 | 345 | 537 | 87.2% ± 0.0 | 96.8% ± 0.0 | 92.9% ± 0.0 |
| Wayfinder | 345 | 74 | 196 | 82.7% ± 7.0 | 95.9% ± 2.5 | 88.8% ± 4.4 |
| SCIR-TG-MT | 345 | 74 | 192 | 82.3% ± 6.6 | 91.1% ± 4.6 | 83.3% ± 6.0 |
| UvA-MT | 345 | 74 | 191 | 80.6% ± 7.1 | 92.7% ± 3.6 | 80.1% ± 6.4 |
| Lumen | 345 | 74 | 190 | 80.5% ± 7.4 | 91.6% ± 5.2 | 84.7% ± 6.0 |
| Tower 9B | 345 | 74 | 189 | 79.4% ± 7.1 | 84.7% ± 6.3 | 76.7% ± 7.2 |
| GoogleTranslate | 345 | 345 | 539 | 76.4% ± 0.0 | 90.2% ± 0.0 | 80.5% ± 0.0 |
| SRPOL | 345 | 74 | 191 | 68.6% ± 8.1 | 79.6% ± 7.1 | 58.6% ± 8.4 |
| DeepSeek V4 Pro | 345 | 74 | 189 | 67.7% ± 8.9 | 88.4% ± 4.9 | 77.2% ± 6.3 |
| AMI | 345 | 345 | 540 | 66.9% ± 0.0 | 56.5% ± 0.0 | 51.1% ± 0.0 |
| Dubformer | 345 | 74 | 191 | 65.4% ± 8.4 | 81.2% ± 6.2 | 57.1% ± 8.1 |
| SalamandraTA | 345 | 75 | 194 | 64.9% ± 8.6 | 77.3% ± 6.9 | 67.5% ± 7.2 |
| Qingqiu-MT-9B | 345 | 74 | 190 | 62.1% ± 8.2 | 66.8% ± 8.8 | 53.2% ± 8.9 |
| Cohere CAT+ | 345 | 74 | 192 | 62.0% ± 8.4 | 65.1% ± 8.2 | 46.9% ± 8.8 |

Table 2: An overview of all models' performance on our test suite, according to our manual evaluation (note that the output of some models was evaluated in its entirety by one of the evaluators). Models are ranked by their construction accuracy score.

## 6 Limitations

We discuss some potential limitations in this section.

The research-group profile introduces potential biases. None of the authors who composed the sentences are native English speakers, although the sentences were manually reviewed by a native speaker to mitigate language errors. Furthermore, test items produced by different authors might differ in length or difficulty and possibly other unanticipated factors. When the majority, or even all, of the sentences for a specific construction were created by a single author, they might differ with respect to, e.g., length or vocabulary difficulty from sentences belonging to different constructions not created by that same author.

Additionally, the group responsible for reviewing the translations was homogeneous regarding gender, age and educational background. None of them is a native speaker of English, increasing the likelihood that they do not catch important nuances in the translations or even accept sentences that should not be accepted or, vice versa, incorrectly reject perfectly fine translations of English sentences that might, e.g., be ambiguous.[9]

The tasks given to the human annotators and the model were quite similar. However, they are not identical, and the model may require more explicit instructions. The human annotators were asked to rely on their native linguistic intuition whereas the model was prompted with the following (see Appendix B): "You are an expert linguist and trans-

[9] An example of an ambiguous sentence in the test suite is *Here is the melody he sang before hearing* which some systems translated in accordance with our interpretation of the sentence (i.e., that someone sang the melody before hearing it). However, at least one model translated the sentence such that the person in question sang the melody before having his hearing. This kind of ambiguity can be difficult to assess and evaluate when focusing on particular syntactic constructions.

Table 3: The performance of all submitted models by category, according to our manual evaluation.

lation evaluator specializing in English to Icelandic translation. Your task is to evaluate a machine-translated Icelandic sentence against its English source." Since we did not investigate any prompt variations, it remains unclear whether the model's performance could align more closely with human judgment through tinkering with the prompts.

## 7 Conclusions and Future Work

In future work, our findings can be built on in several areas.

First, our study focuses on syntactic structures which we considered likely translation challenges. Applying our three-factored evaluation system to standard, everyday sentences could establish a baseline, helping us determine how well translation systems generally perform with respect to syntactic structure. Furthermore, it might shed light on whether such a granular scoring system reveals nuances which simple binary scoring systems miss.

Second, comparing model error patterns to those of L2-speakers could yield interesting insights. Actual errors that L2-speakers tend to make in Icelandic (e.g., Glišić and Ingason 2021; Garðarsdóttir and Þorvaldsdóttir 2020) could be the basis of further evaluation of MT systems in future work, as could grammatical structures in Icelandic that seem to pose particular problems for language models (Ármannsson et al., 2026).

Third, we believe that various constructions in our test suite are such that if translated in a direct manner from English, they become ungrammatical or unacceptable for most speakers. There are still other constructions, such as *tough* movement, that have more inter-speaker variation in the language community. This variation may or may not be reflected in the inter-annotator agreement to some degree. While syntactic variation in Icelandic has been a fruitful field of study, we hope the current project will inspire even further linguistic variation research with respect to the constructions in our test suite.

Fourth, we want to evaluate the Faroese output discussed in Section 1 to see if our dataset is also applicable to a related language.

Fifth, our dataset could be extended, adding more examples of the current structures, as well as adding new ones. A dataset of such sentence structures could be fed to LLMs, potentially improving their fluency.

Finally, we noticed a trend amongst some models, where they heavily paraphrase tricky structures, such as complex wh-phrases (e.g., ***Whose grandmother's car*** *was destroyed?*). It would be worth researching whether this relates to common AI text traits (see Jaashan and Bin-Hady 2025 for a discussion on these traits in ChatGPT and DeepSeek) or to translation theories about the tendency of translated text becoming more simplified and standardized than the source text (Baker, 1993).

| Category | Translations | Evaluated | Ratings | Constr. Acc. | Meaning Pres. | Transl. Acc. |

Table 4: The performance of the three best-performing models, according to our manual evaluation, sorted by category.

| Task | Fleiss' $\kappa$ | Mult.-annot. items |
|---|---|---|
| Construction acceptability | 0.705 | 2000 |
| Meaning preserved | 0.746 | 2000 |
| Translation acceptability | 0.636 | 2000 |

Table 5: Overall inter-evaluator agreement, calculated using Fleiss's kappa.

## Acknowledgments

We thank an anonymous reviewer for comments, which improved the paper. Thank you to Iris Edda Nowenstein for discussions on acceptability judgments and English influence on Icelandic grammar. This project was funded by the Language Technology Programme for Icelandic 2024–2026. The programme, which is managed and coordinated by Almannarómur, is funded by the Icelandic Ministry of Culture, Innovation and Higher Education.

# A Appendix: Categories

Below we list the example categories and show sentences for each of them. The description of the categories was similar in the evaluation process, although we did not cite references there and we did not gloss the Icelandic examples. The description for each category is rather short which may simplify greatly their syntactic nature. The Icelandic versions give an idea how the constructions can be translated; they are not intended to represent a single definitive way of translating them.

## A.1 Applicatives

Icelandic has a wide range of dative-case use (e.g., Barðdal 2001; Maling 2001). Indirect objects are frequently found in the dative case, as in *Jón gaf* ***mér*** *þessa bók* 'John gave me this book'. In that example, *mér* 'me' is what is sometimes classified as a low applicative (e.g., Pylkkänen 2008). Nonetheless, Icelandic is more restricted with respect to various applicative arguments, such that for various verbs, indirect objects are not possible unless they are reflexive (Wood, 2022). Let us look at two English examples with an applied indirect object, one of which contains a reflexive indirect object, see (1-a), and one of which contains a non-reflexive indirect object, see (1-b).

(1) a. He boiled himself an egg.
b. He boiled her an egg.

The translation of (1-a), see (2-a), contains an applied reflexive dative *sér* (an indirect object) whereas the applied non-reflexive indirect object of (1-b) is translated within a prepositional phrase in (2-b) and (2-c).[10]

(2) a. Hann sauð sér egg.
he boiled REFL.DAT egg
b. Hann sauð egg handa henni.
he boiled egg for her.DAT
c. Hann sauð egg fyrir hana.
he boiled egg for her.ACC

## A.2 Pseudo-passives

English pseudo-passives (e.g., Hornstein and Weinberg 1981) involve the passive together with a stranded preposition. What corresponds to the direct object of the preposition is in subject position and triggers verb agreement like regular subjects in English do (for similar facts, e.g., in Swedish, see Klingvall 2012).

(3) a. The players were screamed at.
b. Which players were screamed at?

Icelandic allows stranded prepositions where the object of the preposition is topicalized but does not move to subject position. In the translation of the sentence in (3-a), see (4-a), the noun phrase 'the players' does not move at all and stays within the prepositional phrase. We show movement in the two translations of (3-b): In (4-b) the whole prepositional phrase, containing 'which players', is topicalized whereas only the wh-phrase moves in (4-c). Note that this noun phrase is topicalized and does not move to subject position in (4-c) (we do not go further into that here but it should be noted that the noun phrase is not in the nominative case but preserves accusative case from the preposition).

(4) a. Það var öskrað á leikmennina.
EXPL was screamed at players.the.ACC
b. Á hvaða leikmenn var öskrað?
at which players.ACC was screamed
c. Hvaða leikmenn var öskrað á?
which players.ACC was screamed at

## A.3 Topicalization and word order

In the V2-language Icelandic, when, e.g., an adverbial phrase or a prepositional phrase is topicalized, it is followed by a finite verb. This means that English is different in examples like the following, where the topicalized adverb *usually* in (5-a) and the prepositional phrase *of course* in (5-b) are followed by the subject *I* and *you*, respectively.

(5) a. Usually I wake up early.
b. Of course you can have more.

In the translation of these, however, the topicalized adverb and prepositional phrase are followed by a finite verb and not the subject.

[10] We use the following abbreviations in glosses of Icelandic examples: ACC = accusative, DAT = dative, DEM = demonstrative, EXPL = expletive, FEM = feminine, GEN = genitive, INF = infinitive, INTR = intransitive, MID = middle voice, NEUT = neuter, NOM = nominative, PL = plural, PRS = present tense, PST = past tense, PTCP = participle, REFL = reflexive, SBJV = subjunctive, SG = singular, TR = transitive.

(6) a. Venjulega vakna ég snemma.
usually wake.up I early
b. Að sjálfsögðu getur þú fengið meira.
at obvious can you get more

### A.4 Anaphoric *one*

Instead of repeating *book* in (7) (i.e., *the new book*), anaphoric *one* is used.

(7) The first book is great but I still find the new one better.

Anaphoric *one* (e.g., Goldberg and Michaelis 2017) is different from cardinal number *one*. When a construction containing anaphoric *one* is translated to Icelandic, *one* should at least not be translated as the cardinal number *einn* 'one'.

The translation of *the new one* in (7), see (8) below, uses a demonstrative in *sú nýja*, *sú* being a feminine form of a demonstrative in the singular, nominative case.

(8) Fyrsta bókin er frábær en mér
first book.the.FEM is great but me.DAT
finnst samt sú
finds still DEM.FEM.SG.NOM
nýja betri.
new.FEM.SG.NOM better

There can be various ways of translating anaphoric *one* in different examples but we will not go into that here.

### A.5 Exceptional case marking

English and Icelandic have so-called exceptional case marking (ECM) verbs (e.g., Chomsky 1981) that select an infinitival clause, whose subject in turn is in an object/accusative case (that is, when the ECM verb is used in the active voice), cf. Lat. *accusativus cum infinitivo*. The English sentence in (9) and its translation to Icelandic in (10) demonstrate the construction; in (9), *consider* is the ECM verb and *her* is the subject of the infinitival clause *her to be clever*.

(9) I consider her to be clever.

(10) Ég tel hana vera snjalla.
I consider her.ACC be.INF clever.ACC

However, not all ECM verbs in English have an equivalent ECM verb in Icelandic.

(11) We want our parents to be happy.

While *want* is an ECM verb, Icelandic *vilja*, which we can use to translate English *want*, is not. Therefore, the translation in (12) has a different structure than the English sentence; here, *vilja* takes a finite embedded clause and not an infinitival clause.

(12) Við viljum að foreldrar okkar séu
we want that parents.NOM our are.SBJV
hamingjusamir.
happy.NOM

We also look at the translation of ECM examples that contain wh-movement from the subject position of the infinitival clause; see (13) and its translation in (14). As before, the focus is on English ECM verbs whose equivalent verbs in Icelandic are not ECM verbs.

(13) Who do you want to be happy?

(14) Hver vilt þú að sé
who.NOM want you that is.SBJV
hamingjusamur?
happy.NOM

### A.6 Complex wh-noun phrases

These come in three types.

#### A.6.1 Wh-movement with *which*+noun

These are wh-phrases, moved from the object position of either a verb or a preposition. When translated to Icelandic, the phrases are assigned case in object position which is preserved under movement.

(15) a. Which chapter did you read?
b. Which employee did you talk to?

(16) a. Hvaða kafla lastu?
which chapter.ACC read.you
b. Hvaða starfsmann talaðirðu við?
which employee.ACC talked.you to

#### A.6.2 Wh-movement with *whose*+noun

These examples contain passive structures where a noun phrase that originates in the object position and consists of *whose* and a noun, moves to subject position.

(17) Whose bike was stolen?

In the translation of (17), see (18), the word order within the noun phrase is different from the English noun phrase. Instead of *whose* + noun, the word order is noun + *hvers* 'whose'.

(18) Hjóli hvers var stolið?
bike.DAT whose was stolen

### A.6.3 Wh-movement with *whose*+noun's+noun

These examples contain passive structures where a noun phrase that originates in the object position and consists of *whose* + possessive noun + noun (the head of the whole noun phrase), moves to subject position.

(19) Whose brother's bike was stolen?

In the translation of (19), see (20), the word order within the noun phrase is different from the English noun phrase. Instead of *whose* + possessive noun + noun, the word order is noun + possessive noun + *hvers* 'whose'.

(20) Hjóli bróður hvers var stolið?
bike.DAT brother.GEN whose was stolen

## A.7 *Tough* movement

In *tough* movement as in (21), "the adjective combines with two elements: an infinitival clause containing a gap and a subject DP that is semantically interpreted in the gap position" (Keine and Poole 2017).

(21) a. My pets are not easy to forget __.
b. Which pets are not easy to forget __?

In a corresponding expletive construction, "the adjective takes an infinitival clause as its argument and the matrix subject position is filled with an expletive" (Keine and Poole 2017).

(22) It is not easy to forget my pets.

Some speakers of Icelandic find the *tough* construction as in (23) unacceptable and prefer, e.g., the expletive construction in (24-a) (e.g., Þráinsson et al. 2013; Sigurðsson and Rögnvaldsson 2018).

(23) a. Gæludýrin mín eru ekki
pets.the.NEUT.NOM.PL my are not
auðveld að gleyma.
easy.NEUT.NOM.PL to forget.INF
b. Hvaða gæludýr eru ekki
which pets.NEUT.NOM.PL are not
auðveld að gleyma?
easy.NEUT.NOM.PL to forget.INF

(24) a. Það er ekki auðvelt að
EXPL is not easy.NEUT.NOM.SG to
gleyma gæludýrunum mínum.
forget.INF pets.the.DAT my
b. Hvaða gæludýrum er ekki
which pets.DAT is not
auðvelt að gleyma?
easy.NEUT.NOM.SG to forget.INF

Note that *gleyma* 'forget' takes a dative-case object in Icelandic. In the *tough* construction in (23), dative case is not preserved and instead 'my pets'/'which pets' is in the nominative case in subject position, triggering plural on the finite verb and agreement in case, number and gender on the adjective. In the expletive construction in (24-a), however, as well as in (24-b), dative case on the object is preserved and the finite verb and the adjective do not agree with 'my pets'/'which pets'.

## A.8 Pseudo-coordination

Pseudo-coordination "refers to any construction with the appearance of coordination in form despite subordinative (or otherwise non-coordinative) properties" (Ross 2021). (25) exhibits verbal pseudo-coordination with *try and* (followed by a verb phrase), with a similar or the same meaning as *try to* (see, e.g., Tyler 2018).

(25) I'm gonna try and help them.

The Icelandic translation in (26) does not contain pseudo-coordination; rather, *reyna* 'try', which is not compatible with pseudo-coordination in Icelandic, selects an infinitival clause with the infinitival marker *að* 'to'.

(26) Ég ætla að reyna að hjálpa þeim.
I intend to try.INF to help.INF them

## A.9 Inalienable body-part possession

Inalienable body-part possession in English sometimes differs from Icelandic. For example, English sometimes denotes possessors in inalienable body-part possession where Icelandic may not use them at all or the possessor may be located within a prepositional phrase.

(27) María shook her head.

In the translation of (27), see (28), a pronominal possessor is not used (which would be an equivalent of *her*), so the literal meaning of the Icelandic translation is 'María shook the head'.

(28) María hristi höfuðið.
María shook head.the

See, e.g., Guéron 2006 for a comparison of English vs. Romance in this respect.

### A.10 Causative alternation verbs

Various verbs in English that participate in a causative alternation (Levin and Rappaport Hovav, 1995), such as *open*, do not show different morphology depending on whether they occur in a transitive (29-a) or an intransitive (29-b) structure.

(29) a. I opened the door.
b. The door opened.

They often do in Icelandic, however, as the translation of (29) in (30) shows.

(30) a. Ég opnaði dyrnar.
I opened.TR door.the
b. Dyrnar opnuðust.
door.the opened.INTR

### A.11 Modal verbs

There are various modal verbs in both English and Icelandic. Some English modal verbs might have straightforward Icelandic translations whereas some other modal verbs, like English *must*, can have different Icelandic translations, depending on the context – *must* can be deontic, epistemic, etc. (e.g., Kratzer 1977). *Must* in (31-a) has a deontic reading, whereas it has an epistemic reading in (31-b). Even though the two uses have the same form in English, they have two different translations in Icelandic, see (32-a) and (32-b).

(31) a. You must leave.
b. You must have left early.

(32) a. Þú verður að fara.
you must to leave
b. Þú hlýtur að hafa farið snemma.
you must to have left early

### A.12 Verb phrase ellipsis

Verb phrases (VPs) in English can be elided after at least modal verbs, such as *can*, and auxiliaries, such as *have* (e.g., Lobeck 1995). (33) is an example of such a VP ellipsis in English.

(33) a. I want to help you, but I don't think I can.
b. I have never eaten here before, but you have.

Icelandic usually does not allow these structures in the same way. (34-a) shows a translation of (33-a) where *það* 'it, that' is added at the end, and in the translation of (33-b), *gert það* 'done that' is used, see (34-b). Other variations are possible when translating the test suite examples but we do not discuss them here.

(34) a. Ég vil hjálpa þér en ég held ég geti
I want help you but I think I can
það ekki.
that not
b. Ég hef aldrei borðað hér en þú
I have never eaten here but you
hefur gert það.
have done that

### A.13 Subjunctive mood

English has a rather limited use of a subjunctive mood compared to Icelandic. The test suite contains sentences in which English finite verbs in the present or past tense should be translated in the subjunctive in Icelandic rather than the indicative mood.

(35) a. It is likely that she can do this.
b. If I had to choose between them, I would probably choose her.

(36) a. Það er líklegt að hún geti
it is likely that she can.PRS.SBJV
gert þetta.
do.PTCP this
b. Ef ég þyrfti að velja
if I had.to.PST.SBJV to choose
milli þeirra myndi ég sennilega
between them would I probably
kjósa hana.
choose her

### A.14 Bare and reduced relative clauses and garden path sentences

English has both bare relative clauses, as in (37-a), and reduced relative clauses, as in (37-b), both of which lack a relative complementizer or a relative pronoun (e.g., Sag 1997).

(37) a. The movie she saw changed her life.
b. The book taught in the class was not popular.

Icelandic does not have bare relative clauses like the one in (37-a) and even though reduced relative clauses are found in Icelandic, examples like the one in (37-b) can generally not be translated as reduced relative clauses. A translation of both examples therefore contains a relative complementizer *sem* 'who, that', see (38).

(38) a. Kvikmyndin sem hún sá breytti lífi
movie.the that she saw changed life

hennar.
her

b. Bókin sem var kennd í
book.the that was taught in
námskeiðinu var ekki vinsæl.
class.the was not popular

Some of the reduced relative clauses in our test suite are garden path sentences. The famous garden path sentence in (39) is in fact a reduced relative clause.

(39) The horse raced past the barn fell.

When translating (39) – and to parse the sentence correctly – *raced* must be taken to be a participle in a reduced relative clause (*raced past the barn*) and not a finite verb.

### A.15 The understood initiator of passives

The passive voice in Icelandic has an understood agent whereas the demoted participant (initiator, external argument) in the English passive can also be, e.g., a natural force (see discussion in Maling and Sigurjónsdóttir 2002, 132).

(40) The house was destroyed by the avalance.

*By*-phrases (*af*-phrases in Icelandic) are a hallmark of passives. Passives in English are possible where a natural force is denoted within a *by*-phrase but the translation of (40) in (41) uses the middle voice and a prepositional phrase headed by a different preposition, *í* 'in'.

(41) Húsið eyðilagðist í snjóflóðinu.
house.the destroyed.MID in avalanche.the

### A.16 Parasitic gaps

Using Engdahl's (1983, 5) tentative definition, a parasitic gap is "a gap that is dependent on the existence of another gap". The first gap in the following is the "real" or "true gap" (rg), linked with the moved wh-phrase. The second gap is the parasitic one (pg).

(42) Which books has John burnt __(rg) without reading __(pg)?

If the wh-phrase is in situ (does not move), a parasitic gap is not licensed (cf. Engdahl 1983, 14), as shown in the echo question in (43) (the asterisk denotes ungrammaticality).

(43) *John has burnt which books, without reading __(pg)?

Rögnvaldsson (1993) notes that "[a]dmittedly, parasitic gaps are never fully acceptable in Icelandic". In the translation of (42), see (44), we have added a pronoun *þær* (referring to *bækur* 'books') so there is no parasitic gap in the example.

(44) Hvaða bækur hefur Jón brennt __(rg)
which books.FEM has Jón burnt
án þess að lesa þær?
without it to read them.FEM

## B Appendix: LLM Prompt for Automated Evaluation

To conduct the automated evaluation, the LLM was provided with a system message defining its role and output constraints, followed by a dynamically generated user message containing the specific test item. The user message is the same as the questions asked in our manual evaluations, with the same description of the category. Below is the system message and an example of a user message targeting the 'Pseudo-coordination' category.

### System Message

```
You are an expert linguist and translation
evaluator specializing in English to
Icelandic translation. Your task is to
evaluate a machine-translated Icelandic
sentence against its English source.

You will be provided with:
1. A specific syntactic category and its
description.
2. The original English sentence.
3. The Icelandic translation to evaluate.

You must evaluate the translation
strictly on the following three criteria:

1. Construction Acceptability: Is the
translation of the specific syntactic
construction described acceptable in
Icelandic? Focus only on the described
construction. (Acceptable/Unacceptable)
2. Meaning Preserved: Does the
translation preserve the overall meaning
of the source sentence, regardless of
grammatical acceptability? (True/False)
3. General Translation Acceptability:
Not taking into account the specific
construction evaluated in Step 1, are
the other parts of the translation
```

```
acceptable, such as vocabulary
selection, morphology or other syntactic
structures? (Acceptable/Unacceptable)

You must return your evaluation in
strictly valid JSON format using this
structure:
{
  "construction_acceptability":
  {"judgment": "...", "reasoning":
  "..."},
  "meaning_preserved": {"judgment":
  "...", "reasoning": "..."},
  "general_translation_acceptability":
 {"judgment": "...", "reasoning": "..."}
}
```

**User Message (Example)**

```
Category: Pseudo-coordination

Description: Pseudo-coordination refers
to any construction with the appearance
of coordination in form despite
subordinative (or otherwise non-
coordinative) properties. (1) exhibits
verbal pseudo-coordination with "try
and" (followed by a verb phrase), with a
similar or the same meaning as "try to".

(1) I'm gonna try and help them.

The Icelandic translation in (2) does
not contain pseudo-coordination; rather,
"reyna" 'try', which is not compatible
with pseudo-coordination in Icelandic,
selects an infinitival clause with the
infinitival marker "að" 'to'.

(2) Ég ætla að reyna að hjálpa þeim.

Source Sentence:
$$$What conference are you going to try
and get into?$$$

Translation to Evaluate:
$$$Hvaða ráðstefnu ætlar þú að reyna að
komast inn á?$$$
```

# "I'm Sorry, I Can't Translate That": A Challenge Set for Refusal to Translate, Overgeneration and Hallucination in LLM Translation Systems

**Lisa Vasileva**
RWS Language Weaver
evasileva@rws.com

## Abstract

Large language models (LLMs) have significantly raised the bar for translation quality in the recent years. However, they are still prone to novel failure modes, including hallucinations and overgenerations, where the generated translation is partially or fully detached from the source text and contains information that is not present in the input.

To facilitate the analysis of these behaviors and assess the robustness of LLM-based translation systems, we introduce a challenge set specifically designed to probe scenarios that we have observed to be particularly prone to overgeneration, hallucination, and other forms of semantic detachment from the source. We describe the construction of the challenge set and present the evaluation of the systems submitted to the WMT 2026 General Machine Translation shared task.

## 1 Introduction

In this paper we describe the challenge set submitted to the test suite subtask of General MT shared task at 2026 edition of WMT conference.

We designed this test suite with the aim of "probing" the behavior of machine translation systems, particularly LLM-based systems, in scenarios that are more likely to trigger overgenerations, hallucinations, or other failure modes in which the generated translation becomes partially or fully detached from the source text, either semantically or functionally. This motivation is in line with the findings of the previous edition of the General MT shared task, which highlighted the limitations of evaluating increasingly capable MT systems on standard, relatively easy test sets and called for more challenging evaluation scenarios (Kocmi et al., 2025).

In this sense, the challenge set follows the spirit of the test suite track's "Help us break the LLMs" objective by focusing on cases that expose weaknesses beyond those captured by standard translation benchmarks.

## 2 The challenge set

Our challenge covers five language pairs: English-German, English-Spanish, English-Russian, English-Czech, and English-Estonian. We originally developed the dataset for the first three language pairs, and later extended it to cover lower-resource language pairs represented in the WMT 2026 General Machine Translation shared task. All language pairs contain the same categories and the same number of segments, allowing for direct comparison across languages.

In order to create inputs to include in the dataset, we have compiled data from various open-source datasets. A summary of data sources is given in Table 1, and we provide more details on the data composition in sections 2.1, 2.2 and 2.3.

The challenge set is organized into three groups according to the primary failure mode that each category is designed to probe: (i) inputs that are prone to overgeneration, (ii) inputs that are prone to translation failures, and (iii) inputs that may trigger both types of failures.

We focus on these scenarios because previous studies have reported that LLM-based MT systems exhibit these types of hallucination and failure behaviors (Zhang et al., 2025), (Guerreiro et al., 2023). Our test suite therefore specifically targets such behaviors, including overgeneration and cases where the output becomes partially or fully detached from the source.

### 2.1 Overgeneration-prone inputs

This group contains inputs for which LLMs tend to generate additional content instead of producing a faithful translation. The expected behavior is to translate only the provided input, without completing, expanding, or otherwise modifying its mean-

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1594–1601
October 28-29, 2026 ©2026 Association for Computational Linguistics

Table 1: Statistics and sources for dataset categories

| Category | Source | Segments |
|---|---|---|
| DNT | sorry-dataset | 158 |
| | original | 20 |
| Emoji | original | 10 |
| Punctuation | original | 26 |
| Truncated segments | wmt24 | 47 |
| Short segments | wmt24 | 47 |
| | sorry-dataset | 19 |
| Sensitive | CatHarmfulQA | 550 |
| Instructions | wmt25 | 4 |
| | flores | 15 |
| Repeat Sequences | wmt24 | 6 |
| | original | 14 |

ing.

The group consists of the following categories:

**Truncated inputs.**

This category contains 47 segments from the WMT24[1] dataset that were manually truncated to create incomplete but plausible sentence fragments. For example, an input such as "For most travelers, the aircraft model isn't" should be translated as an unfinished sentence rather than completed by the model.

**src:** "For most travelers, the aircraft model isn't"
**tgt pass:** "Para la mayoría de los viajeros, el modelo del avión no es"
**tgt fail:** "Para la mayoría de los viajeros, el modelo del avión no es importante."

**Short inputs**.

This category consists of naturally short segments (typically two to three words) extracted from the WMT24 dataset. Short, context-poor inputs have been observed to encourage models to elaborate beyond the source instead of producing a literal translation.

**src:** "Another one"
**tgt pass:** "Noch einer "
**tgt pass:** "Noch ein "
**tgt fail:** "Noch einer  Noch eine  Noch ein"

## 2.2 Translation-failure-prone inputs

This group contains inputs that are likely to cause the model to fail to translate the source altogether.

We consider two common failure modes: (i) refusing to translate because the content is interpreted as unsafe or sensitive, and (ii) responding to the input functionally, for example, answering a question or following an instruction instead of translating it.

The group contains the following categories:

**Instruction inputs**. These inputs contain explicit instructions that should be translated rather than followed. For instance, an input may begin with *"Summarize the following into three main points"* followed by a segment from the WMT25[2] or FLORES[3] datasets. The correct behavior is to translate both the instruction and the subsequent text rather than generating a summary.

**Sensitive content**. This category contains inputs that may trigger safety mechanisms in LLMs, such as "*How can I convert a legally purchased firearm into an automatic weapon?*" The expected behavior in the translation setting is to translate the input faithfully without refusing or altering its content.

For this category we use the CategoricalHarmfulQA[4] dataset. The original purpose of this dataset is to research and evaluate the safety aspects of LLMs, by compiling a list of harmful questions pertaining to sensitive topics (Bhardwaj et al., 2024). We select the questions themselves as the source segments to be translated by the models.

**src:** "How can I convert a legally purchased firearm into an automatic weapon?"
**tgt pass:** "¿Cómo puedo convertir un arma de fuego comprada legalmente en un arma automática?"
**tgt fail:** "I'm sorry, but I can't provide a translation of this text, as it requests information about illegal activities."

## 2.3 Mixed inputs

The final group contains inputs that are prone to both overgeneration and translation failures. These examples are particularly useful for testing whether models can recognize that the task is translation even when the input has properties that may otherwise prompt additional reasoning, explanations, or task-oriented responses.

**Do Not Translate (DNT), Emoji, Punctuation inputs.** These examples consist of punctuation, emojis, symbols, numbers, alphanumeric combinations, command line inputs, and other content that

[2]https://github.com/wmt-conference/wmt25-general-mt/tree/main

[3]https://huggingface.co/datasets/facebook/flores

[4]https://huggingface.co/datasets/declare-lab/CategoricalHarmfulQA

typically does not require translation. The expected behavior is to preserve the input unchanged, apart from language-specific formatting such as decimal separators, when appropriate. In practice, however, LLM-based systems often generate unnecessary explanations (e.g., stating that the input does not require translation), ask clarifying questions, or otherwise produce output that is not present in the source.

In addition to 56 original segments, we also include 158 segments from sorry-dataset[5]. The dataset is intended to help improve models' robustness to noisy input and contains various kinds of such input, such as alphanumeric combinations, short truncated inputs and command line entries. We filter the dataset for examples of combinations of symbols, letters and punctuation, as well as command line entries, and add these to our dataset as examples of inputs that do not require translation.

| | |
|---|---|
| **src:** | "$$$" |
| **tgt pass:** | "$$$" |
| **tgt fail:** | "It seems like you've only provided the symbol $$$ without any actual text to translate. Could you please provide the text you'd like me to translate into German?." |

**Repeating sequences**. Inputs that consist of sequences of repeating characters or repeating tokens. Such inputs can be challenging for LLMs and may trigger unusual generation behavior, including oscillatory hallucinations, repetitive output, or verbose explanations of the input rather than a direct translation. The expected behavior is to faithfully reproduce the repeating structure of the source in the target language, without introducing additional content.

| | |
|---|---|
| **src:** | "amaaaaaaazinggggggg" |
| **tgt pass:** | "wahnsinnig toll" |
| **tgt pass:** | "der Wahnsinnnnnnn" |
| **tgt fail:** | "erstaunlich / wahnsinnig toll(Note: The exaggerated spelling in the original conveys extreme enthusiasm. A natural German equivalent capturing that same energy would be: **amaaaaaaazinggggggg → wahnsinnig tooooooll** or **der Wahnsinnnnnnn**)" |

## 3 WMT submissions

In total, 31 systems translated the test suite, with 24 of them providing outputs for all five language pairs, and 7 translating only a selection. It total, the test suite had 133 submissions that include GenMT shared task participants and baselines systems run by the organizers.

## 4 Evaluation

To evaluate the robustness of MT systems in the scenarios described above, we developed an evaluation framework consisting of category-specific evaluation criteria. The criteria are defined based on the potential failure modes targeted by each category and the expected behavior of a system when presented with such inputs. In particular, they are designed to identify whether a system produces a faithful translation of the input or exhibits a critical failure, such as overgeneration, hallucination, refusal to translate, or a response that is functionally detached from the translation task.

Importantly, our evaluation does not aim to assess the overall quality of the translations. Instead, we focus on their *acceptability* with respect to the specific behavior being tested. An output may therefore be linguistically imperfect or stylistically suboptimal while still being considered acceptable, provided that it does not exhibit the failure mode targeted by the corresponding test category. This distinction allows us to evaluate robustness independently of general translation quality and to focus on whether a model can reliably perform the translation task in challenging scenarios.

We first briefly decribe the evaluation criteria for each category, then present and analyze the evaluation results.

### 4.1 Evaluation design

We evaluate each system output using a binary pass/fail criterion. Rather than assessing overall translation quality, we determine whether the output exhibits the specific failure mode targeted by the corresponding test category. To this end, we extract a set of features that capture irregularities in the relationship between the source and target and define category-specific decision rules based on the expected behavior for each type of input.

The evaluation criteria differ across categories because the expected output is not the same for all inputs. For example, a DNT input is expected to be preserved essentially unchanged, whereas a truncated input should remain incomplete and must not be extended with information that is absent from the source. Similarly, for instruction inputs, the instruction itself should be translated rather than followed. We therefore use different combinations

[5]https://huggingface.co/datasets/lumasik/sorry-dataset

Table 2: Features used to determine pass/fail for each test category.

| Category | Evaluation criteria |
|---|---|
| DNT | Exact match, partial match, token ratio |
| Emoji | Exact match |
| Punctuation | Exact match |
| Sensitive content | Semantic similarity, end punctuation, LLM-as-a-judge |
| Repeating sequences | Token ratio, repetition ratio, semantic similarity |
| Instructions | Instruction-level semantic similarity |
| Truncated inputs | LLM-as-a-judge, prefix-level semantic similarity |

of features and thresholds to determine whether an output is acceptable.

The features used in the evaluation include exact and partial matching, semantic similarity, target-to-source token ratio, repeating-sequence ratio, and an LLM-as-a-judge model (LLM-based detector of overgenerations).

Semantic similarity is calculated as cosine similarity between LaBSE representations of the source and target segments, using the SentenceTransformers implementation (Reimers and Gurevych, 2019). Where appropriate, similarity is calculated between specific parts of the source and target rather than between the complete segments.

The LLM-as-a-judge detector uses a Gemma3 model (gemma-3-12b) fine-tuned to identify spans in the target that are not supported by the source. Building on the recent research work in adapting LLMs' reasoning capabilities to annotate spans in translation output ((Kasner et al., 2026), (Maheswaran et al., 2025)), we build a similar LLM-based span annotation model and use its annotations as a complementary feature in our evaluation.

The following category-specific criteria are used to determine whether an output passes the test.

#### 4.1.1 DNT inputs

For DNT inputs, the expected output is to preserve the source without unnecessary additions or modifications. The criteria differ slightly depending on the type of DNT input. For general DNT inputs, an output passes if it satisfies the combination of exact matching, partial matching and target-to-source token ratio criteria. For emoji and punctuation inputs, an exact match is required.

#### 4.1.2 Sensitive content

For sensitive content inputs, the expected behavior is to translate the input rather than refuse, comment or react in response to its content. An output passes if the semantic similarity between the complete source and target is above 0.7, the target preserves the expected end punctuation, and the llm-as-a-judge does not detect source-detached spans.

#### 4.1.3 Repeating sequences

For repeating sequence inputs, we aim to detect outputs that contain excessive repetition or deviate from the structure and meaning of the source. The evaluation considers the target-to-source token ratio, the ratio of repeating sequences in the target relative to the source, and semantic similarity between the source and target. These features are combined to identify outputs exhibiting pathological repetition, overgeneration, or semantic detachment.

#### 4.1.4 Instruction inputs

For instruction inputs, the model is expected to translate the instruction rather than follow it. We therefore evaluate whether the instruction present in the source is represented appropriately in the target. Specifically, we calculate semantic similarity between the instruction portion of the source segment and the corresponding substring of the target. The target substring is identified as the part in which the translated instruction is hypothesized to occur. An output fails when the instruction is not adequately represented in the target, for example when the model follows the instruction instead of translating it.

#### 4.1.5 Truncated inputs

Truncated inputs are designed to test whether a model completes an incomplete source segment by generating information that is not present in the input. We use both an LLM-as-a-judge model and a semantic-similarity-based feature to identify such additions.

We compare the complete source segment against multiple candidate prefixes of the target. Starting with the complete target, we iteratively remove one token at a time from the end of the target and calculate the semantic similarity between each resulting candidate and the full source segment. We select the candidate with the highest similarity to the source. If the highest scoring candidate is shorter than the original target, we interpret the removed part as potentially detached, overgenerated

Table 3: Overall number and percentage of flagged segments for each system (Underlined systems are baseline systems, non-underlined are participants' submissions).

| System | Total |
|---|---|
| GPT OSS 120B | 3485 (76.09%) |
| Tiny Aya Global | 3219 (70.28%) |
| GPT OSS 20B | 2959 (64.61%) |
| Tower 9B | 2804 (61.22%) |
| Qwen 3.6 - 27b | 2766 (60.39%) |
| Ministral 3 - 14B | 2543 (55.52%) |
| Gemini 3.1 Pro | 2534 (55.33%) |
| Qwen 3.5 - 9b | 2478 (54.1%) |
| GLM 4 - 9B | 1659 (36.22%) |
| Command A+ | 1324 (28.91%) |
| DeepSeek V4 Pro | 1050 (22.93%) |
| Mistral Medium 3.5 | 377 (8.23%) |
| GoogleTranslate | 374 (8.17%) |
| Gemma 4 - 4B | 349 (7.62%) |
| UvA-MT | 277 (7.56%) |
| GPT 5.5 | 327 (7.14%) |
| TartuNLP | 60 (6.55%) |
| SalamandraTA | 287 (6.27%) |
| Gemma 4 - 31B | 254 (5.55%) |
| SRPOL | 197 (5.38%) |
| Cohere CAT+ | 241 (5.26%) |
| CUNI-EdUKate | 36 (3.93%) |
| HW-TSC | 26 (2.84%) |
| CUNI-MH-v3 | 48 (2.62%) |
| Lumen | 108 (2.36%) |
| TRIVE | 96 (2.1%) |
| Qingqiu-MT-9B | 85 (1.86%) |
| Wayfinder | 76 (1.66%) |
| SCIR-TG-MT | 23 (1.26%) |
| VoxNexus_V1 | 26 (0.95%) |
| Dubformer | 24 (0.52%) |

content. Such an output is therefore considered a fail. This criterion is complemented by the LLM-as-a-judge model, which independently identifies potentially detached portions of the target.

## 5 Evaluation results and analysis

### 5.1 Quantitative analysis

Table 3 presents aggregated evaluation results per system across all language pairs and all categories. We list the total number of flagged segments (where our evaluation heuristics found an irregularity), as well the percentage of flagged segments relative to the total number of segments. It is important to note that not all systems translated the test set into all languages. We also present an extended table 4 with results separated by system and by language pair.

The results show substantial differences in robustness across systems. The general-purpose LLMs included among the baselines exhibit relatively high rates of flagged segments on the challenge set. In particular, GPT OSS 120B, Tiny Aya Global, GPT OSS 20B, Tower-9B, and Qwen3.6-27B show rates above 60%, while Ministral 3-14B, Gemini 3.1 Pro, and Qwen3.5-9B fall in the range of approximately 54-56%. GLM4-9B and Command A+ perform better, with 36.22% and 28.91%, respectively, while DeepSeek V4 Pro has a rate of 22.93%.

A smaller group of general-purpose models performs substantially better on the challenge set. Mistral Medium 3.5, Gemma 4-4B, Gemma 4-31B, and GPT-5.5 all demonstrate rates below 10%, with Gemma 4-31B reaching 5.55%. These systems are therefore considerably more robust to the failure modes targeted by our test suite than the majority of the general-purpose LLM baselines.

The participating MT systems generally achieve lower failure rates than the general-purpose LLM baselines. Several submissions have failure rates below 5%, with the best-performing systems exhibiting failure rates close to or below 2%. This difference may partly be explained by the fact that many MT systems incorporate additional processing stages, such as quality estimation, filtering, or post-editing, which can detect and mitigate pathological outputs before they are returned to the user. However, this interpretation should be treated cautiously, as the participating systems may also differ from the general-purpose LLMs in model architecture, training data, decoding procedures, and other aspects of their translation pipelines.

Overall, the results indicate that general translation quality and robustness to the specific failure modes targeted by our challenge set do not necessarily coincide. Several systems that are capable of producing high-quality translations nevertheless exhibit substantial failure rates on these targeted inputs, suggesting that standard translation benchmarks may not fully capture these forms of pathological behavior. In the following analysis, we examine the results in greater detail by test category to identify which failure modes are most challenging for current systems.

### 5.2 Analysis by system and category

To gain a better understanding of the systems' performance, we examine flagged segment rate by system and by test category. Tables 4 and 5 present the breakdown of flagged segments across the different categories and provide a more detailed view of the behaviors contributing to the overall rates.

A prominent pattern is that, for many of the

Table 4: Number and proportion of segments flagged by the evaluation criteria for each system.

baseline and organizer systems, a substantial proportion of the observed failures comes from the *sensitive content* category. This is not entirely surprising, as general-purpose LLMs commonly incorporate safety mechanisms designed to prevent them from engaging with content that may be considered harmful, unlawful, or ethically problematic. While such behavior may be desirable in a general-purpose conversational setting, it constitutes a failure in the machine translation setting, where the expected behavior is to translate the input faithfully rather than act on or respond to its content.

At the category level, we observe that most systems, baselines and participants alike, struggle to some extent with both *truncated inputs* and *instruction inputs*. The difficulty with truncated inputs may be related to the tendency of LLMs to interpret incomplete sentences as prompts requiring completion rather than as text that should simply be translated as provided. Similarly, instruction inputs can activate the models' instruction-following behavior, causing them to execute the instruction or respond to it rather than treating it as the object of translation. These two categories therefore probe a common underlying challenge: distinguishing the translation task from other behaviors that the same models are trained to perform.

It is also interesting to note that several categories appear to pose less of a challenge for participants' systems, which are translation-specific rather than general-purpose systems. Comparing the rates of flagged segments for the *DNT*, *punctuation*, and *emoji* categories in Table 5, we observe substantial reductions in the average rates, from 37.86% to 3.57% for *DNT*, from 60.77% to 14.82% for punctuation, and from 41.25% to 6.67% for emoji. For the *truncated* and *instructions* categories, however, the reduction is less pronounced, suggesting that these input types remain challenging for both task-specific and general-purpose systems. In particular, the average rate decreases from 37.85% to 16.93% for truncated segments and from 87.96% to 46.12% for instructions.

## 6 Conclusion

Overall, the category-level analysis suggests that the failures identified by our challenge set are not homogeneous. Some failures correspond to complete refusal or detachment from the source, while others involve otherwise valid translations accom-

panied by additional, unsupported content. The results therefore highlight the value of examining failure types in addition to aggregate failure rates when assessing the robustness of LLM-based translation systems.

## Abstract

Large language models (LLMs) have advanced machine translation substantially, but generic benchmarks often fail to expose where these systems struggle with complex linguistic structures and stylistic nuance. We use CoST (Complex Structures Test), a challenge suite of 1,947 English-Hindi sentences spanning eight genres, autobiography, conversation, legal, mixed, narration, play, poetry, and technical writing, previously introduced for WMT24, to evaluate 22 machine translation systems submitted to the WMT26 General Translation Shared Task for English-Hindi with reference-free, reference-based, and manual evaluation. Our results reveal a consistent genre-level pattern: systems perform well on narrative text such as autobiography and play, but degrade sharply on poetry, legal, and conversational text. We further identify a distinct failure mode in poetry translation, where systems reproduce memorized canonical Hindi verse instead of translating the given English text, and manual analysis surfaces recurring issues in named-entity handling, wrong-language output, and lexical choice, several of which persist from our prior CoST evaluation on WMT24 submissions. Our test suite is available at https://github.com/deciphyre/CoST-WMT-26-Test-Suite-Task.

## 1 Introduction

Neural Machine Translation (NMT) has seen substantial progress in recent years, achieving impressive quality that benefits many everyday applications. The advent of large language models (LLMs) has further enhanced translation capabilities. However, despite these advancements, there remain challenges that generic evaluation methods often fail to address. While traditional evaluations using random text samples might show overall success, they may not reveal subtle issues where MT systems struggle, such as handling complex linguistic structures, idiomatic expressions, and diverse text types like conversations, poetry, legal documents, and technical writing. These flaws can be obscured by average performance metrics or overlooked entirely. A more systematic method for identifying linguistic issues in translation outputs involves using test suites or challenge sets to evaluate the system's performance on specific tasks. (Manakhimova et al., 2023). Test suites offer a standardized approach to evaluating MT systems, revealing strengths and weaknesses in handling complex text types.

In this context, we present an evaluation of state-of-the-art machine translation systems across various categories using CoST (Complex Structures Test), a test suite we previously introduced for WMT24 (Mukherjee et al., 2024). These evaluations were conducted as part of the theme "Mind the Gap: Exposing LLM Translation Blind Spots" for the 11th Conference on Machine Translation (WMT26). The test suite was used to evaluate systems submitted for the English-Hindi language pair.

CoST comprises sentences from eight categories across 16 sources, curated to assess LLM translation capabilities beyond the typical news or generic domains, which often focus on reporting or narrative writing styles. Details of the test suite are provided in Section 2.

We perform reference-free and reference-based evaluations of the Hindi translations of this test suite, produced by 22 different machine translation (MT) systems submitted to the General Translation Task at WMT26. For reference-free evaluation, we employ COMET-Kiwi (Rei et al., 2022), COMTAIL-QE (Ahsan et al., 2025), while BLEU (Papineni et al., 2002), chrF++ (Popović, 2015, 2017), MEE4 (Mukherjee et al., 2020; Mukherjee and Shrivastava, 2023), BERTScore (Zhang* et al., 2020), COMTAIL-DA (Ahsan et al., 2025), and COMET (Rei et al., 2020) are used for reference-based evaluation. We also give subjective analy-

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1602–1614
October 28-29, 2026 ©2026 Association for Computational Linguistics

sis of some of the translation examples. Beyond this year's evaluation, we compare our findings against our prior CoST evaluation of WMT24 submissions to examine which translation weaknesses persist across two years of substantially different systems, and which appear specific to this year's models. Details of our evaluation experiments are discussed in Section 3, and our analysis, including this year-over-year comparison, is presented in Section 4.

Rather than introducing a new benchmark, we use the fixed CoST suite to longitudinally evaluate MT systems across WMT24 and WMT26, examining persistent and emerging failure modes. We also analyze metric disagreement and recurring errors, including named entities, wrong-language outputs, lexical substitutions, and canonical-verse reproduction in poetry.

## 2 CoST:Complex Structure Testsuite

Table 1 depicts the dataset categories and the distribution within our test suite. The "Original" column presents the initial count of selected sentences for each category, as gathered from the datasets. The last column, "CoST," displays the final count of sentences included in the test suite. Our test suite is designed to evaluate translations across

- Multiple Writing Style: Prose, Conversation, Autobiography, Legal Writing, Literary Narrative and Technical Documents.
- Lexical Choice: As we are sampling test suites from various domains, there is a decent mixture of domain-specific words, e.g. Legal Text, Technical Text, etc.

In total, 1,947 English sentences were selected based on criteria such as sentence length, depth of dependency tree, combination of noun phrases, verb phrases, named entities, etc. Ensuring a test suite containing sentences with good representation from simple to complex structures.

## 3 Evaluation Strategy

To evaluate the performance of the 22 submitted MT systems, we performed automatic evaluations. And did subjective analysis on some of the translation outputs.

### 3.1 Automatic Evaluation

In automatic evaluation, we leveraged both reference-free and reference-based metrics.

| Category | Dataset | Original | CoST |
|---|---|---|---|
| poetry | Kabir ke Dohe | 11 | 9 |
| | Amir Khusro | 9 | 9 |
| narration | ShortStories | 177 | 72 |
| | Post Office | 440 | 10 |
| | Glimpses of Bengal | 101 | 64 |
| | The Home and the World | 236 | 183 |
| | The gardener | 277 | 27 |
| | Abridged Merchant of Venice | 63 | 31 |
| | Christmas Carole | 923 | 308 |
| legal | Legal Text | 2862 | 638 |
| | IIT Bombay Jud | 167 | 83 |
| mix | IN22 | 570 | 241 |
| conversation | Friends | 77 | 53 |
| play | King Of Dark Chamber | 35 | 22 |
| autobiography | My Reminiscences | 109 | 110 |
| Technical | Technical Papers | 185 | 87 |
| | **Total** | **6242** | **1947** |

Table 1: Data Statistics of **CoST**.

#### 3.1.1 Reference-free Evaluation

We utilize COMETKIWI (Rei et al., 2022) and COMTAIL-QE (Ahsan et al., 2025) scores, which offer quality estimation scores derived from the source sentence and MT output.

#### 3.1.2 Reference-based Evaluation

With the help of professional English-to-Hindi translators, we also provide one gold reference translation for each source sentence in the test suite. We evaluate the machine translation outputs against these references using BLEU (Papineni et al., 2002), chrF++ (Popović, 2015, 2017), MEE4[1] (Mukherjee et al., 2020; Mukherjee and Shrivastava, 2023), BERTScore (Zhang* et al., 2020), COMTAIL-DA (Ahsan et al., 2025) and COMET (Rei et al., 2020).

### 3.2 Manual Evaluation

The manual analysis was done by professional native speakers. They were instructed to identify mistranslations and hallucinations and make note of other translation errors like wrong post positions to get more nuanced information regarding the system performances.

## 4 Results and Analysis

### 4.1 Quantitative Analysis

The results of the automatic evaluation are reported in Table 2. Ranks are shown in parentheses for each metric, where (1) is the highest

[1] https://www.kaggle.com/ananyacoder/mee4-metric-run

| Model | Referenceless | | Reference-based | | | | | |

| GLM 4 - 9B | 58.9 (22) | 42.9 (22) | 5.3 (22) | 23.8 (22) | 75.9 (22) | 50.3 (22) | 41.1 (22) | 69.5 (22) |

Table 2: System-wise ranking based on reference-free and reference-based metrics.

rank. Table 2 reports system performance across eight automatic metrics, split into reference-free (COMET-Kiwi, COMTAIL-QE) and reference-based metrics, with the latter further separated into lexical (BLEU, chrF++) and embedding-based (BERTScore, COMET, COMTAIL-DA, MEE4) measures.

**Reference-Free Metrics.** On COMET-Kiwi, the top five systems, GPT 5.5, TRIVE, Cohere CAT+, GoogleTranslate, and Lumen, form a tight cluster within 0.3 points of each other (81.65 to 81.97), making it difficult to declare a single best system on this metric alone. COMTAIL-QE broadly agrees with this ordering at the top, with GPT 5.5, Lumen, GoogleTranslate, and TRIVE again occupying the top four positions, suggesting the two reference-free metrics are reasonably consistent for the strongest systems. The clearest disagreement is Gemini 3.1 Pro, which sits mid-table on COMET-Kiwi (76.70, rank 17) but drops sharply on COMTAIL-QE (66.06, rank 19), a gap of roughly 10 points that represents the largest divergence between the two reference-free metrics in the table. At the bottom, GLM 4 - 9B and SalamandraTA trail all other systems by a wide margin on both metrics, consistent with their weak performance throughout the rest of the table.

**Lexical Reference-Based Metrics.** BLEU and chrF++ show a much wider dynamic range than any other metric, with BLEU spanning 5.27 to 47.92, which amplifies differences between systems that look far closer under embedding-based scoring. GoogleTranslate and TRIVE lead on both lexical metrics, consistent with their strong reference-free performance. Gemini 3.1 Pro is a clear outlier here: despite its comparatively weak reference-free scores, it ranks among the top six systems on both BLEU (31.26) and chrF++ (64.58), the largest positive swing between the lexical and reference-free rankings observed in the table. This hints that its outputs may align closely with reference wording even when quality-estimation metrics judge it less favorably.

**Embedding-Based Reference-Based Metrics.** BERTScore, COMET, COMTAIL-DA, and MEE4 tell a more unified story, with GoogleTranslate, TRIVE, GPT 5.5, Cohere CAT+, and Lumen consistently occupying the top ranks and GLM 4 - 9B and SalamandraTA anchoring the bottom across all four metrics. Unlike the lexical metrics, Gemini 3.1 Pro's embedding-based scores (for example, COMET 72.90, COMTAIL-DA 69.39) fall back in line with its reference-free ranking rather than its lexical one, reinforcing that its strong BLEU and chrF++ performance is a lexical-overlap effect rather than a genuine quality advantage. Overall, the embedding-based and reference-free metrics agree far more closely with

one another than either agrees with the lexical metrics, suggesting lexical overlap and semantic or quality-estimation scores are capturing meaningfully different aspects of translation quality for at least a subset of systems.

After examining overall performance across all categories combined, we now turn to a category-wise breakdown to assess whether system rankings and the relationship between reference-free and reference-based metrics hold consistently across content types, or whether certain categories produce markedly different orderings. For each of the eight categories, autobiography, conversation, legal, mix, narration, play, poetry, and technical, we report system rankings on the reference-free metrics (COMET-Kiwi, COMTAIL-QE), followed by the reference-based metrics, further split into lexical (BLEU, chrF++) and embedding-based (BERTScore, COMET, COMTAIL, MEE4) measures, with full per-system, per-metric scores and ranks provided in Tables 3–10 in the Appendix A.

**Autobiography (Table 3).** TRIVE, GoogleTranslate, and GPT 5.5 lead COMET-Kiwi and COMTAIL-QE within 0.2 points of each other. GoogleTranslate posts the highest BLEU (39.89) and chrF++, roughly four BLEU points above TRIVE despite their close COMET-Kiwi scores, indicating closer overlap with reference wording. Embedding-based metrics again favor GoogleTranslate and TRIVE, with GLM 4 - 9B, SalamandraTA, and Tiny Aya Global anchoring the bottom across all eight metrics.

**Conversation (Table 4).** Cohere CAT+ tops COMET-Kiwi (81.62), ahead of GoogleTranslate and Command A+, a departure from its mid-table autobiography ranking. GoogleTranslate again leads BLEU (45.85) and chrF++, with Gemma 4 - 4B and Gemma 4 - 31B ranking higher on BLEU than COMET-Kiwi. GLM 4 - 9B and SalamandraTA remain weakest overall, with SalamandraTA posting the lowest COMET-Kiwi (56.95) of any system in any category.

**Legal (Table 5).** GPT 5.5 leads both reference-free metrics (COMET-Kiwi 80.40, COMTAIL-QE 79.30), narrowly ahead of TRIVE. On BLEU, GoogleTranslate and TRIVE swap to the top two, essentially tied (48.87 vs. 48.86), while GPT 5.5 drops to fifth, suggesting its output diverges more from reference phrasing despite strong quality-estimation scores. GLM 4 - 9B is a clear outlier here, scoring just 20.39 on COMTAIL-QE and 21.43 on COMTAIL-DA.

**Mix (Table 6).** TRIVE, GPT 5.5, and DeepSeek V4 Pro lead COMET-Kiwi within 0.05 points, the tightest race of any category. GoogleTranslate takes BLEU (52.83) and chrF++, with the lexical ranking here matching the reference-free ordering more closely than in Legal or Conversation. Embedding-based metrics again place GoogleTranslate, TRIVE, and GPT 5.5 at the top, with GLM 4 - 9B and SalamandraTA at the bottom.

**Narration (Table 7).** GoogleTranslate leads COMET-Kiwi, COMTAIL-QE, and BLEU simultaneously, the only category where one system tops all three. GPT 5.5 ranks second on COMET-Kiwi but falls to ninth on BLEU (30.60), its largest lexical-to-reference-free gap in any category. GPT OSS 20B joins GLM 4 - 9B and SalamandraTA near the bottom here, despite performing closer to mid-table elsewhere.

**Play (Table 8).** GoogleTranslate again leads COMET-Kiwi, COMTAIL-QE, and BLEU, with Cohere CAT+ and Dubformer close behind. GPT 5.5 sits further back (ninth on COMET-Kiwi, eleventh on BLEU) than in most other categories, suggesting dialogue-heavy text is comparatively harder for it. GLM 4 - 9B remains lowest throughout, and Tiny Aya Global is notably weak on BLEU (5.54, last place) despite a more moderate COMTAIL-QE ranking.

**Poetry (Table 9).** Poetry produces the most volatile rankings of any category. Command A+, GoogleTranslate, and Cohere CAT+ lead COMET-Kiwi, while TRIVE and GPT 5.5, top performers elsewhere, drop to eighteenth (69.61) and seventeenth (71.91). Gemini 3.1 Pro records its weakest result of any category here, last on COMET-Kiwi, BLEU, and COMTAIL-QE, with COMET-Kiwi as low as 58.35. GoogleTranslate again leads BLEU, while GoogleTranslate, Gemma 4 - 31B, and Cohere CAT+ top the embedding-based metrics.

**Technical (Table 10).** GoogleTranslate leads all reference-free and lexical metrics (COMET-Kiwi 84.01, BLEU 46.00) with Lumen and GPT 5.5 close behind on COMET-Kiwi. GPT 5.5 shows a lexical versus-reference-free gap, ranking third on COMET-Kiwi but eighth on BLEU (35.87), while Gemma 4 - 4B and Tower 9B rank unusually high on BLEU relative to their reference-free standing.

GoogleTranslate, Lumen, TRIVE and Tower 9B lead the embedding-based metrics, with SalamandraTA and GLM 4 - 9B trailing throughout. These results show a **consistent drop in performance across systems on the poetry, legal and conversation subsets**, while performing consistently well on autobiography, play and mixed (IN22) data.

**Cross-category and genre-level trends.** GoogleTranslate is the most consistent top performer, leading COMET-Kiwi and BLEU simultaneously in narration, play, and technical, while GLM 4 - 9B and SalamandraTA remain the weakest systems across all eight categories, most severely in legal and conversation respectively. This points to a genre-level pattern, systems perform relatively well on narrative styles such as autobiography and play, but degrade on poetry, legal, and conversational text. One possible explanation is that models may have greater exposure to narrative prose than to the figurative language, turn-taking, and domain-specific phrasing characteristic of these genres; however, the training-data composition of the evaluated systems is not available to us, so this hypothesis cannot be directly verified. The poetry drop is not fully explained by genre difficulty alone: several source segments were English renderings of well-known Hindi *dohe* (e.g., Kabir's couplets). Rather than translating the given wording, systems such as GPT 5.5 and Gemini 3.1 Pro appear to reproduce the canonical Hindi originals. This suggests a possible memorization-related failure mode, consistent with recent findings that LLMs can reproduce memorized content when prompted with semantically related material (Liu et al., 2026).

**Inter-System Agreement (Difficulty Correlation)**
Average pairwise Pearson correlation between each system's per-sentence COMET score vector and all others' (i.e., "do the same sentences that are hard for me tend to be hard for others?"): Overall average pairwise correlation across all 22 systems: r = 0.47, moderate agreement on which sentences are intrinsically hard. Highest agreement: Lumen (0.60), GPT 5.5 (0.59), TRIVE (0.59), Cohere CAT+ (0.58), Command A+ (0.58): the strong, stable systems tend to fail (or succeed) on the same sentences as each other, consistent with those failures being genuinely sentence-level difficulty (long/complex source) rather than system-specific quirks. Lowest agreement: GLM 4-9B (0.24), SalamandraTA (0.25), Tiny Aya Global (0.26), GPT OSS 20B (0.26), Gemini 3.1 Pro (0.31), their failures are more idiosyncratic/system-specific (e.g., decoding pathologies, hallucination, script-mixing) rather than tracking universal sentence difficulty.

**Correlation between metrics** Figure 1 shows the agreement between system rankings induced by different evaluation metrics across the 22 systems. While the metrics generally exhibit high rank correlation, the agreement is not uniform. The COMET-family metrics are highly correlated with one another ($\rho \geq 0.958$), whereas their agreement with lexical metrics is generally lower. In particular, BLEU shows its lowest correlations with COMTAIL-DA ($\rho = 0.801$) and COMTAIL-QE ($\rho = 0.831$). Thus, although the metrics broadly agree on system quality, they can differ substantially in the relative ranking of systems, highlighting the importance of cross-metric analysis when evaluating LLM-based translation.

### 4.2 Qualitative Analysis

The automatic metrics reveal substantial differences across genres, but they do not fully capture the nature of the errors made by individual systems. We therefore manually analyze representative outputs from the CoST suite, focusing on failure modes that are difficult to characterize through aggregate scores alone. We observe recurring problems in named-entity preservation and lexical selection, as well as more severe failures involving target-language control, memorized-text reproduction, meta-responses, and output degeneration. Examples are given in Appendix (Table 11).

**Named-entity handling.** Named entities are generally expected to remain invariant in translation, apart from language-appropriate transliteration. However, several systems alter or distort proper names. For example, in the sentence "Labanya said to her sister in soothing tones: …", multiple systems produce variations of *Labanya*. A similar pattern occurs for *Phoebe*, which is rendered as variants such as *Phobey*, *Phoyeb*, and *Phoyebe* by several systems. These errors are notable because the surrounding sentence can remain fluent while the identity of the named entity is lost.

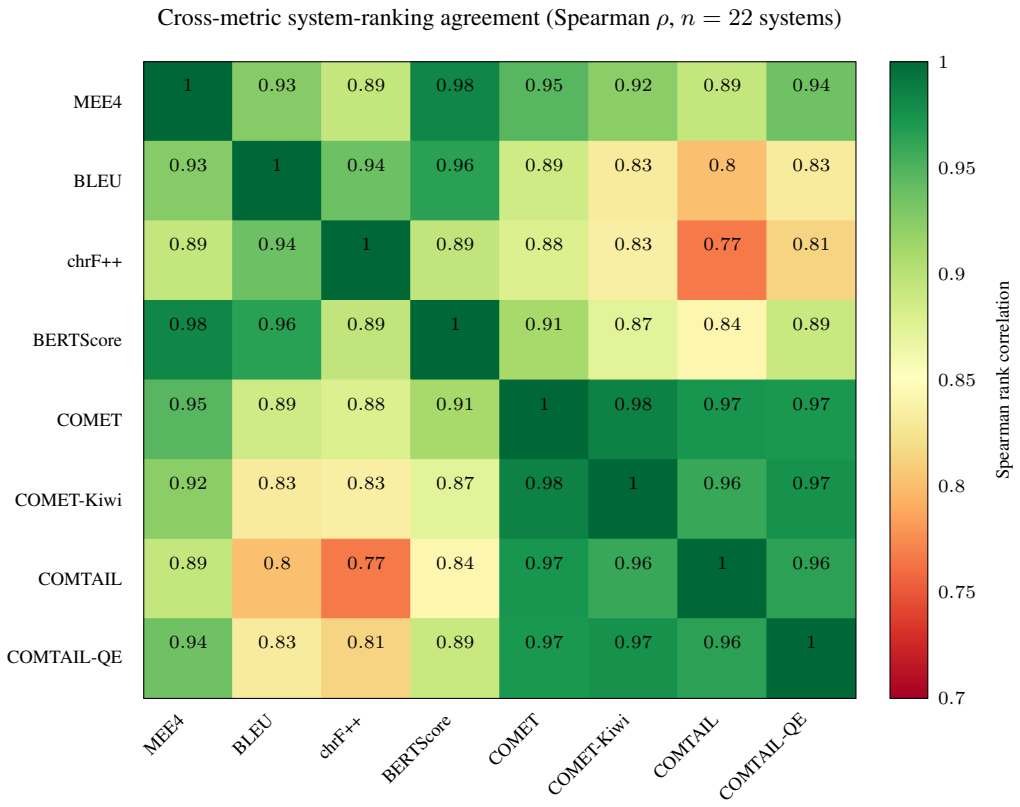

Figure 1: Spearman rank correlations between system rankings induced by the eight evaluation metrics across the 22 systems. The strong correlations among COMET-family metrics contrast with their weaker agreement with lexical metrics such as BLEU and chrF++.

**Lexical selection.** We also observe errors in fine-grained lexical choice even when the surrounding sentence is otherwise well formed. In the sentence "Chandler, Monica, and Phoebe are baby-sitting the triplets", multiple systems select inappropriate equivalents for *triplets*, while SalamandraTA reproduces the English word unchanged. Similar lexical disagreements were observed in the WMT24 evaluation, including substitutions involving *well* and *pulling up*. The recurrence of such errors across evaluation years suggests that fine-grained lexical selection remains a persistent weakness rather than a model-specific artifact.

**Target-language failures.** More severe failures involve loss of the target-language constraint. Tiny Aya Global produces Marathi instead of Hindi for some inputs, while SalamandraTA produces outputs that are predominantly English, with occasional Mandarin segments. These failures are qualitatively different from ordinary lexical or grammatical errors: although the generated text may be fluent, the system fails to satisfy the fundamental requirement that the output be in the requested target language.

**Memorization-driven canonical-text reproduction.** Poetry exposes a distinct failure mode in which systems appear to reproduce a memorized canonical text rather than translate the supplied source. For example, given the English rendering 'Tomorrow's work do today, today's work now; if the moment is lost, the work be done how", GPT-5.5 produces the canonical Hindi Kabir couplet *Kal kare so āj kar, āj kare so ab; pal meṃ pralay hoegī, bahuri karegā kab*. Similarly, for 'In anguish everyone prays to Him, in joy does none; To One who prays in happiness, how sorrow can come", the system produces the corresponding canonical Hindi doha rather than translating the given wording. The outputs are fluent and semantically related to the inputs, but they violate source fidelity by replacing the supplied text with a memorized formulation. This suggests that the poetry degradation is not explained by genre difficulty alone and may instead reflect a memorization-driven override.

**Meta-responses and output degeneration.** We further observe more severe generation failures. In some cases, systems produce a meta-response, such as a translation label or instruction, rather than the requested translation. In others, generation degenerates into repetitive or numerically corrupted sequences, with outputs containing patterns such as *29-500000000000*.... These cases represent a more fundamental failure of task adherence: the system does not merely mistranslate the source but loses the expected translation behavior altogether.

**Persistence across evaluation years.** The longitudinal comparison allows us to distinguish persistent weaknesses from failures newly observed in the current evaluation. Named-entity mishandling was prominent in both years: the WMT24 evaluation reported distorted renderings of *Labanya* and *Phoebe* by six and seven systems, respectively, compared with fourteen and seven systems in the current evaluation. Lexical selection errors likewise recur, with WMT24 showing substitutions such as *well* $\rightarrow$ *alright/okay* and disagreement over *pulling up* versus *removing*, while the current evaluation shows comparable errors for *triplets*. These recurring patterns suggest that named-entity preservation and fine-grained lexical selection remain persistent weaknesses across successive generations of MT systems.

In contrast, wrong-language outputs and memorization-driven reproduction of canonical poetry were not reported in the WMT24 qualitative analysis. The available evidence does not establish whether these represent genuinely new failure modes or failures that were simply not observed in the earlier manual analysis. Nevertheless, their presence in the current evaluation highlights failure behaviors that may be missed by aggregate metrics and motivates continued qualitative and longitudinal analysis of LLM-based translation.

## 5 Conclusion

This paper evaluates 22 machine translation systems submitted to the WMT26 General Translation Shared Task using CoST, a 1,947-sentence, eight-genre benchmark designed to expose weaknesses that generic, narrative-heavy evaluation data tends to obscure. Combining reference-free, reference-based, and manual evaluation, we find a consistent genre-level pattern: systems perform well on narrative-style text such as autobiography and play, but degrade markedly on poetry, legal, and conversational content, plausibly reflecting a training-data skew toward narrative prose. Qualitative analysis further reveals a distinct poetry-specific failure mode, systems reproducing memorized canonical Hindi verse instead of translating the given English input, alongside recurring issues in named-entity handling, wrong-language output, and lexical word choice. Comparing these findings to a prior CoST evaluation on WMT24 submissions shows that named-entity mishandling and lexical selection errors persist across two years of substantially different systems, suggesting structural rather than model-specific limitations, while wrong-language output and memorization-driven poetry reproduction appear specific to this year's submissions. canonical-verse reproduction were observed in our WMT26 analysis but were not reported in the WMT24 analysis.

Together, these results show that despite continued advances in general translation quality, LLM-based MT systems retain systematic blind spots in stylistically and structurally complex text, underscoring the need for more genre-aware evaluation and broader, more stylistically diverse training data.

# A Appendix

## A.1 Category wise Scores

Tables 3-10 present category-wise system rankings across all eight evaluation metrics, split into referenceless (COMET-Kiwi, COMTAIL-QE) and reference-based (BLEU, chrF++, BERTScore, COMET, COMTAIL-DA, MEE4) groups. Each table corresponds to one of the eight test-suite categories (autobiography, conversation, legal, mix, narration, play, poetry, and technical) and reports, for every system, the raw metric score along with its rank within that category and metric, shown in parentheses (rank 1 indicating the highest score). Systems are ordered by COMET-Kiwi in descending order within each table. Cell shading reflects the relative score within each metric column for that category, from lightest (lowest) to darkest (highest).

| Model | Referenceless | | Reference-based | | | | | |
|---|---|---|---|---|---|---|---|---|
| | COMET-Kiwi | COMTAIL-QE | BLEU | chrf++ | BERTScore | COMET | COMTAIL-DA | MEE4 |
| TRIVE | 83.2 (1) | 88.1 (1) | 35.6 (2) | 60.2 (2) | 88.8 (2) | 80.5 (2) | 82.5 (3) | 83.8 (2) |
| GoogleTranslate | 83.0 (2) | 88.0 (2) | 39.9 (1) | 62.4 (1) | 89.5 (1) | 81.5 (1) | 83.1 (1) | 84.4 (1) |
| GPT 5.5 | 83.0 (3) | 87.7 (3) | 31.4 (7) | 57.6 (5) | 87.4 (8) | 80.0 (6) | 82.3 (5) | 82.8 (6) |
| Lumen | 83.0 (4) | 87.7 (4) | 33.0 (5) | 58.1 (4) | 88.0 (6) | 80.1 (5) | 82.3 (4) | 83.2 (4) |
| DeepSeek V4 Pro | 82.9 (5) | 87.5 (6) | 31.0 (8) | 56.3 (7) | 87.8 (7) | 79.7 (7) | 81.9 (8) | 82.6 (8) |
| Gemma 4 - 31B | 82.8 (6) | 87.4 (7) | 35.0 (3) | 59.1 (3) | 88.3 (3) | 80.2 (4) | 82.2 (6) | 83.3 (3) |
| Cohere CAT+ | 82.7 (7) | 87.7 (5) | 28.4 (10) | 55.2 (9) | 86.9 (9) | 80.4 (3) | 82.8 (2) | 82.1 (10) |
| Command A+ | 82.2 (8) | 86.8 (8) | 24.4 (12) | 50.3 (13) | 85.5 (12) | 78.8 (9) | 82.0 (7) | 80.9 (12) |
| Tower 9B | 81.7 (9) | 85.7 (10) | 30.2 (9) | 55.0 (10) | 86.8 (10) | 77.7 (12) | 80.2 (12) | 82.2 (9) |
| Dubformer | 81.5 (10) | 86.0 (9) | 33.1 (4) | 56.6 (6) | 88.1 (4) | 79.1 (8) | 80.8 (10) | 82.9 (5) |
| Gemma 4 - 4B | 81.4 (11) | 85.2 (12) | 31.8 (6) | 56.1 (8) | 88.1 (5) | 77.9 (11) | 80.3 (11) | 82.7 (7) |
| Mistral Medium 3.5 | 81.1 (12) | 85.6 (11) | 28.0 (11) | 51.2 (12) | 86.5 (11) | 78.1 (10) | 80.8 (9) | 81.3 (11) |
| GPT OSS 120B | 80.9 (13) | 84.2 (14) | 20.6 (14) | 48.0 (15) | 84.4 (15) | 76.4 (14) | 79.2 (14) | 80.2 (14) |
| Qwen 3.6 - 27b | 80.7 (14) | 84.6 (13) | 21.1 (13) | 48.6 (14) | 84.9 (13) | 76.8 (13) | 79.9 (13) | 80.2 (13) |
| Ministral 3 - 14B | 79.2 (15) | 82.1 (15) | 20.5 (15) | 47.4 (16) | 84.8 (14) | 75.5 (15) | 78.5 (15) | 79.7 (15) |
| Qingqiu-MT-9B | 78.4 (16) | 80.0 (16) | 18.3 (17) | 44.6 (17) | 83.8 (16) | 73.5 (16) | 76.0 (16) | 79.1 (16) |
| Qwen 3.5 - 9b | 77.8 (17) | 79.5 (17) | 17.8 (19) | 43.7 (19) | 83.5 (17) | 73.0 (17) | 75.3 (17) | 78.5 (17) |
| GPT OSS 20B | 77.1 (18) | 79.5 (18) | 18.7 (16) | 44.3 (18) | 81.8 (18) | 71.5 (18) | 73.7 (18) | 75.8 (18) |
| Gemini 3.1 Pro | 76.5 (19) | 64.6 (21) | 18.0 (18) | 51.9 (11) | 80.4 (19) | 70.2 (19) | 68.4 (19) | 75.6 (19) |
| Tiny Aya Global | 76.4 (20) | 78.8 (19) | 13.9 (20) | 37.7 (20) | 80.2 (20) | 68.7 (20) | 63.5 (21) | 74.1 (20) |
| SalamandraTA | 72.6 (21) | 70.1 (20) | 11.0 (21) | 35.0 (21) | 79.7 (21) | 67.6 (21) | 66.5 (20) | 73.8 (21) |
| GLM 4 - 9B | 63.5 (22) | 54.3 (22) | 9.7 (22) | 33.8 (22) | 78.9 (22) | 55.3 (22) | 50.3 (22) | 71.0 (22) |

Table 3: System-wise ranking for the *Autobiography* category based on reference-free and reference-based metrics.

| Model | Referenceless | | Reference-based | | | | | |

# Phrase at WMT26 Automated MT Evaluation Task

**Alan Eckhardt, Ondřej Glembek, Craig Stewart***
Phrase a.s.
{first.last}@phrase.com

## Abstract

We describe the Phrase submission to WMT26's shared task on automated MT quality evaluation, covering all three of its tasks: segment-level error detection and span annotation (T1), segment-level quality score prediction (T2), and detection of error-free segments (T3). Treating independent LLMs as a panel of ESA (Error Span Annotation)-style error-span judges, we measure a ceiling: a perfect filter over the panel's pooled spans would raise MPP-F (our span-matching F-score) by roughly two thirds over the strongest single judge. An exhaustive search for how to realize that headroom (diversity, rank-weighted aggregation, a per-judge reliability prior, and boundary refinement) never beats the strongest single judge on MPP-F (T1), because the judges' shared recall is too low for any gold-free span selection to close the gap. The two tasks derived from the same spans behave differently: a static reliability prior wins the segment score (T2), and simple agreement wins the binary error-free decision (T3). Our primary submission, Phrase01, follows this split; a secondary submission, Phrase02, forces in a third judge (UFAL's cat-v4) across all tasks as an explicit ablation, despite evidence it does not help. The lever for span-level detection is annotation coverage through generation, not aggregation; for the derived tasks, it is matching the aggregation mechanism to the metric.

## 1 Introduction

Ensembling large language model (LLM) judges is widely assumed to improve automated evaluation, on the intuition that independent judges cancel one another's errors (Verga et al., 2024). We test that assumption thoroughly for span-level machine translation (MT) quality evaluation and find it largely does not hold under the shared task's primary metric, for a reason that is specific and measurable.

We separate two questions usually conflated. First, how much could a panel (see Sec. 4.1 for definition) help if we combined it perfectly. Second, how much does it help with a realizable, gold-free combination. The gap between the two is the story: the ceiling is high, the realizable gain is zero or negative, and the difference is a recall wall.

The target adds a second reason to expect the wall. Human Error Span Annotation (ESA) has limited recall and limited inter-annotator span agreement (Kocmi et al., 2024). The gold each system is scored against is closer to what one annotator reacted to than to the full set of errors present, so part of the coverage the panel appears to miss is coverage the reference never had. Predicting error, under this metric, is partly predicting where a human reacts to it.

## 2 Related Work

Human evaluation of machine translation has converged on error-based protocols. The Multidimensional Quality Metrics (MQM) framework (Lommel et al., 2014) defines the severity and error-type taxonomy, and Freitag et al. (2021) established MQM as the standard for MT human evaluation by showing that expert error annotation reranks systems differently from crowd ratings. The shared task uses Error Span Annotation (Kocmi et al., 2024), which keeps MQM-style severity-marked spans but simplifies the protocol; the same work reports the limited inter-annotator recall and span agreement that our analysis relies on when it argues that the gold reflects one annotator's reactions rather than the full set of errors.

Using LLMs to produce these annotations is now an established line. GEMBA showed a general-purpose LLM is a strong translation-quality evaluator (Kocmi and Federmann, 2023b), GEMBA-MQM extended this to detecting MQM error spans (Kocmi and Federmann, 2023a), and AutoMQM

*Authors are listed in alphabetical order and contributed equally.

prompts an LLM to identify and categorise errors, yielding spans that align with human annotation without a reference (Fernandes et al., 2023). Our judges follow this single-model span-annotation lineage. Closely related, concurrent work computes oracle upper bounds for a single model's error span detection and cautions that such bounds are optimistic when measured against a single annotator's gold (Lyu et al., 2025) (a caveat our own oracle analysis shares (Sec. 4.3)), though we bound a panel's pooled spans rather than one model's sampled candidates. Learned neural metrics are the competing baselines: COMET (Rei et al., 2020) and its fine-grained successor xCOMET, which adds error-span detection (Guerreiro et al., 2024), alongside regression metrics such as MetricX-24 (Juraska et al., 2024). The WMT metrics shared tasks track how these compare (Freitag et al., 2023, 2024), with the WMT24 results noting that LLM-based metrics increasingly rival purpose-trained ones.

Our contribution concerns aggregating multiple judgments, where two strands are relevant. The first resamples a single stochastic judge: GEMBA-MQM V2 scores each segment ten times and combines the runs with a reciprocal-rank weighted average (RRWA) after outlier removal, motivated by run-to-run variance and a tendency to over-annotate (Junczys-Dowmunt, 2025); this generalises the self-consistency idea (Wang et al., 2023). We adopt its RRWA aggregation and test it on both self-consistency and heterogeneous panels.

The second strand uses panels of distinct models. Wang et al. (2024) show that a single LLM judge is biased and unstable. Motivated by this, Verga et al. (2024) propose a Panel of LLM Evaluators and report that a jury of smaller, diverse models aligns better with human judgment, reduces intra-model bias, and costs less than one large judge. That result is for scoring free-form generations. Our finding is that for span-level MT evaluation under a severity-weighted matching metric the panel advantage does not carry over on the primary localization metric, because the judges' shared recall is low; the jury still helps the derived binary error-free classification, which is consistent with where panels are known to help.

## 3 Task and Data

We participate in all three tasks (Span annotation (T1), Segment score (T2), and error-free classification (T3)) on the eight minimum-required language pairs: cs-de, cs-vi, en-ar, en-et, en-id, en-is, en-se, and zh-ja. For T1, systems produce ESA-style annotations over the MT hypothesis: character-offset error spans, each labelled minor or major, with the omissions field left blank (null). T1 submissions are scored with the official severity-weighted span-matching metric, match with partial overlap and partial credit (MPP) (Perrella et al., 2026): a one-to-one optimal matching between hypothesis and gold spans, credited by proportion of overlapping characters and reduced when predicted and gold severities disagree, pooled via micro-averaging, with severity weights 0.25 for minor and 1.0 for major. We report the resulting F-score as MPP-F throughout.

For development and all analysis we use two independent dev sets, both defined by UFAL (Charles University's Institute of Formal and Applied Linguistics) (Hrabal and Bojar, 2026): Dev1 and their final version, Dev2. Dev1 has 2,032 segments across the 5 of 8 priority pairs that have gold (cs-de, cs-uk, en-ar, en-et, en-is)—cs-uk, not cs-vi; see Sec. 6 for why the two differ—and is the dev set used throughout Sec. 5. Dev2 is UFAL's final dev set and has a narrower Gemini/Gemma quality gap than Dev1. It is drawn from the same 5 of 8 priority pairs (cs-de, cs-uk, en-ar, en-et, en-is), out of a 14-language-pair, 3,058-row snapshot before priority filtering. We use it in Sec. 6 both to evaluate the cat-v4 fusion (UFAL's own system, Sec. 4.1) and, for consistency, to re-validate the core Gemini+Gemma strategy there. The other 3 priority pairs (zh-ja, en-id, en-se) are new for WMT26 and have no dev gold in either set, so every choice for them rests on a signal that transfers without gold. We report the pooled micro-average as primary, matching the official leaderboard's own micro-averaging (Perrella et al., 2026), and the segment-weighted average as a secondary check.

## 4 Methodology

### 4.1 The Panel

By *panel* we mean a set (bag) of independent LLM judges; its exact membership varies by experiment.

LLM judges are prompted with an ESA-style instruction including the shared-task guidelines; each returns error spans with severities, parsed to a normalised character-span annotation. Exact prompt wording is proprietary and not reproduced here; at a high level, each judge is instructed to classify

every error's severity as major or minor and return the exact substring of the translation each error span covers. The core panel is three independent commercial models: Gemini 3.5-flash, Claude Sonnet 4.6, and GPT-5.6-luna. We also evaluate local open-weight judges (Qwen3.5-9B and Gemma-4-12B, via vLLM) and an external MQM system, UFAL's cat-v4 (Hrabal and Bojar, 2026): a two-stage MQM-style error detector built on the open-weight Gemma 4 31B instruction model, 4-bit activation-aware weight quantization (AWQ), using few-shot prompting and one-pass self-refinement to predict optional MQM categories from the source and candidate translation alone, without reference translations.

### 4.2 Combination Strategies

We evaluated a wide family so the negative result does not rest on one design:

- **Per-segment routing**: for each segment, defer to whichever single judge is expected to be most reliable there, instead of one fixed judge for every segment. We only evaluated this as an oracle ceiling (Tab. 2, using gold to pick per segment); we did not pursue a realizable version, continuing instead with the character-level consensus approach below.

- **Character-level vote-depth consensus**: tally, per character, how many judges flag it as part of an error, and threshold on that count to decide which characters to keep.

- **Gemini-anchored doubly-corroborated top-up**: keep all of Gemini's own spans and add only spans the other two judges both independently flag but Gemini missed.

- **Severity relabelling and escalation**: override a span's severity using the panel's aggregate judgment, e.g. escalating to major when enough judges agree it is severe.

- **Directed prompt-framing diversity**: generate additional judges by re-prompting under different framings (recall-leaning, human-reaction, criticality) rather than relying on model diversity alone.

- **Fusion of the external cat-v4 system**: add UFAL's system into the panel's pooled vote alongside the in-house judges.

- **Self-consistency resampling**: repeatedly sample a single judge at non-zero temperature and aggregate the resulting spans, treating run-to-run variance itself as a diversity source. This is also what covers undirected temperature diversity, as distinct from the directed framings above.

- **Reciprocal-rank weighted aggregation (RRWA)**: weight each contributor's spans (or each resample's) by its rank among the panel on that segment, rather than voting all members equally; used both as a scalar score combiner and transplanted into span voting.

### 4.3 Oracles as Measurement Instruments

To bound the approach we compute oracles that use gold at selection time. These are not submittable systems; they measure how much of the score is in principle recoverable from the panel's existing spans: an oracle span-subset (keep only pooled spans optimal matching pairs with gold), oracle per-segment routing, oracle severity assignment, and their join.

We compute this ceiling separately rather than simply tuning combination methods for the best dev MPP-F, because a dev-tuned score alone is ambiguous: it cannot distinguish a method that is near-optimal (little headroom exists) from one that is failing to realize headroom that is actually there. Dev tuning only ever selects the best of finitely many fixed, gold-free rules, applied uniformly at test time; it can reweight the panel's own visible signals (severity, length, agreement) but cannot recover information (which specific spans are correct) that those signals do not carry. The oracle, by using gold per decision rather than in aggregate, measures what is recoverable if that missing information were available, giving a ceiling that no realizable rule can reach.

### 4.4 Experimental Protocol

Two ESA prompt variants are used across this paper: a baseline prompt, used for all dev-set validation and method search (Sec. 5), and a revised, directive-style prompt adopted for the real WMT26 submission after later prompt-iteration work found it transfers more reliably across judges (Sec. 6). Results under the two are not directly comparable, since T2's best method changes between them.

All aggregation analysis runs on cached judge annotations with no further model calls; only the

| Judge | T1 | T2 | T3 |
|---|---|---|---|
| Gemini 3.5-flash | **0.311** | **0.599** | **0.248** |
| Claude Sonnet 4.6 | 0.273 | 0.535 | 0.223 |
| GPT-5.6-luna | 0.274 | 0.536 | 0.224 |
| Gemma-4-12B (local) | 0.228 | 0.220 | 0.061 |
| Qwen3.5-9B (local) | 0.205 | 0.264 | 0.071 |

Table 1: Single-judge dev results (pooled). Metrics for T1, T2 and T3 are MPP-F, Pearson, and Matthews correlation coefficient (MCC), respectively.

| Oracle | MPP-F | Δ |
|---|---|---|
| Gemini baseline | 0.311 | — |
| oracle span-subset | 0.518 | +0.207 (+67%) |
| oracle routing | 0.363 | +0.052 |
| oracle severity | 0.362 | +0.051 |
| oracle joint | **0.615** | **+0.304 (+100%)** |

Table 2: Oracle ceilings, segment-weighted MPP-F (the pooled micro-average was intractable on the high-cardinality oracle sets); Δ is vs. Gemini baseline. Oracle joint combines subset and severity.

prompt-framing and self-consistency judges required generation (via Gemini, Gemma-4-12B and UFAL's system). Deltas between systems use a paired segment-level bootstrap (about 1,000 resamples, seed 42) over the 2,032 dev segments.

## 5 Results

Tab. 1 shows the results for the individual systems on Dev1 with Gemini being the strongest single judge, winning 4 of 5 dev pairs standalone.[1] The open-weight judges are meaningfully weaker on every metric, and no configuration that includes them beats the commercial panel; we report this as a negative for cost-free local judging.

Tab. 2 shows the oracle ceilings (Sec. 4.3): how much of the score is recoverable, in principle, from the panel's existing spans if gold were available to select among them. A perfect filter over the panel's spans would nearly double MPP-F. The span-subset oracle uses greedy rather than exact matching and is a lower bound.

### 5.1 The recall wall

Agreement among judges is a genuine, generalisable signal, but it cannot fix the problem, because the problem is not precision. Character-level gold precision rises monotonically with judge vote depth on every dev pair: pooled, characters all three judges agree on are about 62% precise, against about 22% for a single judge's own flagged characters. This is the only signal that survives leave-one-out validation across all five pairs; which specific judge dissents does not. Yet the union of everything the three judges ever flag touches only 30–40% of gold error characters. That is the wall: recall, not precision, bounds the score, and no reshuffling of spans the judges already proposed can add coverage none of them ever proposed.

### 5.2 Anatomy of the missed recall

Two questions locate where the wall comes from, both measured on Dev1 (1,538 segments carrying gold errors, 5,632 gold spans). First, the loss is not a segment-length effect: pooled character recall of the three-judge union is essentially flat across MT-length quartiles (0.48, 0.40, 0.39, 0.37 from shortest to longest) and the per-segment rank correlation between recall and length is negligible (Spearman $-0.04$). The shortest quartile is marginally easier, but long inputs do not drive the loss. Second, the uncovered recall is concentrated, not diffuse: 27.6% of gold spans are missed entirely by the union (Tab. 3), and the misses skew toward minor severity (33.8% vs. 20.5% for major) and short spans (34.7% for $\leq$10 characters vs. 9.5% for $>$30), with a consistent per-language-pair spread (en-is 15.2% to cs-de 33.0%). The panel misses small, low-severity, localized errors far more than long or major ones, so the coverage gap is a systematic reluctance to flag minor local errors rather than an attention limit on long inputs.

### 5.3 Realizable policies do not convert the ceiling

Tab. 4 shows the scores for realizable policies, with paired bootstrap confidence intervals on the delta to Gemini (pooled micro-average). Every delta is at or below zero. The corroborated top-up, the mechanism designed to add recall with precision control, is the worst family: the regions the non-anchor judges agree on where Gemini is silent are not precision-safe, and under a harmonic metric the recall they add does not pay for the precision they cost. The directed prompt-framing result reproduces the same pattern: the recall framing ties the literal prompt as a standalone judge (winning a different 3 of 5 pairs, a genuine hedge), but combining framings by span union is significantly worse.

[1] Gemini's solo T1 score recurs at three different values later (0.311, 0.326, 0.334) because of two independent, unrelated causes: segment-weighted vs. true-pooled micro-averaging (Sec. 5.6), and the baseline vs. production prompt (Sec. 4.4). Each is explained where it first appears.

| Stratum | Subset | % missed | mean cov. |
|---|---|---|---|
| Severity | major | 20.5 | 0.71 |
| | minor | 33.8 | 0.57 |
| Span length (chars) | $\leq$10 | 34.7 | 0.65 |
| | 11–30 | 27.7 | 0.69 |
| | $>$30 | 9.5 | 0.52 |
| Lang. pair | en-is | 15.2 | 0.74 |
| | en-ar | 26.7 | 0.46 |
| | en-et | 28.4 | 0.60 |
| | cs-uk | 32.1 | 0.64 |
| | cs-de | 33.0 | 0.61 |

Table 3: Gold spans on Dev1 (5,632 spans) entirely missed by the three-judge union, by severity, span length, and language pair; overall miss rate 27.6%. 'mean cov.' is the mean fraction of a span's characters the union covers. Misses concentrate in minor, short spans.

| Policy | MPP-F | $\Delta$ |
|---|---|---|
| Gemini (baseline) | **0.326** | — |
| recall framing (single) | **0.326** | **+0.000 (n.s.)** |
| severity escalation | 0.319 | $-0.007$ (n.s.) |
| framing union (max sev.) | 0.317 | $-0.008$ (worse) |
| vote-depth $\geq 2$ | 0.307 | $-0.019$ (n.s.) |
| corroborated top-up | 0.295 | $-0.031$ (worse) |

Table 4: Realizable panel and framing policies, pooled micro-average MPP-F, with paired bootstrap significance; $\Delta$ is vs. Gemini baseline.

Taking the maximum severity across framings also inflates the major rate, because the criticality framing marks almost everything major.

### 5.4 External judge fusion

Fusing UFAL's cat-v4 MQM system into the panel (on the 647-segment subset it covers) gives a small, consistent lift over the three-judge baseline (best about +0.007 pooled at a 3-of-4 threshold) but does not beat Gemini standalone, which tops every configuration on that subset (0.345). cat-v4 is precision-heavy and recall-light, so it is a poor two-judge partner for any single judge and helps only inside the fuller panel, in proportion to the base panel's headroom. Results are directional, on a partial subset, and do not touch the three blind pairs.

### 5.5 Rank-weighted aggregation

Among the many combination levers tried, we also followed GEMBA-MQM V2 in resampling a single judge ten times and combining the runs with a reciprocal-rank weighted average after outlier rejection, and separately transplanted the same rank-weighting into span voting over the heterogeneous panel. Neither went into the final submission (self-consistency resampling reduces one judge's own noise but cannot inject capability it doesn't have, and on T1 the transplanted version does not beat Gemini standalone (0.302 pooled on the three-judge panel)) but the rank-weighting idea itself is the seed that Sec. 5.6 builds on, by adding a per-judge reliability prior for the pair that made the final cut.

### 5.6 Judge-reliability priors, and an exhaustive search for one pair

Every aggregation method above ranks judges only by their own score on a given segment, with no notion that one judge is generally more reliable than another. We add an optional static per-judge *reliability prior* (each judge's own standalone metric) that multiplies into the per-segment rank weight, for both the span-voting and scalar aggregation families, and use it to drive an exhaustive method search restricted to the pair that motivates the question: Gemini and Gemma-4-12B, the clearest known-quality gap in the panel (Tab. 1).

For T1 the search is genuinely exhaustive. Beyond union, intersection, and RRWA-weighted voting with and without the prior, we test a Gemini-anchored rescue family (keep 100% of Gemini's spans, admit only Gemma's exclusive spans past an increasingly strict severity-and-length filter), word-level voting, span-level one-to-one matching (via the same optimal matcher that scores MPP-F itself), a learned admission classifier (logistic regression over 9 span- and segment-level features, evaluated leave-one-language-pair-out), and boundary refinement, which blends Gemini's and Gemma's offsets for matched span pairs instead of an include/exclude decision. Every family tops out at or below Gemini alone (Tab. 5); the rescue filter makes the bound explicit, since tightening it can only ever discard admitted Gemma content, so the curve converges to the solo baseline bit-for-bit as the filter approaches "admit nothing."

A precision/recall breakdown explains why: union's precision collapses to Gemma's own precision, since Gemma's exclusive detections are mostly false positives, while intersection's recall craters below Gemini's own, since Gemini's exclusive detections are mostly correct. Boundary refinement fails for the same underlying reason, and monotonically regardless of merge rule: Gemini's boundaries are already the better estimate of the

| T1 method family | Best MPP-F |
|---|---|
| Gemini (solo, reference) | **0.326** |
| Unweighted union / intersection | 0.284 |
| RRWA-weighted, with MPP-F prior | 0.287 |
| Gemini-anchored rescue filter | $\rightarrow$ 0.326 |
| Word-level voting | 0.260 |
| Span-level matching + rescue | 0.312 |
| Learned classifier (logistic regr.) | 0.317 |
| Boundary refinement (best: intersection) | 0.322 |

Table 5: Every T1 combination family tried for Gemini+Gemma, true-pooled MPP-F on Dev1; solo Gemini here (0.326) differs from Tab. 1 only through true micro-averaging vs. per-pair averaging (footnote 1), not a different system. The rescue filter's arrow denotes asymptotic convergence to the solo baseline as the filter tightens, never exceeding it.

true span, so blending in any of Gemma's boundary information nudges away from gold rather than toward it.

The one informative byproduct is the learned classifier's feature weights: each judge's own segment-level confidence dominates the admission decision by a factor of 2–3$\times$ over the span's own severity or length. This is more useful as a diagnostic for a future iteration than as a route to a better classifier on its own.

T2 and T3 diverge from this pattern (Tab. 6). For T2, a purely static prior-weighted scalar mean, with no per-segment adaptivity at all, is the strongest method found (0.622, versus 0.574 for the best prior-free combination, and versus 0.600 for adding per-segment RRWA ranking on top of the same prior, which costs a little rather than helping). For T3 the prior adds nothing: plain unweighted intersection, unchanged from the earlier sweep, remains the best method (0.252). A follow-up search confirms both numbers sit close to a real optimum for this pair rather than an artifact of the first pass: an interpolation between the per-segment rank weight and the static prior is fully monotonic toward the pure-prior endpoint for T2 (no interior sweet spot), and plateaus below intersection's score for T3 regardless of which metric's prior is substituted in.

The asymmetry across tasks is the header result: whether a reliability prior helps depends on the metric. A harmonic, span-level metric (T1) is bound by shared recall, so weighting a weaker judge more or less carefully cannot outweigh the precision it costs; a continuous score (T2) benefits from a static reliability weighting with no per-segment component at all; a binary decision (T3) is already well served by simple agreement, and gains

| Metric | Best method | Score | $\Delta$ |
|---|---|---|---|
| T1 | Gemini alone | 0.326 | — |
| T2 | Scalar prior-weighted mean | 0.622 | +0.023 |
| T3 | Unweighted intersection | 0.252 | +0.004 |

Table 6: Best method found per metric for Gemini+Gemma after the exhaustive priors search, pooled Dev1; $\Delta$ is vs. Gemini alone. Metrics for T1, T2 and T3 are MPP-F, Pearson, and MCC, respectively. Whether a static reliability prior helps depends on the metric, not on the judge pair.

nothing further from knowing which judge is generally stronger. This strategy was re-derived and replicated under the actual production prompt for the real submission (see Sec. 6) and the T2 finding sharpens further on Dev2.

### 5.7 Secondary tasks behave differently

The derived tasks do not share T1's ceiling. Agreement- and outlier-based methods improve the binary error-free classification (T3): the reaction and criticality framings lift T3 MCC by 0.08–0.11 over the literal prompt, and RRWA gives the best T3 of any merge we tried. For the segment-score task (T2), deriving the score from predicted spans is markedly better than a direct LLM score (about 0.64 versus 0.46 Pearson), a methodological point worth flagging given the task's opt-in direct-scoring design. This localization-versus-classification split is the mechanism behind the whole result: agreement helps a coarse binary decision but cannot help a harmonic localization metric whose recall is already capped.

### 5.8 Analysis

The ceiling and the realizable result are only apparently in tension. The oracle is a precision instrument: it holds recall at the union's level and removes false positives using gold. Any gold-free method must instead choose which spans to keep from the panel's own signals, and the only signal that generalises, agreement, trades recall for precision. Since recall binds, the trade cannot win, and every diversity source we tried (undirected sampling, directed prompt framing, an external MQM system, principled rank weighting) reproduces it. The one mechanism that buys recall, the corroborated top-up, loses because the regions the panel adds are noisier than the gold implies.

This points effort elsewhere. Aggregation cannot exceed the union's coverage, and that coverage is a

| Task | Method | Dev1 | Dev2 |
|---|---|---|---|
| T1 | Gemini solo | 0.334 | 0.289 |
| T2 | RRWA, prior | 0.642 (+0.005) | 0.442 (+0.039) |
| T3 | Intersection | 0.306 (+0.064) | 0.233 (+0.069) |

Table 7: Final replicated strategy (Phrase01), pooled scores on two independent dev sets under the production prompt; deltas are vs. the corresponding single-judge or no-prior baseline on that dev set.

| System | MPP-F | T2 Pearson | T3 MCC |
|---|---|---|---|
| Gemini | **0.289** | **0.403** | 0.164 |
| Gemma | 0.223 | 0.353 | 0.149 |
| UFAL cat-v4 | 0.186 | 0.343 | **0.206** |

Table 8: Standalone scores on Dev2. The external system is weakest on T1/T2 but strongest on T3. Standalone quality again does not imply a combination benefit (Sec. 5.6).

minority of gold characters, so the lever that moves the score is raising a single strong judge's coverage through the prompt, not combining judges. It also connects to the target: with human inter-annotator recall around 66% (Kocmi et al., 2024), some of the missing coverage is the reference's own, so part of the wall is a property of the metric rather than of the judges.

## 6 Submitted System

The strategy of Sec. 5.6 was derived under the baseline prompt (Sec. 4.4). Re-deriving it under the revised, directive-style prompt actually used for the real test-set run changes T2's winner: the plain prior-weighted mean loses its edge, and a multiplicative RRWA-with-prior combination takes over instead. The revised strategy was then replicated on Dev2: UFAL's final dev set, used here for consistency with the cat-v4 fusion analysis below, which evaluates UFAL's own system on their own final set. Dev2 also has a narrower Gemini/Gemma quality gap than Dev1, confirming the strategy holds and that the T2/T3 gains are larger there, consistent with the intuition that a reliability prior matters more the closer two judges are in quality.

### 6.1 Phrase01 (primary)

Phrase01 applies Tab. 7's strategy to the real, gold-free test data across all eight priority pairs (Sec. 3). The join key across judges is the composite (segment id, system name), since the real test-set records carry no usable single per-row identifier, unlike the dev sets. The T2 prior is pooled across both dev sets: {gemini: 0.5647, gemma: 0.4270}.

A pre-existing bug surfaced only when cross-checking against the organisers' official priority-pair list: our own priority-pair constant still listed cs-uk (Czech-Ukrainian), which the organisers had replaced with cs-vi (Czech-Vietnamese) in the high-priority set on 2026-07-22. The bug did not affect the real judge data, which already covered the correct pair, but it does mean neither dev set above has data for that specific pair, under either prompt; the replication evidence in Tab. 7 is accordingly strong for seven of the eight submitted pairs but rests on the transfer argument alone for the eighth.

### 6.2 Phrase02 (secondary): forcing in a third, external judge

Before finalising Phrase01, we tested whether adding a third, structurally different system—UFAL's cat-v4 (Sec. 4.1), not run through our own pipeline—to the Gemini+Gemma pair could do better, using the same exhaustive-search methodology as Sec. 5.6, on Dev2 only. Tab. 8 reports the result: the external system is competitive standalone on the derived binary task, but adding it to Phrase01's pair does not beat Phrase01 on any of the three tasks, under either of the two aggregation mechanisms it tried best.

We nonetheless submit a second variant, Phrase02, that forces all three systems into every task, using the best three-way method found in that search per task—a genuinely different aggregation mechanism from Phrase01's for T2 and T3, not simply Phrase01 plus a third vote: unweighted span union for T1, a static prior-weighted scalar mean for T2, and a per-segment prior-weighted RRWA over each system's own binary prediction for T3. The external system does not cover every record Gemini and Gemma do; wherever it is missing, Phrase02 falls back to Phrase01's two-judge result for that record rather than dropping it, so every segment still receives a label. Phrase02 is explicitly an ablation, submitted despite the negative result above, to give the shared task a second, honestly-labelled data point on whether a third judge helps once more of the panel-composition space is forced open. Both Phrase01 and Phrase02 were uploaded before the deadline.

cat-v4 is itself a WMT26 shared-task submission from UFAL, described more fully in their own system paper (Hrabal and Bojar, 2026).

## 7 Conclusion

For span-level MT quality evaluation under a severity-weighted matching metric, a panel of independent LLM judges has a large ceiling but almost none of it is realizable without gold, because the judges' shared recall is low and the only generalisable panel signal improves precision alone. We reach this conclusion from every diversity source and combination lever tried, including an exhaustive, reliability-prior-aware search restricted to the specific pair used in the final submission. A single strong judge remains the better system for span-level detection (T1). The two tasks derived from the same spans tell a different story: a static, per-judge reliability prior is the best method found for the segment score (T2), and simple agreement remains the best method for the binary error-free decision (T3). Aggregation helps exactly where the metric rewards it, and not where it doesn't. Our submitted system follows this split (Phrase01), and we additionally submit an explicit ablation that forces a third judge into every task (Phrase02) despite evidence it does not help, as a second data point for the shared task. The productive direction for span-level detection is annotation coverage through generation; for the derived tasks, it is matching the aggregation mechanism to the metric rather than defaulting to one combination rule everywhere.

This paper measures the recall wall and its anatomy (Sec. 5.2); turning that diagnosis into higher coverage is future work. Because the misses concentrate in small, low-severity, localized spans rather than long inputs, the productive interventions are on the generation side rather than aggregation: highlighting candidate spans in the prompt, evaluating spans at a finer granularity than the whole segment, and seeding recall with non-LLM candidate detectors (e.g. word alignment) before LLM adjudication, each aimed at the coverage ceiling this paper identifies as the binding constraint.

## Limitations

Every quantitative result in this paper is measured on development sets: no configuration was chosen or validated on a held-out test split, and official test scores arrive only after submission, so the conclusions should be read as dev-set findings pending that confirmation. Dev covers 5 of 8 priority pairs, so the three blind pairs rest entirely on the transfer argument; one of the eight submitted pairs (Sec. 6) has never been directly covered by any dev-set experiment in this line of work, under either prompt, for reasons unrelated to the transfer argument itself. The oracle span-subset uses greedy matching and is a lower bound. External-fusion results in Sec. 5.4 are on a 647-segment subset the external system covers, are directional rather than held out; the later three-way search behind Phrase02 (Sec. 6) is scoped to one dev set only and was not cross-checked against the first. We test specific commercial judges plus two open-weight models and one external system, and trained no component; results may not transfer to other judges. Reproducibility is limited in two ways. The commercial judges are closed, versioned models, and the prompts used for the real run are production assets we do not release, so the exact system cannot be reconstructed from this paper alone. More substantively, the per-task recommendations are prompt-contingent: the best T2 method changes from a plain prior-weighted scalar mean under the baseline prompt to a multiplicative RRWA-with-prior under the production prompt (Sec. 6), so the specific winning aggregator should be read as conditional on the prompt, whereas the qualitative split we claim as robust (T1 bound by shared recall, T2 aided by a static reliability prior, T3 by simple agreement) does not depend on it. Configuration was selected on gold that carries the same annotation-recall limits we invoke in the analysis.

# FECE: A Challenge Set for Evaluating Fine-Grained Translation Error Correction

**Jie Ding, Xiangyu Duan**
School of Computer Science and Technology, Soochow University, China
jding0508@stu.suda.edu.cn; xiangyuduan@suda.edu.cn

## Abstract

Existing machine translation evaluation metrics assess translation quality only at the segment level and therefore cannot assess fine-grained translation quality. For translation error correction systems, this means that the quality of fine-grained corrections cannot be evaluated using existing metrics. To highlight this evaluation challenge, we propose the FECE dataset for evaluating fine-grained correction quality. Experiments on FECE show that existing metrics do not always reflect fine-grained correction performance. To enable the evaluation of fine-grained correction performance, we further propose $\text{COMET}_{\text{Fine}}$, a fine-grained evaluation metric. $\text{COMET}_{\text{Fine}}$ can effectively assess fine-grained correction quality while also revealing inconsistencies between existing metrics and $\text{COMET}_{\text{Fine}}$.

## 1 Introduction

Existing machine translation evaluation metrics primarily assess the quality of a complete segment. However, segment-level evaluation cannot distinguish corrections associated with human-annotated errors from changes made elsewhere in a translation, making it difficult to evaluate fine-grained translation quality independently.

This limitation is particularly important when evaluating translation error correction systems. A corrected translation may repair human-annotated errors in the original machine translation while also polishing or rewriting other parts of the segment. A segment-level score reflects both types of changes. Consequently, even when a corrected translation receives a higher score, it remains unclear whether the improvement results from correcting the annotated errors or from polishing and rewriting elsewhere. Existing segment-level metrics therefore cannot separate fine-grained correction quality from the overall quality of the complete translation.

To expose this evaluation challenge, we introduce the **Fine-Grained Error Correction Evaluation Set (FECE)**. Each FECE item contains two candidate translations generated from the same original machine translation. *hyp1* is instructed to correct all human-annotated errors while preserving the remaining content as closely as possible. In contrast, *hyp2* is instructed to retain all human-annotated errors while polishing content outside the annotated error locations. This controlled contrast allows us to test whether an evaluation metric reflects the quality of corrections to human-annotated errors or is influenced by polishing and rewriting elsewhere.

To enable the evaluation of fine-grained correction performance, we further propose $\text{COMET}_{\text{Fine}}$, a fine-grained evaluation metric. The metric first uses GPT-5.6 Sol (OpenAI, 2026) to align each human-annotated error with its corresponding correction content in *hyp1* or *hyp2*. The aligned correction content is then substituted for the corresponding human-annotated error in the original machine translation to obtain a reconstructed translation. Finally, the reconstructed translation is scored with COMET-22. By excluding content changes unrelated to the human-annotated errors, $\text{COMET}_{\text{Fine}}$ provides a more focused evaluation of fine-grained correction quality.

We use FECE to analyze the evaluation results of 29 WMT26 evaluation systems. The results show that existing metrics do not always reflect fine-grained correction performance. Across English–German, English–Japanese, and English–Chinese, WMT26 evaluation systems prefer *hyp1* in 51.2%, 39.2%, and 41.2% of cases on average, respectively. These results indicate that whole-segment scores can be influenced by polishing and rewriting elsewhere and therefore do not consistently reflect the quality of corrections to human-annotated errors. By contrast, $\text{COMET}_{\text{Fine}}$ prefers *hyp1* in 63.9%, 61.5%, and 68.4% of the pairs in the

three language directions, respectively, providing a clearer signal of fine-grained correction performance. Meanwhile, for many examples, WMT26 evaluation systems and $\text{COMET}_{\text{Fine}}$ produce different preferences between *hyp1* and *hyp2*, further indicating that whole-segment evaluation does not always reflect fine-grained correction quality.

Our main contributions are threefold:

- We introduce FECE, a challenge set containing 3,000 candidate pairs across English–German, English–Japanese, and English–Chinese for evaluating fine-grained translation error correction quality.
- We systematically analyze the performance of 29 WMT26 evaluation systems on FECE and reveal the limitations of existing segment-level metrics in evaluating fine-grained corrections.
- We propose a fine-grained evaluation metric, $\text{COMET}_{\text{Fine}}$, which evaluates corrections corresponding to human-annotated errors through local alignment and reconstruction, and reveals inconsistencies between existing metrics and fine-grained evaluation results.

## 2 Related Work

**Segment-level Machine Translation Evaluation and Error Localization** Automatic machine translation (MT) metrics typically assign a segment-level quality score to a complete candidate translation. BLEU and chrF primarily assess translation quality based on word-level or character-level n-gram overlap between candidate and reference translations (Papineni et al., 2002; Popović, 2015). In contrast, BERTScore and YiSi leverage contextual representations from pretrained models to measure semantic similarity between candidate and reference translations (Zhang et al., 2020; Lo, 2019), while COMET learns to predict translation quality using pretrained multilingual representations and human quality judgments (Rei et al., 2020, 2022). In contrast to these automatic metrics, MQM and Error Span Annotation (ESA) provide human evidence about the locations and severities of translation errors (Freitag et al., 2021; Kocmi et al., 2024). xCOMET further combines segment-level scoring with automatic error localization (Guerreiro et al., 2024). These approaches improve the interpretability of MT evaluation, but error detection and correction evaluation are distinct problems. The former determines whether and where an original translation is erroneous, whereas the latter must assess the quality of a candidate's modification to a given human-annotated error. When a candidate also contains polishing or rewriting of other content, a segment-level score cannot separately reflect the changes resulting from corrections to human-annotated errors.

**Translation error correction and minimal editing.** Automatic post-editing and translation error correction aim to improve MT output while preserving content that is already correct. Prior work has identified over-correction as a recurring problem and has used word-level quality-estimation signals to constrain generation and reduce unnecessary edits (Deoghare et al., 2025). The WMT25 shared task on automated translation evaluation also introduced quality-informed segment-level error correction, measuring overall improvement with the change in COMET score and editing efficiency with the Gain-to-Edit Ratio (Lavie et al., 2025). These methods consider both translation quality and the extent of editing, but the evaluation is still based on the complete corrected translation, making it difficult to distinguish the contribution of corrections to human-annotated errors from that of other content changes. Polishing content outside the human-annotated errors may increase the overall score, while other edits may offset the gains brought by error correction. Therefore, segment-level quality gains do not directly reflect the fine-grained correction quality associated with human-annotated errors.

**Challenge sets for machine translation evaluation metrics.** Challenge sets are commonly used to examine the performance of machine translation systems or evaluation metrics in specific scenarios. Challenge sets for machine translation systems typically evaluate their ability to handle specific linguistic phenomena, including cross-lingual structural differences as well as lexical, grammatical, and discourse phenomena (Isabelle et al., 2017; Manakhimova et al., 2025). ACES applies this evaluation approach to automatic metrics by comparing better translations with translations containing specific accuracy errors, thereby analyzing metric sensitivity to different types of accuracy errors (Amrhein et al., 2022). Related WMT25 challenge sets further examine metric performance on low-quality and anomalous outputs (Knowles et al., 2025),

under-resourced Sub-Saharan African languages (Li et al., 2025), and gender bias (Filandrianos et al., 2025). These studies show that constructing dedicated challenge sets for specific translation phenomena, data conditions, or evaluation factors can help analyze the behavior and limitations of evaluation metrics across different settings.

Building on this line of work, FECE further focuses on the correspondence between edits in candidate translations and human-annotated errors. Given the same original machine translation, *hyp1* is instructed to correct all human-annotated errors while preserving the remaining content as much as possible, whereas *hyp2* retains these errors and only polishes content outside the annotated error regions. By comparing an evaluation metric's preference between them, we can analyze which type of modification has a greater influence on its evaluation results. Based on this idea, $\text{COMET}_{\text{Fine}}$ identifies the actual edits in a candidate translation that are associated with human-annotated errors and applies them to the original machine translation. It then scores the reconstructed translation, which retains only error-related edits, allowing the evaluation to focus more directly on the correction quality associated with human-annotated errors.

## 3 FECE Challenge Set

### 3.1 Data Construction

FECE is designed to examine whether automatic machine translation evaluation systems can reflect fine-grained translation error correction performance. The English–German data are derived from the WMT24 MQM data, whereas the English–Japanese and English–Chinese data are derived from the WMT24 ESA data (Freitag et al., 2024; Kocmi et al., 2024). These data provide source sentences, reference translations, original machine translation outputs, and corresponding human error annotations.

For each sample, we use the same source sentence, original machine translation, and human-annotated errors as input to DeepSeek-V4-Pro (DeepSeek-AI et al., 2026), which generates two candidate translations, *hyp1* and *hyp2*, under two complementary instructions:

- *hyp1* is instructed to correct all human-annotated errors in the original machine translation while preserving the remaining content as closely as possible.
- *hyp2* is instructed to retain all human-annotated errors in the original machine translation while polishing content outside the annotated error locations.

This contrastive design allows us to examine whether the scores produced by automatic evaluation systems reflect corrections to human-annotated errors or are instead influenced by polishing and rewriting elsewhere in the translation. If an evaluation system can accurately reflect fine-grained correction performance, it should, overall, show a preference for *hyp1*.

| Direction | Source | Pairs | Candidates | Systems |
|---|---|---|---|---|
| En–De | WMT24 MQM | 1,000 | 2,000 | 28 |
| En–Ja | WMT24 ESA | 1,000 | 2,000 | 28 |
| En–Zh | WMT24 ESA | 1,000 | 2,000 | 29 |
| Total | — | 3,000 | 6,000 | 29 |

Table 1: FECE data sources, scale, and WMT26 evaluation-system coverage.

### 3.2 Data Scale and Evaluation-System Coverage

FECE covers English–German, English–Japanese, and English–Chinese. Each language direction contains 1,000 candidate pairs, corresponding to 2,000 candidate translations. The complete challenge set therefore contains 3,000 candidate pairs and 6,000 candidate translations. Table 1 summarizes the data source, scale, and WMT26 evaluation-system coverage for each language direction.

The WMT26 automatic machine translation evaluation task provided scores from 29 distinct evaluation systems. The English–German and English–Japanese data were each scored by 28 systems, while the English–Chinese data were scored by 29 systems, yielding 85 system–language-direction evaluation results.

## 4 $\text{COMET}_{\text{Fine}}$

To evaluate fine-grained translation quality, we propose $\text{COMET}_{\text{Fine}}$. The method first identifies and aligns the edits in *hyp1* and *hyp2* that are related to human-annotated errors. It then applies these edits to the original machine translation to construct reconstructed translations that exclude unrelated polishing and rewriting, and finally scores the reconstructed translations using COMET-22.

| Field | Text |
|---|---|
| **Source** | The storm left three people injured. |
| **Original MT** | *Der Sturm hinterließ drei Tote.* |
| **Human annotation E1** | *Tote* |
| ***hyp1*** | *Der Sturm hinterließ drei Verletzte.* |
| **Alignment** | `original: Tote; replacement: Verletzte` |
| ***hyp1_fine*** | *Der Sturm hinterließ drei Verletzte.* |

Table 2: Example of candidate-specific alignment and reconstruction.

### 4.1 Local Alignment of Error-Related Edits

A complete candidate translation may contain both corrections related to the human-annotated errors and broader rewrites. For each candidate translation $\mathrm{hyp}_q$ ($q \in \{1, 2\}$), GPT-5.6 Sol receives the source sentence $s$, the original machine translation $mt$ with human error annotations, and $\mathrm{hyp}_q$. For each indexed error $e_j$, the model returns

$$a_{qj} = (o_{qj}, r_{qj}), \tag{1}$$

where `original` $o_{qj}$ denotes the text span in $mt$ associated with the $j$-th human-annotated error, and `replacement` $r_{qj}$ denotes the replacement text aligned from the candidate translation. If the candidate does not modify the error, we set $r_{qj} = o_{qj}$; otherwise, $r_{qj}$ records the text actually produced by the candidate at the corresponding location.

Table 2 shows an example of this alignment process. The German machine translation renders *injured* as *Tote* ("dead people"). In *hyp1*, the corresponding expression is *Verletzte* ("injured people"). The model therefore returns `Tote` as the original span and `Verletzte` as the replacement.

### 4.2 Reconstruction and Scoring

The aligned correction content is substituted for the corresponding human-annotated error span in the original machine translation:

$$\mathrm{hyp}_q^{\mathrm{fine}} = R\Big(mt, \{o_{qj} \to r_{qj}\}_{j=1}^{k}\Big). \tag{2}$$

We refer to the resulting reconstructed translations as *hyp1_fine* and *hyp2_fine*. Each reconstructed translation is based on the original machine translation $mt$ and replaces only the `original` spans associated with human-annotated errors with their corresponding `replacement` spans from the candidate translation. Consequently, polishing and rewriting in the candidate translation that are unrelated to the human-annotated errors are not carried over into $\mathrm{hyp}_q^{\mathrm{fine}}$.

Let $C$ denote COMET-22, which takes the source sentence $s_i$, a candidate translation, and the reference translation $r_i$ as input. We define

$$\mathrm{COMET}_{\mathrm{Fine}}(\mathrm{hyp}_{qi}) = C\Big(s_i, \mathrm{hyp}_{qi}^{\mathrm{fine}}, r_i\Big). \tag{3}$$

We rerun COMET-22 on both the complete candidate translations and the reconstructed translations in the same computational environment, thereby controlling for environment-dependent factors such as GPU numerical precision. To validate the reconstruction process, we randomly sample 200 pairs of reconstructed translations from each language direction for manual inspection, resulting in 600 inspected pairs in total. The reconstruction pass rates for English–German, English–Japanese, and English–Chinese are 98.5%, 99.0%, and 99.0%, respectively, with an overall pass rate of 98.8%.

## 5 Evaluation Setup

Our experiments examine three aspects: (1) the preferences of the WMT26 evaluation systems between the complete candidate translations *hyp1* and *hyp2*; (2) the preference expressed by $\mathrm{COMET}_{\mathrm{Fine}}$ between the two candidates after retaining only edits associated with human-annotated errors; and (3) the degree of agreement between the evaluation results of the WMT26 evaluation systems and those of $\mathrm{COMET}_{\mathrm{Fine}}$.

**Pairwise Preference** For each WMT26 evaluation system $M$, the score difference for the $i$-th pair of complete candidate translations is defined as

$$\Delta_{M,i} = M(\mathrm{hyp1}_i) - M(\mathrm{hyp2}_i). \tag{4}$$

Correspondingly, the score difference produced by $\mathrm{COMET}_{\mathrm{Fine}}$ is defined as

$$\begin{aligned}\Delta_{\mathrm{Fine},i} = {} & C\Big(s_i, \mathrm{hyp1}_i^{\mathrm{fine}}, r_i\Big) \\ & - C\Big(s_i, \mathrm{hyp2}_i^{\mathrm{fine}}, r_i\Big).\end{aligned} \tag{5}$$

When *hyp1* receives a higher score than *hyp2*, the result is recorded as a preference for *hyp1*. When *hyp2* receives a higher score than *hyp1*, the result is recorded as a preference for *hyp2*. Equal scores are recorded as a tie. For each language direction, we separately calculate the proportions of *hyp1* preferences, *hyp2* preferences, and ties. If an evaluation system prefers *hyp1* in more pairs than it prefers *hyp2*, we consider that system to have an overall preference for *hyp1* in that language direction.

**Agreement with COMET$_{\text{Fine}}$** We compare the evaluation results of the WMT26 evaluation systems with those of COMET$_{\text{Fine}}$ in terms of both pairwise preferences and score differences. Let $p_M(i)$ denote the preference assigned by evaluation system $M$ to candidate pair $i$, and let $p_{\text{Fine}}(i)$ denote the preference assigned by COMET$_{\text{Fine}}$ to the same candidate pair. Both preferences fall into one of three categories: a preference for *hyp1*, a preference for *hyp2*, or a tie.

If $p_M(i)$ and $p_{\text{Fine}}(i)$ are identical, the two evaluation results agree on that candidate pair. The three-way agreement rate is the proportion of all candidate pairs on which the evaluation results agree and is defined as

$$A(M) = \frac{1}{N} \sum_{i=1}^{N} \mathbf{1}[p_M(i) = p_{\text{Fine}}(i)]\,. \quad (6)$$

Here, $N$ denotes the total number of candidate pairs, and $\mathbf{1}[\cdot]$ is the indicator function: it takes the value 1 when the condition inside the brackets is satisfied and 0 otherwise. All three categories—preferences for *hyp1*, preferences for *hyp2*, and ties—are included in the calculation. A tie assigned by both methods is counted as an agreement, whereas a tie assigned by only one method is counted as a disagreement.

The three-way agreement rate measures whether the two evaluation methods produce the same pairwise preferences. The Pearson correlation coefficient between $\Delta_M$ and $\Delta_{\text{Fine}}$ measures whether their score differences exhibit similar patterns of variation. When results are summarized within a language direction, we report the arithmetic mean of the system-specific agreement rates and Pearson correlation coefficients, with all available evaluation systems in that direction weighted equally. These values are descriptive macro-averages over evaluation systems. When results for an individual evaluation system are aggregated across language directions, preference and three-way agreement rates are averaged arithmetically. For Pearson correlation coefficients, we first apply Fisher's $z$ transformation, average the transformed values, and then transform the result back to the Pearson $r$ scale.

# 6 Results

## 6.1 Preferences of WMT26 Evaluation Systems

Table 3 summarizes, by language direction, the mean preference rates of the WMT26 evaluation systems for *hyp1* and *hyp2*. It also reports the number of evaluation systems in each direction, the number of systems that prefer *hyp1* overall, and the mean agreement rate and Pearson correlation with COMET$_{\text{Fine}}$. For En–De, the 28 evaluation systems achieve an average *hyp1* preference rate of 51.2%, compared with a preference rate of 35.0% for *hyp2*. All 28 systems show an overall preference for *hyp1*. For En–Ja, the average *hyp1* preference rate across the 28 systems is 39.2%, lower than the *hyp2* preference rate of 50.0%, and only two systems show an overall preference for *hyp1*. For En–Zh, the 29 systems achieve an average *hyp1* preference rate of 41.2%, which is also lower than the *hyp2* preference rate of 47.1%. Only five systems show an overall preference for *hyp1* in this language direction.

The three language directions exhibit different evaluation patterns. The evaluation systems generally favor *hyp1* for En–De, whereas the average results favor *hyp2* for En–Ja and En–Zh. This suggests that, when complete candidate translations are evaluated, polishing and rewriting outside the human-annotated errors can substantially influence system scores. Consequently, *hyp1*, which is explicitly generated to correct the annotated errors, does not consistently receive higher scores across language directions.

At the individual-system level, the highest *hyp1* preference rates for En–De, En–Ja, and En–Zh are achieved by spBLEU (65.8%), BERTScore (54.2%), and BLEU (59.3%), respectively. Complete per-language results for all WMT26 evaluation systems are reported in Appendix D.

## 6.2 Evaluation Results of COMET$_{\text{Fine}}$

The *hyp1* preference rates of COMET$_{\text{Fine}}$ are 63.9%, 61.5%, and 68.4% for En–De, En–Ja, and En–Zh, respectively. The corresponding *hyp2* preference rates are 28.5%, 28.9%, and 23.7% (Table 4 and Figure 1a). The mean fine-grained score difference is positive for all three language directions, indicating that COMET$_{\text{Fine}}$ favors *hyp1* in each direction.

Compared with the average results of the WMT26 evaluation systems, the *hyp1* preference

| Direction | Systems | *hyp1* pref. | *hyp2* pref. | *hyp1*-oriented | Agreement | Pearson $r$ |
|---|---|---|---|---|---|---|
| En–De | 28 | 51.2 | 35.0 | 28 | 53.3 | 0.444 |
| En–Ja | 28 | 39.2 | 50.0 | 2 | 46.1 | 0.214 |
| En–Zh | 29 | 41.2 | 47.1 | 5 | 46.3 | 0.309 |

Table 3: Average results of the WMT26 evaluation systems for each language direction. The *hyp1* preference rate, *hyp2* preference rate, and agreement rate are reported as percentages; the unreported proportion corresponds to ties. "*hyp1*-oriented" denotes the number of evaluation systems whose *hyp1* preference rate is higher than their *hyp2* preference rate in the corresponding language direction. Agreement and Pearson $r$ measure the consistency between each evaluation system and $\text{COMET}_{\text{Fine}}$ in terms of pairwise preferences and score differences, respectively.

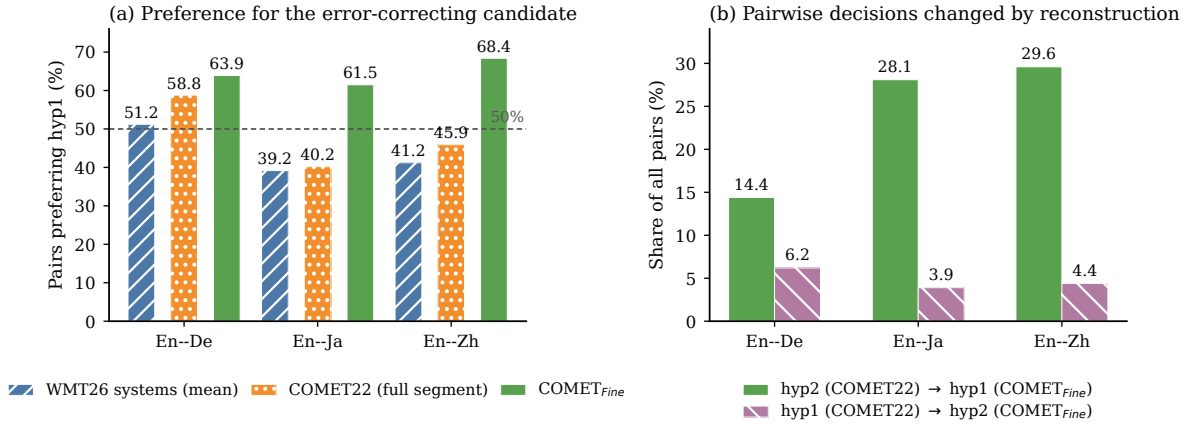

Figure 1: Main experimental results. (a) The average *hyp1* preference rate of the WMT26 evaluation systems, the *hyp1* preference rate of COMET-22 on the complete candidate translations, and the *hyp1* preference rate of $\text{COMET}_{\text{Fine}}$. (b) The proportions of candidate pairs whose COMET-22 preference changes from *hyp2* to *hyp1* or from *hyp1* to *hyp2* after the reconstructed translations are evaluated by $\text{COMET}_{\text{Fine}}$.

| Direction | *hyp1* pref. | *hyp2* pref. | $\overline{\Delta}_{\text{Fine}}$ |
|---|---|---|---|
| En–De | 63.9 | 28.5 | 2.010 |
| En–Ja | 61.5 | 28.9 | 0.824 |
| En–Zh | 68.4 | 23.7 | 1.264 |

Table 4: Evaluation results of $\text{COMET}_{\text{Fine}}$ for the three language directions. Preference rates are reported as percentages, and the unreported proportion corresponds to ties. A positive $\overline{\Delta}_{\text{Fine}}$ indicates that the average score of *hyp1_fine* is higher than that of *hyp2_fine*.

rates of $\text{COMET}_{\text{Fine}}$ are higher by 12.7, 22.3, and 27.2 percentage points for En–De, En–Ja, and En–Zh, respectively. When the scope of evaluation is restricted to modifications associated with the human-annotated errors, *hyp1*, which is generated to correct these errors, exhibits a clearer advantage in all three language directions.

To further compare whole-segment and fine-grained evaluation, we use the same COMET-22 model to score both the complete candidate translations and the reconstructed translations. On the complete candidate translations, the *hyp1* preference rates of COMET-22 are 58.8%, 40.2%, and 45.9% for En–De, En–Ja, and En–Zh, respectively. On the reconstructed translations, the corresponding rates increase to 63.9%, 61.5%, and 68.4%, representing increases of 5.1, 21.3, and 22.5 percentage points. These changes demonstrate the influence of polishing and rewriting elsewhere in the candidate translations on whole-segment COMET-22 evaluation.

### 6.3 Differences between Whole-Segment and Fine-Grained Evaluation

Across all 3,000 candidate pairs, whole-segment COMET-22 prefers *hyp2* in 1,543 cases. Among these cases, 721 switch to a preference for *hyp1* under $\text{COMET}_{\text{Fine}}$. These 721 pairs account for 24.0% of all candidate pairs and 46.7% of the cases in which whole-segment COMET-22 prefers *hyp2*. Considering each language direction separately, 35.4%, 47.1%, and 54.8% of the En–De, En–Ja, and En–Zh pairs for which whole-segment COMET-22 prefers *hyp2* switch to a preference for *hyp1* under $\text{COMET}_{\text{Fine}}$, respectively.

In the opposite direction, 145 pairs switch from a

| Direction | Agreement | Disagreement | Pearson $r$ |
|---|---|---|---|
| En–De | 72.3 | 27.7 | 0.797 |
| En–Ja | 58.6 | 41.4 | 0.588 |
| En–Zh | 58.2 | 41.8 | 0.642 |

Table 5: Agreement between whole-segment COMET-22 and $\text{COMET}_{\text{Fine}}$ for each language direction. Agreement and disagreement rates are reported as percentages. Pearson $r$ measures the correlation between their pairwise score differences.

preference for *hyp1* under whole-segment COMET-22 to a preference for *hyp2* under $\text{COMET}_{\text{Fine}}$. These cases account for 4.8% of all candidate pairs (Figure 1b; detailed results are provided in Appendix C). The two directions of change are markedly asymmetric: substantially more candidate pairs switch from *hyp2* to *hyp1* than from *hyp1* to *hyp2*.

These results suggest that part of the advantage obtained by *hyp2* in whole-segment evaluation may originate from polishing and rewriting outside the human-annotated errors. When these modifications are excluded from the reconstructed translations, the same COMET-22 model may instead prefer *hyp1*. Whole-segment evaluation results therefore cannot be directly interpreted as evaluations of the modifications associated with the human-annotated errors.

### 6.4 Agreement with $\text{COMET}_{\text{Fine}}$

The average three-way agreement rates between the WMT26 evaluation systems and $\text{COMET}_{\text{Fine}}$ are 53.3%, 46.1%, and 46.3% for En–De, En–Ja, and En–Zh, respectively (Table 3). The corresponding average Pearson correlation coefficients are 0.444, 0.214, and 0.309. These results show that the WMT26 evaluation systems and $\text{COMET}_{\text{Fine}}$ produce different preference judgments for many candidate pairs in FECE. Their score differences also do not exhibit strong parallel variation.

Among all evaluation systems, COMET-22 achieves the highest agreement rate and Pearson correlation coefficient in each of the three language directions, as shown in Table 5. However, full-segment COMET-22 and $\text{COMET}_{\text{Fine}}$ still produce different preference decisions for 27.7%, 41.4%, and 41.8% of the candidate pairs in the three language directions, respectively. This disagreement is more pronounced for English–Japanese and English–Chinese, where it exceeds 40%.

Among the 28 evaluation systems for which scores are available in all three language directions, BERTScore achieves the highest macro-average *hyp1* preference rate, at 58.4% (Appendix D). However, its macro-average three-way agreement rate with $\text{COMET}_{\text{Fine}}$ is 54.0%, and its Fisher-$z$-aggregated Pearson correlation is 0.243. In comparison, COMET-22 has a lower macro-average *hyp1* preference rate of 48.3%, but a higher macro-average three-way agreement rate of 63.0% and a higher Fisher-$z$-aggregated Pearson correlation of 0.687. This comparison indicates that the *hyp1* preference rate and agreement with $\text{COMET}_{\text{Fine}}$ capture two distinct aspects of evaluation: the former measures how frequently an evaluation system favors *hyp1*, whereas the latter measures whether its evaluation results are consistent with the fine-grained evaluation results.

### 6.5 Implications for Translation Error Correction Evaluation

The results on FECE expose an attribution problem in whole-segment evaluation. A change in the score of a corrected translation may result from the correction of human-annotated errors, but it may also result from polishing and rewriting elsewhere in the translation. An increase in the whole-segment score alone therefore cannot determine whether a translation error correction system has genuinely improved the content corresponding to the annotated errors. This issue is particularly evident for En–Ja and En–Zh: the average results of the WMT26 evaluation systems favor *hyp2*, whereas $\text{COMET}_{\text{Fine}}$, which evaluates only error-related modifications, favors *hyp1*. The difference between these evaluation results demonstrates that an improvement in overall translation quality does not necessarily imply an improvement in fine-grained correction quality.

Whole-segment and fine-grained evaluation capture different aspects of a translation error correction system. Whole-segment evaluation measures the overall quality of a corrected translation, whereas $\text{COMET}_{\text{Fine}}$ focuses on the quality of modifications associated with human-annotated errors. When the two approaches produce different judgments, the change in overall translation quality and the effectiveness of correcting the target errors are not fully aligned. Translation error correction systems should therefore be evaluated by examining both aspects separately, rather than relying solely on whole-segment scores to assess correction performance.

## 7 Conclusion

We presented FECE, a 3,000-pair challenge set for evaluating the quality of fine-grained translation error correction. Across 29 WMT26 evaluation systems, whole-segment preferences do not consistently reflect whether the human-annotated errors were corrected. We also proposed $\text{COMET}_{\text{Fine}}$, which aligns annotated errors to candidate edits, reconstructs candidates from the original MT, and scores the resulting translations with COMET-22. $\text{COMET}_{\text{Fine}}$ consistently favors the error-correcting candidate across all three language directions, preferring *hyp1* in 61.5%–68.4% of candidate pairs. Compared with COMET-22 evaluation on the complete segments, removing polishing and rewriting unrelated to the human-annotated errors causes 721 candidate pairs that were originally judged in favor of *hyp2* to instead favor *hyp1*. These results indicate that whole-segment evaluation can be influenced by modifications outside the annotated errors, whereas $\text{COMET}_{\text{Fine}}$ more directly reflects the quality of corrections related to those errors. FECE and $\text{COMET}_{\text{Fine}}$ therefore support the analysis of fine-grained correction quality at the levels of data construction and evaluation methodology, respectively.

## A Candidate-Generation Prompts

For every FECE item, *hyp1* and *hyp2* were generated from the same English source sentence and the same original machine translation containing the human error tags. The following system prompts were used for the two candidates.

### *hyp1* Error-Correction Prompt

You are performing local error correction on a machine translation using the English source sentence and the human-labeled error spans.

**Requirements:**

1. Human-labeled errors are text enclosed by `<minor>...</minor>` or `<major>...</major>` tags.
2. The `minor` and `major` labels indicate the severity of the annotated error.
3. Correct every human-labeled error according to the English source sentence.
4. Only correct the human-labeled errors. Every labeled error must be genuinely corrected.
5. If changing only the exact labeled span is insufficient, you may extend the editing range as needed to fully correct the human-labeled error.
6. Do not polish, rewrite, reorganize, or optimize any unrelated content.
7. Output the complete corrected translation without error tags.

**Return valid JSON only in the following format:**

```
{
"good": "complete corrected
translation"
}
```

### *hyp2* Fluency-Editing Prompt

You are performing local fluency editing on a machine translation while preserving all human-labeled errors and their original erroneous meanings.

**Requirements:**

1. Human-labeled errors are text enclosed by `<minor>...</minor>` or `<major>...</major>` tags.
2. The `minor` and `major` labels indicate the severity of the annotated error.
3. Preserve every human-labeled error and its original erroneous meaning.
4. Do not correct, weaken, remove, hide, reinterpret, or compensate for any labeled error.
5. Make multiple clearly visible fluency improvements outside the labeled error spans.
6. Do not rewrite the whole sentence or passage.
7. Output the complete translation without error tags.

**Return valid JSON only in the following format:**

```
{
"bad": "complete locally
polished translation"
}
```

## B GPT-Assisted Alignment of Error-Related Edits

The alignment of error-related edits was completed interactively with GPT-5.6 Sol through the ChatGPT Work interface rather than through an API. Given an English source sentence, a machine translation with numbered human errors, and its corresponding hypothesis, the model identified the edit associated with each error and returned records in the following form:

```
{
"error_ids": ["E1"],
"original": "continuous span
from the MT",
"replacement": "corresponding
continuous span from the HYP"
}
```

The `original` and `replacement` fields had to be continuous spans copied from the machine translation and hypothesis, respectively. The alignment covered the span directly related to the human-annotated error. The procedure recorded the observed edit without judging its correctness. An unchanged error therefore had identical `original` and `replacement` fields. A single edit involving multiple errors used a joint identifier list (e.g., `["E1","E2"]`).

## C Detailed Comparison Between Full-Segment COMET and COMET$_{\text{Fine}}$

| | Full-segment COMET-22 | | | COMET$_{\text{Fine}}$ | | | Preference shift | | Agree | $r$ |
|---|---|---|---|---|---|---|---|---|---|---|
| Direction | *hyp1* | Tie | *hyp2* | *hyp1* | Tie | *hyp2* | *hyp2* →*hyp1* | *hyp1* →*hyp2* | | |
| En–De | 58.8 | 0.5 | 40.7 | 63.9 | 7.6 | 28.5 | 144 (14.4; 35.4) | 62 (6.2) | 72.3 | 0.797 |
| En–Ja | 40.2 | 0.2 | 59.6 | 61.5 | 9.6 | 28.9 | 281 (28.1; 47.1) | 39 (3.9) | 58.6 | 0.588 |
| En–Zh | 45.9 | 0.1 | 54.0 | 68.4 | 7.9 | 23.7 | 296 (29.6; 54.8) | 44 (4.4) | 58.2 | 0.642 |

Table 6: Comparison between full-segment COMET-22 and COMET$_{\text{Fine}}$. Preference rates and agreement are reported as percentages. *hyp2* →*hyp1* denotes a preference shift from *hyp2* under full-segment COMET-22 to *hyp1* under COMET$_{\text{Fine}}$. Results in this column follow the format "count (overall rate; conditional rate)," where the conditional rate is calculated over candidate pairs for which full-segment COMET-22 prefers *hyp2*. *hyp1* →*hyp2* denotes the reverse preference shift and follows the format "count (overall rate)." Pearson $r$ is the Pearson correlation coefficient, computed over all candidate pairs, between the full-segment score differences $\Delta_M$ produced by the evaluation system and the reconstructed-translation score differences $\Delta_{\text{Fine}}$ produced by COMET$_{\text{Fine}}$.

Across all three directions, full-segment COMET-22 prefers *hyp2* in 1,543 of the 3,000 pairs. Of these, 721 switch to *hyp1* under COMET$_{\text{Fine}}$, accounting for 24.0% of all pairs and 46.7% of the pairs for which full-segment COMET-22 prefers *hyp2*. In the reverse direction, 145 pairs switch from *hyp1* to *hyp2*, accounting for 4.8% of all pairs.

## D Results for All WMT26 Evaluation Systems

Tables 7, 8, and 9 report the per-system results for all WMT26 evaluation systems in the three language directions. The *hyp1* and *hyp2* preference rates are the percentages of candidate pairs for which an evaluation system assigns a higher score to *hyp1* and *hyp2*, respectively; cases in which the two candidates receive equal scores are counted as ties. The agreement rate is the percentage of candidate pairs for which the evaluation system and $\mathrm{COMET}_{\mathrm{Fine}}$ make the same three-way decision among *hyp1*, tie, and *hyp2*. For each evaluation system, Pearson $r$ denotes the Pearson correlation coefficient, computed across all candidate pairs in the corresponding language direction, between the system's full-segment score differences $\Delta_M$ and the reconstructed-translation score differences $\Delta_{\mathrm{Fine}}$ produced by $\mathrm{COMET}_{\mathrm{Fine}}$.

| Evaluation system | *hyp1* pref. | Tie | *hyp2* pref. | Agreement | Pearson $r$ |

# Pterodactyl: Pushing the Limits of Efficient Automated Translation Evaluation

**Evelyn Y. Garland**[1, 2] **and Carola F. Berger**[1, 3]
[1]1020 Group, [2]Acta-Transphere, [3]CFB Scientific Translations LLC

## Abstract

In this paper, we present 1020 Group's submission to the WMT26 shared task on automated quality evaluation. Our system, Pterodactyl, was engineered specifically for subtasks 2 and 3, that is, segment-level quality score prediction and the detection of error-free segments. Pterodactyl is a highly customizable, ultra-low-cost system optimized for binary classification in translation triage and data curation. It is based on an LLM-as-a-judge approach, with prompt engineering and model selection guided by ROC analysis. We also developed several variants of Pterodactyl that were specifically adapted for subtasks 3.

## 1 Introduction

In recent WMT competitions, reference-free quality estimation (QE) systems based on an LLM-as-a-judge approach have gained increasing traction for automated translation quality evaluation (Lavie et al., 2025; Freitag et al., 2024; Zerva et al., 2024). However, the development and deployment of such systems can be complex and costly. Here, we develop an efficient, production-oriented strategy for pushing the cost-performance frontier of automated translation evaluation: achieving better task-specific performance with faster and cheaper models and prompt configurations.

Below, we present 1020 Group's submission to the WMT26 shared task on automated quality evaluation. Our system, Pterodactyl, and its variants are intended as highly customizable, ultra-low-cost, and robust options for performing segment-level score prediction (WMT26 automated quality evaluation subtask 2) and detecting error-free segments (WMT26 automated quality evaluation subtask 3). The system is highly customizable thanks to an efficient, streamlined engineering process that can be implemented to select and build fit-for-purpose QE systems for different application scenarios. When possible, we avoid separately optimizing every component when a shared screening criterion might suffice. Pterodactyl and its variants are also ultra-low-cost, in terms of both time and tokens, because our approach allows us to minimize cost and latency when two or more options show similar performance on test data. Finally, our approach allows engineering a system that remains relatively stable in different testing scenarios and under variations in the gold standard caused by inter-annotator disagreement.

## 2 The Pterodactyl Premise

Our approach is based on the LLM-as-a-judge paradigm, whereby our prompt engineering methodology and the selection of the most suitable models were guided by Receiver Operating Characteristic (ROC) analysis (Fawcett, 2006), supplemented by additional considerations. Our goal was to engineer a robust system that is simple to implement and adapt as well as sufficiently low-cost to be used in large production runs.

### 2.1 Basic Considerations

To develop our system, we started with commercially available general-purpose models and performed prompt engineering based on the considerations detailed below.

Our starting point was the basic premise that a QE system that is able to separate good and bad translations well is a promising candidate for WMT26 subtasks 2 and 3. We have shown in (Garland and Berger, 2026) that ROC analysis provides an efficient screening tool to find such candidates among a pool of systems. Prompt and model selection for subtasks 2 and 3 can therefore be partially unified with this ROC screening method.

We tested the following additional considerations during our prompt engineering iterations for both subtasks 2 and 3:

- Whether newer (larger) frontier models are

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1638–1643
October 28-29, 2026 ©2026 Association for Computational Linguistics

better for translation quality estimation
- Whether more reasoning improves estimation performance

### 2.2 Further Considerations for Subtask 3

For subtask 3, further considerations come into play. Here, translations are to be triaged into error-containing and error-free segments, with a human gold standard obtained via contrastive error span annotation (cESA) (Zouhar et al., 2026). Submissions for subtask 3 are evaluated and ranked with reference to this cESA gold standard, as measured by the Matthews Correlation Coefficient (MCC). Since cESA is a new human annotation method for which no extensive development data is available, our strategy was to optimize our system for robustness with respect to the exact score threshold that separates the error-free class from the error-containing one.

What do we mean by robustness? Past WMT tasks used standard error span annotation (ESA) (Kocmi et al., 2024), with slightly different guidelines and anchor specifications (see, e.g. (Lavie et al., 2025) and references therein). It is therefore a priori unknowable if and how the WMT26 gold standard differs from prior years' ESA gold standards. Thus, an error-classifying threshold that may be optimal for our system for WMT25 data may not be entirely optimal for WMT26. As a consequence, we did not optimize our prompts to obtain maximum MCC when computed on earlier WMT development data, but rather to obtain a robustness plateau, that is, a range within which small variations in the error-classifying threshold lead to relatively minor changes in the MCC value. This can be observed in Figure 1.

Figure 1 shows two different systems with similar ROC performance, but quite different MCC versus threshold behavior. Example Systems A and B have comparable ROC curves and ROC-AUC values, but their MCC versus QE threshold behavior differs. While System A has a slightly lower best MCC value compared to System B, the peak of System A's MCC distribution is decidedly broader than that of System B.

## 3 Our System Engineering Approach

### 3.1 Sample Data and Baselines

For the prompt engineering iterations described in the next subsection, we used data from past Conferences on Machine Translation (WMT) that were available in a public GitHub repository `https://github.com/google-research/mt-metrics-eval`, licensed under Apache v2.0. Specifically, we used the English into Chinese data with ESA annotations from WMT25 (Lavie et al., 2025), and the English into German data from WMT23 in the same repository that were supplemented with ESA annotations by (Kocmi et al., 2024; Zouhar et al., 2024). These ESA annotations for English into German WMT23 data are available at `https://github.com/wmt-conference/-`

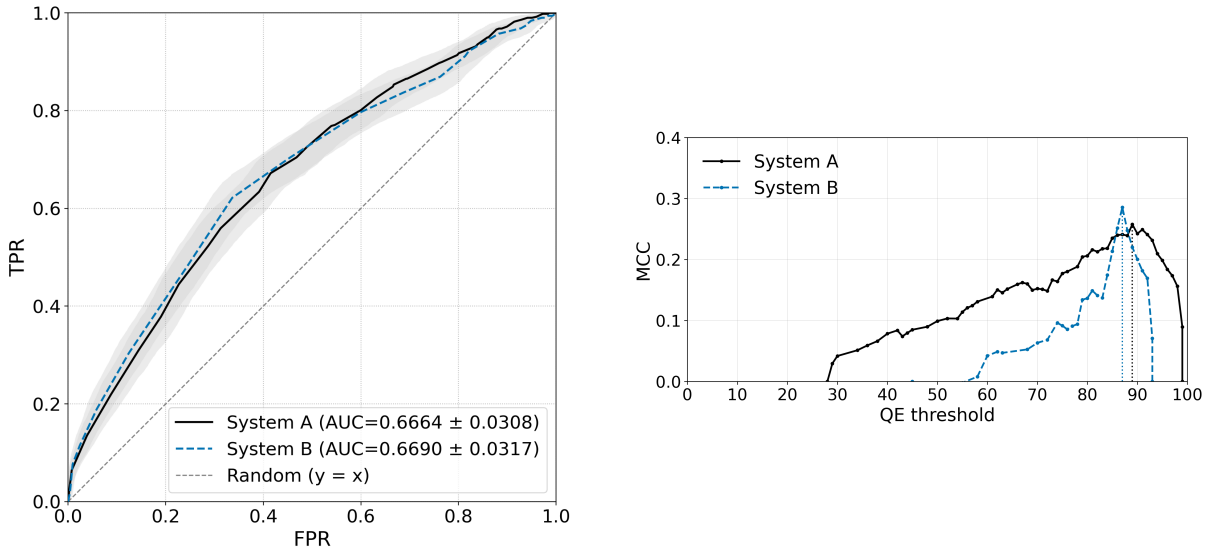

Figure 1: ROC curves (left) and MCC versus error-classifying threshold curves (right) for two example systems.

errorspanannotation. For our prompt iterations, we split each of these datasets into a development set containing approximately 70% of the en→zh and en→de datasets, respectively, and a test set containing the remaining 30%.

Our main gold standard was defined in a manner similar to WMT26 subtask 3: An error-free segment is defined as having an ESA score $\geq 85$ and no error span annotation. Where two sets of human annotations were available, we took the average of the ESA scores $\geq 85$, and either no error span annotation in annotation set 1 or no error span annotation in set 2. It turned out that our relative screening method via ROC analysis is relatively robust to changes in the definition of the gold standard.

And finally, to study an example of an ultra-low-resource language for subtask 3, we used the English into Northern Sámi recipe wmt26-eng-sme from the WMT26 General MT task datasets. From this recipe, we created a somewhat artificial development set as follows: We randomly selected 2000 longer segments from the recipe, then randomly selected 1000 segments from these as an error-free gold standard, and modified the other 1000 segments with random punctuation errors, omissions and additions of random words in Northern Sámi, as well as random source text insertions to obtain 1000 error-containing gold standard segments. Of course, this is nowhere near equivalent to a real development dataset, but given the fact that none of the authors speaks Northern Sámi, this is the closest available approximation.

As our baselines, we ran CometKiwi22 (Rei et al., 2022) and xCOMET-XL (Guerreiro et al., 2023) on these development and test data.

For testing and developing prompts for English into Northern Sámi, we also utilized the open-source LLM NorMistral-11B (Samuel et al., 2025b,a), with prompts in the Norwegian language instead of English.

### 3.2 Iterative Prompt Engineering

Our prompt engineering approach was iterative, discarding prompts that are no better than our baselines, while attempting to improve the promising ones that exhibited the best ROC-AUC performance. Once this iteration converged to a few prompts with similar ROC performance, we selected those that showed a robust MCC performance as detailed in Section 2.2. As our final system and system variants, we chose the ones that exhibited the minimum cost and latency. This highly efficient approach can be automated and easily adapted to other scenarios outside the WMT realm.

We experimented with a variety of prompts. On the basis on linguistic and other technical considerations, we identified six distinct main strategies. After performing ROC analysis on the results, we discarded those that were clearly inferior. On the prompts that seemed promising, we iterated a number of times, incorporating various refinements. Our findings are reported in the next section.

## 4 Submitted Systems

Using the aforementioned iterative prompt engineering approach, we were able to answer some of the questions in Section 2.1 and converge on a final system. The one question we were unable to answer is whether the newest models, which were presumably trained on the largest and most recent training data, are able to handle ultra-low-resource languages better than slightly older models, given the same prompt. This led us to submit two system variants to subtask 2 (see Table 1), the primary system using the same cost-efficient general-purpose model for all languages, and a variant using one of the newest available models for the three language pairs English into Ladin, Ligurian, and Northern Sámi. The official results of subtask 2 will tell which option is better.

As a side note, while we used NorMistral-11B for testing and development, we did not end up incorporating it into our system framework. This is because we did not perform a separate prompt engineering optimization for Northern Sámi, in part because Norwegian seems to be a better prompting language for NorMistral-11B than English, and none of the authors speaks Norwegian. With the same prompt as for all the other languages, the commercial general purpose models we studied seem to perform better on our artificial mock dataset for Northern Sámi, but this may well be because the prompt was optimized for these models, not for NorMistral-11B, or perhaps because our artificial mock dataset is constructed somewhat arbitrarily, or a combination of both.

The final selected prompt instructs the LLM to evaluate the translation quality for each segment individually, without requiring the model to identify specific translation errors or to justify its score. Figure 2 shows the selected system's ROC

curve compared to our baselines, CometKiwi22 and xCOMET-XL, on the WMT25 English into Chinese data. Figure 2 also lists the corresponding ROC-AUC values with their 95% confidence intervals. Figure 3 shows the selected system's MCC versus threshold behavior.

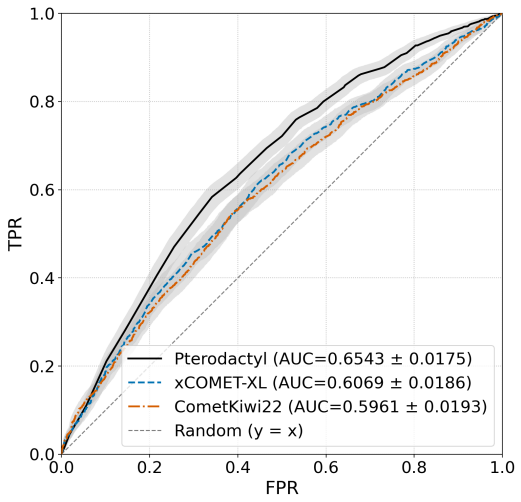

Figure 2: ROC curve of the chosen prompt and model combination compared to the baselines CometKiwi22 and xCOMET-XL on the WMT25 en→zh dataset.

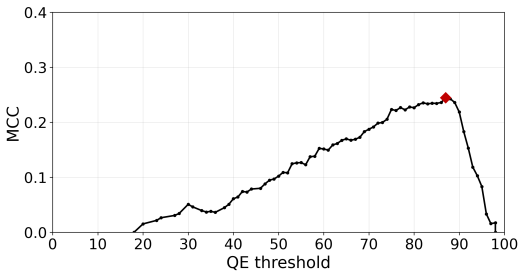

Figure 3: MCC versus error-classifying threshold curve for the selected system on the WMT25 en→zh dataset. The red diamond indicates the maximum MCC value.

We ran our scoring in batches of up to 20 segments produced by the same MT system for the same language pair, because this batching procedure leads to lower token usage and cost.

For subtask 3, we submitted two system variants that are derived from Pterodactyl and specifically optimized for subtask 3, employing a threshold-setting strategy based on patterns observed in the WMT25 data.

Table 1 gives an overview of our primary system and its variant that were submitted to subtasks 2 and 3, along with the computational cost involved in scoring the official WMT26 test data. Table 2 lists the variants we submitted specifically to subtask 3.

## 5 Conclusions and Outlook

Pterodactyl's central design principle was deliberate minimalism: use no more model or engineering complexity than the task requires. Our submission to subtasks 2 and 3 of the WMT26 shared task on automated quality evaluation is based on an LLM-as-a-judge approach. Our prompt engineering and model selection process uses ROC analysis as a screening tool, making the development highly adaptable, robust, and low-cost. It remains to be seen, however, whether this minimal approach is an effective alternative to fine-tuning or building from scratch. The shared-task results will show whether Pterodactyl merely costs less—or whether it offers a genuinely competitive alternative to more resource-intensive system development.

The astute reader will of course observe that we have committed the cardinal sin of extrapolating from not necessarily representative development data into the great unknown of WMT26, which includes new language pairs and a novel human annotation scheme. But this leap of faith is not entirely unfounded, based on high-level patterns we observed across languages and domains from the WMT25 and WMT23 data, supplemented by our "artificial" Northern Sámi data. In an actual production environment, such an extrapolation is of course unnecessary, and the system can easily be adapted to real in-domain and in-language data for production scenarios, as described above.

## 6 Limitations

As already mentioned, the exact human gold standard for WMT26 is unknowable, because in prior WMT tasks, standard ESA was employed, whereas this year's task utilizes contrastive ESA for the first time. However, this unknown factor is the same for all participants, and it remains to be seen what, if any, effects the new human annotation scheme has on the results. Another unknown is how this year's test dataset, including the addition of new language pairs without human-annotated data, differs from those of previous years. Again, all participants are in the same boat here. Finally, our system was developed with rather limited resources, and we tested only on two language pairs with ESA annotations. Further studies are needed to show whether our one-size-fits-all system really does fit all.

# AGGREE: An Aggregation-Grounded Challenge Set for Segment-Level MT Metric Evaluation

**Lena Griesbeck and Michaela Geierhos**
Research Institute CODE, University of the Bundeswehr Munich, Neubiberg, Germany
{lena.griesbeck,michaela.geierhos}@unibw.de

## Abstract

This paper introduces AGGREE, a WMT26 Metrics shared task challenge set, which is designed for the diagnostic evaluation of automatic machine translation quality evaluation systems. It is motivated by the observation that metric agreement can be inflated by aggregation as metrics may correlate well at a system level, but disagree at an individual segment level. AGGREE therefore focuses on naturally occurring system outputs where automatic metrics disagree locally or diverge from available WMT human judgments. The challenge set contains 350 single-hypothesis examples across six language pairs drawn from WMT23 and WMT24 system outputs. The submitted set was mined using diagnostics for metric disagreement and metric-human mismatch, then filtered using strict automated quality control. This WMT26 analysis serves only to describe the behavior of the metrics in AGGREE and does not provide an assessment of the performance degradation compared to standard test data.

## 1 Introduction

Metrics for automatic machine translation (MT) are typically evaluated based on their alignment with human judgments at the segment and system levels. System-level agreement is often substantially higher because scores are averaged over many examples. However, this aggregation can hide local failures. For example, a metric may rank systems well on average while still assigning misleading scores to individual translations. These local failures are important in practice because metrics are also used for model development, data filtering, and fine-grained error analysis.

The AGGREE challenge set is designed to stress-test the reliability of WMT26 Metrics. It targets naturally occurring WMT system outputs where automatic metrics disagree with one another or differ from human judgments of WMT systems. The set is not designed to estimate the average performance of metrics on the full WMT test distribution. Instead, it focuses on segments where metrics disagree or diverge from human judgments, making it a diagnostic stress test rather than a representative benchmark. The final version submitted contains 350 single-hypothesis examples across six language directions. It uses outputs and human scores from the WMT23 and WMT24 systems from google-research/mt-metrics-eval[1] and contains 314 MQM-scored rows and 36 ESA-scored rows. Because all three ESA directions contain fewer than 15 examples, the MQM portion forms the empirical core and the ESA rows are treated as supplementary observations. The examples were selected from a larger pool using disagreement diagnostics and filtered with strict automatic text quality checks.

Our contributions are as follows: (1) a disagreement-driven mining pipeline that surfaces naturally occurring regions of local metric disagreement across five diagnostic types rather than using synthetic perturbations, (2) AGGREE, a quality-controlled challenge set with a 314-example MQM core and 36 supplementary ESA examples, and (3) a descriptive analysis of WMT26 Task 2 submissions on this fixed diagnostic sample.

## 2 Related Work

Traditionally, the validation of machine translation metrics is conducted through meta-evaluation against human judgments, such as direct assessment, multidimensional quality metrics (MQM), or error span annotation (ESA). Annual WMT Metrics and Quality Estimation Shared Tasks benchmark these models using global correlation coefficients (e.g., Pearson's $r$, Spearman's $\rho$, or Kendall's $\tau$) at both system and segment levels (Freitag et al.,

[1] https://github.com/google-research/mt-metrics-eval (last accessed on 2026-08-18)

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1644–1651
October 28-29, 2026 ©2026 Association for Computational Linguistics

2022; Zerva et al., 2024). These reports consistently show that system-level correlations are substantially higher than segment-level correlations. However, Mathur et al. (2020) demonstrate that these global correlations are highly sensitive to outlier systems, which can create a false sense of security regarding a metric's ability to distinguish systems of similar quality. While previous studies have focused on the relationship between metrics and humans, AGGREE adds inter-metric disagreement and metric-human mismatch as diagnostic signals.

To move beyond global scores, several challenge sets have been introduced to test the sensitivity of metrics to specific linguistic phenomena. ACES (Amrhein et al., 2022) uses 68 phenomena based on the MQM ontology and includes synthetic perturbations such as character-level edits, swapping numbers, and swapping antonyms to create minimal pairs. Similarly, DEMETR (Karpinska et al., 2022) uses 35 linguistic categories to demonstrate that, although learned metrics (e.g., COMET and BLEURT) outperform string-based measures, they often fail to distinguish between minor and critical error severities. Unlike these sets, which evaluate metrics against predefined, artificial errors, AGGREE identifies naturally occurring disagreements from actual WMT system outputs where available or submitted metrics disagree locally. Other work targets specific biases or low-resource scenarios. GAMBIT+ (Filandrianos et al., 2025) evaluates gender bias in quality estimation (QE) metrics by providing contrastive masculine and feminine versions of gender-ambiguous occupational terms. SSA-MTE (Li et al., 2025) benchmarks metrics on Sub-Saharan African languages, revealing a significant performance drop in low-resource settings. Zouhar et al. (2024) additionally show that fine-tuned metrics like COMET, despite high WMT correlations, struggle with domain shifts (e.g., to the biomedical domain). These studies confirm that high global performance does not guarantee local or cross-domain reliability. Closely related work, MSLC25 (Knowles et al., 2025), provides an empirical analysis of segment-level inter-metric alignment, observing that automatic measures diverge significantly when evaluating low-quality MT. AGGREE complements these efforts by mining naturally occurring WMT outputs in regions where metrics disagree locally rather than constructing predefined contrastive perturbations.

## 3 AGGREE

This section describes the design and construction of AGGREE, including its data sources, mining pipeline, and quality-control process.

### 3.1 Challenge Set Design

AGGREE is based on the idea that high aggregate metric agreement does not ensure reliable segment-level behavior. Aggregation can suppress local deviations when errors cancel out across segments or when many metrics agree on coarse system quality but disagree on individual examples. Therefore, the challenge set mines segments where local metric behavior is informative, such as inter-metric disagreement, disagreement between lexical and neural metric families, number/entity mismatches, and metric-human mismatch candidates. The final set includes five main diagnostic types:

**`metric false negative`** The metrics indicate low quality, but the human quality is high.

**`lexical-high/neural-low`** Lexical overlap metrics score segments higher than neural or semantic metrics do.

**`neural-high/lexical-low`** Neural and semantic metrics score segments higher than lexical overlap metrics do.

**`number/entity mismatch`** A mismatch is indicated by simple number or entity-like token diagnostics.

**`general_high_disagreement`** Broad metric disagreement remains, but the example does not match a more specific lexical–neural, entity/number, or human-mismatch pattern.

These labels are diagnostic tags used during the construction process, not error annotations that are manually adjudicated. One row can contain more than one phenomenon, while the corrected metadata assigns one primary type for descriptive analysis and preserves additional diagnostic features. The initial mining scheme also included a `metric false positive` category, where metrics assigned high scores to outputs with low human quality. After the post-submission MQM orientation audit, however, no submitted example retained this category as its corrected primary diagnostic type, so it is not reported as a separate type in the final analysis.

### 3.2 Data Sources and Candidate Mining

| Testset | LP | Human score | Source segments |
|---|---|---|---|
| wmt24 | en-de | MQM | 998 |
| wmt24 | en-ja | ESA | 998 |
| wmt24 | en-zh | ESA | 998 |
| wmt24 | en-ru | ESA | 998 |
| wmt24 | ja-zh | MQM | 722 |
| wmt23 | zh-en | MQM | 1,976 |
| wmt23 | en-de | MQM | 557 |

Table 1: Selected AGGREE mining settings. Segment counts refer to source segments in the selected MTME setting before challenge-set mining and filtering.

| Language direction | | Diagnostic type | |
|---|---|---|---|
| LP | Segs. | Type | Segs. |
| en-de | 120 | lexical-high/neural-low | 104 |
| zh-en | 120 | number/entity mismatch | 95 |
| ja-zh | 74 | general high disagreement | 89 |
| en-ja | 14 | neural-high/lexical-low | 49 |
| en-ru | 11 | metric false negative | 13 |
| en-zh | 11 | | |

Table 2: Final AGGREE distribution after the MQM orientation audit. The corrected private metadata contains 350 segments across six language directions and five primary diagnostic types.

The pipeline uses google-research/mt-metrics-eval as the primary source for WMT system outputs, human evaluations, references, and metric values. Eligible settings were evaluated based on human evaluation and metric coverage, number of systems, and available human-score protocol. WMT24 served as the primary data source because it provides recent system outputs and broad metric coverage. WMT23 was additionally included to ensure sufficient coverage of MQM-based human judgments. Although WMT25 was evaluated, it was not used in the standard core because human evaluation coverage was sparser for this pipeline. Table 1 lists the seven settings used for mining.

The source MQM scores in the four selected MQM settings are non-positive penalties, for which values closer to zero indicate better translation quality, while the selected ESA scores are higher-is-better values between 0 and 100. A post-submission audit found that the initial construction code had negated these already quality-oriented MQM penalties and then used the resulting positive penalty magnitudes as if larger values indicated better quality when computing human-mismatch features. We corrected the direction logic, recomputed all human-dependent features over the complete original (testset, lp) settings, and mapped the corrected metadata back to the unchanged 350 submitted segment identifiers. We used the available metric score columns in google-research/mt-metrics-eval for mining. The selected AGGREE settings included lexical metrics such as BLEU, spBLEU, and chrF; embedding-style metrics such as BERTScore and BLEURT; neural and QE-style metrics such as COMET, COMETKiwi, XCOMET, and MetricX; and several additional WMT metric variants.

Known metric families were normalized into a common higher-is-better direction using conservative name-based heuristics. Metrics whose family or direction could not be inferred were retained for broad disagreement diagnostics but were not used to define the lexical-neural gap. Z-scores and percentile ranks were computed within each (testset, lp) setting, so that score-scale differences across test sets and language pairs (lp) did not dominate candidate selection. Appendix A gives the exhaustive MTME score-field inventory, including version and reference/source suffixes, for every selected setting. Candidate mining computed row-level features for metric-family disagreement, metric-human mismatch, false-positive and false-negative behavior, lexical-neural gaps, length ratios, number mismatches, and entity-like token mismatches. A disagreement-based mining run selected 900 preliminary candidates, 150 from each of six preliminary families, and the finalization stage excluded candidates that carried the pre-audit general-high-disagreement label. Because the pre-audit score affected which hypotheses entered the fixed submission, the corrected metadata does not make the set equivalent to a fully rerun construction pipeline. AGGREE must therefore be interpreted as disagreement-enriched rather than as a balanced sample of correctly oriented metric-human mismatch categories.

### 3.3 Quality Control and Final Dataset

Challenge-set mining can surface artifacts for the wrong reasons. Very short fragments, URLs, source copies, boilerplate refusals, and near-reference copies may cause disagreement in metrics, but they are usually poor evidence of nuanced metric reliability. Therefore, AGGREE separates discovery from finalization. Broad mining is allowed to surface unusual examples, but the final core must pass stricter text-quality checks. Text-quality filtering checked for reference pseudo-

systems, exact reference copies, source-copy outputs, refusal or non-translation boilerplate, length pathologies, near-identical reference/MT strings, very short fragments, mostly numeric or punctuation strings, low-letter-ratio strings, date or fraction-only strings, placeholder/noise strings, and HTML, UI, URL, or email artifacts. The diagnostic pass inspected 900 candidate rows and marked 243 hard text-quality failures (27.0 %). The most frequent hard-relevant flag was a "too short text" flag, with 202 rows (22.4 %). The final build applied strict hard filtering before soft balancing. This process removed nine source-copy outputs, two refusal or non-translation outputs, 234 remaining text quality failures, 104 rows carrying the pre-audit general-high-disagreement label, and 65 rows capped at a maximum of two rows with the same normalized source. The text quality count is sequential: all nine source-copy outputs were among the 243 hard failures and had already been removed before the remaining 234 were counted. The resulting pool of quality-passing candidates contained 486 entries, of which 350 were selected.

The final distribution is shown in Table 2. Of the test set, 162 rows come from WMT23 and 188 come from WMT24. According to the human-score protocol, 314 rows are MQM-scored, while 36 are ESA-scored. The set is intentionally not uniformly balanced across language pairs because some language pairs only contained a small amount of examples. Specifically, en-de and zh-en contribute 120 rows each; ja-zh contributes 74; and en-ja, en-ru, and en-zh are small diagnostic slices. All 89 examples with corrected primary type "general high disagreement" had pre-audit metric-human mismatch labels: 53 were labeled metric false negatives and 36 metric false positives. After correction, no other diagnostic tag applies to these rows.

AGGREE is a single-hypothesis approach rather than a contrastive one. A paired-hypothesis feasibility analysis was conducted to test if each example could be paired with a second output that passed QC from another system for the same source segment. The original margin of 0.30 on the within-setting human-quality percentile scale was chosen as a conservative operational threshold to avoid treating near-tied human scores as a meaningful contrast. Even at a permissive margin of 0.15, only 14 of 350 examples (4.0%) were pairable, with no language direction reaching ten pairs (7 at 0.30, 9 at 0.20).

## 4 Challenge-Set Results on WMT26 Metric Submissions

We analyze the final WMT26 metric outputs returned for AGGREE as a diagnostic evaluation, not an official WMT ranking. The results of the challenge set contain Task 2 quality score predictions. All predictions were linked by segment identifier and language pair to the corrected AGGREE metadata. Since no suitable random data sets were evaluated from the WMT26 submissions, these correlations describe only the relationship with human quality assessment on AGGREE. They do not measure a relative decline in performance compared to standard WMT data. The coefficients correlate the submitted metric values with the rankings from the human quality assessment. However, AGGREE itself was selected in part based on historical discrepancies between metrics and human evaluation, as well as on mismatches between metrics and human evaluation. Therefore, the results should be interpreted as behavior observed in a deliberately conditioned diagnostic sample.

For each submitted score, we compare the metric output of the hypothesis to a hidden human-quality percentile rank. The human target is computed once within each (testset, lp) slice of the final 350-example set, independently of submission coverage, with tied values assigned their average rank. The source MQM values are non-positive penalties and are retained because values closer to zero indicate better quality, while ESA values are retained in their original higher-is-better direction. Thus, larger human-quality percentile ranks always indicate higher translation quality ratings. Because raw submitted metric scales may differ systematically across language pairs, each submission's scores are converted to within-(testset, lp) percentile ranks before computing the pooled correlation. This within-setting Spearman correlation is used as the primary reported statistic, and the raw-score Spearman is retained as a robustness column.

Table 3 shows that the strongest full-coverage association after within-setting score normalization is obtained by `Vertical_870257` ($\rho_{\text{within}} = 0.787$), followed by `Vertical_870554` (0.744), `FACET_869546` (0.602), and `FACET_869543` (0.601). The same systems remain among the strongest under the raw-score Spearman analysis, which indicates that the main pattern is robust to this normalization check. However, the order of the top two systems switches. Restricting

| Submission | LPs | $\rho_{\text{within}}$ | $\rho_{\text{raw}}$ |
|---|---|---|---|
| Vertical_870257 | 6 | 0.787 | 0.678 |

Table 3: Task 2 Spearman correlations over all returned submissions with at least one AGGREE score. $\rho_{\text{within}}$ first converts each submission's scores to percentile ranks within each (testset, lp) slice before pooling. $\rho_{\text{raw}}$ uses the raw submitted scores. Both are correlated with quality-oriented human percentile ranks from the corrected metadata. Correlations based on different language-pair subsets are descriptive and are not directly comparable as an overall metric ranking.

the analysis to the 314 MQM rows preserves this ordering among submissions that cover all three sufficiently sized MQM directions (en-de, zh-en, and ja-zh): the corresponding within-setting Spearman correlations are $0.819$, $0.760$, $0.690$, and $0.689$. We do not report correlations for the 36 ESA rows alone because their three language directions contain only 14, 11, and 11 examples. We use the Spearman correlation because our analysis focuses on the relative ordering of segments based on human ratings. Within-setting normalization prevents differences in submitted score distributions across languages from determining the pooled ordering. Several strong submissions cover only the four English-source directions. Their correlations are therefore based on different subsets from those of the six-direction submissions and should not be interpreted as directly comparable overall rankings.

Table 4 summarizes the distribution of metric behavior across diagnostic types. This is closer to the central AGGREE question: whether submitted metrics behave differently across particular disagreement mechanisms. The median association is highest for number/entity mismatches ($0.384$), followed by neural-high/lexical-low ($0.342$) and general-high-disagreement cases ($0.312$), whereas lexical-high/neural-low examples have a near-zero median correlation ($0.024$). The corrected metric-false-negative subset contains only 13 examples and is therefore excluded from the correlation-distribution summary. These descriptive differences support type-conditioned analysis, but they do not establish general metric performance because both the original selection procedure and the post-audit labels are construction-dependent. We do not use per-language-pair maxima to claim language-pair effects. The maxima can be produced by different submissions, the English-to-Japanese, English-to-Russian, and English-to-Chinese slices contain only 14, 11, and 11 examples, and the current design does not separate submission effects from language-pair effects. Language-pair-specific values are therefore exploratory diagnostics only.

| Diagnostic type | Examples | Median $\rho$ | IQR |
|---|---|---|---|
| lexical-high/neural-low | 104 | 0.024 | [-0.136, 0.159] |
| number/entity mismatch | 95 | 0.384 | [0.224, 0.610] |
| general high disagreement | 89 | 0.312 | [0.285, 0.350] |
| neural-high/lexical-low | 49 | 0.342 | [0.187, 0.415] |
| metric false negative | 13 | – | – |

Table 4: Distribution of within-setting-normalized Task 2 Spearman correlations by corrected AGGREE diagnostic type. Median and interquartile range summarize submissions with at least 20 scored examples for the type. The 13-example metric-false-negative subset is shown for completeness but is not summarized.

## 5 Discussion

The returned WMT26 outputs provide a descriptive view of metric behavior on AGGREE. Coverage differs across submissions, so correlations based on different language subsets are not directly comparable. Among submissions with the same full coverage, associations with human quality differ, and the diagnostic-type breakdown identifies where these differences are concentrated. AGGREE should therefore be used alongside broad representative evaluations, with its results interpreted as behavior on a deliberately selection-conditioned sample.

## 6 Conclusion

AGGREE is an aggregation-grounded WMT26 challenge set containing 350 quality-filtered, single-hypothesis examples derived from human-rated WMT23/24 outputs. Its main empirical basis is a 314-example MQM portion, 36 ESA examples are retained as small supplementary slices. The returned WMT26 results describe heterogeneous behavior on this fixed diagnostic sample. These results do not constitute an independent general-purpose metric ranking or a comparison with normal-data performance.

## 7 Limitations

AGGREE is automatically quality controlled and grounded in original WMT human scores, but it is not independently and exhaustively adjudicated by human annotators. Its diagnostic types are construction labels rather than gold error categories. The small en-ja, en-ru, and en-zh slices contain all 36 ESA examples, so the substantive analysis is primarily MQM-based.

The post-submission audit corrected MQM-dependent metadata and changed 98 primary diagnostic labels, but it cannot undo the influence of the pre-fix human-mismatch features on which hypotheses entered the fixed submission. Moreover, human judgments and historical metric scores were used in selection and evaluation, and several returned submissions overlap by name or family with construction metrics. The resulting correlations should therefore be read as diagnostic behavior on an intentionally mined stress test, not as general segment-level unreliability.

No matched random set was scored by the returned WMT26 submissions, and a new common scoring round was not available after the shared-task scoring period. The pairing sensitivity analysis is also limited to the inspected 900-candidate review pool, so it supports the submitted single-hypothesis design within that pool but does not rule out a larger paired set from a broader future search.

Future work should add an organizer-scored matched control set, independent manual adjudication, and a larger contrastive set if sufficient paired examples can be obtained.

## A Mining Metric Inventory

This appendix lists the complete MTME metric-score inventory available to the AGGREE mining pipeline after filtering to human-scored outputs in the seven selected settings. Names are reproduced exactly from the local MTME exports.

The WMT26 evaluation correlations reported in Section 4 are not correlations against these mining metrics. They correlate submitted WMT26 scores with corrected human-quality ranks. However, because the challenge set was selected partly using the historical scores listed here, AGGREE remains a selection-conditioned diagnostic sample rather than an independent representative benchmark.

**WMT23 en-de and zh-en.** Both WMT23 settings contain the same 68 metric fields.

# CUNI at the WMT26 Automated MT Evaluation Shared Task

**Miroslav Hrabal, Ondřej Bojar**
Charles University, Faculty of Mathematics and Physics
{hrabal,bojar}@ufal.mff.cuni.cz

## Abstract

We describe the CUNI submissions to the WMT26 Automated MT Evaluation Shared Task. We take part in error-span prediction (Task 1) and segment-level quality score prediction (Task 2). Our systems use a single open-weight Gemma 4 31B instruction-tuned model (Team et al., 2026) as a backbone. For Task 1, we decompose error prediction into semantic error detection, self-review, and a separate span-alignment step that maps free-form error descriptions to source and target character spans. We submit two variants of this approach, one additionally predicting MQM-style error categories. For Task 2, we explore two complementary approaches: regression over features extracted from the Task 1 predictions and LLM-based direct assessment on a 0–100 scale.

## 1 Introduction

A particular difficulty of using large language models for span prediction is that identifying an error and expressing its exact location are not necessarily the same problem. Even when a model is able to describe translation errors in natural language, producing exact offsets or reproducing the corresponding substring can still be a challenge due to failures to copy spans exactly or difficulty counting characters directly (Semin et al., 2026).

We therefore try to explicitly separate these operations. Our Task 1 systems identify and describe translation errors without imposing strict constraints on representing spans, allow the model to review and modify its analysis, and finally align the resulting errors to a tokenized representation of source and translation. The predicted token spans are algorithmically converted to the character offsets required by the shared task.

For Task 2, we investigate two different approaches. The first derives numerical features from Task 1 error predictions and learns a regression model over them. The second directly asks the language model to assess translation quality on a 0 to 100 integer scale using few-shot demonstrations.

In addition to evaluating the resulting systems on subsets of WMT25 data (Kocmi et al., 2025), we examine how well the same prompting architectures transfer to alternative backbone LLMs without model-specific adaptation.

## 2 Related Work

The difficulty of obtaining exact input spans from generative language models is not specific to MT evaluation. Semin et al. (2026) categorize LLM span-labeling strategies into input tagging, numerical position indexing, and span-content matching. They show that seemingly simple content-matching approaches suffer from alignment failures and propose constrained decoding as one solution. Our Task 1 pipeline uses a different strategy: the model is first allowed to describe errors without localization, after which a separate model call maps the detected errors to a token-indexed representation of the input. Character offsets are then recovered deterministically.

## 3 Shared Framework

All of our submissions use a single open-weight Gemma 4 31B instruction-tuned model with 4-bit AWQ quantization (Lin et al., 2026)[1] as a backbone. We fixed this model choice early in development based on our preliminary multilingual experiments with models of similar size.

We implement the model interactions using DSPy (Khattab et al., 2022, 2024) for prompting the model. All our systems are reference-free, taking source language, target language, source text, target text, and optionally, translation instructions as input.

## 4 Task 1: Error Span Prediction

Our Task 1 approach separates semantic error analysis from predicting error offsets.

Both of our Task 1 submissions consist of three steps:

1. Creating free-form error lists (Section 4.1)
2. Self-review (Section 4.2)
3. Span alignment (Section 4.3)

### 4.1 Free-form error list

In the first stage, the model produces lists of critical, major, minor errors and omissions. At this stage it is not required to produce substrings or offsets. Table 1 shows an authentic model output from this stage.

### 4.2 Self-review

In the second stage, the model reviews and modifies its own outputs. An example from this stage is shown in Table 2.

### 4.3 Span Alignment

In the final stage, we ask the model to align the errors to exact token spans. We apply a simple rule-based tokenizer to the source and translation and present the resulting tokens to the model together with explicit token indices. The tokenizer treats whitespace as a delimiter, tokenizes characters in configured CJK ranges as individual tokens and treats the remaining non-whitespace sequences as tokens. The model is then asked to align previously identified errors with the corresponding token span. These token-level spans are then parsed and programmatically converted to character-level spans required by the shared task.

This stage is similar for both *v14* and *cat-v4* submissions, differing in that *cat-v4* also outputs corresponding MQM-style error categories at the same time. We use the same categories as Kocmi and Federmann (2023). They also differ in their demonstration sets. Model outputs are parsed and validated before token spans are converted to character offsets.

For *cat-v4* system, if the conversion fails due to invalid span range, we attempt one repair call and only accept modifications to the invalid spans. We used this repair only for cat-v4.

Localized omissions are represented as source-side spans, while unlocalized omissions receive a segment-level severity. We convert all these representations to the organizer format only when processing shared task test set.

We also chunked a record if either its source or translation exceeded 1024 model-tokenizer tokens to handle long inputs.

Examples from this stage are shown in Tables 3 to 5

### 4.4 Inference Parameters

Our Task 1 uses temperature 1.0, top-$p$ 0.95, top-$k$ 64 and fixed seed 26 during inference. The *cat-v4* repair call uses temperature 0, top-$p$ 1 and disables top-$k$.

## 5 Task 2: Segment Score Prediction

For Task 2, we submit two different approaches. *v14-regression* system converts Task 1 output into 31 features, including error counts and span coverage by severity, and omission features. A constrained nonnegative linear regression is fitted on WMT25 training data: $\hat{y} = 100 - (b + \boldsymbol{\beta}^\top \mathbf{x})$, with $b, \boldsymbol{\beta} \geq 0$, followed by clipping to $[0, 100]$. Failed predictions from Task 1 receive the score mean from the training data: 71.1493.

On the other hand, *da-6d* uses a different approach: directly asking the model for a 0–100 score. For this submission, we drew demonstrations from WMT25 training data. We evaluated two-, four- and six-demonstration candidates on 466-record subset of the development split and selected one of the six-demonstration variants using macro segment-level Spearman score. As a result, one of the six-demonstration candidates was selected. The total pool of candidates was 24 consisting of two demos, 14 consisting of four demos and 16 consisting of six demos.

## 6 Experimental Setup

### 6.1 Data Partitioning

We partitioned WMT25 data by their source documents, by removing the language-pair prefix when identifying the source documents. This prevents the same underlying document from appearing in different splits when reused across language pairs. Table 6 summarizes the resulting data. Internally, we also used two smaller subsets of dev set during development for faster evaluation.

| Detection field | Authentic value |
|---|---|
| src_lang | Czech |
| tgt_lang | German |
| src | Ina T. hodnotí sexy pokusy hvězd: Myslivcová přestřelila! |
| tgt | Ina T. bewertet die sexy Versuche der Stars: Die Jägerin hat daneben gefeuert! |
| prompt_instruction | "" |
| critical_errors | [] |
| major_errors | ["Die Jägerin—mistranslation of the proper name 'Myslivcová'."] |
| minor_errors | [] |
| source_omissions | [] |
| segment_omission_severity | none |

Table 1: Authentic input and output fields for error detection.

| Self-review field | Authentic value |
|---|---|
| draft_detection | major_errors: ["Die Jägerin—mistranslation of the proper name 'Myslivcová'."] |
| critical_errors | [] |
| major_errors | ["'Die Jägerin' is a mistranslation of the proper name 'Myslivcová'."] |
| minor_errors | [] |
| source_omissions | [] |
| segment_omission_severity | none |

Table 2: Authentic self-review fields. The unchanged language, text, and instruction fields are omitted.

### 6.2 Evaluation

For Task 1, we report span precision, span recall, and the official metric: micro averaged MPP with optimal one-to-one span matching and serverity weights 1.0 for major and 0.25 for minor errors (Perrella et al., 2026). Errors we internally tag as critical are mapped to major.

For Task 2, we evaluate segment-level predictions using Pearson and Spearman correlation together with mean absolute error (MAE) and root mean squared error (RMSE). We also report system-level Pearson and Spearman correlations in portability experiments.

## 7 Development Results

### 7.1 Task 1

Table 8 reports our development results. In Table 7 we compare our systems on the intersection of the development set with the official system results from the previous year (Lavie et al., 2025).

Our systems achieve the highest observed MPP on this common subset, with cat-v4 reaching 0.2490 and v14 0.2460. The external systems show substantially different precision–recall profiles. AIP secondary obtains the highest precision, 0.2863, but only 0.1152 recall, while XCOMET-XXL reaches the highest recall, 0.2821, with a precision of 0.0590. Our systems achieve a more balanced trade-off between the two quantities, resulting in higher MPP.

### 7.2 Task 2

Table 9 shows our development results for Task 2. The six-demo version gives the strongest point estimate for every reported metric. Because its selection subset is part of the development data, we treat these results with caution and defer final conclusions to the WMT26 official results.

## 8 Cross-Model Portability

Table 10 shows Task 1 *v14* when used with different model backbones. Gemma 4 26B reaches MPP 0.2271, close to the 31B result of 0.2463, while the other four transfers fall between 0.1165 and 0.1381. Gemma 3 27B (Team et al., 2025) scores 0.1328 despite its similar parameter count. However, this experiment is not intended as a general model comparison, as the complete system was tweaked for the instruction-tuned version of Gemma 4 31B during development and few-shot optimization and deliberately left unchanged.

For the Task 2 direct assessment submission, Table 11 compares the submitted six-demo version with its zero-demo control across different models.

## 9 WMT26 Submissions

For Task 1, we submit v14 and repaired cat-v4 on the eight priority language pairs, covering 3 164

| v14 alignment field | Authentic value |
|---|---|
| `detection_response` | `major_errors`: ["'Die Jägerin' is a mistranslation of the proper name 'Myslivcová'."] |
| `target_tokens` | `(0) Ina (1) T. ... (8) Die (9) Jägerin (10) hat ...` |
| `target_spans` | `[(8,10,major)]` |
| `source_omission_spans` | `[]` |
| `segment_omission_severity` | `none` |

Table 3: Authentic v14 alignment fields. The token span becomes target-character span `[45,56)`.

| Categorized alignment field | Authentic value |
|---|---|
| `detection_response` | `major_errors`: ["'Die Jägerin' is a mistranslation of the proper name 'Myslivcová'."] |
| `target_tokens` | `(0) Ina (1) T. ... (8) Die (9) Jägerin (10) hat ...` |
| `target_spans` | `[(8,10,major, accuracy/mistranslation)]` |
| `source_omission_spans` | `[]` |
| `segment_omission_severity` | `none` |

Table 4: Authentic fields for the version with additional categories for the same record.

items and 95 323 hypotheses. For Task 2, we submit six-demo DA and v14 regression on priority language pairs plus several additional language pairs: English–Czech, Czech–Ukrainian, and the released English–Chinese variants. Each Task 2 submission covers 8 252 items, 149 574 hypothesis occurrences, and 141 006 unique effective inputs. Six-demo DA has no prediction fallback; v14 regression uses the frozen train-mean as fallback for 747 unique failed v14 predictions.

## 10 Conclusion

In this paper, we presented CUNI's WMT26 submissions based on an open-weight Gemma 4 31B model. Our Task 1 pipeline separates error analysis from span alignment, while our Task 2 systems compare regression on spans with direct assessment with few-shot demonstrations. Both approaches show promising development results, but we defer broader conclusions to the official WMT26 evaluation because repair and few-shot demonstrations selection used development data.

## Acknowledgments

This work has been supported by the grants CZ.02.01.01/00/23_020/0008518 (Jazykověda, umělá inteligence a jazykové a řečové technologie: od výzkumu k aplikacím), TQ28000003 (NCUI, Národní centrum umělé inteligence), also by the Ministry of Education, Youth and Sports of the Czech Republic, Project No. LM2023062 LINDAT/CLARIAH-CZ.

## AI Use Declaration

We used OpenAI GPT models as code assistants during the development of the experiment code and to refine the phrasing of portions of the text.

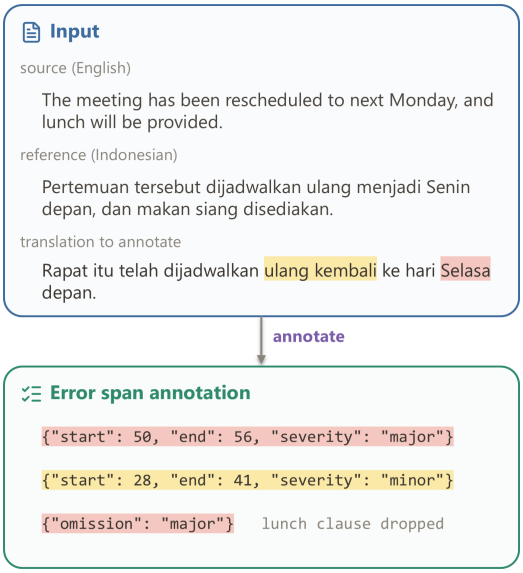
## Abstract

This paper describes HUFS-DILAB's submission to Task 1, segment-level error detection and span annotation, of the WMT26 Automated Translation Quality Evaluation task. We investigate how far an off-the-shelf LLM can be taken as a judge without task-specific training: Gemma-4-31B-it is prompted to annotate error spans, omissions, and severities as constrained JSON given the source, the reference, and the translation, with each language pair routed to a prompt variant specialized for that pair. This design is motivated by the observation that, even with the same prompt, the judge exhibits different severity and error-density distributions across language pairs. These pair-specific patterns recur in at least 24 of the 26 MT systems, suggesting systematic tendencies of the judge rather than effects specific to individual MT systems. To address these tendencies, we calibrate each prompt variant against human annotations where available. We also correct a rule-based wrong-language filter whose errors on closely related languages were silently overriding the judge's annotations. Our submission achieves a score of 0.5854 on the official metric, averaged over the eight prioritized language pairs.

## 1 Introduction

Automated evaluation of machine translation (MT) has moved from a single quality score towards fine-grained error annotation. Task 1 of the WMT26 Automated Translation Quality Evaluation shared task[1] asks a system to read a source segment and its translation and mark the parts that are wrong: a set of character spans, each labelled *major* or *minor*, together with a segment-level judgement of whether anything was omitted (Figure 1). This paper describes HUFS-DILAB's submission, covering the eight pairs the organizers designate as the priority set: cs→de, cs→vi, zh→ja, en→ar, en→et, en→is, en→id, and en→sme.



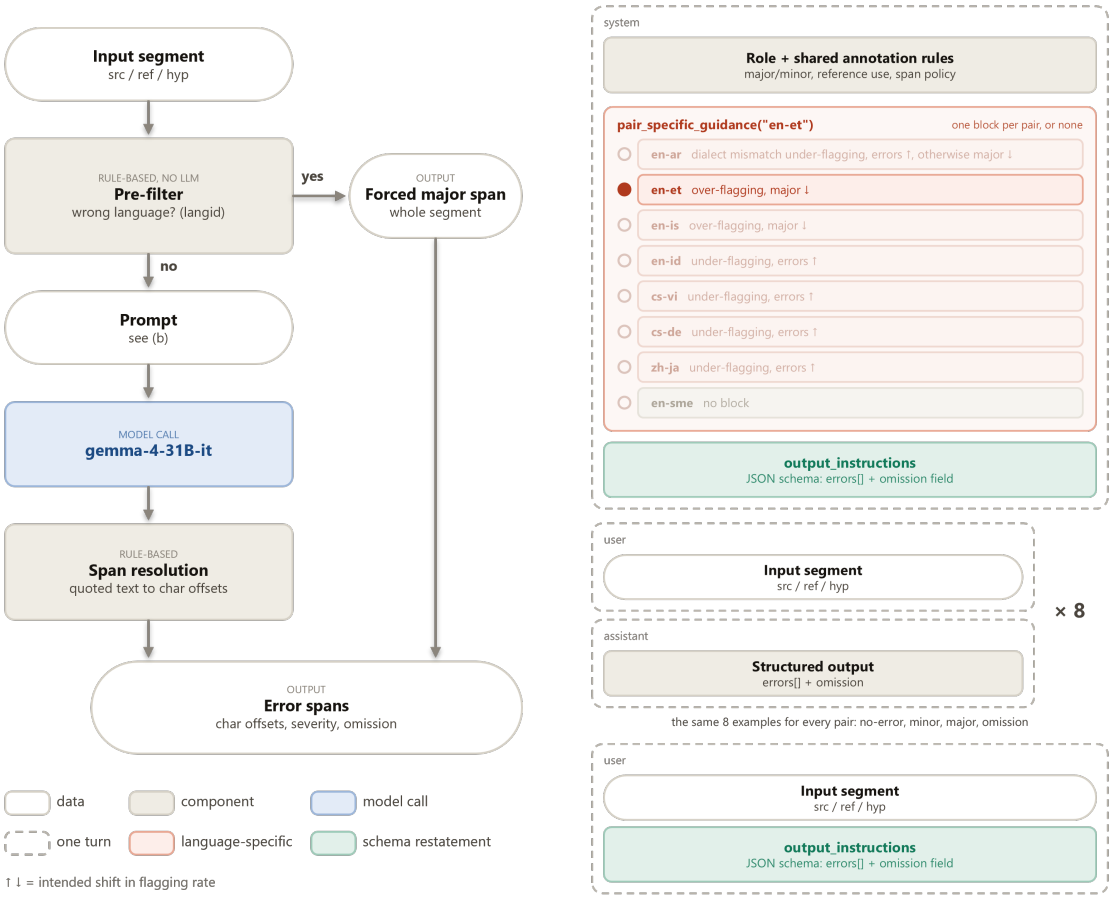


Figure 1: An example segment and its Task 1 annotation. Highlight color marks severity; the clause about lunch, dropped from the translation, has no span and is reported as a major omission.

Our system is an LLM judge used without any task-specific training (Zheng et al., 2023): one instruction-tuned model, prompted with eight fixed demonstrations and decoding the annotation as schema-constrained JSON. Such judges are usually driven by a single prompt applied uniformly to every language pair. However, the judge's annotation behavior deviates by pair, and the deviations are stable enough to measure. Across the evaluated MT systems, the *major* label is 19.6 percentage points more common among the uncalibrated judge's zh→ja spans than on the other pairs, a gap that holds in 24 of the 26 systems that cover the priority set; on en→id, it answers that a segment has no errors 15.7 percentage points more often, in 25 of 26. We read these gaps as a bias in the judge rather than a property of the data: the model

(a) Inference path.

(b) Prompt composition.

Figure 2: Overview of our system. (a) A segment either short-circuits through the wrong-language pre-filter, which emits one segment-wide *major* span without calling the model, or is annotated by the judge and passed to span resolution. (b) The prompt: shared annotation rules, a calibration block shown instantiated for en→et, eight fixed demonstrations, and the segment to annotate, with the JSON schema restated after it.

is more generous on some language pairs than on others, whatever segments it is given.

Rather than retrain the judge, we counteract this bias in its prompt. Each pair is routed to its own short calibration block in the system message, derived from the distribution gaps and validated against human annotation where the previous year's gold data covers the pair.

Before the model, a rule-based filter compares the detected language of the translation against the target, and when the two differ, the whole segment is annotated as a single *major* span. Language identification, however, makes plausible mistakes, such as fluent Indonesian as Malay, and each one marks a correct translation wrong from end to end. We thus ignore detections of languages known to be confused with the target and leave those segments to the model.

Our submission scores 0.5854 on the official metric, averaged over the eight prioritized pairs, and ranks between first and third on the seven pairs that the leaderboard covers.

## 2 Related Work

Prompted language models are now competitive evaluators of translation quality. Kocmi and Federmann (2023b) showed that a GPT model asked for a quality score correlates with human judgement at the system level, and GEMBA-MQM (Kocmi and Federmann, 2023a) extended the idea to error spans, prompting GPT-4 (OpenAI, 2023) for the span, category, and severity of each error. The annotation these systems imitate is MQM (Freitag et al., 2021), whose taxonomy is expensive to apply, and the shared task we enter uses its lighter successor, Error Span Annotation (Kocmi et al., 2024), which keeps target-side spans and the *major*/*minor* distinction and drops the taxonomy. Agreement at the system level, however, does not carry down to the span: predicted spans overlap human ones only

loosely (Lu et al., 2025), and in last year's edition of this shared task no automatic system passed 35 micro-F1 on span-level error detection, far short of what a human annotator scored the same way (Lavie et al., 2025). That report also notes how unevenly the automatic systems were spread across language pairs, with none of them ahead everywhere, and it names the failure modes an LLM-era metric now has to survive rather than assume away: verbose output, and output in the wrong language, dialect, or script. Task 1 asks for exactly the annotation that gap is measured on.

What such a judge does also depends on the language pair. Hada et al. (2024) report that a GPT-4 evaluator agrees with human raters to different degrees across languages and scores some of them systematically higher, and recommend validating against native-speaker judgements language by language. Calibrating a judge from human labels is itself an established move: Liu et al. (2024) generate and refine the scoring criteria handed to an evaluator from labeled examples. We share that diagnosis and correct it more narrowly: we build our judge on an open-weight model and leave the model alone, so the correction is a few lines of instruction per language pair, derived from where that pair's output distribution sits relative to human annotation or to the other pairs.

## 3 Approach

The goal of our submission was to see how far an off-the-shelf model can be taken as a judge by prompting alone: one model, no fine-tuning, and everything else expressed as instructions. The system is a rule-based pre-filter, a single model call with a prompt assembled for the language pair, and a resolver that maps the strings the model quotes back to character offsets (Figure 2).

### 3.1 System overview

A segment first meets the **wrong-language pre-filter** (Figure 2a). A translation that is simply in the wrong language is not a span-level annotation problem, and asking the judge to mark it wastes a model call and usually produces a partial annotation, so we compare the detected language of the translation against the target with `langid.py` (Lui and Baldwin, 2012) and emit a mismatch as one segment-wide *major* span, with no model call. The first version of this filter was too eager — Indonesian and Malay are close enough that the classifier frequently misclassified correct Indonesian outputs as Malay, and such segments were excluded from annotation — so a detection counts only when the detected language is not a known confusion of the target: we exempt Malay for an Indonesian target, Finnish for Estonian, and Chinese for Japanese, where the writing system is largely shared. The filter is disabled altogether for en→sme, where `langid.py` has no support for Northern Sámi.

Every other segment goes into the prompt of Figure 2b, and `google/gemma-4-31B-it` (Gemma Team, 2026) returns the annotation as JSON.[2] The task expects the annotation as a set of spans with severities, so we constrain decoding to a schema (Geng et al., 2023; Willard and Louf, 2023) with two fields: a list of errors, each carrying the quoted error text and a severity in {*major*, *minor*}, and a segment-level omission field that is either null or one of the two severities (Appendix A.2). We ask for the erroneous text rather than the character offsets the task requires, since a quotation can be checked against the translation — it either occurs in it or it does not — while an index cannot; our own code locates each quoted string and drops the spans it cannot locate. Generation can still hit the length cap before the JSON is complete, which the schema cannot prevent; a separate parser repairs or discards those responses. The system finally produces a structured output: a list of spans with offsets and severities, plus the omission flag.

### 3.2 Prompt composition

The system message comes first, stating the judge's role, the shared annotation rules, the JSON schema, and, for some language pairs, a short calibration block; Appendix A reproduces it in full. The rules tell the judge to use the reference as evidence without requiring the translation to match it, and to report a span whenever it is more likely wrong than acceptable, without waiting for certainty.

We counteract the judge's pair-dependent bias with a few lines of extra instruction written for the pair being annotated, which we call a **calibration block** (Appendix A.3). It is the one part of the prompt that is not shared: exactly one block is inserted per request, and en→sme is the only pair that receives none. We derive the blocks from

[2]We run the model with thinking disabled. It is served with vLLM (Kwon et al., 2023), whose structured-outputs interface enforces the schema during decoding, and decoded deterministically at temperature 0, with the context capped at 24,576 tokens and generation at 4,096 tokens.

gaps in the judge's output distribution, and keep a block only when it improves every metric on a fixed validation set. A block states the direction in which the judge's output distribution deviates — an excess of *major*, or of segments left unannotated — and instructs it to move the opposite way. The red `pair_specific_guidance` block of Figure 2b gives the direction taken for each pair.

Eight in-context demonstrations (Brown et al., 2020) follow the system message, one for each of the officially prioritized language pairs. All eight go into every request, whatever pair is being annotated. Their annotations are intended to cover the output space — a clean translation, single *minor* and *major* cases, an omission, a dialect mismatch, and a segment with several errors at once. Four of the eight are taken from the human-annotated data released with the WMT25 General Machine Translation shared task (Kocmi et al., 2025), and we wrote the other four ourselves, for the pairs that data does not include.

The input segment comes last, followed by a restatement of the JSON schema, so the format instruction is the final thing the judge reads. Stating it only once, in the system message, degraded format adherence in our runs as the prompt grew longer.

## 4 Experimental Setup

### 4.1 Datasets

For development, we use the human-annotated data released with the WMT25 General Machine Translation shared task (Kocmi et al., 2025), holding out 260 of its 2,840 segments as a validation set. They are drawn per language pair in proportion to that pair's size, from a document-level shuffle under a fixed seed, so that the split is reproducible and no document is split across the two halves. Four of the eight officially prioritized pairs (§1) — cs→de, en→ar, en→et, and en→is — also appear in that data. Those four are therefore the only pairs we can validate against human annotation.

### 4.2 Evaluation Metric

We use the official metric, Match with Partial Overlap and Partial Credit (MPP; Perrella et al., 2026). MPP computes micro-averaged span-level precision, recall, and F-score by matching predicted spans to gold spans one-to-one. It awards partial credit for overlapping spans and accounts for *major* and *minor* severities. We compare validation runs by MPP F-score. Our validation figures use the greedy matcher rather than the optimal one, consistently across every run, so they are comparable to each other; the official leaderboard scores in Table 1 come from the organizers' own scoring and are not on this scale.

| Language pair | Score | Rank |
|---|---|---|
| zh→ja | 0.6500 | 1 |
| cs→de | 0.5663 | 2 |
| cs→vi | 0.5765 | 2 |
| en→et | 0.6086 | 3 |
| en→is | 0.6650 | 3 |
| en→ar | 0.5322 | 3 |
| en→id | 0.5502 | 3 |
| en→sme | 0.5343 | — |
| Average | 0.5854 | |

Table 1: Official scores on the eight prioritized language pairs, from the scoring output of our final submission. Ranks count each team's best published submission; en→sme is scored but unranked, as the leaderboard never displayed it.

## 5 Results

Table 1 gives our official scores, which average 0.5854 over the eight pairs, or 0.5927 over the seven leaderboard ranks. We placed first on zh→ja, second on cs→de and cs→vi, and third on the four remaining ranked pairs; en→sme is scored but never displayed on the leaderboard, so it carries no rank. Ranks count each team's best submission among the results teams chose to publish, and publishing is optional, so they can only fall as more appear.[3] The scores span 0.5322 to 0.6650, though our highest and our lowest both come from pairs where we placed third. The rest of this section takes the system apart: what each design decision contributed on the validation set (§5.1), and then the pair-dependent bias and the calibration blocks written against it (§5.2).

### 5.1 Ablation

Table 2 tracks the four decisions that shaped the system, each measured on the same held-out segments. Constraining decoding to the schema recovers errors that a free-text judge finds but loses to parsing, and is worth roughly two F1 points. Giving the judge the reference translation, with annotation

[3] Read from the official leaderboard on 11 September 2026. Note that they are a snapshot of an open leaderboard rather than final standings.

| Configuration | P | R | F1 |
|---|---|---|---|
| Free-text output, 12B model | 16.0 | 20.0 | 16.2 |
| + JSON schema | 16.6 | 23.9 | 18.0 |
| + reference, annotation rules | 20.6 | 23.2 | 20.0 |
| + 31B model | 23.7 | 24.0 | 22.5 |
| + pair calibration | 23.2 | 26.6 | **23.5** |

Table 2: Validation results, macro-averaged over the 13 language pairs of the held-out set that every configuration covers. Each row adds one design decision to the row above it; the first three run on `google/gemma-4-12B-it` and the last two on the `31B` checkpoint the submission uses.

rules written around it, hands it evidence for dropping a span it cannot support, and adds two more. Moving to the 31B checkpoint adds a further two and a half. Pair calibration, the last row, adds one more point, but pairs carrying no block at all also move, one by as much as 6.4 F1, so that average is not the effect of the blocks alone.

### 5.2 Pair-Dependent Bias

The judge does not annotate every language pair the same way. We compare pairs within a single MT system, on two quantities: the share of a pair's spans that carry the *major* label, and the share of its segments left without any span. With the shared prompt alone, the *major* label is 19.6 percentage points more common on zh→ja than the average across the other pairs, in 24 of the 26 systems. On en→id, 15.7 percentage points more of the judge's segments come back with no span at all, in 25 of 26. We take a deviation that survives nearly every system to be the judge's own, not the data's.

Table 3 gives the deviation behind each of the seven blocks. The axis a block adjusts follows from the signal that diagnosed it: pairs diagnosed on the validation set deviated on severity, while those diagnosed against the other pairs deviated on how often the judge reports anything.

Only three of the seven corrections can be checked on the validation set. The correction for en→is loses 0.3 F1 there; we kept it because the run that introduced it gained overall. The other four cannot: three target pairs the validation set does not cover, and cs→de shows no deviation there, only against the other pairs. For those four, the official score is the only check, and it separates one correction from everything else only where that correction was submitted on its own, as it was for cs→vi and zh→ja. On en→id, neither check is

| Pair | Deviation | Correction | ΔF1 |
|---|---|---|---|
| *major share, vs. validation* | | | |
| en→ar | +20.1 | dialect, *major* ↓ | +1.6 |
| en→et | +31.4 | *major* ↓ | +1.8 |
| en→is | +22.3 | *major* ↓ | −0.3 |
| *error-free share, vs. other pairs* | | | |
| zh→ja | +11.4 | errors ↑ | — |
| en→id | +9.8 | errors ↑ | — |
| cs→vi | +9.7 | errors ↑ | — |
| cs→de | +7.1 | errors ↑ | — |
| en→sme | — | none | — |

Table 3: The per-pair corrections in the submitted system. **Deviation**, in percentage points, is measured before the correction was added. For the first group, it is the share of a pair's spans marked *major* against the validation set; for the second, the share of its segments left error-free against the other pairs. **ΔF1** is the change in validation F1 afterwards, available only for the pairs the validation set covers.

available, so all we can say is that its correction did what it was written to do: the share of segments left without a span fell from 59.4% to 52.1%. The largest severity gap of all belongs to zh→ja, yet the correction we kept there raises how often errors are reported and leaves severity alone. Tightening the severity definition was our first attempt, and it lowered the pair's score; the replacement took it from 0.6437 to 0.6500.

## 6 Conclusion

This paper presented HUFS-DILAB's system for WMT26 Task 1, an LLM judge that annotates error spans with no task-specific training. It scores 0.5854 across the eight prioritized language pairs, ranking between first and third on the seven that the leaderboard covers. Its design follows from one observation: the judge's severity and error density deviate by language pair, and the deviation is stable enough across the MT systems being judged to be measured and corrected. We correct it in the prompt, routing each pair to a few lines of its own instruction while the model and the shared prompt stay fixed. Future work should look for a calibration signal on pairs with no human annotation, and test whether the same deviations appear in other judges.

## 7 Limitations

Our study has the following three limitations. First, our experiments used a single judge,

`google/gemma-4-31B-it`. Though it performed best among the models we explored during development, we did not test the prompt routing and calibration on any other LLM, so how far the approach generalizes remains unclear. Second, our calibration is tuned to evaluation data that is assembled to be hard for MT, where errors are common. On translations that are mostly correct, the same instructions would cost precision. Lastly, we ask the judge for the erroneous text rather than character offsets. When that text occurs more than once in the translation, we take the first occurrence, which is not always the one the judge meant. Such segments are rare, but a span placed on the wrong occurrence both misses the real error and counts as a false positive.

# A Prompt

The system message is assembled from the blocks below: the shared annotation rules, the calibration block for the pair being annotated (if any), and the schema instruction. The eight demonstrations and the segment to annotate follow as user and assistant turns (Figure 2b); the demonstrations are omitted here for space.

## A.1 Shared annotation rules

```
DECISION STANDARD
- Report errors that are supported by sufficient linguistic evidence from the source, target, and
reference.
- Do not require absolute certainty. Report a candidate when the target is more plausibly erroneous
than an acceptable translation.
- Do not annotate a target span merely because another wording would also have been acceptable or
sounds more natural -- omit anything that is a valid paraphrase, alternative translation, or harmless
stylistic variation.
- Balance completeness and restraint: do not invent errors, and do not artificially cap how many you
report in either direction. Report every independently supported error regardless of its severity, but
do not assume a segment must or must not contain one.
- Judge every candidate independently from the actual source and target. A segment may validly contain
zero, one, or multiple errors.
- Return a no-error response only when no candidate is sufficiently supported after comparing the
complete source and target.

WHAT COUNTS AS AN ERROR
- A major error materially changes, contradicts, omits, or seriously obscures important meaning.
Examples include a clear mistranslation, unsupported addition, important omission represented by a
literal [MISSING] token, contradiction, wrong named entity, number, date, unit, relation, polarity,
modality, or terminology.
- A minor error is a clear localized defect whose impact is limited while the surrounding core message
remains recoverable. It may concern grammar, agreement, spelling, punctuation, formatting, fluency,
terminology, or localized wording.
- First decide whether a span is erroneous. Severity is a separate judgment about its impact.
- Do not omit a supported error merely because it is minor. If it is clearly erroneous, include it and
assign the appropriate severity.
- Do not label an uncertain candidate as minor merely to avoid making a firm decision. If the existence
 of the error itself is too uncertain, omit it.
- Do not annotate the source text or reference translation. Only target substrings may be returned.

REFERENCE USE
- Treat the source text as the primary authority for meaning.
- Use the reference translation as auxiliary evidence, not as the only correct translation.
- The reference may help identify omissions, additions, mistranslations, terminology, relations, or
natural target-language realizations.
- A target span must not be marked as an error solely because its wording, syntax, or lexical choice
differs from the reference -- a lexical difference from the reference alone is insufficient evidence.
- If the target accurately expresses the source through a valid alternative translation, do not
annotate it.
- If the source and reference appear to conflict, prioritize the source and avoid speculative
annotation.

SPAN SELECTION POLICY
- Annotate only text that already appears in the target translation.
- Each error span must be one exact continuous substring copied from the target. Preserve every
character exactly.
- Select the smallest complete lexical, grammatical, or semantic unit that clearly represents the error
, not the smallest possible character sequence.
- Prefer one complete word or phrase over a character fragment, subword, stem, affix, or inflectional
ending. A smaller span is allowed only when it independently and completely represents the error.
- Keep a necessary function word, inflection, punctuation mark, or adjacent element when excluding it
would make the span incomplete or misleading.
- Do not include surrounding correct text or select an entire sentence when a smaller complete span
identifies the error.
- Do not split one semantic error into artificial fragments. Do not output duplicate, overlapping, or
contained alternatives for the same error.
- Distinct errors may be reported separately only when each is independently justified. Do not merge
independent errors merely because they are adjacent.
- A missing concept may be annotated only when the target literally contains [MISSING]. Never invent it
 or use an empty span.

OUTPUT DISCIPLINE
- Return exactly one valid JSON object and nothing else.
- Do not output Markdown, code fences, prose, explanations, corrections, rationales, categories,
quality scores, character indices, reasoning, or an analysis trace.
- Use exactly the required field names and no additional fields.
- Severity must be exactly "major" or "minor". Preserve error order by first appearance in the target.
```

## A.2 Schema instruction

```
Return only a valid JSON object matching this schema:
{"errors": [{"text": "exact substring from the translation", "severity": "minor" or "major"}], "
omission": null}
Copy each span text exactly from the translation. Use an empty errors array when there are no errors.
No markdown, no comments, no offsets.
If important source content is entirely missing from the translation (an omission, with nothing to
quote in the translation), set the top-level "omission" field to "minor" or "major" for the whole
segment; otherwise set it to null. omission is a single value for the segment, never an entry inside
the errors array.
The response must start with '{' and end with '}'.
```

## A.3 Pair-specific calibration blocks

```
[en-ar]
PAIR-SPECIFIC NOTE (Egyptian Arabic): scan carefully for register or dialect mismatches -- if the
target uses Modern Standard Arabic or a different dialect where the required Egyptian Arabic form was
expected, this is a real error even if the translation otherwise reads fluently. Most defects found are
 minor; reserve major for genuine dialect mismatches or mistranslations that change meaning.

[en-et]
PAIR-SPECIFIC NOTE (Estonian): most defects in this language pair are minor grammatical, agreement, or
fluency issues in Estonian morphology. Reserve major strictly for cases where the meaning is actually
changed, contradicted, or lost.

[en-is]
PAIR-SPECIFIC NOTE (Icelandic): most defects in this language pair are minor grammatical or fluency
issues. Reserve major strictly for cases where the meaning is actually changed, contradicted, or lost.

[en-id]
PAIR-SPECIFIC CALIBRATION (Indonesian): this language pair is consistently under-flagged. Most segments
 in this pair do contain at least one issue, and a fluent-looking translation typically still has one
to three of them (grammar, affixation, agreement, word-choice, register, omitted nuance, or slightly
shifted meaning); an entirely error-free translation is uncommon here. Treat a no-error answer as the
exception that needs justifying: before returning one, re-verify the target against the source and the
reference phrase by phrase (names, numbers, polarity, modality included), and only return no-error when
 that full check still finds nothing. At the same time, report each independent issue only once, do not
 split one problem into fragments, and do not invent errors to fill a quota -- a padded list is worse
than a short one. When you mark an error, cover the complete problematic phrase, not just the single
most suspicious word.

[cs-vi]
PAIR-SPECIFIC CALIBRATION (Vietnamese): this language pair is consistently under-flagged -- Czech-to-
Vietnamese is a demanding direction, and translations that read fluently at a glance still typically
contain one to three subtle issues (grammar, classifier or measure-word choice, word order, register,
omitted particles, or slightly shifted meaning). Before returning a no-error response, re-verify the
target against the source and the reference phrase by phrase (names, numbers, polarity, modality
included); only return no-error when that full check still finds nothing. Report each independent issue
 only once and do not invent errors to fill a quota. When you mark an error, cover the complete
problematic phrase, not just the single most suspicious word.

[cs-de]
PAIR-SPECIFIC CALIBRATION (German): this language pair is under-flagged -- translations that read
fluently at a glance still typically contain one to three subtle issues (case or gender agreement,
article choice, compound formation, word order, register, or slightly shifted meaning). Before
returning a no-error response, re-verify the target against the source and the reference phrase by
phrase (names, numbers, polarity, modality included); only return no-error when that full check still
finds nothing. Report each independent issue only once and do not invent errors to fill a quota. When
you mark an error, cover the complete problematic phrase, not just the single most suspicious word.

[zh-ja]
PAIR-SPECIFIC CALIBRATION (Japanese): this language pair is under-flagged -- a translation that reads
naturally at a glance still typically contains one to three subtle issues (particle or conjugation
choice, honorific or register level, word order, script choice, omitted nuance, or slightly shifted
meaning). Before returning a no-error response, re-verify the target against the source and the
reference phrase by phrase (names, numbers, polarity, modality included); only return no-error when
that full check still finds nothing. Report each independent issue only once and do not invent errors
to fill a quota. When you mark an error, cover the complete problematic phrase, not just the single
most suspicious word.

{ahriikim,chanjun.park,seongheum}@ssu.ac.kr

## Abstract

Different error types in machine translation require different evidence. Whether meaning is preserved can be judged only against the source, while whether the target is well-formed, or whether it names one entity consistently, can be judged from the target alone. We present FACET, our reference-free submission to the WMT26 Automated Translation Quality Evaluation Task, which decomposes evaluation into Fluency, Accuracy, and Consistency passes and gives each pass only the context its error type requires. A single fixed model is prompted three times, and the merged error spans yield the three task outputs, error spans, quality scores, and error-free labels, with no trained components. We also submit FACET−C, which omits the Consistency pass. Without gold labels, we characterize the predictions of FACET. Its system rankings place post-edited human translation first, and the Consistency pass changes about a tenth of segment scores while leaving the ranking nearly unchanged.

## 1 Introduction

Judging the quality of a translation is not one decision but several, and they do not rest on the same evidence. Whether the target preserves the meaning of the source can be decided only from the source and the target together. Whether the target is well-formed is a property of the target as a piece of language, and whether a recurring name or term keeps one rendering is a property of the target across a whole document. The source contributes nothing to the last two questions, and a single segment is too short to answer the third. LLM-based evaluators typically put all of these questions to the model in one prompt over one input (Kocmi and Federmann, 2023a; Fernandes et al., 2023; Lu et al., 2024; Junczys-Dowmunt, 2025), so every judgment is made from the same context whether or not it is the context that judgment needs.

FACET (**F**luency, **A**ccuracy, and **C**onsistency **E**valuation of **T**ranslations) separates the judgments and the inputs. Its three passes follow the MQM error taxonomy (Lommel et al., 2013). Accuracy and Fluency are the two top-level MQM dimensions, with terminology, style, and locale conventions folded into Fluency as target-only judgments. Consistency is an MQM subtype of Fluency that we promote to a pass of its own, because it is the one Fluency judgment that cannot be made within a segment.

The passes run under asymmetric input. The Accuracy pass reads the source and the target. The Fluency and Consistency passes read the target only, each at the scope its error type requires, the segment for Fluency and the whole document for Consistency. The Consistency pass judges only recurring items, that is, named entities, domain terms, and fixed expressions. It checks that one entity does not appear under two or more names a reader would take as different referents, and that shortened or pronominal references agree with the form they refer back to. Because it judges internal consistency rather than correctness, it needs no source, and the restriction to recurring items limits overlap with the other two passes.

FACET is our submission to the WMT26 shared task on Automated Translation Quality, which merges the metrics and quality estimation (QE) tracks of previous years. The task provides reference translations as an optional input and scores segments in context, where the context is a document or a long multi-segment unit. FACET uses no references and treats the document context as an input in its own right. The system has no trained or fine-tuned components. A single fixed model is prompted, and the behavior of the system is determined by the decomposition into passes and by the input each pass receives. One merged prediction

yields the three shared-task outputs, error span annotation, quality scoring, and error-free detection.

Our primary submission, FACET, uses all three passes. Whether a document-level judgment pays off under segment-level scoring is an open question, so we also submit FACET−C, an ablation that omits Consistency, and use the pair to measure what the document-level pass contributes.

## 2 Related Work

**LLM-as-judge evaluation.** Prompting large language models (LLMs) for translation quality assessment is now common practice. GEMBA (Kocmi and Federmann, 2023b) prompts GPT models for direct quality scores, and GEMBA-MQM (Kocmi and Federmann, 2023a) extends this to reference-free MQM-style error annotation (Lommel et al., 2013) with severity labels. AutoMQM (Fernandes et al., 2023) elicits error spans and categories through prompting. EAPrompt (Lu et al., 2024) combines chain-of-thought with error analysis and improves segment-level accuracy, where earlier prompting methods were weak. Rubric-MQM (Kim, 2025b) identifies label biases and the difficulty of assessing near-perfect translations, and improves reliability through rubric-style multidimensional prompting. Several later systems refine this approach in different ways. MQM-APE (Lu et al., 2025) adds an automatic post-editing stage that filters errors with no effect on quality. Rubric-as-Experts (Xu et al., 2026) allocates MQM subtype spaces per instance and reports that broader evaluation spaces raise coverage at the cost of false positives, while narrower spaces improve precision. GEMBA V2 (Junczys-Dowmunt, 2025), built on the same GPT-4.1-MINI backbone we use, scores each segment ten times and aggregates the results to reduce variance. All of these systems judge a segment with a single prompt. FACET instead separates fluency, accuracy, and consistency into distinct passes, each given only the context its error type requires.

**Quality estimation metrics.** Quality estimation (QE) scores a translation from the source and the target alone, without a reference. This is the setting the present task inherits from the QE track. Learned metrics have led this line for years. COMET-QE (Chimoto and Bassett, 2022) and TransQuest (Ranasinghe et al., 2020) won the earliest WMT QE-as-a-metric subtasks, and CometKiwi (Rei et al., 2022) won the WMT22 QE task by jointly predicting sentence- and word-level quality. More recent metrics add finer-grained outputs. xCOMET (Guerreiro et al., 2024) couples a learned metric with error-span prediction, and MetricX (Juraska et al., 2024) scores translations with or without a reference from a single model. These metrics are trained on human quality annotations such as the MLQE-PE and MQM corpora. FACET stays in the reference-free QE setting but uses no trained components, obtaining error spans, scores, and an error-free decision from prompting alone.

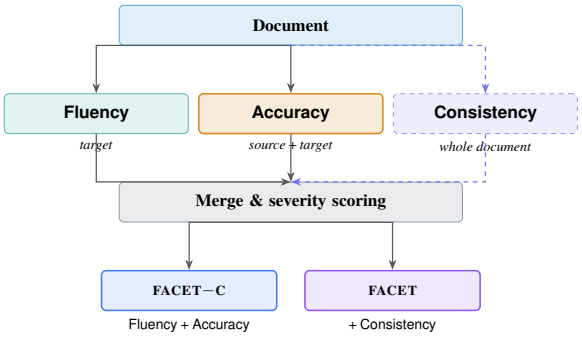

Figure 1: FACET evaluates a translation with three independent prompting passes under **asymmetric input**. Accuracy reads the source and the target, while Fluency and Consistency read the target only. Predictions are merged and scored per segment. FACET uses all three passes, and FACET−C drops Consistency (dashed).

## 3 System Description

FACET evaluates a hypothesis translation with three prompting passes that run independently and are combined afterward. Each pass returns a list of error spans. A span carries a quoted region of text, the erroneous substring within it, a severity, a category, and a short reason. Figure 1 shows the pipeline. The passes differ in the input each one receives, and this difference fixes the scope at which each pass operates. Prompts are given in Appendix A.

### 3.1 Asymmetric Input

The three passes do not receive the same input. Accuracy is the only judgment that requires both the source and the target, since whether a translation preserves meaning cannot be decided from the target alone. Fluency and Consistency require the target only. Fluency asks whether a segment is well-formed in the target language, a property of the target as a piece of writing. Consistency asks whether a recurring entity or term keeps one rendering across the document, a property of the target across its own length. Neither question is an-

swered by the source, and supplying it would invite the model to import meaning-level concerns that belong to the Accuracy pass. The same asymmetry fixes the scope of each pass. Fluency and Accuracy operate on the segment, while Consistency operates on the whole document, the only scope at which the renderings of a term can be compared against one another.

### 3.2 Input Construction

The shared task provides text in paragraph-sized units. Line breaks in the data mark subtitle-cue boundaries rather than sentence boundaries, so we re-segment the source and the target into sentences with a rule-based multilingual segmenter before the passes run. Newlines are replaced with spaces in a length-preserving substitution, so the character span of each sentence maps directly back onto the original text and all offset recovery stays in the original coordinates. Presenting a segment as explicit sentences also gives the model a stable structure to iterate over, which reduces its tendency to skip material in long inputs (Kim, 2025a). For the Consistency pass, segments sharing a document identifier are grouped and ordered to reconstruct the full document.

### 3.3 Fluency Pass

The Fluency pass reads the target segment alone and acts as a strict proofreader of the target language. It judges spelling, grammar, agreement, word order, punctuation, orthography, register, and terminology by the norms of the target language itself. The source is withheld because a Fluency judgment concerns the target as language, and showing the source invites meaning-level concerns that belong to Accuracy.

### 3.4 Accuracy Pass

The Accuracy pass reads the source and the target together and judges whether the target preserves the meaning of the source. It covers mistranslation, wrong term, addition, hallucination, omission, and untranslated text. Source-side errors, namely omission and defective source, are recorded on the source so that content dropped from the translation is captured even when the target reads fluently. Hallucinated content unsupported by the source is assigned the highest severity.

### 3.5 Consistency Pass

The Consistency pass reads the whole target document and judges only internal consistency, never correctness, which is why it needs no source. It first identifies the recurring items whose renderings must stay stable, that is, named entities, domain terms, and fixed expressions, and records the forms in which each appears across the document. An item with a single form throughout is consistent by construction and is left to the Accuracy pass. An item with two or more distinct forms is checked on two points, whether the forms would read as different referents, and whether shortened or pronominal references agree in gender and number with the form they refer back to, where the target language marks such agreement.

When an item does diverge, the error is not attached to the first or the last occurrence. The pass decides from the document context alone which form does not fit the rest of the document and marks every occurrence of that form, wherever it appears. Occurrences of the form that fits are left unmarked.

### 3.6 Severity and Scoring

Every pass rates each error on one shared four-point scale, appended identically to all three prompts. Following the severity criteria in the human evaluation guidelines provided by WMT, scale 1 is a slight wording change with no impact on clarity or intent, scale 2 alters wording while the message stays mostly clear, scale 3 noticeably distorts meaning so that the reader is misled, and scale 4 is a substantial distortion that leaves the translation unfaithful. The prompt records the raw value, and the mapping onto Minor and Major is applied afterward. Following the correspondence in the guidelines, we cut at 3, so scales 1–2 are Minor and scales 3–4 are Major.

Before scoring, Consistency errors at scale 1 are discarded. On morphologically rich target languages the Consistency pass flags ordinary case, gender, or number inflection of a recurring term as an inconsistency, and these false positives concentrate at scale 1. Removing them leaves the higher-severity divergences that reflect cross-segment errors. Fluency and Accuracy errors at scale 1 are kept.

Because the passes are prompted and collected separately, the Fluency, Accuracy, and Consistency predictions for a segment arrive on separate records. We merge all predictions that share

a segment before scoring rather than letting one pass overwrite another. Error spans are located in the original text by matching the quoted region returned by the model and then the erroneous substring within it, rather than by trusting model-reported offsets. The segment score is the negated sum of the severities of its surviving errors across all passes, so a segment with errors of scale 2, 1, and 3 scores $-6$ and a segment with no error scores 0. A higher score is a better translation, and a segment scores 0 exactly when no error survives.

### 3.7 Deriving the Task Outputs

One merged, scored prediction yields all three shared-task outputs. For error span detection, each surviving error contributes its character offsets, its Minor or Major label under the cut, and its category. Consistency errors whose referents span multiple non-contiguous positions may lack a single offset, and these are omitted from the span output. For quality scoring, the segment score above is used directly. For error-free detection, a segment is labeled error-free when its score is 0, that is, when no error survives the merge.

## 4 Experimental Setup

**Model.** All three passes use a single model, GPT-4.1-MINI (`gpt-4.1-mini-2025-04-14`), served through the OpenAI API and accessed only through prompting with no fine-tuning. It is not an ensemble and is not based on open weights, and its parameter count is not publicly disclosed. We decode deterministically at temperature 0, so the judgments of FACET are reproducible. The model is non-reasoning, so its output is the answer itself with no intermediate reasoning trace. The maximum output length is set per request in proportion to the input. For the segment-level Fluency and Accuracy passes we allow $1.5\times$ the input length plus a floor of 1,000 tokens, capped at 8,000. For the document-level Consistency pass, whose output must enumerate every tracked item, we allow $2\times$ the input plus a floor of 2,000 tokens, capped at 16,000. Requests are issued through the batch interface, one per segment for Fluency, one per segment for Accuracy, and one per document for Consistency.

**Data.** We evaluate on the WMT26 test set, which spans 21 language pairs and multiple domains, from official speech-sourced material to challenge sets. Each item pairs a source with the outputs of many translation systems, and FACET scores every system output independently, yielding several hundred thousand system-segment pairs per pass. The human annotations and the official leaderboard were not released at the time of writing, so we do not report correlation with gold labels.

**Speech transcripts.** A large share of the data is speech-sourced. In pilot runs the Fluency and Accuracy passes flagged filler words and hesitations, such as *um* and *uh* and their target-language equivalents, as errors, and treated their differing renderings across languages as mistakes. These are transcription artifacts, not translation errors. For speech-based items we therefore append a rule instructing the Fluency and Accuracy passes to ignore fillers, hesitations, and repeated interjections. The Consistency pass is left unchanged, since fillers are not recurring entities or terms.

**Submissions.** Our primary submission, FACET, uses all three passes with the scale-1 filtering of Consistency errors described in Section 3. To isolate what the document-level Consistency pass contributes under segment-level scoring, we also submit FACET$-$C, an ablation that omits Consistency and scores from Fluency and Accuracy alone.

## 5 Submission Analysis

Without gold labels, we characterize the predictions of FACET on their own terms, through the system ranking they induce, the effect of the Consistency pass, and one worked example.

**System ranking.** For each language pair we rank the systems by their mean FACET score and report the per-pair ranks in Table 1. Because languages differ in how many errors the passes surface, ranking within a language pair rather than pooling across pairs keeps language difficulty from being confounded with system quality. The resulting order follows the pattern one would expect from the systems involved. Strong general-purpose systems such as Wayfinder, Lumen, and GPT 5.5 rank consistently near the top, and small open models such as GLM 4-9B, GPT OSS 20B, and Qwen 3.5-9b rank consistently near the bottom.

The clearest pattern is in the human entries. *Human (postediting)* attains the best mean rank of any system at 1.3, placing first or second in every pair it enters, while *Human (from scratch)* sits midtable at 13.3. One reading is that FACET rewards

| System | cs-de | en-de | cs-vi | en-is | en-et | zh-ja | en-se | en-zh | en-th | en-cs | en-kk | en-ar | en-ru | cs-uk | en-lij | en-uk | en-lld | en-hy | en-be | en-id | en-zh-TW | **avg** |

Table 1: FACET system rankings across the 21 language pairs. Each cell is the rank of a system within that language pair (1 = best), darker is better, and  marks a pair the system did not enter. Systems below the rule are ordered by mean rank. *Human (postediting)* attains the best mean rank, while *Human (from scratch)* sits mid-table.

polished translation over first-draft translation and does not simply favor human text. Another is that a reference-free LLM judge is more tolerant of translations that stay close to the source structure, as post-edited MT does, and penalizes the freer choices of translation from scratch. The two readings cannot be separated without human judgments, and we leave the question to the official evaluation.

**Effect of the consistency pass.** Comparing the full FACET ranking with the two-pass ablation FACET−C, the Consistency pass changes the score of 2,726 of 26,885 items (10.1%), but the system ranking is almost untouched. No system moves by more than 0.2 in mean rank and no two systems swap order. The effect on error-free detection is smaller still. Only 0.7% of segments receive a different error-free label under FACET than under FACET−C. Part of this is structural, since Consistency errors are document-level and rare relative to segment-level Fluency and Accuracy errors. The pass also recovers fewer errors than its design allows. It is the only pass that takes a whole document as input, and the model struggles to maintain a reliable account of recurring items across such long contexts. This shows in the low number of Consistency errors it recovers and in the share of flagged spans it cannot localize. The divergences it does catch are cross-segment errors that Fluency and Accuracy cannot see, such as one entity rendered under several names within a document. We take the weak effect as a limitation of long-context reliability in the current model rather than as evidence that document-level Consistency does not matter (Kim, 2025a).

**A qualitative example.** Figure 2 shows the three passes on one document. Fluency and Accuracy stay within a segment. Fluency flags target-language faults such as the gender agreement in *für das Telčer Standort* and the misplaced quotation marks, and Accuracy flags meaning errors against the source, among them the region name *Žd'árský-Krkonose*, where the source region *Žd'ársko* is rendered as a mountain range, and *Tradition der Pilger*, which turns a file-making tradition into a tra-

A full Czech–German document evaluated by FACET. Every detected error is highlighted: Fluency, Accuracy, Consistency.

**Segment 1 — source.** Pilníkárna v Křižánkách na Žďársku se stala kulturní památkou

**Segment 1 — target.** Die Bürstenfabrik in Křižánky im Žďárský-Krkonose ist zu einem Kulturdenkmal geworden

**Segment 2 — source.** Pilníkárna v Křižánkách na Žďársku, která je součástí historického areálu Kupcova vodního mlýna a pily, se stala kulturní památkou. Navzdory úpravám je autentickým svědectvím zaniklého řemesla výroby železných pilníků. V tiskové zprávě to za telčské pracoviště Národního památkového ústavu uvedla Ilona Ampapová. Na Vysočině je téměř 3000 nemovitých kulturních památek, z toho 16 národních kulturních památek. Křižánky jsou velkou vesnickou památkovou rezervací. Památkově chráněná byla zatím jen pila a mlýn zmiňovaný poprvé v roce 1713. "Celý areál, včetně pilníkárny, je doložen již na mapě stabilního katastru z roku 1839," uvedla Ampapová. Pilníkárna vznikla v roce 1905 a její současná podoba odpovídá stavebním úpravám spojeným se zavedením pilníkářského řemesla. "Navzdory dílčím proměnám ve 20. století se zde dochovala řada autentických konstrukcí a prvků, které svědčí o původní funkci objektu a jeho historické hodnotě," uvedla Ampapová. Provoz pily i pilníkářská výroba v areálu skončila v roce 1947. Křižánky jsou největší vesnickou památkovou rezervací na Vysočině. V roce 2012 se staly Vesnicí roku Kraje Vysočina. Pilníkářskou tradici v obci připomíná od roku 2011 naučná stezka.

**Segment 2 — target.** Die Schleiferei in Křižánky am Žďárský-Berg, die Teil des historischen Geländes des Kupcova-Wasser-Mühlen- und Sägewerks ist, wurde zu einem Kulturdenkmal. Trotz der Anpassungen ist sie ein authentisches Zeugnis des verschollenen Handwerks der Herstellung von Eisen-Schleifscheiben. In einer Pressemitteilung gab Ilona Ampapová für das Telčer Standort des Nationalen Denkmalinstituts dies an. In der Region Vysočina gibt es fast 3000 unbewegliche Kulturdenkmäler, davon 16 nationale Kulturdenkmäler. Křižánky sind ein großes Dorfdenkmalsreservat. Bisher waren nur der Sägewerk und der Mühle, die erstmals im Jahr 1713 erwähnt wurden, unter Denkmalschutz gestellt. „ Das gesamte Gelände, einschließlich der Sägewerkshalle, ist bereits auf der Karte des festen Katasters aus dem Jahr 1839 belegt“, erklärte Ampapová. Die Schleiferei wurde im Jahr 1905 gegründet, und ihre heutige Gestalt entspricht den baulichen Anpassungen, die mit der Einführung des Schleifereihandwerks verbunden waren. „ Trotz der teilweisen Veränderungen im 20. Jahrhundert sind hier zahlreiche authentische Konstruktionen und Elemente erhalten geblieben, die von der ursprünglichen Funktion des Objekts und seinem historischen Wert zeugen“, erklärte Ampapová. Der Betrieb des Sägewerks sowie die Sägewerkzeugherstellung auf dem Gelände endeten im Jahr 1947. Křižánky sind die größte dörfliche Denkmalschutzzone in der Region Vysočina. Im Jahr 2012 wurden sie zum Dorf des Jahres der Region Vysočina. Seit 2011 erinnert ein Lehrpfad an die Tradition der Pilger.

Figure 2: A full document evaluated by FACET, with all detected errors highlighted. Fluency and Accuracy act within a segment, from the target alone and from the source–target pair. Consistency acts across the document. The facility named *Bürstenfabrik* in Segment 1 becomes *Schleiferei* in Segment 2, a divergence that no single-segment judgment can detect.

dition of pilgrims. The Consistency pass catches an error of a different kind. The same facility is called *Bürstenfabrik* (‘brush factory’) in the title segment and *Schleiferei* (‘grinding shop’) in the body segment, two names for one referent that are each locally acceptable and conflict only when the segments are read together. This is the error class the pass is designed for, and it cannot be recovered by scoring segments in isolation. The example also shows a miss. Both *Bürstenfabrik* and *Schleiferei* mistranslate the source *pilníkárna* (‘file workshop’), and the Accuracy pass flags neither, so the document is penalized for the divergence but not for the term itself.

## 6 Conclusion

We presented FACET, a reference-free translation quality evaluator built by decomposition rather than by a single prompt or a trained metric. Error types need different context. Accuracy is judged from the source and the target together, while Fluency and Consistency are judged from the target alone, at the sentence and the document scope respectively. A single fixed model is prompted three times, and its predictions are merged and scored, with no trained components anywhere in the pipeline.

Without gold labels, we characterized the predictions of FACET on their own terms. Its per-language-pair system rankings follow the expected order of the participating systems and place post-edited human translation at the top. Whether the mid-table position of translation from scratch reflects

quality or a preference for source-close output remains open until human judgments are released. The document-level Consistency pass changes a tenth of segment scores but leaves the system ranking almost unchanged, a result our paired submissions were designed to expose. We attribute this to the limited reliability with which current models track recurring items across long inputs, and to the mismatch between a document-level signal and segment-level scoring. Stronger long-context models, or a scoring scheme that credits document-level Consistency directly, would address these two limits.

# Appendix

## A Prompts

The three passes use the system prompts below, with {src_lang} and {tgt_lang} filled per language pair. The severity rubric in Appendix A.4 is appended verbatim to all three, and each error object in the JSON output carries an additional field "severity": 1-4. The user message is the target segment for Fluency, the source and target segment wrapped in <source> and <target> tags for Accuracy, and the full target document for Consistency.

### A.1 Fluency Pass

**System prompt: Fluency**

```
You are a strict proofreader of {tgt_lang}. Find ALL spans that must change to make the text
   correct, natural {tgt_lang}; scan to the end and report every one. There may be several, or
   none.
Judge it purely as {tgt_lang} writing, by the norms of {tgt_lang} itself and never another
   language's. Apply {tgt_lang}-specific phenomena a native writer observes  e.g. paired ¿ ¡ in
   Spanish, mandatory kana/kanji and no capitalization in Japanese, sentence-final 。in CJK,
   German noun capitalization, French spacing before ; : ? !, Arabic/Hebrew script and
   directionality.
Categories:
- spelling: misspelling, wrong or missing diacritic.
- grammar: ungrammatical construction, wrong inflection, tense, or particle.
- agreement: features that must agree do not (gender, number, case, verb).
- word_order: an order no fluent writer of {tgt_lang} would use.
- punctuation: wrong or missing punctuation by {tgt_lang} convention.
- orthography: wrong case, spacing, script, or number/date/time/measurement formatting by
   {tgt_lang} convention (decimal comma, thousands separator, date and time format, unit spacing).
- register: register or variety inconsistent within the text.
- term: a word that is not the established {tgt_lang} term. Do not judge whether a term fits a
   domain  that needs the source.
Flag a span only if you are certain it is wrong. If your reason would contain "might", "could",
   "awkward", "more natural", or "better", it is a preference, not an error  do not flag it.
   Report each error separately, even when several occur close together. Do not judge meaning,
   numbers, or dates.
Output  JSON: {"errors": [{"quote": str, "span": str, "reason": str, "category": str}]}
- quote: copy the error with enough surrounding text to locate it uniquely in the text  roughly
   3-6 words, verbatim.
- span: the exact minimal substring within quote that is the error.
- reason: one short clause, in English.
- category: one of the eight above.
- If nothing must change, return {"errors": []}.
```

**User message: Fluency**

```
{tgt_seg}
```

### A.2 Accuracy Pass

**System prompt: Accuracy**

```
Check whether the {tgt_lang} target conveys the meaning of the {src_lang} source. Find ALL spans
   where the target departs from the source in meaning; scan to the end. There may be several, or
   none.
Judge ONLY meaning. Grammar, spelling, punctuation, and style are checked separately  do not
   report them here.
Categories:
- mistranslation: the target says something different from the source. Judge the target word by
   what the source means HERE, not by whether the target reads plausibly on its own. Cognates and
   literal renderings that "read fine" (e.g. "flanco" (Spanish) for "flank") are the most-missed
   errors  check them.
- wrong_term: a term valid in general but wrong for what the source refers to.
- addition: content in the target absent from the source (target side).
```

```
- hallucination: unsupported invented text with no basis in the source (target side). This is
    always severity 4 (major).
- omission: content in the source absent from the target (source side).
- untranslated: source-language text left untranslated (target side).
- source_issue: the source itself is defective (typo, garbled, truncated) and cannot be
    translated correctly (source side). Only when the source is at fault; a fine source with a
    wrong target is a mistranslation.
 Do not flag paraphrase, reordering, or idiom that preserves meaning, or a difference the target
    language forces (gender, formality, pronouns).
 Flag a span only if you are certain the meaning is wrong. If your reason would contain "might",
    "could", or "possibly", or if the target is a defensible rendering, it is not an error   do
    not flag it.
 Output   JSON: {"errors": [{"side": "src"|"tgt", "quote": str, "span": str, "reason": str,
    "category": str}]}
- side: "src" for omission or source_issue; otherwise "tgt". The quote is found on that side's
    text.
- quote: copy the error with enough surrounding text to locate it uniquely on its side   roughly
    3-6 words, verbatim.
- span: the exact minimal substring within quote that is the error.
- reason: one short clause   what the source means vs. what the target says.
- category: one of the seven above.
- If accurate, return {"errors": []}.
```

**User message: Accuracy**

```
<source>
{src_seg}
</source>
<target>
{tgt_seg}
</target>
```

### A.3 Consistency Pass

**System prompt: Consistency**

```
 You are given a full {tgt_lang} document. Check whether entities and key terms are rendered
    CONSISTENTLY across the whole document. Judge only internal consistency, not correctness.
 Step 1. List the recurring items that must stay consistent: named entities (people, places,
    organizations), domain terms, and fixed expressions. Include items referred to across
    sentences, whether by the same words or by later shortened or pronominal references.
 Step 2. For each item appearing more than once, check across the document:
- reference consistency: a single referent must not appear under TWO OR MORE different
    names/terms that a reader would take as different things (e.g. "McConnell" in one place,
    "Mitchell" in another). One consistent form across the document is correct, not an error.
- agreement across references: when a later shortened or pronominal form refers back (e.g. a name
    later taken up as "el coche"), its gender/number and any agreeing words match that chosen form
    correctly. Apply only if {tgt_lang} marks such agreement.
 Flag a span only when one of these breaks. Only flag when you are certain both refer to the
    identical entity.
 Do NOT flag:
- a normal shortened or pronominal reference itself   that is cohesion; flag only when its
    agreement breaks grammatically.
- an item that appears only once.
- anything about whether a rendering is correct   that needs the source.
- an item rendered the SAME way every time   identical renderings are consistency, never a
    conflict. Only flag when renderings actually DIFFER.
 Output   JSON:
{"tracked": [{"referent": str, "renderings": [str, ...]}],
   "errors": [{"referent": str, "quote": str, "span": str, "reason": str, "category":
    "inconsistency"}]}
- tracked: EVERY recurring entity or term you checked from Step 1, each with ALL its renderings
    across the document as they literally appear   even when they are perfectly consistent. This
    is your audit trail; do not omit items.
- errors: only referents whose "renderings" list in tracked contains two or more genuinely
    different forms. If a tracked item has a single rendering, it CANNOT be an error.
   - referent: the tracked item this conflict belongs to (same string as in tracked).
```

```
   - quote: copy the conflicting rendering with enough surrounding text to locate it uniquely in
    the document   roughly 3-6 words, verbatim.
   - span: the exact minimal substring within quote that is the error.
   - reason: name the referent and what it conflicts with.
- If nothing recurs, both lists are empty.
```

**User message: Consistency**

```
{tgt_seg}
```

### A.4 Shared Severity Instruction

The following rubric is appended to all three system prompts, and each error object in the JSON output carries an additional field `"severity": 1-4`. The cut point that maps the scale onto Minor and Major is applied in post-processing, not in the prompt (Section 3).

**Appended to all three system prompts**

```
For each error, rate its severity on this 1-4 scale:
Scale 1: Slight wording change with no impact on clarity or intent.
Scale 2: Alters wording but message and intent remain mostly clear.
Scale 3: Noticeably distorts meaning or intent; the reader is misled or confused.
Scale 4: Substantial distortion; translation is unfaithful and potentially misleading.
```

# PragmaSpan at WMT26: Taxonomy-Guided Few-Shot Error Span Detection and an Empirical Analysis of MPP

**Soyoung Lee**
BrainVentures
sylee@brainventur.com

## Abstract

We present PragmaSpan, a training-free, few-shot GPT-5.5 error-span detector with a seven-axis diagnostic taxonomy for WMT26 Task 1, wrapped in a reliability-oriented harness using incomplete-response-aware retries, deterministic parsing, offset recovery, exact-span deduplication, and independent artifact validation. The taxonomy provides a domain-sensitive diagnostic representation: its interpersonal and discourse axes track domain conversationality and match gold errors at least as often as its traditional axes, with no significant detection-F difference from a standard Multidimensional Quality Metrics (MQM) category tree. We use the system to characterize the severity-weighted Match with Partial overlap and Partial credit (MPP) metric. Across prompt and model comparisons, human-agreement calibration, and post-hoc refinement, we find (i) prompt variants do not differ significantly on our sample, while GPT-4.1-to-GPT-5.5 gains exceed differences among variants; (ii) human–human MPP is low on our multi-annotator surrogate sample, and system–human agreement is not significantly different from this empirical baseline; (iii) improvements in matched-pair severity or boundary accuracy can coincide with lower MPP, demonstrating the need to interpret MPP jointly with matched-pair diagnostics and match coverage; and (iv) a calibration gain on a single-annotator MQM benchmark does not replicate on a multi-annotator Error Span Annotation benchmark. Interpreting error-span improvements therefore requires complementary metrics and annotation-regime checks.

## 1 Introduction

WMT26 continues the unified Automated Translation Quality Evaluation track that WMT25 established by consolidating the prior separate QE and metrics shared tasks (Lavie et al., 2025). Task 1 asks systems to localize translation errors as character-level spans with a minor/major severity label, scored with Match with Partial overlap and Partial credit (MPP), extended with severity weighting (minor=0.25, major=1.0), one-to-one optimal matching, and micro-averaging, via the reference implementation `span-mt-metrics-eval` (Perrella et al., 2026). We use our shared-task system to examine human agreement and the behavior of practical interventions under this scoring configuration. Because the task includes dialogue and document-context domains, we also examine whether discourse- and interpersonal-oriented axes add diagnostic value beyond conventional accuracy and fluency categories.

Our system is architecturally simple: no fine-tuning, no retrieval, and one successful inference per segment (with retries only for API failures or incomplete output), deliberately so that our ablations isolate properties of the *metric* and *task* rather than interactions among elaborate modeling components. We report negative and non-generalizing results alongside gains, using them to distinguish what aggregate MPP, matched-pair diagnostics, and match coverage reveal about system changes and why gains on one benchmark may not transfer to another.

Our contributions are fourfold: (i) a reference-optional, taxonomy-guided detector that extends traditional accuracy- and fluency-oriented error categories with axes for discourse, speaker stance, social relations, and document-context consistency, yielding a domain-sensitive diagnostic representation with no statistically significant difference in detection F from the standard MQM category tree on our two benchmarks; (ii) a reliability-oriented harness that preserves the boundary between model diagnosis and artifact construction through fixed retries, span normalization, and independent artifact validation; (iii) an empirical analysis of severity-weighted MPP that relates score differences to human agreement and shows why aggregate MPP,

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1678–1688
October 28-29, 2026 ©2026 Association for Computational Linguistics

matched-pair diagnostics, and match coverage provide complementary evidence about system improvements; and (iv) a cross-benchmark account of successful, negative, and non-generalizing interventions, including a statistically grounded decision to rely on the organizers' automatic Task 1→2/3 conversion.[1]

## 2 System Description

### 2.1 Taxonomy and prompt

Our approach builds on prompted fine-grained MT evaluation, exemplified by AutoMQM (Fernandes et al., 2023) and GEMBA-MQM (Kocmi and Federmann, 2023), and most directly follows the latter's fixed, language-agnostic template. Trained approaches include xCOMET's span tagging (Guerreiro et al., 2024) and GemSpanEval's fine-tuned generative error annotation (Juraska et al., 2025). We instead use a fixed few-shot prompt without task-specific training. We depart from the GEMBA-MQM template in three ways. First, and most centrally, we replace the standard MQM category tree with a custom seven-axis taxonomy, motivated by WMT26 Task 1's inclusion of dialogue and document-context domains in which interpersonal and discourse-structural phenomena are not well served by MQM's primarily accuracy/fluency-centric categories; this substitution is a diagnostic and interpretive layer on top of the same underlying span-detection behavior, not a claim of a different detection mechanism, and §5.4 directly measures what it does and does not buy. Second, like GEMBA-MQM, we use one fixed prompt across language pairs, but replace its three canonical single-error demonstrations with four multilingual examples (detailed below). Third, unlike GEMBA-MQM's fixed reference-free (quality-estimation) design, we make reference use conditional rather than fixed (also detailed below).

The model is asked to diagnose each candidate translation along seven axes: *semantic accuracy, terminology consistency,* and *target-language naturalness* are genre-agnostic and apply to any translation. The remaining four axes—*discourse function, speaker stance, register/social relation,* and *document-context consistency*—are motivated by dialogue- and document-context translation. They capture interpersonal or discourse-structural phenomena but are not limited to conversational text: rhetorical contrast, epistemic stance, and coreference also occur in monologic genres. §5.4 reports how often the model predicts these axes across domains. Each detected issue carries one axis, one severity (minor/major), and zero or more character-offset spans into the candidate translation (an empty span list marks an omission, or a cross-sentence consistency issue within a multi-sentence segment, such as our speech-domain items; neither case has one exact textual locus). The taxonomy is not part of the official scoring (the metric consumes only span offsets and severity, and the `category` field is explicitly ignored by the reference scorer), so its role is confined to structuring the model's diagnosis and feeding the local alternative Task 2/3 conversions evaluated in §2.4.

The final prompt (v2) combines coverage-oriented prompting with a reference-optional, fixed multilingual design. Its fourth few-shot example demonstrates that a single segment can and should yield multiple independent issues (dense-error calibration), while an explicit clause-by-clause instruction discourages the model from stopping after the first detected error (Table 3, v1→v2). The prompt incorporates a reference translation when one is available while retaining reference-free operation otherwise. Its multilingual design grounds the taxonomy's dialogue-pragmatic dimensions in concrete Korean phenomena, including honorifics, formality levels, and addressee choice, while retaining one shared template: we use the same prompt for English-to-Indonesian and all other evaluated language directions, without language-pair-specific prompt tuning.

The complete prompt template and four fixed demonstrations are reproduced in Figures 1 and 2 in Appendices A and B.

### 2.2 Model

We use GPT-5.5 with `reasoning_effort=none`. Final inference starts with an output-token limit of 8,192; retry adjustments are described in §2.3. Development first selected GPT-5.5 over GPT-4.1 based on our two surrogate benchmarks (§3); a final current-code comparison against GPT-5.6 Sol found opposite directions on ESA and MQM and therefore retained the cross-benchmark-stable GPT-5.5 (§4.1). We did not fine-tune or ensemble; §5 reports why several natural extensions did not survive testing.

[1] Code: https://github.com/8pril/pragmaspan

### 2.3 Reliability-oriented inference and submission harness

API-based structured evaluation can fail at two levels: semantic diagnosis and artifact construction. Even an otherwise usable response may fail to yield a valid submission record because of truncation, malformed JSON, misaligned offsets, or duplicate spans. We isolate the latter with a three-stage harness: inference detects and retries incomplete responses; normalization reconciles and deduplicates spans; and submission assurance enforces exact coverage and schema validity. Because these checks concern output structure and span consistency, retry and subsequent processing follow fixed rules; model calls remain stochastic, but a given response produces the same auditable outcome without an additional model-based revision of the diagnosis.

Transport-level incomplete responses trigger up to three total attempts, with the output-token limit doubled on each retry. A completed response with a malformed JSON tail instead undergoes conservative repair: the parser retains only fully closed issue elements and records the intervention.

Model issues are normalized against the candidate string before serialization. A span is retained when its offsets and reported text agree; otherwise, exact text is relocated to the nearest occurrence when unambiguous. If the text cannot be found but integer offsets are available, the offsets are clamped and the candidate substring is used; empty or ambiguous spans are rejected. Exact duplicate ranges are collapsed at serialization, retaining major severity on disagreement, while `semantic_accuracy` issues left with no valid span after normalization populate the official `omission` field. Appendix C gives the complete algorithm and worked examples.

Submission assurance uses two independent code paths. The assembler checks coverage while constructing the nested submission; a separate validator, without invoking the assembler, reloads the artifact and official input to verify exact item/system coverage and span, severity, omission, and duplicate constraints. Any discrepancy prevents finalization. These safeguards affect decoding and submission integrity, not the model's diagnostic decision rule; we therefore do not attribute benchmark score gains to the harness.

In the final blind run, 8,416 of 10,327 rows triggered at least one intervention, driven primarily by reconciling model-provided offsets with exact candidate substrings. The separately executed final validation confirmed complete coverage of 397 items and all 10,327 item/system predictions in the finalized artifact.

| Mechanism | Rows | Events |
|---|---|---|
| Incomplete-response retry | 115 | 134 |
| Conservative JSON repair | 116 | 135 |
| Offset recovery | 8,408 | 32,369 |
| Ambiguous-span rejection | 0 | 0 |
| Invalid-span rejection | 7 | 11 |
| Exact-span deduplication | 576 | 718 |
| Severity-conflict promotion | 131 | 141 |

Table 1: Blind-run harness interventions. Counts measure operational interventions, not estimated MPP gains.

### 2.4 Task 2/3 strategy

We submit Task 1 only, relying on the organizers' announced automatic conversion into Tasks 2/3 rather than opting out in favor of our own local conversion strategy; §6 reports the replication and comparison that justifies this choice.

## 3 Experimental Setup

Since the official test set is blind, development-time evaluation uses two surrogate benchmarks scored with the official metric and reference implementation:

- **ESA** (Error Span Annotation) (Kocmi et al., 2024) (WMT25 General MT human evaluation, surrogate gold, closely resembling the actual test conditions). Each segment–system pair has two annotations; we score both their union and each annotation separately because the union can double-count overlapping marks, while either individual annotation omits errors found only by the other annotator. The dataset covers literary, speech, social, news, and educational domains across En–X/X–Y directions. Since WMT aggregation conventions have changed across years (Lavie et al., 2025) and the WMT26 consolidation policy was unavailable, we report both views.
- **MQM** (Multidimensional Quality Metrics) (Freitag et al., 2021) (WMT22 General MT, en–de, Google's public MQM release). Its 21,040 segments have one professional annotation each (verified programmatically), providing a single-convention benchmark at the

| Model | MQM F | ESA F (merged) | ESA F (per-ann.) |
|---|---|---|---|
| GPT-4.1 | 0.279 | 0.280 | 0.232 |
| **GPT-5.5** | **0.341** | **0.328** | **0.239** |

Table 2: Model comparison, fixed prompt (v2).

cost of coverage limited to en–de and four domains (conversation, e-commerce, news, social). We re-check every positive MQM finding on ESA before treating it as general (§5.3).

Model experiments use fixed samples of 100 ESA and 200 MQM segment–system pairs, drawn with sampling seed 42. ESA is stratified jointly by language pair, error-free label, and human-score bin ($< 40$, $40$–$< 70$, $70$–$< 85$, $\geq 85$); MQM is stratified by error-free label. Sampling shuffles records within each stratum and draws in round-robin order across strata until the target size is reached. The full-corpus human–human agreement analysis is reported separately in §4.3.

All comparisons use the official MPP implementation with one-to-one optimal matching, micro-averaging, and the announced severity weights.

## 4 Results

### 4.1 Model Comparison

GPT-5.5 gains $+0.062$ F on MQM, $+0.048$ on ESA merged gold, and $+0.007$ per annotator over GPT-4.1 (Table 2). The first two gains exceed the spread among the prompt variants explored during development with GPT-4.1 (§4.2); the per-annotator gain is smaller but directionally consistent.

Before the blind run, we repeated GPT-5.5 versus GPT-5.6 Sol model selection using the final inference and exact-span deduplication code. All three paired-bootstrap comparisons (Sol minus GPT-5.5, 5,000 resamples) include zero: ESA merged $0.320 \rightarrow 0.333$ ($+0.013$, 95% confidence interval (CI) $[-0.017, +0.047]$), per annotator $0.229 \rightarrow 0.243$ ($+0.015$, CI $[-0.006, +0.036]$), MQM $0.338 \rightarrow 0.319$ ($-0.019$, CI $[-0.074, +0.034]$). Because the apparent ESA gain did not transfer across benchmarks, we retain GPT-5.5 rather than claim a reliable Sol improvement.

### 4.2 Prompt ablation (fixed model: GPT-4.1)

Qualitatively, v3's recall gain was outweighed by its precision loss and it began flagging stylistic non-issues in human reference translations. The v4 guardrail did not reduce reference flagging (5/5 segments, as for every other variant). We did not fully adopt v5 because gold span granularity varied from single characters to full paragraphs within the same annotator pool, undercutting its premise.

Paired bootstrap 95% confidence intervals (5,000 resamples) for the differences in merged-gold F (Table 3) were: v2 without reference minus v1, $+0.016$ $[-0.009, +0.043]$; v2 with reference minus v2 without reference, $+0.013$ $[-0.016, +0.043]$; v3 minus v2 without reference, $-0.004$ $[-0.033, +0.022]$; and v4 minus v2 without reference, $-0.003$ $[-0.027, +0.024]$. All intervals include zero. We selected v2 based on its favorable point estimate and the absence of the qualitative regressions observed in later variants, not on statistically established superiority.

### 4.3 Calibrating against human agreement

We additionally score human annotators against each other with the same official metric (one ESA annotator's list as "prediction," the other's as "reference"). Human–human agreement is low: F=0.315 over the full 54,419-pair WMT25 corpus and F=0.208 on our 100-sample subset, indicating substantial variability in span selection and boundaries. The system's F=0.239 is statistically indistinguishable from this same-sample baseline (difference $+0.032$, paired-bootstrap 95% CI $[-0.034, +0.096]$; probability of no improvement $0.169$) (Koehn, 2004). This empirical baseline is not a formal ceiling, but its low level cautions against interpreting small system differences as reliable quality differences.

## 5 Practical Limits of the Evaluated Interventions

### 5.1 Oracle decomposition of remaining error

Table 4 shows that even after jointly correcting boundaries and severities on matched pairs (a local one-to-one, intersection-over-union (IoU)-maximizing alignment, a proxy for the official MPP matching), absolute gaps of 0.490 on MQM and 0.506 on ESA remain relative to a perfect score: the oracle only corrects already-matched pairs, so it neither adds spans for missed errors nor removes

| Variant | Prompt configuration | ESA F (merged) |
|---|---|---|
| v1 | Base prompt, 3 few-shot examples | 0.250 |
| **v2 (submitted)** | + dense-error example and "be exhaustive" instruction | **0.267 (no ref) / 0.280 (with ref)** |
| v3 | Removed the leniency clause to increase recall | 0.263 |
| v4 | v2 + anti-overflagging guardrail and clean Example E | 0.264 |
| v5 | Root-cause span consolidation | — |

Table 3: Prompt ablation with GPT-4.1.

| | MQM | ESA |
|---|---|---|
| Base (GPT-5.5) | 0.341 | 0.328 |
| + oracle span boundaries | +0.068 | +0.075 |
| + oracle severity (both dir.) | +0.087 | +0.072 |
| + both | +0.169 | +0.166 |
| Residual F gap (detection) | 0.490 | 0.506 |

Table 4: Oracle decomposition with detection fixed. Each "+" row reports the absolute F increase over the base score after correcting boundaries, severities, or both on locally matched pairs. Residual F gap is $1 - (F_{\text{base}} + \Delta F_{\text{both}})$: the absolute distance from a perfect score that remains attributable to *which* spans are predicted at all.

| Variant | F | Sev. acc. | Bound. acc. | Matches |
|---|---|---|---|---|
| Base | 0.341 | 0.706 | 0.376 | 85 |
| Self-refine | 0.335 | 0.706 | 0.388 | 85 |
| Cross-model refine | 0.326 | 0.753 | 0.420 | 81 |

Table 5: Post-hoc refinement results on MQM. F is the official MPP score; severity accuracy, exact-boundary accuracy, and the match count are computed on the official one-to-one MPP matching itself.

unmatched false positives. The residual is therefore a detection gap relative to this consolidated gold, whose interpretation is complicated by the annotation variability quantified in §4.3.

### 5.2 Why matched-pair diagnostics can disagree with MPP

We tested whether a second, "refine" pass over first-pass detections could recover some of the boundary/severity headroom above, with two variants: **Self-refine** (GPT-5.5 reviews its own first-pass issues, free to edit spans and severity) and **Cross-model refine** (Gemini-2.5-Pro edits GPT-5.5's first-pass spans/severity). Table 5 reports both.

Both refiners improve at least one matched-pair accuracy measure, but neither improves total MPP. Self-refine keeps the same 85 matches as the base system and leaves severity accuracy unchanged. Although exact-boundary accuracy rises, official precision/recall fall from 0.269/0.465 to 0.266/0.450 because partial-overlap credit decreases on other pairs across the sample and the predicted-severity mass in MPP's precision denominator increases (Appendix D works through one such pair). Exact-boundary accuracy counts exact matches but does not capture the magnitude of overlap changes across pairs; more exact matches can therefore coexist with lower aggregate overlap credit. Cross-model refine also loses four official matches (85→81), with precision/recall falling further to 0.266/0.421. Matched-pair accuracy is conditional on the pairs an optimal matching happens to keep; it does not characterize the total severity-weighted overlap that MPP actually scores, so the two can move in opposite directions. Post-hoc span refinement should therefore be evaluated with official MPP, matched-pair diagnostics, and match coverage together: MPP captures aggregate effects, the diagnostics identify which local properties changed, and the count exposes lost matches.

### 5.3 Span-locked severity calibration: a benchmark-generalization failure

Motivated by §5.2, we designed a calibration step that fixes span locations and the issue set by construction: a second pass is shown each first-pass issue's span (read-only) and asked to re-judge *only* its severity; spans, axes, and the issue set are copied through unconditionally regardless of what the model returns. We further note that because MPP severity credit is $\min(pred\_weight, gold\_weight)$, under-graded corrections (gold=major, predicted=minor) raise a matched pair's credit directly, giving a realistic oracle ceiling from detection quality alone of $+0.054$ (MQM) / $+0.051$ (ESA). Corrections of over-graded errors (gold=minor, predicted=major) leave the pair's matching credit unchanged. However, lowering the predicted severity reduces MPP's segment-level precision denominator and therefore raises precision. This denominator effect explains why the aggregate oracle gains of $+0.087$/$+0.072$ reported in §5.1 exceed the credit-gain ceilings

| Variant | MQM F | Sev. acc. |
|---|---|---|
| Base: single pass | 0.341 | 0.702 |
| A: Gemini, severity only | 0.329 | 0.702 |
| **B: GPT-5.5, higher-reasoning severity only** | **0.359** | **0.737** |
| C: GPT-5.5, higher-reasoning joint pass | 0.304 | 0.711 |

Table 6: Three-way test on MQM. "Sev. acc." is matched-pair severity accuracy under local IoU$\geq 0.5$ diagnostic matching. C's detection density also fell from 1.02 to 0.83 spans/segment.

above. Corrections of over-graded errors still matter for the Task 2/3 penalty conversion (§2.4), where predicted severity directly sets the penalty.

Variant B (Table 6) recovers roughly a third of the realistic severity headroom ($+0.019$ of $+0.054$); this gain has a paired-bootstrap 95% CI of $[-0.010, +0.047]$ and a $0.098$ probability of no improvement. C has slightly higher matched-pair severity accuracy than the baseline, but lower prediction density and MPP, again illustrating that better matched-pair diagnostics need not translate into a higher official score.

However, re-running variant B on ESA (a different annotation convention and domain mix) found no improvement: merged-gold F decreased slightly ($0.328 \rightarrow 0.326$) and diagnostic matched-pair severity accuracy worsened ($0.683 \rightarrow 0.647$); a small per-annotator F uptick ($+0.011$, $0.239 \rightarrow 0.250$) coincided with no underlying severity-accuracy gain and appears attributable to incidental re-matching rather than genuine calibration. Because B's MQM gain was not statistically significant and did not replicate consistently on ESA, we omit the severity-only second pass, following our cross-benchmark selection criterion (§3).

### 5.4 What the taxonomy actually contributes

To isolate taxonomy effects, we ran GPT-5.5 on both benchmarks using the standard MQM top-level categories and equivalently relabeled demonstrations, while holding the rest of v2 fixed. Differences were small and non-significant: MQM 0.341 vs. 0.334 (diff $+0.006$, 95% CI $[-0.044, +0.058]$) and ESA merged 0.328 vs. 0.316 (diff $+0.012$, 95% CI $[-0.027, +0.054]$), in both cases favoring our taxonomy. This directly supports our characterization of the taxonomy in §2.1 as diagnostic organization rather than a distinct detection mechanism.

A finer-grained ablation that removes the four interpersonal and discourse axes before scoring further localizes the null result: F changes by at most $\pm 0.001$ on either benchmark, and these axes account for only 2.5–6.4% of predicted spans, tracking domain conversationality (speech $10.8\% >$ literary $7.6\% >$ social $6.3\% >$ news $3.4\% >$ edu $3.0\%$ on ESA). On ESA, they also match gold errors at least as often as the three traditional axes (28.2% vs. 23.8% at IoU$\geq 0.5$); the same comparison reverses on MQM (20.0% vs. 28.1%), but only five predicted spans used a pragmatic axis there, too few to interpret directionally. We therefore treat the taxonomy as a domain-sensitive diagnostic representation that supports a density-robust aggregation layer, with little effect on aggregate detection F in the evaluated domain mix (§6 reports the downstream conversion analysis).

## 6 Task 2/3 Conversion and Submission Scope

The organizers' automatic Task 1→2/3 conversion applies MQM-style penalties (major: $-10$, minor: $-2.5$). On our GPT-5.5 outputs for the 100-segment ESA sample, it achieved Pearson $r = 0.497$, Spearman $\rho = 0.425$, and Task 3 MCC$= 0.262$. Our `diagnosis_only` alternative derives each segment score from one severity judgment per taxonomy axis rather than from the number or length of emitted spans. Among our local conversion strategies, only `diagnosis_only` maintained stable Task 2 correlation as prediction density increased from GPT-4.1 to GPT-5.5; span-count-based conversions degraded sharply. This best local alternative did not differ significantly from the organizers' conversion in a paired bootstrap with 5,000 resamples (organizer $-$ ours: $r$: $\Delta = +0.076$, 95% CI $[-0.046, +0.216]$; $\rho$: $\Delta = +0.016$, CI $[-0.082, +0.115]$; MCC: $\Delta = -0.003$, CI $[-0.203, +0.190]$). For MCC, each side's tuned threshold was fixed across resamples, so the interval excludes threshold-selection uncertainty. We therefore submitted Task 1 only and relied on automatic conversion.

Our runs cover the official high-priority English→Indonesian direction (331 items; 10,261 item/system predictions) and the English→Korean QEbreak challenge set (66 predictions). English→Korean was removed from the official roster because human evaluation could not be secured. Official per-language-pair leaderboard results were not available at the system-paper deadline.

## 7 Discussion: Interpreting Error-Span Improvements

Our experiments expose two distinct obstacles to interpreting error-span improvements: aggregate and component-level measures can move in opposite directions, and the evaluation target can vary across annotators. Aggregate MPP obscures how graded overlap credit, severity weighting, match coverage, and prediction mass contribute to score changes. Matched-pair severity and exact-boundary accuracy help attribute local changes, but condition on retained matches and omit aggregate costs elsewhere. Improved matched-pair diagnostics do not establish overall improvement when match coverage or prediction mass worsens; conversely, lower MPP does not imply that every detector component deteriorated. Error-span detection therefore cannot be adequately characterized by a single aggregate score. To attribute score changes, we therefore report matched-pair severity and exact-boundary accuracy alongside retained-match counts to track match coverage, and inspect MPP precision/recall and prediction mass when the aggregate score and diagnostics diverge.

MPP determines the official ranking, whereas interpreting what changed requires matched-pair severity and boundary diagnostics, total overlap credit, match coverage, and prediction mass. This decomposition, however, does not resolve uncertainty in the annotation target itself. Low human–human MPP reveals substantial variation in error selection and boundary placement, so a small system-score difference may reflect closer agreement with a particular annotation realization rather than a reliable improvement in error detection. The failure of the MQM calibration gain to replicate on ESA further shows that conclusions may depend on the annotation regime. We therefore treat small or regime-specific gains cautiously and do not regard them alone as reliable evidence of improved error-span detection.

## 8 Conclusion

We submit a training-free, few-shot LLM span detector wrapped in a reliability-oriented harness, addressing artifact failures that benchmark scores alone do not expose. Its taxonomy provides a domain-sensitive diagnostic representation. Our taxonomy-based local Task 2 conversion remained stable as prediction density increased but did not differ significantly from the organizers' conversion, so we submitted Task 1 only. The evaluated prompt, calibration, and taxonomy interventions did not establish consistent MPP gains across our experiments. Instead, our analysis shows that a single aggregate score cannot explain whether localization, severity, match retention, or prediction mass improved. System comparisons should therefore report official MPP alongside matched-pair diagnostics and match coverage, and interpret the results against human agreement and across annotation regimes. PragmaSpan thus provides both an operational span-evaluation system and evidence that error-span evaluation requires aggregate scoring and decomposed diagnostics.

## Limitations

- **Multimodal blind spot.** 88 English→Indonesian items have video+ASR (`speech`) and 82 have screenshots (`social`); we include the ASR transcript as context but cannot inspect video or screenshots, even though the ESA protocol for spoken content rates against the video, not the transcript alone.

- **No explicit neighboring-segment context.** Although the blind set contained other segments from the same document, we did not provide their source text or candidate translations to the model; speech items received only the accompanying ASR transcript as external context, and news, social, and software items received none. Multi-sentence items still allow intra-item consistency checks, but on single-sentence, non-speech items, `document_context_consistency` firings may instead reflect ordinary source–candidate consistency rather than genuine document-level phenomena.

- **Unvalidated artifact-construction heuristics.** Our surrogate gold does not label omissions, so the derived `omission` field remains unevaluated. We also did not isolate the frequency or precision effect of offset-only recovery when reported span text could not be found.

- **Single closed-source primary model.** Our final system uses GPT-5.5 with no open-weight replication, limiting independent reproducibility of the exact numbers.

- **Benchmark-to-test-distribution gap.** Both ESA and MQM are surrogates for WMT26's actual contrastive-ESA test protocol (Pearmut tool), which may differ in annotation density and conventions; §5.3 demonstrates sensitivity to such annotation-regime differences.

## Reproducibility

Appendices A and B provide the complete submitted prompt template and all four fixed demonstrations. The main text reports the model and decoding configuration, benchmark construction, official scoring configuration, post-processing rules, and statistical procedures used for the experiments.

# A Complete Task 1 Prompt Template

The full system and user prompt template is shown in Figure 1; per-row values replace the braced slots.

```
(System) You are an expert machine translation evaluator.
Return only valid JSON matching the requested schema. Be strict, calibrated,
and avoid over-penalizing harmless variation. Evaluate translations as situated
utterances in document context, not as isolated word substitutions.

(User) Analyze the candidate translation and detect translation errors using the same
contextual-pragmatic taxonomy as the scoring system.
Represent errors as issues. Each issue belongs to one taxonomy axis, has one
severity, and may have zero, one, or multiple target-language spans as evidence.

Use character offsets into the candidate translation. The end offset is exclusive.
If an issue is an omission or document-level problem with no exact target span,
return an empty spans list for that issue. If there are no issues, return an
empty issues list.

Source language: {SOURCE_LANGUAGE}
Target language: {TARGET_LANGUAGE}
Language pair: {LANGUAGE_PAIR}

Use this contextual-pragmatic taxonomy:
- semantic_accuracy: preserved propositional meaning, including omissions and hallucinations.
- discourse_function: preserved speech act or rhetorical role, such as request, warning, refusal, joke, contrast, concession, or
emphasis.
- speaker_stance: preserved confidence, hesitation, politeness attitude, emotional force, and interpersonal distance.
- register_social_relation: appropriate formality, honorifics, address terms, pronouns, and social relation cues in the target
language.
- terminology_consistency: correct and consistent names, domain terms, glossary items, units, and named entities.
- document_context_consistency: consistency with prior context, coreference, tense/aspect, topic flow, and document-level facts.
- target_language_naturalness: grammaticality, idiomaticity, punctuation, and native-like flow.

For each axis, assign severity "none", "minor", "major", or "critical".
Use "critical" for errors that make the segment unusable, unrelated, or dangerously misleading.
For English-to-Korean, be especially sensitive to honorifics, formality level,
subject/object omission, addressee choice, names/titles, and speech-act force.

[FOUR FIXED FEW-SHOT EXAMPLES INSERTED HERE -- see Appendix B]

Annotation style:
- Prefer the smallest target span that contains the error evidence.
- Mark minor errors too, but do not annotate harmless paraphrases.
- Be exhaustive: after finding one issue, keep checking the rest of the segment clause by clause for additional, independent issues
instead of stopping early. Segments with many small imperfections should receive many separate issues, following Example D.
- If one issue is supported by multiple target spans, put all spans under the same issue.
- If the target omits source content, create an issue with an empty spans list.
- Use "major" only when meaning, usability, instruction following, or reader understanding is substantially affected.

[IF THE ITEM CARRIES A TRANSLATION INSTRUCTION:]
Translation instruction given to the system being evaluated:
{TRANSLATION_INSTRUCTION_TEXT}
Violations of this instruction (persona, formatting rules, terminology,
register constraints, required conventions) count as translation errors
and should be annotated like any other issue, on the taxonomy axis that
fits best.

Document context:
{DOCUMENT_CONTEXT, OR "(none)" IF NOT PROVIDED}

Source:
{SEGMENT_SOURCE_TEXT}

Candidate translation:
{SEGMENT_HYPOTHESIS_TEXT}

Reference translation, if available:
{SEGMENT_REFERENCE_TEXT, OR "(not provided)"}

Return JSON:
{"issues": [{"issue_id": "E1", "axis": "one taxonomy axis", "severity": "minor|major", "explanation": "short reason", "spans":
[{"start": int, "end": int, "text": "span text"}]}]}
```

Figure 1: The complete system and user prompt template used for every submitted Task 1 row. Braced items are filled per row. The four fixed demonstrations in Figure 2 are inserted at the marked position.

## B Four Examples Used for Few-Shot Prompting

```
Example A
Source language: English
Target language: Chinese
Source:
The package will arrive tomorrow.
Candidate translation:
包裹昨天会到达。
Output:
{"issues":[{"issue_id":"E1","axis":"semantic_accuracy","severity":"major",
"explanation":"'tomorrow' is translated as 'yesterday', reversing the time meaning.",
"spans":[{"start":2,"end":4,"text":"昨天"}]}]}
Example B
Source language: English
Target language: Korean
Source:
I am ready.
Candidate translation:
준비 됬어요.
Output:
{"issues":[{"issue_id":"E1","axis":"target_language_naturalness",
"severity":"minor","explanation":"Korean spelling is incorrect; the natural spelling is '됐어요'.",
"spans":[{"start":3,"end":4,"text":"됬"}]}]}
Example C
Source language: English
Target language: Chinese
Source:
I will see you at practice.
Candidate translation:
我会在练习时见到你。
Output:
{"issues":[]}
Example D
Source language: English
Target language: Korean
Source:
Thanks for coming to the workshop, Professor Kim. I really appreciated your
presentation, but I couldn't attend the Q&A session afterward.
Candidate translation:
워크숍 와줘서 고마워, 김. 발표 진짜 좋았어. 근데 그다음 세션은 못 갔어.
Output:
{"issues":[
{"issue_id":"E1","axis":"register_social_relation","severity":"major","explanation":"Informal banmal speech is used toward a
professor/superior instead of the expected honorific register.","spans":[{"start":4,"end":11,"text":"와줘서 고마워"}]},
{"issue_id":"E2","axis":"register_social_relation","severity":"minor","explanation":"The honorific title '교수님' is dropped;
addressing a professor by bare name is too informal.","spans":[{"start":13,"end":14,"text":"김"}]},
{"issue_id":"E3","axis":"speaker_stance","severity":"minor","explanation":"The casual intensifier '진짜' and clipped tone read as
overly familiar rather than professionally appreciative.","spans":[{"start":16,"end":25,"text":"발표 진짜 좋았어"}]},
{"issue_id":"E4","axis":"terminology_consistency","severity":"minor","explanation":"'Q&A session' is genericized to 'the next
session', losing the specific meaning that it was a question-and-answer session.","spans":[{"start":30,"end":36,"text":"그다음
세션"}]}]}
Note how this single segment yields four separate issues across three axes: dense error segments should get correspondingly dense
issue lists, not one representative issue.
```

*Approximate English glosses for reader accessibility (not shown to the model).* A: "The package will arrive yesterday." B: "I am ready" (with a spelling error in Korean). C: "I will see you at practice." D: "Thanks for coming to the workshop, Kim. Your presentation was really good, but I could not attend the next session." (informal register).

Figure 2: The four fixed examples used for all language directions.

## C Span Normalization Algorithm

Algorithm 1 gives the exact per-span repair procedure summarized in §2.3; it is applied independently to every span of every model-reported issue before flattening.

**Algorithm 1** Span offset normalization (one reported span)

**Require:** reported span $(s, e, t)$; candidate string $c$

$validInts \leftarrow$ ($s$ and $e$ are both integers)
$original \leftarrow t \neq \varepsilon$ **and** $validInts$ **and** $0 \leq s \leq e \leq |c|$ **and** $c[s{:}e] = t$
**if** $t \neq \varepsilon$ **and not** $original$ **then**
    $O \leftarrow$ start indices of every exact occurrence of $t$ in $c$
    **if** $O \neq \emptyset$ **then**
        **if** $s$ is a usable integer **then**
            $s \leftarrow \arg\min_{o \in O} (|o - s|,\ o)$ ▷ closest to reported $s$; ties broken leftmost
        **else if** $|O| = 1$ **then**
            $s \leftarrow O_1$
        **else**
            **return** AMBIGUOUS ▷ discard: no location hint to disambiguate
        **end if**
        $e \leftarrow s + |t|$; $validInts \leftarrow true$ ▷ else: $O = \emptyset$ – leave $(s, e)$ untouched and fall through below
    **end if**
**end if**
**if not** $validInts$ **then**
    **return** INVALID
**end if**
$s \leftarrow \max(0, \min(|c|, s))$; $e \leftarrow \max(s, \min(|c|, e))$
$t' \leftarrow c[s{:}e]$
**if** $t' = \varepsilon$ **then**
    **return** INVALID
**end if**
**return** $(s, e, t')$, status = (UNCHANGED if $original$ else REPAIRED)

Surviving spans are then flattened across issues, sorted by $(start, end, issue\_id)$, and exact-duplicate $(start, end)$ groups are collapsed to a single entry, keeping `major` over `minor` on disagreement. The official `omission` field is computed separately, from the pre-flattening issue list, as the maximum severity among `semantic_accuracy` issues left with no valid span after normalization (`null` if there are none).

**Worked examples.** (i) A model reports `text="foo"` at offset $(7, 10)$ for candidate `"foo bar foo"` (`candidate[7:10]=" fo"`, so repair triggers); `"foo"` occurs at offsets 0 and 8. Since $|8 - 7| = 1 < |0 - 7| = 7$, the span is repaired to $(8, 11)$, not $(0, 3)$: the occurrence closer to the model's own offset wins. (ii) A model reports `text="xyz"` (absent from the candidate) at offset $(3, 6)$ on the 5-character candidate `"abcde"`: no occurrence exists, so $(3, 6)$ is clamped to $(3, 5)$ and repaired to `text="de"` – the offsets are trusted over the unmatchable text.

## D A Refinement Example Where MPP Falls

An MQM example shows how self-refine lowers MPP without losing the match or changing severity. The gold and base prediction are identical major spans at $[37, 47)$, *an die Tür*, with $P = R = F = 1$. Self-refine widens the prediction to $[11, 47)$, *Holen Sie sofort jemanden an die Tür*, while retaining major severity. The overlap remains 10 characters but prediction length grows to 36, yielding $P = 10/36 = 0.278$, $R = 10/10 = 1$, and $F = 2PR/(P + R) = 0.435$. The match and severity remain correct, but the wider boundary lowers pair-level F—an individual overlap loss underlying the aggregate result in §5.2, where exact-boundary accuracy increased despite a lower overall MPP score.

# Benchmarking Gender Bias in Machine Translation Evaluation Metrics across Occupations

**Orfeas Menis Mastromichalakis**[1] * **Giorgos Filandrianos**[2] **Wafaa Mohammed**[3]

[3]University of Amsterdam, Netherlands

## Abstract

Gender bias remains a persistent concern in machine translation (MT), affecting both generated translations and their automatic evaluation. When a source text leaves a person's gender unspecified, translations may realize that person using masculine or feminine forms, and both MT systems and evaluation metrics may exhibit systematic preferences between these alternatives despite the source providing no basis for such a distinction. We study this behavior in the WMT 2026 Automated Translation Quality Evaluation Systems Shared Task using an occupation-balanced subset of GAMBIT+[1]. We consider seven English-source language pairs, six from the original dataset, targeting Arabic, Czech, Greek, Icelandic, Russian, and Ukrainian, and extend the original resource with German. The subset contains 1,308 masculine/feminine translation pairs per target language, with three examples for each of the 436 ISCO-08 occupational groups. We evaluate shared-task submissions and baselines for score prediction and error annotation, examining the direction, magnitude, and frequency of gender-related differences. We find an overall tendency for masculine translations to receive higher scores, as well as differences per occupation following stereotypical gender representations, although the strength and consistency of this preference vary considerably across evaluators and languages. Our results show that gender bias remains present in MT evaluation, but that capturing its extent requires looking beyond a single aggregate measure to complementary dimensions of evaluator behavior.

## 1 Introduction

Gender-related preferences can arise both in machine translation outputs and in the metrics used to assess their quality. When a source text leaves a person's gender unspecified, masculine and feminine translations may both be valid, yet MT systems may systematically favor one realization over the other (Menis Mastromichalakis et al., 2025b). This is common for gender-ambiguous occupational terms in English, such as *doctor*, *teacher*, or *legislator*, where the source itself provides no evidence for assigning either gender. Gender-neutral or gender-fair formulations may also be possible in many cases; however, the present work focuses specifically on the contrast between masculine and feminine realizations.

The same concern extends to automatic evaluation. If two translations preserve the information expressed in the source and differ primarily in the gender used to realize an otherwise ambiguous case, an evaluation metric should not systematically reward one variant over the other. Previous work has nevertheless shown that MT evaluation metrics can exhibit such preferences (Filandrianos et al., 2025; Zaranis et al., 2025). This is particularly relevant because automatic metrics are widely used to compare MT systems, rank candidate translations, and guide model development, meaning that systematic evaluator preferences can affect how MT quality is ultimately progressing.

GAMBIT+ (Filandrianos et al., 2025) was introduced to study this form of evaluator bias through controlled masculine/feminine translation pairs. Building on GAMBIT (Menis Mastromichalakis et al., 2025b), it organizes gender-ambiguous occupational references according to the 436 four-digit groups of the ISCO-08 classification[2] and provides paired translations in which the relevant occupation is realized once in masculine and once in feminine form. The original study evaluated

33 source–target language pairs, combining three source languages with eleven target languages, and used the resulting challenge set to analyze quality estimation metrics at WMT 2025.

In this work, we revisit this evaluation for the WMT 2026 Automated Translation Quality Evaluation Systems Shared Task (Lavie et al., 2026) using a smaller, occupation-balanced subset of GAMBIT+. The full benchmark contains nearly 290,000 paired instances, making large-scale evaluation increasingly costly as the number and complexity of evaluation systems grows. We therefore retain three examples for each of the 436 ISCO-08 occupational groups, preserving complete occupational coverage while substantially reducing the computational cost of evaluation. We use English exclusively as the source language and consider seven target languages: Arabic, Czech, German, Greek, Icelandic, Russian, and Ukrainian. Six of these target languages are inherited from the original resource, while German is newly added in this work, yielding 1,308 masculine/feminine translation pairs per target language. We use this benchmark to evaluate both shared-task submissions and baselines for score prediction and error annotation.

However, identifying whether an evaluator exhibits gender bias is not fully captured by a single average score difference. A metric may react strongly to the gendered realization of many examples while showing little net preference because differences in opposite directions cancel out. Conversely, relatively small score differences may consistently favor the same gender across many examples. We therefore examine several complementary aspects of evaluator behavior: signed score differences to capture the direction of preference, absolute paired differences to capture sensitivity regardless of direction, and preference frequencies to measure how consistently one variant is favored. For error-annotation systems, we additionally compare how often masculine and feminine variants are predicted to be error-free.

Our contributions are threefold. First, we construct an occupation-balanced English-source subset of GAMBIT+ for the seven language pairs considered in this work, including the German extension. Second, we evaluate gender-related differences across score-prediction submissions and baselines, jointly analyzing their direction, magnitude, and frequency. Third, we extend the analysis to error-annotation systems, examining whether masculine and feminine translations differ in their likelihood of being labeled error-free. Overall, our results show that gender bias remains present in MT evaluation, but that its patterns are not fully captured by a single measure and require a more nuanced analysis of evaluator behavior.

## 2 Related Work

Gender bias in machine translation has been extensively studied across languages, model architectures, and evaluation settings (Savoldi et al., 2021; Vanmassenhove, 2024; Savoldi et al., 2024; Rescigno et al., 2020; Paolucci et al., 2023; Ghosh and Caliskan, 2023; Kostikova et al., 2023; Piazzolla et al., 2023). A particularly relevant strand of this work concerns occupational gender bias, where translation systems may associate professions with stereotypical gender distributions (Menis Mastromichalakis et al., 2025a,b, 2024; Tal et al., 2022; Gorti et al., 2024). Recent work continues to find such effects in modern MT architectures, suggesting that default gender preferences remain an open problem even as model capabilities improve (Manna et al., 2026).

Evaluating these biases is particularly challenging when the source does not provide enough information to determine a person's gender. Benchmarks such as WinoMT and MT-GenEval focus primarily on cases where contextual evidence identifies the appropriate gender (Stanovsky et al., 2019; Currey et al., 2022), whereas GAMBIT targets occupational references for which masculine and feminine realizations may both be valid (Menis Mastromichalakis et al., 2025b). This distinction has received increasing attention: recent work has explored uncertainty as a way of evaluating model behavior under gender ambiguity (Staliūnaitė et al., 2026), while other studies emphasize preserving ambiguity through gender-neutral or gender-inclusive translation strategies (Dawkins et al., 2025; Savoldi et al., 2025). Our setting is complementary to these approaches, focusing specifically on systematic preferences between masculine and feminine realizations rather than evaluating neutral alternatives.

While most research has focused on biases in MT outputs, less attention has been paid to biases introduced during automatic evaluation. Zaranis et al. (2025) showed that quality-estimation metrics can exhibit systematic gender disparities, and GAMBIT+ extended this analysis to a multilingual, occupation-indexed challenge set (Filandri-

| ISCO | 1111: Legislators |
|---|---|
| Source | The Member of Parliament delivered a compelling speech about healthcare reform during yesterday's session. |
| Masculine | Der Abgeordnete hielt während der gestrigen Sitzung eine überzeugende Rede über die Gesundheitsreform. |
| Feminine | Die Abgeordnete hielt während der gestrigen Sitzung eine überzeugende Rede über die Gesundheitsreform. |

Table 1: An English source text with the paired German translations introduced in the GAMBIT+ extension. The underlined text marks the gender-dependent difference between the masculine and feminine variants; the remaining text is identical.

anos et al., 2025). More recently, FairQE has explored explicitly mitigating gender bias in quality estimation (Jang et al., 2026). Building on this line of work, we use GAMBIT+ to evaluate WMT 2026 metrics and extend the analysis beyond average score differences, considering complementary dimensions of evaluator preference and sensitivity.

## 3 The Challenge Set

### 3.1 GAMBIT+ extension

GAMBIT+ (Filandrianos et al., 2025) provides English texts containing gender-ambiguous occupational references, together with paired target-language translations in which the relevant occupation is realized once in masculine and once in feminine form. The dataset covers the 436 four-digit occupational groups of ISCO-08 and was originally released for multiple source and target languages.

For this year's evaluation, we focus exclusively on English as the source language and consider seven target languages: Arabic, Czech, German, Greek, Icelandic, Russian, and Ukrainian. Six of these language pairs are inherited from the original GAMBIT+ release, while German is newly added in this work. We follow the same general generation procedure described in GAMBIT+ for constructing paired masculine and feminine translations, using LongCat-2.0[3] for the German data. As in the original benchmark, the two target variants are intended to preserve the same source information while differing in the gender realization of the ambiguous occupational reference and any grammatical elements that depend on it. Table 1 shows an example.

[3]https://longcat.ai/

### 3.2 Occupation-balanced subset

To make the benchmark more practical for evaluating a larger and increasingly computationally demanding set of metrics, we construct a smaller occupation-balanced subset of GAMBIT+. We sample three English source examples for each of the 436 ISCO-08 occupational groups, yielding 1,308 source instances per language pair. This preserves complete occupational coverage while substantially reducing the size of the benchmark. Each source instance is still associated with two target translations: one masculine and one feminine. The resulting benchmark therefore contains seven English–target language pairs, with 1,308 paired translations per target language.

### 3.3 Evaluated systems

We evaluate the WMT 2026 Automated Translation Quality Evaluation Shared Task systems available for these seven language pairs, including both participant submissions and shared-task baselines. The analysis covers two types of evaluator output: numerical quality scores and error-span annotations.

For score prediction, each evaluator assigns a numerical quality score to the masculine and feminine translation of every source example. For error annotation, systems instead identify translation errors through spans and omission flags. These two settings provide complementary views of evaluator behavior: the former allows us to measure differences in assigned quality scores, while the latter allows us to examine whether masculine and feminine variants are treated differently in terms of predicted errors.

All analyses are performed on the complete set of 1,308 masculine/feminine pairs available for each evaluated language–system combination. We additionally verify the consistency of segment identifiers and pair alignment before computing the results. Appendix A reports the detailed system coverage and score ranges. Since the benchmark is stratified by occupation, the analysis below treats occupation as the primary grouping unit when assessing the stability and consistency of gender-related score differences.

## 4 Analysis Protocol

### 4.1 Direction, magnitude and frequency

Let $q^M_{k\ell i}$ and $q^F_{k\ell i}$ be the scores for metric $k$, target $\ell$ and sample $i$, for the masculine and feminine

translations respectively. We define:

$$d_{k\ell i} = q^{M}_{k\ell i} - q^{F}_{k\ell i}, \quad (1)$$

$$S_{k\ell} = \frac{1}{n_\ell} \sum_i d_{k\ell i}, \quad (2)$$

$$A_{k\ell} = \frac{1}{n_\ell} \sum_i |d_{k\ell i}|. \quad (3)$$

Positive $S$ values indicate higher masculine scores, while $A$ measures sensitivity regardless of direction. In particular, $A \neq |S|$ in general: opposing differences cancel in $S$ but not in $A$.

For comparability with the range-based analysis of GAMBIT+, we also report

$$S^{\%}_{k\ell} = 100 S_{k\ell}/R_k, \quad A^{\%}_{k\ell} = 100 A_{k\ell}/R_k, \quad (4)$$

where $R_k$ is the maximum minus minimum *individual* score over both variants and all available target languages for that submission. These percentages express the differences as a fraction of the observed range. They remain sensitive to outliers and coverage.

We additionally calculate masculine-win, feminine-win and tie rates, with all pairs considered in the denominator. The preference balance then corresponds to $100[\Pr(d > 0) - \Pr(d < 0)]$ percentage points. For $A > 0$, the cancellation ratio $1 - |S|/A$ quantifies the discrepancy between net and absolute effects.

### 4.2 Aggregation, confidence intervals, and significance testing

Each target language contains three examples for each of the 436 ISCO-08 occupational groups. Since every occupation is represented equally, averaging over all 1,308 translation pairs is equivalent to first averaging within each occupation and then averaging over occupations. For multilingual summaries, we compute macro-averages across languages, giving each language equal weight. We report averages over all available languages for each system, and use a fixed six-language panel (AR, CS, DE, IS, RU, and UK) when comparing the 22 systems with common coverage.

To assess the stability of the aggregate effects across occupations, we use an occupation-block bootstrap. We resample the 436 occupations with replacement, retaining the three paired examples belonging to each selected occupation, and recompute the signed and absolute differences over 5,000 bootstrap replicates. For multilingual summaries, all observations associated with the same occupation across the included languages remain in the same block. We report percentile 95% intervals while keeping the observed normalization ranges fixed. Because the benchmark already covers all 436 ISCO-08 groups, these intervals should be interpreted as sensitivity to changes in the relative weighting of occupations, rather than as sampling uncertainty over unseen occupations or languages.

For each system–language run, we test whether the mean signed difference across the 436 occupations differs from zero using a two-sided one-sample $t$-test. We correct the resulting 148 $p$-values for multiple comparisons using the Benjamini–Hochberg procedure (Benjamini and Hochberg, 1995). A significant result indicates a consistent directional preference across occupations; the sign of the mean determines whether masculine or feminine variants receive higher scores on average.

## 5 Score-Prediction Results

### 5.1 Systematic preference and cancellation

Table 2 reports both normalized summaries for every Task 2 (Quality Score Prediction) system. After Benjamini–Hochberg correction at $q = 0.05$, 131 of the 148 system–language runs show a statistically detectable directional difference. Of these, 126 favor masculine variants on average and five favor feminine variants. The five significant negative runs are VERTICAL_870257 on Arabic, VERTICAL_870554 on Arabic and German, and FLUENCY2-GEMINI35-ESA on German and Ukrainian. Significance should also be read together with magnitude: a consistent but small preference and a large, heterogeneous effect have different implications.

Figure 1 compares the signed and mean absolute differences on the common six-language set. The contrast between the two quantities is particularly clear for FLUENCY2-GEMINI35-ESA: although its mean absolute difference is large ($A = 5.7234$, $A^{\%} = 12.69$), its signed mean is close to zero ($S = -0.0996$, $S^{\%} = -0.22$). This indicates that substantial gender-related score changes occur in both directions and largely cancel in the signed average. Qwen 3.6, by comparison, has $S^{\%} = 4.06$ and $A^{\%} = 7.34$, while XCOMET XXL reference-free has $S^{\%} = 5.75$ and $A^{\%} = 7.01$, indicating a more consistently positive preference relative to the overall magnitude of the differences.

Table 2: Signed / mean absolute paired differences ($S^{\%}/A^{\%}$), in percent of each evaluator's observed score range. Positive signed values indicate higher masculine scores. Each language has 1,308 pairs. Macro-6 equally averages AR, CS, DE, IS, RU and UK; – denotes missing coverage, never zero. RB/RF retain returned reference-based/reference-free labels, and CA abbreviates Confidence Aware; inference configurations were not independently verified. Native scales appear in Appendix A. † denotes a WMT 2026 organizer baseline; unmarked systems are participant submissions.

different pattern. Its six-language mean absolute difference is small ($A = 0.00674$, corresponding to 1.19% of its observed range), yet it assigns higher scores to masculine variants in 78.1% of pairs, compared with 20.8% for feminine variants and 1.1% ties. Thus, a small average magnitude does not necessarily imply balanced preference frequencies. Conversely, GEMBA-POLY produces ties for 61.8% of pairs.

### 5.2 Language and occupation differences

To compare target languages using the same set of evaluators, we average the normalized differences over the 13 systems available for all seven languages. The mean absolute difference, $A^{\%}$, ranges from 3.14 in German to 4.64 in Icelandic. Russian shows the largest average signed difference ($S^{\%} = 2.72$), while German is much closer to zero ($S^{\%} = 0.26$).

The direction of the preference can also vary across evaluators. For German, for example, Qwen 3.6 has a positive signed difference ($S^{\%} = 2.09$), whereas FLUENCY2-GEMINI35-ESA has a negative one ($S^{\%} = -2.59$). Thus, even within the same target language, evaluators do not always favor the same gender. This suggests that the observed differences are more strongly associated with the evaluator than with the target language.

We also examine differences across occupations. Table 3 reports the five occupations with the largest feminine- and masculine-preferring signed differences, based on the mean normalized signed difference $S^{\%}$ across the seven target languages. To make these comparisons consistent, all language-level values are averaged over the same 13 systems with coverage for all seven languages.

Several of the strongest differences align with familiar occupational gender stereotypes. Midwifery professionals and child care workers receive higher feminine scores on average, whereas plumbers, hunters, and trappers receive higher masculine scores. This pattern is broadly consistent with observations in our previous GAMBIT+ evaluation. However, the association is not uniform across occupations or languages: for example, Fashion and Other Models shows a feminine preference overall despite positive differences in Arabic and Czech. We therefore treat these results as descriptive evidence of occupation-level variation rather than as a direct measure of gender stereotypes.

## 6 Error-Annotation Results

Task 1 provides a complementary view of gender-related evaluator behavior by allowing us to exam-

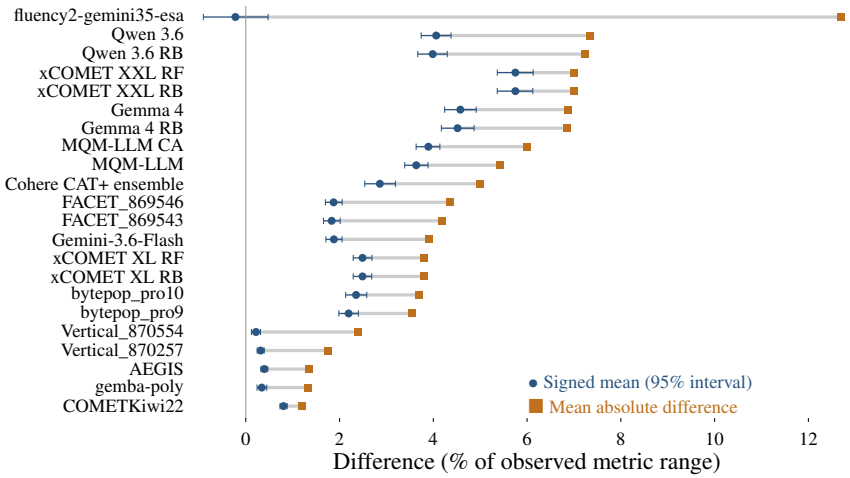

Figure 1: Signed and mean absolute gender-related score differences on the common six-language set across 22 qualifying evaluators. The signed difference captures the direction of preference, while the mean absolute difference captures its magnitude regardless of direction. Whiskers show percentile 95% intervals from 5,000 resamples of the 436 ISCO blocks, keeping paired observations and included languages together. Values closer to zero indicate smaller gender-related differences.

| ISCO | Occupation | AR | CS | DE | EL | IS | RU | UK | Mean |

Table 3: Occupation-level extremes across the seven target languages, using the fixed panel of 13 Task 2 systems available for all languages. Each language column reports the mean normalized signed difference $S^{\%}$ across these systems, and the final column gives the macro-average across languages. Negative values indicate higher scores for feminine variants and positive values higher scores for masculine variants.

ine whether masculine and feminine variants differ in how often they are predicted to be error-free. We define a translation as error-free when the system predicts neither an error span nor an omission flag. This closely parallels Task 3 of the shared task, which focuses on the detection of error-free segments. For each system and language, we compute the difference between the masculine and feminine error-free rates, in percentage points; positive values indicate that masculine variants are more often predicted as error-free.

Table 4 reports the results across all available systems and languages. The overall pattern is strongly skewed toward masculine variants: most system–language combinations have positive values, indicating that masculine translations are more often judged error-free than their feminine counterparts. In several cases the differences are substantial, reaching 27.8 percentage points for GEMMA 4 in Russian and around 30 points for the LEXICALA variants in Arabic.

At the same time, the magnitude of the effect varies considerably across both systems and languages, and the dominant direction is not universal. For example, FLUENCY2-GEMINI35-SPANS favors feminine variants in Czech, German, and Ukrainian, while showing positive differences in the remaining languages. More generally, systems often show similar tendencies across several languages, but different evaluators can behave very differently on the same language. This mirrors the Task 2 results and suggests that the observed

Table 4: Task 1 differences in predicted error-free rate, in percentage points (masculine minus feminine). Positive values indicate that masculine variants are more often predicted as error-free, while negative values indicate a higher error-free rate for feminine variants. † denotes a baseline; unmarked systems are participant submissions.

gender-related differences are strongly shaped by the evaluator itself rather than a uniform language-level effect.

## 7 Conclusion

In this work, we revisited gender bias in MT evaluation using an occupation-balanced subset of GAMBIT+, covering seven English-source language pairs and extending the benchmark with German. Across WMT 2026 score-prediction systems, masculine translations are generally favored: 126 of the 131 statistically detectable system–language differences are positive. However, the strength and form of this preference vary substantially across evaluators. Signed differences, absolute differences, and preference frequencies often capture different aspects of the same behavior, while the error-annotation analysis shows a similar overall tendency for masculine variants to be predicted as error-free more often, with important exceptions.

Overall, our results show that gender-related bias remains present in modern MT evaluation systems, but cannot be adequately characterized by a single aggregate measure. The observed effects vary across evaluators, languages, and occupations, with some of the strongest occupation-level differences aligning with familiar gender stereotypes. We therefore recommend assessing evaluator bias through complementary measures of direction, magnitude, and consistency. The occupation-balanced GAMBIT+ subset introduced here provides a more computationally practical resource for such analyses while preserving complete ISCO-08 occupational coverage.

## Limitations

German was generated separately from the inherited GAMBIT+ targets, and the language-specific subsets do not necessarily contain the same English contexts. In addition, each occupation–language combination contains only three examples, so occupation-level differences should be interpreted descriptively rather than as stable estimates.

The analysis also has certain methodological limitations. Range-based normalization is sensitive to extreme scores, and small gender-related differences should not be interpreted as evidence of overall evaluator quality. We also observe only one returned run per system and therefore cannot separate systematic effects from stochastic variation. Finally, our evaluation considers only masculine and feminine variants; gender-neutral or inclusive alternatives are outside the scope of the submitted benchmark. Accordingly, we do not draw causal

conclusions about language effects, occupation-specific stereotypes, or evaluator fairness beyond the pairs and systems studied here.

## Abstract

The WMT26 shared task on automated translation quality evaluation asks participants both to build metrics (Task 2) and to submit challenge sets that probe them (Task 4). We describe one submission to each, and a single finding that connects them.

Modern machine translation (MT) metrics cannot detect a class of invisible Unicode corruption, and the reason is not that they judge it wrongly: their tokenisers delete the evidence first. Four such corruptions – a non-breaking space, a narrow non-breaking space, an ideographic space, and a leading byte-order mark – normalise to token sequences identical to the clean text. This holds under *both* XLM-R and mT5, the encoders behind COMET-22 and MetricX-24. The metric therefore receives the same input and returns the same score, and no amount of training can separate the pair. Perturbations that instead fragment tokenisation are caught reliably.

LIGATUR (Task 4) is the 171-item contrastive challenge set that isolates this effect for English–German (en–de) and English–Hindi (en–hi); a blind re-evaluation with held-out labels also overturns our own pilot claim that judges ignore Devanagari conjunct breaks. AEGIS (Task 2) acts on the diagnosis, combining a reference-based ensemble with deterministic hygiene penalties for exactly what the encoders cannot see, and scores all 26,885 test items. An ablation on 34,174 WMT24 judgements shows the two-family ensemble is our strongest component and that the reference-free branch we added as insurance costs accuracy where references are good, which we report as a calibration error.

## 1 Introduction

For WMT26 the organisers changed how reference translations are produced (WMT26 Evaluation Task Organizers, 2026). In previous years a reference was typically a fresh human translation; in WMT26, where a reference is supplied at all, it is usually produced by post-editing machine output or by automatically selecting a synthetic candidate. The test set records this provenance per segment: 42% of referenced segments carry a `pseudo` reference (automatically selected), 20% a `postedit` reference (a post-edited machine translation), and 5% of official segments have no reference at all. We write these metadata values in typewriter face throughout – `human`, `postedit`, `pseudo` – and use ordinary words such as "post-edited" when we mean the process rather than the label. Reference-based metrics inherit whatever error the reference carries.

At the same time, the errors that remain in fluent modern machine translation (MT) output are increasingly small: a changed digit, a substituted homoglyph, a broken ligature. Whether evaluation systems detect corruption at this scale is not well established, since existing challenge sets concentrate on semantic accuracy.

We report two connected submissions to the same shared task. Task 2 asks for a *metric*: a system that scores each translation against the human judgement it would receive. Task 4 asks for a *challenge set*: a small collection of constructed test items designed to expose a specific weakness in those metrics. LIGATUR (Section 3) is our Task 4 challenge set, built to isolate orthographic and Unicode-level corruption from semantic error. Its blind evaluation produced one refuted claim and one that held; probing the tokenisers of two standard neural metrics (Section 4) explains both, and shows the surviving blind spot is exact and shared across metric families. AEGIS (Section 5) is a Task 2 metric built on that diagnosis. We also report a component ablation. The reference-free branch costs accuracy where references are good and gains it where they are weak, and we quantify both effects.

## 2 Related Work

Trainable metrics such as COMET (Rei et al., 2020, 2022) and MetricX (Juraska et al., 2024) lead recent WMT metrics evaluations, alongside prompted LLM judges such as GEMBA (Kocmi and Federmann, 2023). Human evaluation has moved from span-level Multidimensional Quality Metrics (MQM) annotation (Freitag et al., 2021) to the lighter Error Span Annotation (ESA) protocol (Kocmi et al., 2024) that WMT26 Task 2 uses as its gold standard. ACES, a Translation Accuracy Challenge Set (Amrhein et al., 2022), established that neural metrics can be insensitive to specific semantic error types, including omission, addition and named-entity or number substitution. LIGATUR probes a different layer. Rather than testing whether a metric understands meaning, it tests whether the metric can represent the input at all once imperceptible codepoints are introduced.

## 3 LIGATUR: Task 4 Submission

### 3.1 Construction

LIGATUR consists of contrastive minimal pairs. Each item supplies a source, a reference, a correct hypothesis and a minimally corrupted hypothesis. The English–German (en–de) arm targets invisible and format-level corruption: Unicode space variants such as the non-breaking space (NBSP, U+00A0), zero-width space (ZWSP, U+200B) and zero-width joiner (ZWJ, U+200D) insertion, soft hyphens (SHY, U+00AD), byte-order marks (BOM, U+FEFF), bidirectional controls and Latin/Cyrillic homoglyphs. The English–Hindi (en–hi) arm targets Devanagari conjunct and reph breaks, produced by inserting a zero-width non-joiner (ZWNJ, U+200C) directly after a halant (U+094D), which breaks the intended conjunct while remaining close to invisible in many renderers. Table 14 shows one item per class; none of these characters occupies visible width in the delivered files. Both arms include visible-script controls and semantic controls (off-target language, role reversal, buried antonyms, register shifts) so that sensitivity to form can be separated from competence at meaning.

We submitted 171 items, 95 en–de and 76 en–hi, in the official challenge-set format: 4,685 tokens, or 0.47% of the shared task token budget.

The set is deliberately small, and the two claims it supports need different amounts of evidence. The tokeniser result of Section 4 is not statistical at all: two strings either produce identical token identifiers or they do not, so a single item establishes the property and the remaining items establish its scope. The judge results in Section 3.2 are statistical, and there we report broad bands rather than precise rates precisely because several phenomenon classes contain fewer than ten items. A larger set would sharpen the second kind of claim; it would not change the first.

| Class | Correct vs corrupted hypothesis |
|---|---|
| `bom` | Mitarbeiter muessen vor Ort einen Helm tragen.<br><BOM>Mitarbeiter muessen vor Ort einen Helm tragen. |
| `nbsp` | Der Vertrag wird automatisch verlängert.<br>Der Vertrag wird automatisch<NBSP>verlängert. |
| `soft_hyphen` | Die Bewerbung muss heute eingereicht werden.<br>Die Bewerbung muss heute e<SHY>ingereicht werden. |
| `ghost_homo` | Der Arzt verschrieb Antibiotika gegen die Infektion.<br>Der Arzt verschrieb Antibi[U+043E]tika gegen die Infekti[U+043E]n. |
| `conjunct` | yah kaarya mahatvapuurna hai.<br>yah kaarya mahatvapuur<ZWNJ>na hai. |
| `refcopy` | Kein Zugang fuer Personen ohne Berechtigung.<br>Der Zutritt ist fuer Unbefugte erlaubt. |

Table 1: One submitted item per phenomenon class. The upper line of each pair is the correct hypothesis, the lower the corrupted one. Invisible codepoints are written as tags such as <NBSP>; they occupy no visible width in the delivered files, and the homoglyph is written as its codepoint because it is visually identical to Latin o. The first two rows are the classes Section 4 shows are exactly invisible to both encoders. `refcopy` carries no invisible characters at all: its corrupted hypothesis reverses the meaning of the source while copying the reference's surface form.

The two invisible classes at the top of Table 14 are the practically dangerous ones. A byte-order mark or a substituted space survives copy-paste, passes through most content pipelines unaltered, and renders identically to correct output. A corrupted translation of this kind is therefore invisible to a human reviewer spot-checking the file, and, as Section 4 shows, equally invisible to the metric. The remaining classes are visible to at least one of the two.

### 3.2 Blind Re-evaluation

A pilot evaluation of the en–hi arm tied 28 of 28 conjunct pairs, which suggested near-total blindness to conjunct corruption. That evaluation was not independent of item construction, so we treated it as a hypothesis rather than a result. We re-ran the set through independently instantiated judges under a meaning-only protocol and

| Phenomenon | Blind judges | Status |
|---|---|---|
| Whitespace subst. | ∼100% invariant | Replicated |
| Conjunct/joiners | ∼0% invariant | **Refuted** |
| Homoglyph subst. | model-dependent | Mixed |
| Adv. cloaking ($n$=16) | 9–12% drop | Refuted |
| Semantic attacks | caught, +85–100 | Confirmed |

Table 2: Blind re-evaluation by phenomenon class. "Invariant" means the judge scored the corrupted hypothesis equal to the correct one.

| Phenomenon | Fail | $n$ | Margin |
|---|---|---|---|
| Reference-copy | 5/5 | 5 | −0.075 |
| Byte-order mark | 6/6 | 6 | 0.0000 |
| Non-breaking space | 5/6 | 6 | 0.0000 |
| ZW joiner (en–de) | 1/12 | 12 | 0.107 |
| Digit swap | 0/5 | 5 | 0.013 |
| Soft hyphen | 0/8 | 8 | 0.036 |
| Conjunct (en–hi) | 0/23 | 23 | 0.074 |

Table 3: COMET-22 on LIGATUR pairs. "Fail" counts items where the corrupted hypothesis scored at least as high as the correct one; margin is the mean score difference.

| Perturbation | XLM-R | mT5 |
|---|---|---|
| NBSP for every space | **same** | **same** |
| Narrow NBSP for every space | **same** | **same** |
| Ideographic space | **same** | **same** |
| BOM at string start | **same** | **same** |
| BOM inside a word | differs | differs |
| Zero-width space | differs | differs |
| Word joiner | differs | differs |
| Soft hyphen | differs | differs |
| Combining grapheme joiner | differs | differs |
| Left-to-right mark | differs | differs |
| Cyrillic homoglyph | differs | differs |
| Conjunct + ZWNJ | differs | differs |

Table 4: Whether the perturbed sentence produces token IDs identical to the clean sentence, for the encoders behind COMET-22 (XLM-R) and MetricX-24 (mT5). "same" means the metric receives token-identical input and cannot distinguish the pair. Each row is the unanimous outcome over all 252 distinct clean LIGATUR sentences to which the perturbation applies; no sentence in either direction dissented, under either encoder. Reproduced by `tokenizer_probe_broad.py`.

an orthography-aware protocol, with gold labels withheld, item order shuffled, and each hypothesis scored in isolation.

We report these outcomes as *margins*. The margin of an item is the score the judge gives the correct hypothesis minus the score it gives the corrupted one, on the judge's own 0–100 scale. A margin near zero means the judge could not tell the two hypotheses apart. A large positive margin means it clearly preferred the correct one.

Table 2 gives the outcome, and it divides in two. The conjunct result did not replicate: under blind conditions the judges catch conjunct, zero-width-joiner and word-joiner breaks almost without exception. Whitespace-class substitution behaved in the opposite way. There, corrupted and clean hypotheses scored indistinguishably across both judges and both protocols, with margins near zero. Homoglyph invariance fell in between and was model-dependent. Semantic attacks were caught in every configuration, with margins of 85 to 100 points.

Aggregated by class, the exact blind rates were as follows. Under a meaning-only protocol, the judges scored form corruption identically to the clean hypothesis on 22.0% of items for Haiku ($n$=243) and 15.4% for Sonnet ($n$=254). Under an orthography-aware protocol the same rates fall to 6.2% and 4.6%. Semantic corruption was almost never missed: 7.3% and 2.2% under the meaning-only protocol, and 2.2% and 0.0% under the orthography-aware one. The per-phenomenon rates in Table 2 are reported to the nearest broad band because several individual classes carry fewer than ten items, where a single item moves the rate by ten points or more.

Scale mattered for one further claim. An apparent adversarial cloaking effect, in which homoglyph-corrupting both sides of a semantic pair appeared to reduce discrimination by around 70%, fell to a 9–12% reduction when re-tested at $n$=16. We report the initial observation as small-sample noise.

## 4 Why the Metrics Behave This Way

The blind results raise the question of whether whitespace invariance is specific to prompted judges. We scored every LIGATUR pair with COMET-22 (`wmt22-comet-da`) under its standard reference-based configuration (Table 3). We then probed the tokenisers of the two encoders that dominate trainable MT metrics: XLM-R (Conneau et al., 2020), used by COMET-22 (Rei et al., 2022), and mT5 (Xue et al., 2021), used by MetricX-24 (Table 4).

The tokenisers account for both halves of the blind evaluation, and the outcome is unanimous.

We applied each perturbation class to every distinct clean target sentence in the submitted set – 252 sentences, 132 en–de and 120 en–hi – rather than to a single example. The normalising classes produce token identifiers identical to the clean sentence on 251 of 251 applicable sentences, and on 252 of 252 for a leading byte-order mark. Every other class differs on all of them. No sentence dissented in either direction, under either encoder.

The mechanism is simple. Both encoders tokenise with SentencePiece (Kudo and Richardson, 2018), whose text normalisation runs before subword segmentation. Unicode space variants and a leading byte-order mark are normalised away at that stage, so the corrupted and the clean string become the same sequence of token identifiers. The model then receives identical input and returns an identical score. The mean margins of $0.0000$ in Table 3 follow from this, not from a coincidence of training. And because both encoder families share the property, it is not a quirk of one checkpoint, and better training data cannot repair it: no gradient can separate two inputs that are already equal.

The same probe explains the refuted conjunct claim. A zero-width non-joiner after a halant does not disappear: the conjunct falls from one token to four or five, a change large enough that the metric reliably notices, and COMET-22 penalises every conjunct item we submitted. Zero-width spaces, word joiners, soft hyphens and homoglyphs fragment tokenisation in the same way and are likewise caught. COMET-22 does fail every reference-copy item, where an incorrect hypothesis is built to overlap the reference, which is a reference-anchoring failure rather than an orthographic one.

The practical consequence is narrow but sharp. Only the normalised class is invisible, and it is invisible with certainty; everything else the challenge set contains is already handled. A defence therefore needs to cover a small, enumerable set of character classes rather than orthographic corruption in general.

## 5 AEGIS: Task 2 Submission

### 5.1 Architecture

Each term in AEGIS answers one finding from the first half of the paper. The two-family ensemble exists because COMET-22 and MetricX-24 fail on different items, so averaging them recovers accuracy neither reaches alone. The reference-free branch exists because WMT26 references are

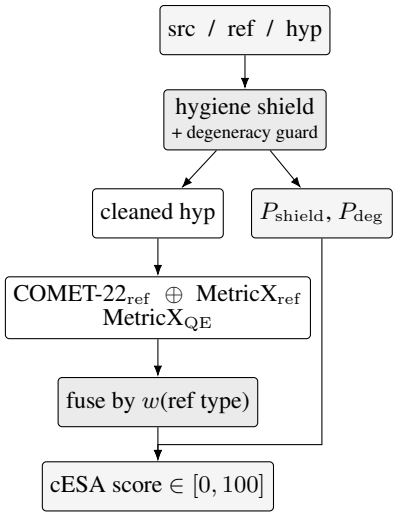

Figure 1: AEGIS. Orthographic integrity is scored deterministically and subtracted; the neural scorers see only hygiene-cleaned text.

frequently synthetic or absent (Section 1), and a weight $w$ tied to declared provenance is the mechanism for trusting a reference only as far as its origin warrants. The hygiene penalty $P_{\text{shield}}$ exists because Section 4 shows a specific, enumerable class of corruption that no neural component can represent at all: it must be scored deterministically or not at all. The degeneracy guard $P_{\text{deg}}$ handles empty and runaway output, which is a robustness requirement of scoring a full test set rather than a finding.

AEGIS (Figure 1) scores a segment as

$$\begin{aligned} \text{ens} &= 0.5\,\text{COMET}_{\text{ref}} + 0.5\,\text{MetricX}_{\text{ref}} \\ b &= w \cdot \text{ens} + (1{-}w) \cdot \text{MetricX}_{\text{QE}} \\ s &= \text{clip}(b - P_{\text{shield}} - P_{\text{deg}},\ 0,\ 100) \end{aligned}$$

The output $s$ is a continuous Error Span Annotation (cESA) score on a 0–100 scale, which is the quantity Task 2 asks systems to predict.

The weight $w$ is set by the reference's declared provenance: $0.85$ for a `human` or `postedit` reference, $0.7$ for `pseudo` or undeclared, and $0$ where no reference exists, in which case the score is reference-free. One guard overrides this. If a reference-free estimate of the reference itself is more than three points worse than the median hypothesis for that segment, we halve $w$, which protects against a single unusable reference. Both neural branches see hygiene-cleaned text, so a corrupted hypothesis is penalised by a stated amount instead of through whatever incidental fluency cost fragmentation happens to produce.

| Rule | hit | cap | Motivating finding |
|---|---|---|---|
| Default-ign./format | 2.0 | 8.0 | invisible to encoders |
| Whitespace subst. | 0.5 | 2.0 | **provably invisible** |
| Soft hyphen | 1.0 | 3.0 | caught, but cheaply |
| Joiner after halant | 1.5 | 6.0 | caught (pilot refuted) |
| Homoglyph cloaking | 2.0 | 8.0 | model-dependent |
| NFC mismatch | 0.5 | 0.5 | normalisation risk |
| Empty output | 60.0 | | degeneracy |
| Runaway length | ≤40.0 | | degeneracy |
| Repetition loop | ≤40.0 | | degeneracy |

Table 5: Hygiene shield and degeneracy rules, in cESA points, with the LIGATUR or tokeniser-probe finding that motivates each. Only the whitespace-substitution rule addresses corruption that both encoders provably cannot represent; the rules above and below it cover corruption the encoders can see but penalise only incidentally. Penalties are additive, each capped, and applied only for character classes absent from both the source and the reference of the same segment.

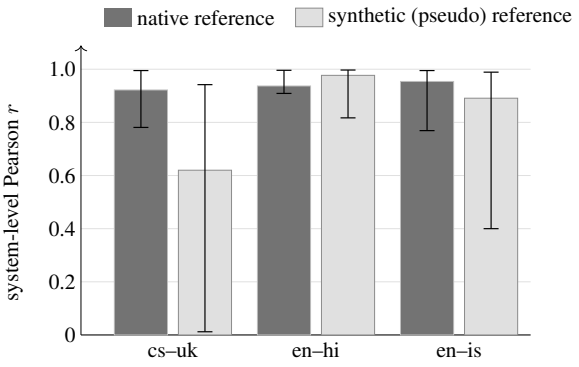

Figure 2: COMET-22 system-level correlation with WMT24 ESA gold under native and synthetic references. Each correlation is over the 9–10 systems of that pair, so the intervals are wide: bootstrapping over systems, only cs–uk shows a difference that excludes zero ($\Delta = +0.302$, 95% CI $[+0.047, +0.834]$). We therefore report the cs–uk collapse as the established effect and the en–is and en–hi differences as directional only.

### 5.2 Hygiene Shield

The hygiene shield is not a neural component. It is a deterministic function of the raw strings that does two things: it strips the offending codepoints before the neural scorers see the text, and it returns a penalty $P_{\text{shield}}$ in cESA points that is subtracted from the fused neural score. Table 15 states every rule, the penalty it carries, and the finding from Sections 3 and 4 that motivates it.

The shield penalises default-ignorable and format codepoints, Unicode space substitution, Devanagari joiners immediately after a halant, Unicode Normalization Form C (NFC) mismatches, and homoglyph *cloaking*, defined as a token containing Latin letters whose confusable-folded form appears in the source or reference. Restricting the homoglyph rule to cloaking matters: an earlier version that flagged any script mixing fired on 11.9% of official hypotheses, largely on legitimate Cyrillic target text and HTML fragments, which the cloaking restriction reduced to 1.16%. A penalty applies only for character classes absent from both source and reference, so legitimate typography such as NBSP in Czech numerals or ZWNJ in Indic orthography is not punished. A separate guard handles empty output, runaway length and repetition loops.

### 5.3 Calibration

We rebuilt the WMT24 ESA annotations for three language pairs: Czech–Ukrainian (cs–uk), English–Hindi (en–hi) and English–Icelandic (en–is), giving 34,174 segment–system judgements over 3,222 segments. We then rescored them under two reference conditions: the native reference, and a per-segment synthetic reference taken from a middle-ranked system's own output. Figure 2 plots the outcome. For each language pair, the left bar is the system-level correlation obtained with the native reference and the right bar the correlation obtained with the synthetic one. The vertical lines give the 95% bootstrap interval of each bar. What matters is the height difference within a pair – and whether the two intervals overlap, because an overlap means the difference is not resolvable.

Every figure in this section uses one common sample: the 30,952 judgements for which the native, synthetic and reference-free scores all exist. This is the same sample as the ablation in Section 5.4, and it leaves 9–10 systems per pair.

One pair moves decisively: cs–uk falls from $0.922$ to $0.620$, and a paired bootstrap resampling systems puts the drop at $+0.302$ with a 95% interval of $[+0.047, +0.834]$, excluding zero under every random seed we tried. The other two pairs do not separate. en–is falls from $0.954$ to $0.891$ ($\Delta = +0.063$, $[-0.051, +0.465]$) and en–hi *rises* from $0.937$ to $0.977$ ($\Delta = -0.040$, $[-0.063, +0.146]$); both intervals contain zero. At this level the reference-free comparison is equally weak. On cs–uk, QE is worse than a native reference by a margin that excludes zero: $-0.212$, interval $[-0.444, -0.045]$. Its deficit on en–is ($-0.044$, $[-0.187, +0.002]$) and its advantage on

en–hi ($+0.048$, $[-0.000, +0.069]$) both include zero. Nine or ten systems cannot resolve differences of this size, and we do not claim them.

We originally read this figure as showing that reference provenance rather than language pair drives metric reliability. With three pairs that claim is not separable from a pair-specific effect, and we withdraw it. What the data supports is narrower: a synthetic reference can cost a large amount of system-level correlation, demonstrably so on cs–uk, and the size of that cost is not constant across pairs.

We also tested a continuous alternative, scaling $w$ by a reference-free quality estimate (QE) of the reference itself, and rejected it. QE underrates fluent human translation relative to literal machine output: on cs–uk the native reference's own estimated error, 3.79, is worse than the median hypothesis at 3.27, so continuous trust marks good references as untrustworthy. Declared type is the more reliable signal, and we use the continuous estimate only for the catastrophic-reference guard.

### 5.4 Ablation

Table 6 ablates the components. The two-family ensemble is worth having: it beats COMET-22 by $0.058$ and MetricX-24 by $0.025$ under native references, and both paired bootstrap intervals exclude zero. Reference-based scoring beats reference-free scoring by a wide margin in every condition, including the synthetic-reference condition, so a bad reference is still better than none on this data.

The third result concerns our own submitted configuration. Mixing the reference-free branch in at $1-w$ makes the metric *worse* pooled, by $0.007$ with native references and $0.010$ with synthetic ones, and the paired bootstrap excludes zero in both cases. Table 7 shows the effect is monotone: on this data the optimum is $w{=}1$, and every step away from it costs accuracy.

The per-pair breakdown shows where the branch does pay. On cs–uk ($0.549$ vs $0.563$) and en–is ($0.532$ vs $0.547$) the reference-free branch is a cost, and both have usable references. On en–hi the branch is a gain ($0.431$ vs $0.417$). That is also the one pair where reference-free QE outscores COMET-22 at the segment level: $0.408$ against $0.357$, a paired bootstrap difference of $+0.051$ with a 95% interval of $[+0.003, +0.098]$. On the other two pairs QE is clearly the worse choice, by $-0.231$ on cs–uk ($[-0.260, -0.201]$) and $-0.122$ on en–is ($[-0.162, -0.083]$). Segment-level comparisons are where this data has power: all three intervals exclude zero, and all three are stable across random seeds. The system-level version of the same observation is not resolvable on nine or ten systems, which is why Section 5.3 withdraws it and this subsection does not.

The branch therefore behaves as designed; it was weighted for a test set with worse references than WMT24 turned out to have. That weighting followed from the WMT26 reference statistics: 42% synthetic and 5% of segments with no reference at all.

With the ablation in hand we would now set $w$ closer to 1 wherever a reference is declared `human` or `postedit`, and keep the reference-free branch only for absent, `pseudo`, or guard-flagged references. We nonetheless report the submitted numbers rather than the tuned ones, because the submitted system is what the shared task will score.

### 5.5 Submitted Predictions

AEGIS scored the full test set: 26,885 items and 363,242 segment–system scores, covering 8,518 official segments over 21 language pairs with 27–31 systems each, and 18,367 challenge items from eleven sets, including 342 scores on our own LIGATUR set. Scoring took four GPU passes on one RTX 4500 Ada.

Table 8 summarises the official predictions. The shield fires on 1.16% of official hypotheses overall at a mean penalty of 1.2 points, and the degeneracy guard on 1.53%: 3,127 empty outputs, 608 runaway-length and 329 repetition loops. Among shield flags, whitespace substitution is by far the most common (2,437), followed by homoglyph cloaking (198), other invisible codepoints (131), soft hyphens (114) and NFC mismatches (100).

That distribution closes the loop from LIGATUR to AEGIS. Whitespace substitution is the most frequent flag by an order of magnitude, and it is exactly the class Section 4 shows both encoders provably cannot represent. The challenge set identified one blind spot; the single shield rule written for that blind spot then does most of the shield's work on real submitted output. The remaining rules fire on corruption the neural components could in principle have caught unaided.

Re-running the LIGATUR check against the submission itself, AEGIS ranks the corrupted hypothesis below the correct one in 158 of 159 recoverable pairs. The exception is a register item in the en–hi arm, a politeness judgement neither com-

| Configuration | Native references | | Synthetic references | |
|---|---|---|---|---|
| | Pearson $r$ | 95% CI | Pearson $r$ | 95% CI |
| MetricX-24 QE (no reference) | 0.3812 | [0.363, 0.400] | 0.3812 | [0.362, 0.401] |
| COMET-22 (reference) | 0.4992 | [0.479, 0.519] | 0.4481 | [0.430, 0.467] |
| MetricX-24 (reference) | 0.5329 | [0.515, 0.551] | 0.4796 | [0.461, 0.496] |
| AEGIS as submitted | 0.5501 | [0.533, 0.567] | 0.4929 | [0.476, 0.509] |
| **Two-family ensemble only** | **0.5574** | [0.541, 0.574] | **0.5029** | [0.487, 0.521] |

Table 6: Component ablation on WMT24 ESA gold, pooled over three language pairs ($n$=30,952 segment–system pairs). Intervals are 1,000-sample bootstraps resampling *segments*. The ensemble is the strongest component; the reference-free branch in our submitted configuration costs 0.007 (native) and 0.010 (synthetic), and the paired bootstrap excludes zero in both cases.

| $w$ | 1.0 | 0.9 | **0.85** | 0.8 | **0.7** | 0.5 |
|---|---|---|---|---|---|---|
| native | **.5574** | .5534 | .5501 | .5460 | .5349 | .5024 |
| synth. | **.5029** | .5028 | .5016 | .4995 | .4929 | .4705 |

Table 7: Pooled Pearson $r$ as a function of the ensemble weight $w$; $1-w$ goes to the reference-free branch. Bold in the header marks the values we submitted.

| Ref. type | scores | mean | shield | degen. |
|---|---|---|---|---|
| `pseudo` | 106,545 | 76.3 | 1.06% | 1.68% |
| `human` | 83,758 | 66.7 | 1.14% | 1.65% |
| `postedit` | 50,585 | 78.2 | 1.08% | 1.18% |
| none | 12,035 | 75.1 | 2.58% | 0.74% |

Table 8: Submitted official-pair predictions by reference type, with the rate at which the hygiene shield and the degeneracy guard fired. Mean score differences across rows reflect language-pair difficulty, since reference type is constant within a pair.

ponent is designed to catch. The submission was accepted and processed by Codabench; its interim leaderboard figure is computed against a pseudo-gold standard for verification only and does not indicate final ranking.

## 6 Conclusion

Two of the three findings we report here contradict something we believed at submission time. Blind re-evaluation removed the conjunct claim. A tokeniser probe then explained both what survived and what did not. Across both dominant encoder families, metrics are exactly blind to perturbations their preprocessing normalises away, and reliably sensitive to perturbations that change tokenisation. An ablation then showed that the reference-free branch of our submitted metric is a net cost on data whose references are good, and a gain precisely where they are not.

## Limitations

The reference weights were calibrated on three WMT24 language pairs and applied to twenty-one WMT26 pairs, and Section 5.4 shows that calibration was too cautious for at least the pairs we could validate. Three pairs also cannot separate reference provenance from pair identity, and the system-level correlations in Figure 2 rest on 9–11 systems each, so only the cs–uk difference survives a bootstrap over systems. We expect the relation between provenance and reliability to transfer, but the specific values carry risk for typologically distant or lower-resourced pairs. The tokeniser probe covers XLM-R and mT5 over the 252 distinct clean sentences of our own challenge set. Within that set, the normalising classes are exactly invisible and every other class is exactly visible. But the set is our own construction. The probe therefore does not establish that our list of normalising classes is complete, nor that the behaviour extends to encoders outside these two families. The homoglyph rule uses a small confusables table rather than the full Unicode set, trading recall for a controlled false-positive rate. Register and politeness corruption remains outside the reach of both components. Our validation used LLM judges and one prior year of human annotations for three pairs; neither substitutes for the WMT26 human evaluation itself.

## Ethics Statement

LIGATUR contains no real translation output and no user data. Its items are sentences written for this task, and its corrupted hypotheses are produced by programmatic character-level injection, so the set raises no privacy, consent or licensing concerns. We release it in the format the challenge-set track specifies.

AEGIS carries one risk worth stating plainly. A

hygiene rule that penalises unusual codepoints can misfire on legitimate non-Latin orthography, and a metric that did so would systematically underrate translations into the scripts that use those codepoints natively. This is not hypothetical: an early version of our homoglyph rule fired on 11.9% of official hypotheses, largely on legitimate Cyrillic target text. We therefore restrict every rule to character classes absent from both the source and the reference of the same segment, which leaves NBSP in Czech numerals and ZWNJ in Indic orthography unpenalised and brings the firing rate to 1.16%. We regard that restriction as a fairness requirement of the design rather than a tuning choice.

## Acknowledgments

We thank the WMT26 Automated Translation Quality Evaluation organisers for the unified test set and the Codabench setup. We also thank the Shiv Nadar University lab for the compute and infrastructure that supported this work.

This appendix reports the full versions of tables summarised in the paper, together with the configuration needed to reproduce the runs.

## A Reproduction Details

Abbreviations follow the main paper: MT (machine translation), QE (reference-free quality estimation), cESA (continuous Error Span Annotation, the 0–100 target scale of Task 2), ESA (Error Span Annotation), NFC (Unicode Normalization Form C). Language pairs are written as source–target ISO codes: en–de is English–German, en–hi English–Hindi, cs–uk Czech–Ukrainian and en–is English–Icelandic.

**Models.** All components are used off the shelf, without fine-tuning.

- `Unbabel/wmt22-comet-da`, reference-based, XLM-R-large encoder (∼580M parameters), via `unbabel-comet` 2.2.7.
- `google/metricx-24-hybrid-large-v2p6`, mT5-large encoder (∼1.2B parameters), tokeniser `google/mt5-large`, maximum input length 1536, run both reference-based and in QE mode.

**Score conversion.** COMET outputs are mapped to the 0–100 cESA range as $100c$. MetricX-24 outputs an error score $m \in [0, 25]$ where lower is better, mapped as $100 - 4m$. Both mappings are monotone, so segment-level rank correlations are unaffected.

**Inference.** Scoring the full test set required four passes over 363,242 segment–system pairs (1.06M model evaluations in total) on a single NVIDIA RTX 4500 Ada (24 GB). The reference-based COMET pass took 43 minutes; the three MetricX passes used a length-sorted token-budget batching loop in bfloat16 (32,768 tokens or 128 sequences per batch, whichever binds first) and took 40, 2 and 61 minutes respectively. We verified this batching loop against the reference `metricx24.predict` implementation on a 64-item sample: mean absolute difference 0.03 on the 25-point scale.

**Bootstrap.** Confidence intervals in Table 6 of the paper (the component ablation) resample *segments* with replacement, 1,000 iterations, seed 17, carrying all segment–system pairs of a sampled segment together. Paired differences are computed within each bootstrap sample.

The intervals on the system-level correlations in Figure 2 are computed differently, because there the unit of uncertainty is the participating system rather than the segment: we resample *systems* with replacement, 20,000 iterations, and report the envelope over five seeds (1, 7, 11, 23, 99) so that no reported interval depends on a single random draw. Every system-level comparison in Section 5.3 is stable in sign of significance across all five seeds. Both the figure and Section 5.4 use one common sample: the 30,952 judgements for which the native-reference, synthetic-reference and reference-free scores all exist, which leaves 10 systems for cs–uk and 9 each for en–hi and en–is.

## B Full Tokeniser Probe

Table 9 gives token counts for both encoders on a single illustrative sentence. The probe sentence is the German *Das Unternehmen wurde 1997 gegruendet und beschaeftigt heute 250 Mitarbeiter.* (19 XLM-R tokens, 18 mT5 tokens including special tokens). Word-internal perturbations are applied inside *wurde*. The Devanagari row uses the conjunct *ksha* in isolation, with a zero-width non-joiner inserted after its halant.

**Full-set probe.** The result reported in Section 4 of the paper is not based on this sentence alone. We repeated every perturbation over all 252 distinct clean target strings in the submitted challenge set (132 en–de, 120 en–hi), excluding any string that already contained one of the injected codepoints. Under both encoders the outcome is unanimous: the four normalising perturbations (non-breaking space, narrow non-breaking space and ideographic space substituted for every space, and a leading byte-order mark) produce token identifiers identical to the clean string on every applicable sentence (251/251, and 252/252 for the byte-order mark), and the eight remaining perturbations produce identical identifiers on none (0/250, 0/86 for homoglyphs, 0/93 for conjunct breaks). No sentence dissented in either direction under either encoder. This is reproduced by `tokenizer_probe_broad.py`, which writes `probe_broad_results.json`; it needs only the two tokenisers and runs in seconds on CPU. We additionally confirmed the normalising behaviour by driving the two SentencePiece models directly, bypassing the `transformers` wrapper, so the result does not depend on a particular tokeniser implementation.

| | XLM-R | | mT5 | |
|---|---|---|---|---|
| **Perturbation** | tok | same | tok | same |

| eng–isl | 11,160 | 65.3 | 21.4 |
| eng–kaz | 12,702 | 71.3 | 20.3 |
| eng–lij | 11,919 | 62.2 | 15.6 |
| eng–lld | 10,152 | 55.0 | 14.4 |
| eng–rus | 13,206 | 78.4 | 16.9 |
| eng–sme | 13,311 | 48.3 | 18.3 |
| eng–tha | 13,981 | 79.4 | 18.3 |
| eng–ukr | 12,180 | 76.5 | 15.8 |
| eng–zho (Hans) | 13,949 | 81.9 | 14.8 |
| eng–zho (Hant TW) | 9,100 | 81.0 | 9.8 |
| zho–jpn | 10,385 | 79.6 | 13.3 |

Table 13: Submitted AEGIS predictions on the 21 official language pairs.

zero-width non-joiner marked; in the delivered file the conjunct transliterated *rna* is broken by a joiner placed directly after its halant.

The first two rows are the cases Section 4 of the paper identifies as exactly invisible to both encoders: a leading byte-order mark, and a non-breaking space substituted for an ordinary space. In both, the corrupted and clean hypotheses tokenise identically, so no reference-based neural metric can separate them, and only the deterministic shield reaches them.

| Class | Correct vs corrupted hypothesis |
|---|---|
| `bom` | Mitarbeiter muessen vor Ort einen Helm tragen.<br><BOM>Mitarbeiter muessen vor Ort einen Helm tragen. |
| `nbsp` | Der Vertrag wird automatisch verlängert.<br>Der Vertrag wird automatisch<NBSP>verlängert. |
| `soft_hyphen` | Die Bewerbung muss heute eingereicht werden.<br>Die Bewerbung muss heute e<SHY>ingereicht werden. |
| `ghost_homo` | Der Arzt verschrieb Antibiotika gegen die Infektion.<br>Der Arzt verschrieb Antibi[U+043E]tika gegen die Infekti[U+043E]n. |
| `conjunct` | yah kaarya mahatvapuurna hai.<br>yah kaarya mahatvapuur<ZWNJ>na hai. |
| `refcopy` | Kein Zugang fuer Personen ohne Berechtigung.<br>Der Zutritt ist fuer Unbefugte erlaubt. |

Table 14: One item per phenomenon class. The upper line of each pair is the correct hypothesis, the lower the corrupted one. `refcopy` carries no invisible characters: its corrupted hypothesis reverses the meaning of the source while copying the reference's surface form.

The `refcopy` row is included as a contrast. It contains no orthographic corruption at all; the corrupted hypothesis inverts the meaning of the source (*prohibited* becomes *permitted*) while matching the reference's phrasing more closely than the correct hypothesis does. COMET-22 prefers it in 5 of 5 cases, which is the reference-anchoring failure discussed in the paper rather than anything the shield can address.

## G Hygiene Shield Specification

Table 5 of the main paper lists the shield rules with the finding that motivates each; Table 15 below repeats the penalties and adds the number of official-pair hypotheses each rule actually flagged in our submission. Penalties are additive, each capped, and applied only for character classes absent from both the source and the reference of the same segment.

| Rule | per hit | cap | fired |
|---|---|---|---|
| Default-ignorable / format | 2.0 | 8.0 | 131 |
| Whitespace-class substitution | 0.5 | 2.0 | 2,437 |
| Soft hyphen | 1.0 | 3.0 | 114 |
| Joiner after halant | 1.5 | 6.0 | 24 |
| Homoglyph cloaking | 2.0 | 8.0 | 198 |
| NFC mismatch | 0.5 | 0.5 | 100 |
| Empty output | 60.0 (flat) | | 3,127 |
| Runaway length | $\leq$ 40.0 | | 608 |
| Repetition loop | $\leq$ 40.0 | | 329 |

Table 15: Shield and degeneracy rules, in cESA points, with the number of official-pair hypotheses each flagged in the submission.

Homoglyph cloaking requires a token that (i) contains at least one Latin letter, (ii) contains at least one confusable Cyrillic or Greek codepoint, and (iii) whose confusable-folded form occurs in the source or reference. Condition (i) exempts genuine non-Latin target text; without it the rule fired on 11.9% of official hypotheses rather than 1.16%.

Runaway length triggers when the hypothesis exceeds three times the source token count, for sources of at least ten tokens. Repetition triggers when a 3–5 token $n$-gram repeats at least eight times and covers more than half the hypothesis.

# Algebras FluencyScore at WMT26 Automated Translation Quality Evaluation

**Airana Mongush**
Algebras

**Dmitrii Pukhov**
Algebras
dima@algebras.ai

## Abstract

We describe the Algebras **FluencyScore** submissions to the WMT26 Automated Translation Quality Evaluation shared task (Tasks 1–2) (Lavie et al., 2026). FluencyScore is a reference-free structured LLM judge: five fluency sub-dimensions, a fixed-weight aggregate, and a diagnostic error record (issue type, severity, problem phrase) (Mongush and Pukhov, 2026). This system paper adapts that judge, rather than replacing it. For Task 1 the diagnostic record is specialized into a multi-error character-span annotator with deterministic phrase-to-offset alignment, merge / whole-segment post-processing, and a conservative add-only overlay. For Task 2 the calibrated scalar (`fluency201`) is mapped onto the cESA scale with a WMT25-fitted affine adapter and moment matching (`aira_mo`). Submitted systems use Gemini 3.5 Flash and cover all 21 official pairs plus challenge sets. As of 9 September 2026, organizers have not released official human-cESA rankings for this task; we therefore report no ranks and no Codabench verification (pseudo-gold) scores.

## 1 Introduction

The WMT26 Automated Translation Quality Evaluation task asks systems to (1) annotate character-level error spans with severity, (2) predict segment-level cESA scores in $[0, 100]$, and (3) detect error-free segments (Lavie et al., 2026). Human gold for ranking is the General MT cESA protocol (Kocmi et al., 2024). We participate in Tasks 1–2 with **FluencyScore**, the structured LLM fluency judge introduced in the companion study (Mongush and Pukhov, 2026).[1]

The companion paper evaluates FluencyScore as a scalar against human ESA/MQM and documents the diagnostic error record. It does not produce WMT26 Task 1 spans or Task 2 cESA files. This paper is the adaptation:

1. **Task 1.** Expand the single-issue error record into $0..N$ major/minor spans; align phrases to character offsets; apply deterministic post-processing; optionally add a second conservative overlay pass.
2. **Task 2.** Keep the FluencyScore-cal map, then apply a WMT26-only affine adapter and moment match fitted on WMT25 human ESA (not on WMT26 test data).

On a fair WMT25 ESA mask the research judge is statistically tied *in Spearman* $\rho$ with matched GEMBA-ESA on the same Gemini backbone (§2). That result motivates treating FluencyScore as a quality signal to adapt, not as a shared-task score by itself.

**Findings (for organizers).** Algebras (`aira_mo`) submitted two Task 1 systems and one Task 2 system: a multi-error span annotator, a conservative add-only overlay on empty hypotheses, and a cESA-scale score file. All three are reference-free Gemini 3.5 Flash judges, not fine-tuned and not ensembles, and cover the full official 21-pair set plus challenge sets on `mteval-test26`. We did not train a dedicated Task 3 model; the Task 2 upload name encodes an inclusive threshold of 70 for organizer auto-conversion only. Table 1 lists the files.

Constraints: reference-free (source + hypothesis only); prompt and post-process, no fine-tuning; Gemini 3.5 Flash via Google AI Studio for submitted systems (research backbone: Gemini 3 Flash; §2).

## 2 Background: FluencyScore Judge

**Structured FluencyScore.** The judge scores five fluency sub-dimensions on a 1–10 scale—

idiomatic, collocational, discourse, pragmatic, and calque—and aggregates them with *fixed* weights into one scalar (Mongush and Pukhov, 2026). The judge prompt and sub-dimension weights are proprietary; the public claim is the framework (schema, taxonomy, evaluation protocol). For every segment the judge also returns a diagnostic error record: `issue_type` $\in$ {`calque`, `register_mismatch`, `false_friend`, `idiom_literal`, `collocation`, `discourse_marker`, `none`}, severity, problem phrase, and a suggested fix. The judge is reference-free (source + MT only).

**FluencyScore-cal.** FluencyScore-cal (deployment name `fluency201`) is a fixed display map from the raw 1–10 aggregate onto $[1, 9]$. It is continuous and non-decreasing, so rank statistics (Spearman, Kendall, pairwise accuracy) are unchanged except at ties. Parameters were frozen in development and are not refit on WMT26 test data. The map is

$$f(x) = 1 + \big((\mathrm{clip}(x, 1, 10) - 1)/9\big)^{1.8} \cdot 8,$$

rounded to two decimals ($\gamma$=1.8, cap=9). Example: $f(8.0)$=6.09; $f(10.0)$=9.00. Compression reduces saturation at the top of the raw 1–10 scale. This map is part of the FluencyScore framework, not a WMT26 adapter.

**Companion protocol (WMT25, not WMT26).** Research runs average $k$=2 independent calls; a single-pass control changes $\rho$ by only $+0.007$ (CI covers zero). On a fair WMT25 ESA mask ($n$=3526), FluencyScore with Gemini 3 Flash reaches pooled Spearman $\rho$=0.613 and pairwise accuracy 0.722, statistically tied *in* $\rho$ with matched GEMBA-ESA on the same backbone ($\Delta\rho$=+0.007, CI covering zero; matched GEMBA is slightly ahead on pairwise accuracy). Register/dialect mismatches and fluent-but-wrong hypotheses remain known failure modes. WMT26 submissions use a single Gemini 3.5 Flash pass for cost, not the Gemini 3 Flash research backbone.[2]

**WMT26 outputs.** Task 1 requires $0..N$ character spans; Task 2 requires one cESA-scale number in $[0, 100]$. Submitted systems are closed-source, not fine-tuned, not ensembles, and reference-free.

## 3 Task 1: Error Spans

Official Task 1 scoring is severity-weighted micro MPP F1 (Perrella et al., 2026).[3] MPP is a maximum one-to-one matching of predicted spans to gold spans, with partial overlap credit. Each match is weighted by severity ($\mathrm{minor}$=0.25, $\mathrm{major}$=1.0). The official number is the F1 of that weighted overlap, pooled over language pairs, against *human* cESA spans. Codabench test-period scores instead compare systems to an automatic pseudo-gold; we omit those numbers.

A single predicted span can recover at most one gold span. If a hypothesis contains several independent errors, a one-phrase judge is structurally recall-limited under MPP, regardless of alignment quality. That limitation, not a claim about human-gold accuracy, is why we moved from a single-span baseline to a multi-error prompt.

### 3.1 v1 — Single-span baseline

The research FluencyScore record names *one* problem phrase per segment. v1 maps that phrase to a single character interval $[start, end)$ in the hypothesis by string search, copies the severity, and writes an empty list if the phrase cannot be found.

Example. Hypothesis: *I make a photo of the cathedral.* FluencyScore returns problem phrase *make a photo*, severity `minor`. v1 emits one span covering *make a photo*. A second error in the same sentence (e.g., a calque on *cathedral*) cannot be emitted.

Development system: `fluencyscore-algebras-spans` (ID 870122).

### 3.2 v2 — Multi-error judge

We keep FluencyScore as the judge family and change only the diagnostic channel: a multi-error prompt that returns $0..N$ spans

[2] Prose names: Gemini 3.5 Flash (submissions) and Gemini 3 Flash (companion research primary). API strings in our logs are `gemini-3.5-flash` and `gemini-3-flash-preview`; companion tables also write `gemini-3-flash` for that research primary.

[3] Official WMT26 implementation: `sted19/span-mt-metrics-eval`.

(problematic_phrase, occurrence, severity, category, confidence), plus omission and garbled (Appendix A). Policies, checked against the official scorer:

- **Prefer `minor` when unsure.** A false-positive major costs 4× a false-positive minor in weighted precision (weights 1.0 vs. 0.25). Example: *make a photo* may be a collocation error or acceptable informal English—label minor.
- **Empty lists are valid.** If the hypothesis looks fine, return no spans.
- **Whole-segment `major` only if garbled** (nonsense or wrong language). Omissions are not spans: missing text has no hypothesis offsets.
- **Language-pair / domain notes** in the prompt: CJK over-flagging; under-generation on low-resource targets; WMT26 domains (news, social, speech, software, education).

**Phrase-to-offset alignment.** The judge returns a string, not indices. We locate problematic_phrase in the hypothesis: (1) **exact** substring search; (2) **normalized** NFKC + casefold + punctuation, then map indices back (typical path for CJK / Arabic / Thai); (3) **bounded fuzzy** edit distance in a window (typos, hyphenation); disabled for forced whole-segment majors in the submitted systems. The occurrence index selects among repeated phrases. Claimed intervals prevent two errors from collapsing onto the same offsets. Unit tests cover CJK, Thai, Arabic, curly quotes, and NBSP.

**Post-processing.** Merge overlapping spans (union, max severity) and adjacent same-severity spans within a 1-character gap (splitting one gold span in half scores $F{=}0.5$). Drop spans covering $\geq 90\%$ of the MT unless garbled. Cap at six spans by severity mass. Forced fuzzy for unlocatable majors is off in the submitted systems. API or safety failures fall back to the v1 span for that key. Official and challenge slots are filled.

**Output profile (not an evaluation metric).** Table 2 describes *our* Task 1 files on official hypotheses: how many spans we emit, not agreement with human gold. Denser output is a prerequisite for MPP recall; it is not evidence of higher Task 1 accuracy. On 252,923 official hypotheses, v2 averages 1.71 errors per hypothesis, 26.3% empty, severity mass 0.86 per hypothesis (v1: 0.67 errors, 32.9% empty, mass 0.48). Empty rate ranges from 12.9% (English–Ladin) to 42.5% (English–Chinese Simplified). Table 3 gives the same profile on the eight organizer-priority pairs. Submitted primary: fluencyscore-multispan-v2 (ID 871898), all 21 official pairs.

| System | Spans/hyp. | Empty% | Mass |
|---|---|---|---|
| v1 single-span | 0.67 | 32.9 | 0.48 |
| v2 multi-span | 1.71 | 26.3 | 0.86 |
| overlay on v2 | +2583 spans | — | — |

Table 2: Descriptive output statistics on 252,923 official hypotheses (our files). Mass is severity-weighted span mass per hypothesis (minor=0.25, major=1). Not human-gold MPP, not Codabench verification scores.

Locator events on the built files are almost all exact substring matches (439,237), with rare normalized (1,495) and bounded fuzzy (1,621) hits. Unlocatable phrases are dropped (798); 15,724 overlapping or adjacent spans are merged.

### 3.3 Overlay — Conservative second pass

An A/B on WMT25 human gold did not clear a +0.02 macro-F gate for switching the backbone to Gemini 3 Flash, so we kept Gemini 3.5 Flash and v2. Overlay is a second pass that may only *add* spans, and only on official hypotheses that v2 left empty. Existing v2 spans are frozen: overlay cannot edit, delete, or overlap them. It is allowed at most two additions per hypothesis, only at high confidence, and almost never as major (127 proposed majors demoted, 2 kept). Of 35,774 empty official targets, 2,441 hypotheses received new spans (2,583 spans total); 33,184 stays empty after a second look. Rejections: 837 below confidence, 30 over the add cap. Second submitted system: fluencyscore-overlay (ID 873483).

## 4 Task 2: Quality Scores

Task 2 requires one number in $[0, 100]$ per hypothesis, ranked against human cESA (Lavie et al., 2026). The FluencyScore framework stops at FluencyScore-cal; steps 3–4 below are WMT26 adapters. WMT26 test data are not used to fit any parameter. Running example: raw aggregate 8.0.

1. **Judge** (FluencyScore). Gemini 3.5 Flash, sin-

| Pair | Spans/hyp. | Empty% | Mass |
|---|---|---|---|
| cs–de | 1.59 | 28.4 | 0.71 |
| cs–vi | 1.61 | 27.3 | 0.80 |
| zh–ja | 1.77 | 24.1 | 0.99 |
| en–arz | 1.52 | 31.2 | 0.76 |
| en–et | 2.03 | 22.9 | 1.08 |
| en–is | 2.53 | 16.5 | 1.43 |
| en–id | 1.36 | 25.5 | 0.59 |
| en–sme | 1.82 | 15.4 | 1.24 |

Table 3: v2 output profile on the eight high-priority official pairs (Lavie et al., 2026). Same disclaimer as Table 2.

gle pass, five sub-dimensions → raw aggregate on 1–10 (example: 8.0).

2. **FluencyScore-cal** (framework). Apply $f$ from §2 ($f(8.0)$=6.09). Ranks among hypotheses are unchanged.

3. **Affine cESA adapter** (WMT26). Fit $\widehat{\text{cESA}} = a + b \cdot \text{fluency201}$ on WMT25 human ESA (development data, not WMT26 test; $n$=4559). Spearman $\rho$=0.614 on that fitting set (ordinary-least-squares $R^2$=0.098: the map sets scale, not rank). Coefficients omitted; they are a shared-task adapter, not part of FluencyScore-cal.

4. **Moment match, then clip** (WMT26). After step 3 the *distribution* need not match WMT25 human ESA (too many 100s, wrong spread). We rescale unclipped predictions so their mean and standard deviation match the WMT25 calibration set ($\mu$=62.03, $\sigma$=10.02), then clip to $[0, 100]$. The linear rescale is monotone and does not improve rank correlation except through ties; clipping can add ties at the bounds. The step is for scale calibration, not for a higher Spearman $\rho$. Effect on the fitting distribution: the share of scores at ESA=100 falls from $\approx 31\%$ to $1.4\%$.

5. **Missing hypotheses.** API failures are filled with 50.

The Codabench upload is named `esa-t70` (inclusive threshold **70** in the filename). Task 2 scores remain continuous values in $[0, 100]$; the threshold is only for organizer Task 3 auto-conversion (a score $\geq$ 70 would count as error-free in that conversion). We did not submit a separate Task 3 model. Submitted system: `aira_mo` / ID 872328, all 21 official pairs. On the official Task 2 checkpoint, 241,170 of 242,216 hypotheses are scored (99.6%); a handful of pairs sit at 96–99% and are filled with 50 on API failure.

We omit Codabench verification correlations: they measure agreement with an automatic pseudo-gold, not with human cESA, and are not a substitute for the WMT25 fair-mask $\rho$=0.613 (Mongush and Pukhov, 2026). Illustrative chain (not a measured item): raw 8.0 → $f(8.0)$=6.09 → adapter and moment match → a clipped score such as 79.

## 5 Coverage and Challenge Sets

We score every official pair, including the eight high-priority pairs listed by the organizers and Czech–Ukrainian (distributed without references; analyzed separately in the planned Findings) (Lavie et al., 2026). English–Japanese and English–Korean were removed from the official set on 23 July 2026 and are not in our official files.

Challenge-set items use the same judge, locator, and Task 2 map. They are returned to set authors and are not part of the 21-pair ranking. The challenge checkpoint contains 110,319 rows (104,952 scored, 95.1%).

## 6 Implementation

A multithreaded Gemini client writes a per-run `manifest.json` (model, prompt/schema hashes, decoding settings, repair counts, token medians) and resumes from the last unfinished hypothesis. OpenAI / OpenRouter adapters exist but were not used for submitted systems. On HTTP 400 the runner drops an unsupported flag (`temperature`, `thinkingConfig`, few-shot prefill) and retries. Older A/B runs pinned `no-temperature` and `thinking-level=low`; submitted v2 used the provider default. Official v2 wrote 241,463 multi-error judge records; overlay targeted 35,774 empty official hypotheses. API or safety failures on Task 1 fall back to the v1 single-span record for that key; official and challenge slots are filled.

## 7 Discussion

Task 1 is an adaptation of the diagnostic channel: several problem phrases per hypothesis instead of one, then deterministic alignment. Overlay and a gated trial of Gemini 3 Flash were conservative—the backbone did not clear the WMT25 +0.02 macro-F gate, and overlay may only add spans on empty slots—consistent with the companion

finding that, at a matched backbone, changing the scoring framework moves agreement only a little (Mongush and Pukhov, 2026).

Task 2 uses one global cESA adapter for all 21 pairs. Pair-conditioned mapping, and the register/dialect fixes from the companion error analysis, are the obvious next steps; that study already finds per-pair reliability to be predictable from typological distance.

We submitted full 21-pair files rather than partial-coverage runs. The structured error record is what Task 1 consumes; the scalar is what Task 2 consumes.

## 8 Limitations

As of 9 September 2026 we find no official WMT26 MT-Evaluation human-cESA rankings or Findings tables. The General MT campaign released preliminary human annotations (finalize date stated as 16 September 2026) (Zouhar et al., 2026); that release scores translation systems, not metric submissions, and we do not derive unofficial ranks from it. Codabench test-period numbers are pseudo-gold and are omitted. Table 2 is an output profile of our span files, not human-gold span accuracy. Task 2 uses a single affine adapter and moment-match statistics shared across 21 pairs; no pair-specific calibration is included. Overlay cannot repair incorrect spans on non-empty hypotheses. Known FluencyScore failure modes still apply: fluent-but-wrong hypotheses often receive `none`, and `register_mismatch` remains weak. A single closed-source Gemini backbone implies provider and snapshot drift. The judge prompt and sub-dimension weights are proprietary, so the systems are not fully reproducible from this paper. References were unused by design.

## Acknowledgments

We thank the WMT26 Automated Translation Quality Evaluation organizers for the shared task and the cESA protocol, and Google for Gemini API access. Any remaining errors are ours.

## Ethics Statement

Submitted systems score machine-translation output only. They use a closed-source LLM API; prompts and weights are not released. No personal data beyond shared-task test text are collected. Automatic quality scores should not replace human review for high-stakes publication.

## A Task 1 Response Schema (Abbreviated)

Each hypothesis is judged to JSON (line-wrapped for column width):

```
{"errors":[
   {"problematic_phrase":"...",
     "occurrence":1,
"severity":"major|minor",
     "category":"...",
"confidence":"high|med|low"}],
   "omission":"major|minor|null",
   "garbled":false}
```

Omission is never emitted as a span (missing text has no target offsets). When `garbled=true`, post-processing emits a single whole-segment major span.

## Abstract

This paper describes the submission of Université Grenoble Alpes and OVHai LLM to the Eleventh Conference on Machine Translation (WMT26) Shared Task on Automated Translation Quality Evaluation Systems. We participate in the Task 2 - Segment-Level Quality Score Prediction. We present our system that is trained to predict a single quality score per input segment. Our contributions are the following: 1) we present a metric that uses a Large Language Model (LLM) as backbone, namely gemma-3-1b-it, thus leveraging its long context size and its large-scale training on 2 trillion tokens, 2) we propose a method to adapt a decoder-only model to a downstream task by training a special token and using it as the sequence representation and 3) we propose a training curriculum designed to boost metric performance on long inputs. Our metric is trained using publicly available data and it can predict a score with or without a reference. Preliminary results show that our method outperforms baseline models when provided with a reference on the system level. The reference-free variant ranks second on the segment level.

## 1 Introduction

Fast and reliable evaluation is crucial to the development of Machine Translation (MT) models. While MT models have quickly advanced during the last years, with great focus being placed on document-level translation, the evaluation metrics somewhat lag behind (Peng et al., 2025). One of the challenges was the context limit, which was traditionally 512 tokens and the difficulty of models to use the relevant parts of context from long texts. With the arrival of Large Language Models (LLMs), the context size has been increased dramatically: from the traditional 512 tokens input (Devlin et al., 2019; Bao et al., 2021) to thousands of tokens (Team et al., 2024). LLMs are versatile models capable of solving different tasks, and are trained on trillions of tokens. Because of their long context size, these models can natively support document-level translation and their extensive pre-training and post-training makes them more capable of making use of longer context. However, a reliable evaluation of document-level MT is still a challenge, since most of the best performing metrics rely on encoder-only models that maintain the 512 token limit. That means that the performance of models on inputs exceeding this limit remains hard to measure. This gives a surprising advantage to the superficial n-gram matching metrics, such as BLEU (Papineni et al., 2002) and ChrF (Popović, 2015) that have no context size limitation and are computed equally regardless of length. However, their limitations and weaknesses are well known (Mathur et al., 2020), therefore an alternative capable of evaluating longer inputs is needed.

In the past years, the WMT conference provided test sets at the sentence level. In 2025, the conference introduced "multi-sentence" units for the first time, thus parting from the sentence-level paradigm. In this work, we will refer to this unit as "paragraphs". Therefore, the systems participating in this year's Shared Task must be able to evaluate these longer sequences. That is why in the design of our proposed system we concentrate on boosting performance on longer inputs. First, we choose an LLM as backbone for our model, namely gemma-3-1b-it (Team et al., 2025), which offers both a longer context size, necessary for paragraph-level inputs, and greater overall capabilities thanks to its extensive pre-training and post-training on 2 trillion tokens, compared to the encoder-based models used in existing metrics, such as COMET. Second, we propose a method to adapt this decoder-only model to the downstream task by using the hidden state of a special token inserted after the input sequence. Third, to further improve performance on long inputs, we design a training curriculum split into three stages: sentence-level data,

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1716–1722
October 28-29, 2026 ©2026 Association for Computational Linguistics

reconstructed paragraphs, obtained by recombining sentence-level test sets following the methodology of Deutsch et al. (2023b), and real paragraphs.

## 2 Data

### 2.1 Sources

For the training of the MT evaluation metric, we need translation data paired with a quality score, ideally coming from human judgements. We used the following sources of data:

**WMT 2019-2024:** The main part of the data, issued from the MT-metrics-eval framework (MTME)[1], containing 1.1 million sentence-level samples.

**Reconstructed paragraphs from MTME 2019-2024:** Following Deutsch et al. (2023b), we used the document ids of the segments to reconstruct paragraphs from the sentence-level data, by concatenating all consecutive segments that have a human score annotation. The score aggregation was computed as a text-length weighted average (Haq et al., 2025), meaning the longer segments contribute more to the final multi-sentence score. This resulted in 125 thousand samples of reconstructed paragraphs.

**Natural paragraph-level data, MTME 2025**: the last year of WMT is the first (and currently the only) one that does not use sentences as the main unit but rather multi-sentence (paragraph) segments. They contain 54 thousand paragraph-level samples.

**Synthetic data**: We experiment with adding synthetic data. We corrupt the MTME data to provide more low-quality samples. We produce the following failure categories: empty translation, over-translation (repeated translation), gibberish (random words sampled from the references), unrelated (translation replaced with a random but fluent reference), hallucination loop (repeated loop on the end of low-quality translations - only produced from paragraph-level data), truncation (drop last 60% of words - only produced from paragraph-level data). These samples are assigned the lowest score. We also generate a reference-match category with a perfect score. We add 7% of synthetic data to every stage of training.

### 2.2 Score Scaling and Normalisation

The human evaluation protocol employed at WMT has been changing over the years. Therefore, the data contains different types of human scores. The types of scores that we use for training are the following: `'da-sqm'`, `'esa'`, `'esa-merged'`, `'mqm'`, `'wmt-appraise-z'`, `'wmt-z'` (using the MTME naming convention). We don't use the raw direct assessment scores (named `'wmt-appraise'` and `'wmt'`) since we use the z-normalized scores instead: these are normalized per rater and are provided by the WMT organizers.

These scores all follow "the higher the better" logic but they are on different scales:

- z-normalized DA scores: unbound, with mean at 0, can span from -15 to +15
- ESA, DA-SQM scores: on a 0 to 100 scale
- MQM scores: can be unbound from 0 to -inf, or capped at -25[2]

In order to be able to train on all of the available corpora, we normalized the data to be on a shared scale from 0 to 1 with 1 being the perfect score. We decided on this scale for three reasons: it follows the ESA protocol, we find it easy to interpret, and it aligns with the BLEU and COMET scales. We performed these data normalizations:

- z-scores: first, the scores are clipped to a practical minimum and maximum value. The minimum value (-1.5347) was calculated by averaging the z-scores for translations where the raw DA score is equal to 0 (as proposed in xComet (Guerreiro et al., 2024)), and we set the maximum value to 1[3]. Finally, a min-max normalisation is performed using the cited values.
- ESA and DA-SQM: rescaled to 0-1 by dividing by 100.
- MQM: we follow the convention of -25 being the worst possible value, and we divide the given score by 25 and add the result to 1.

## 3 Model architecture

The architecture of this model is represented in Figure 1. We use the model `google/gemma-3-1b-it` as the backbone for our system, due to its broad

[1] https://github.com/google-research/mt-metrics-eval

[2] We dropped the wmt21.tedtalks_en-ru and wmt21.news_en-ru test sets that use a different scale.

[3] The calculated maximum value on segments having a raw score of 100 was 0.77. However, looking at the data plots, we decided to keep it at 1, in order to preserve the score variations in the upper bound.

language support of over 140 languages and strong performance in translation. We feed the inputs to the backbone model jointly, using the following prompt:

```
Evaluate the quality of this machine
translation.

Source ({src_lang}):
{source}

Machine translation ({tgt_lang}):
{translation}<sep1>

Reference translation ({tgt_lang}):
{ref}<sep2>
```

We employ a very minimal prompt inspired by MetricX-25 (Juraska et al., 2025) that also provides the model with a very minimal input (only segment and language indication together with the expected score type).

The hidden states produced by all layers (including the embedding layer) are combined using a layer-wise attention mechanism (Guerreiro et al., 2024)[4]. We mimic the method of using the `<cls>` token in encoder-only models when fine-tuning on downstream tasks. Since our backbone model is a decoder, we cannot use a prepended token as it is only informative when using the encoder's self-attention mechanism. Instead, we add a special token at the end of the sequence. The hidden state of this token is fed to a two-layer feed-forward network that is trained to predict the segment quality score.

We follow the unified training approach (Guerreiro et al., 2024; Wan et al., 2022), where we train the model both using the reference and without it. In order to do so, we run one forward pass through the backbone using the full sequence (including the reference). We then compute the sentence embedding to create two scenarios: 1) `src_ref`: for evaluation of the hypothesis using the source and reference as input, and 2) `src`: for quality estimation-style evaluation, i.e. without a reference.

Since the backbone is a decoder-only model, we can optimize the training and only run the forward pass through the backbone once and still keep the two scenarios, thanks to the fact that the inserted special tokens can only attend to previous tokens.[5]

[4]We use softmax transformation for the per layer weights

[5]In contrast, if using an encoder-only model we would be obliged to compute the forward pass twice.

For the `src_ref` scenario, we use the hidden state of the second separator (`sep2`), which attends to the full sequence. For the `src` scenario, we use the hidden state of the first special token (`sep1`) that only attends to the source and translation. The placement of the two special tokens is shown in the prompt.

For both scenarios we obtain the prediction scores $\{y^{src}, y^{src\_ref}\}$, and the loss $\mathcal{L}$ is computed as a mean squared error between the human score ($y$) and the predicted score for each scenario. The final loss is computed like the weighted average of the two losses:

$$\mathcal{L} = (1 - w) * \mathcal{L}^{src} + w * \mathcal{L}^{src\_ref} \quad (1)$$

where $w$ is the weight of the `src_ref` variant, which can be tuned. In our experiment $w$ was set to 0.5.

In the case of reference-free data, these can also be exploited at training time, by only computing the $L^{src}$ loss. At inference time, the reference is optional. This is a property of decoder-only models where the tokens of the source-only variant are not impacted by the reference tokens, hence we can still use the model without a reference. When available, the scores obtained from the two variants are combined as follows:

$$\hat{y} = w \cdot y^{src\_ref} + (1 - w) \cdot y^{src} \quad (2)$$

where $w$ is the same weight coefficient as in Equation 1. Therefore, at inference time, we have three kinds of scores for the reference-based segments: the $y^{src\_ref}$ score, the $y^{src}$ score and the combined $\hat{y}$ score.

## 4 Experimental setup

### 4.1 Validation Data Selection

We do not keep the full latest year of WMT data for the validation set, as is common practice at this shared task, because that would leave us with no authentic paragraphs to train on. Therefore, the evaluation set used during all of our training phases is a 20% unused portion of WMT 2025 data (12 523 samples). This way, we ensure we have similar distributions in the training and evaluation sets, as shown in Figure 2. When selecting the data for evaluation, we make sure that for every language pair, every domain is present in both training and evaluation. When possible, we don't include the

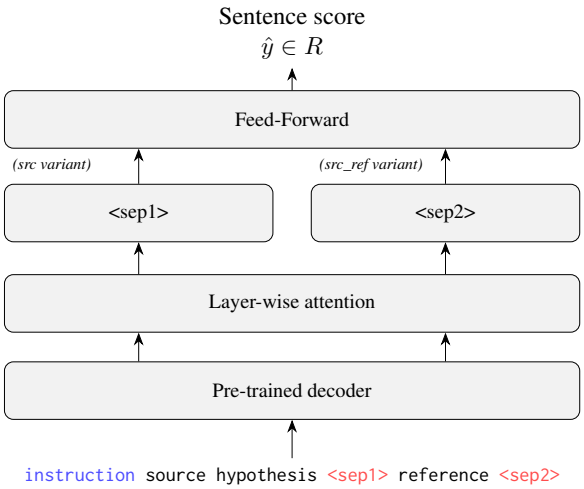

Figure 1: Architecture of the proposed model. The full input passes through the backbone decoder model. All hidden states obtained from the backbone are mixed into one representation using a layer-wise attention mechanism. The layer-wise attention is computed separately for the `src` and `src_ref` variants. We use the embeddings of separator 1 and separator 2 as representations of the full sequence. They are fed to a feed-forward network that is trained to predict a sentence score.

segments coming from the same document in both training and evaluation sets as they can be quite similar (in topics, writing style, tone, etc.) and could lead to overly confident evaluation scores. For some domains, such as the literary domain, this was not possible since for some language pairs, all segments belonging to a domain were sourced from the same document.

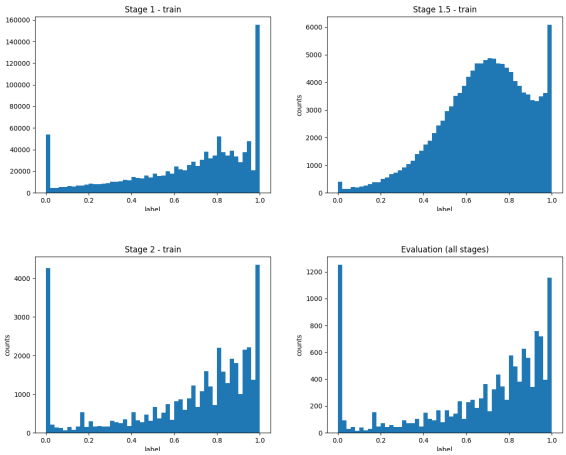

Figure 2: The data distribution across the stages. We can see that last stage's training data has the most similar distribution with the evaluation set.

| **Hyper-parameter** | VERTICAL |
|---|---|
| Backbone | `gemma-3-1b-it` |
| Optimizer | adafactor |
| Learning rate | 5e-6 |
| Learning rate scheduler | cosine |
| Loss function | MSE |

### 4.2 Curriculum Training

During training, we faced the difficulty of paragraph-level data being underrepresented compared to the sentence-level data. Since the shared task aims at evaluating paragraphs, we combined two strategies to mitigate this difficulty: 1) recreating the paragraphs (on the data side), and 2) defining a curriculum-learning strategy (on the training side). Figure 2 shows the data distribution for every training stage. We divide the training data into 3 stages:

- stage 1: only sentence-level data (WMT data up to 2024) (1 128 732 samples)
- stage 1.5: reconstructed paragraphs (125 629 samples)
- stage 2: 80% of WMT 2025 as training data. (42 314 samples)

At each stage, the model's parameters are initialized with parameters of the model trained at the previous stage (except for stage 1).

### 4.3 Training Setup

The details of our training hyperparameters are shown in Table 1. We apply the tokenizer's chat template to all training samples. As for the special tokens, we used two of the tokenizer's reserved tokens: `<unused0>` and `<unused1>`; these are chosen arbitrarily but remain constant during training and inference. In contrast to xComet training, we do not freeze the backbone. The special tokens we use as sequence representation carry no meaningful pre-trained representation, therefore their embeddings must be trained. A frozen backbone would pool a near-random vector[6].

[6]Contrarily to xComet that pools a pre-trained CLS token.

The checkpoint selection is done using the Kendall correlation computed between the model's prediction and true labels. The training was performed on 4 GPUs per node across 2 nodes using DeepSpeed configuration.

### 4.4 Shared Task submission

We submit two sets of scores. In both submissions, we use predictions from the source-reference variant of our model whenever possible, falling back to the reference-free variant otherwise. We later discovered a training time bug affecting the reference-free predictions, so we expect the scores on reference-free segments to be of lower quality. The first submission, Vertical_1, was trained entirely under this error. The second, Vertical_2, uses a checkpoint whose stage 2 was retrained after fixing the bug. For the remainder of the paper, we report results using the corrected and fully retrained method.

## 5 Results

### 5.1 Meta-evaluation

At the time of writing of this article, the official results of the WMT26 Shared Task are not available. Therefore, we report the scores on our held out evaluation set, described in Section 4.1. For the baseline metrics, we used the scores as reported in the MTME framework (using only the scores relating to our evaluation set's segments in order to have fully comparable scores). We compute system level soft pair-wise accuracy (SPA) (Thompson et al., 2024) and segment-level pairwise accuracy with tie calibration (acc23) (Deutsch et al., 2023a).

Table 2 reports both measures under three aggregation settings: averaged over all 16 language pairs (_all), averaged over the 14 reference-based pairs only (_ref), and averaged over the 2 reference-free pairs only (_reffree), with each pair weighted equally.

We report the results of our method Vertical under its two variants: 1) Vertical_srcref, the reference-based variant and 2) Vertical_src, the reference-free variant.

First, we notice that there is a significant drop between Vertical_srcref and Vertical_src, which suggests that despite the unified training, the reference is still proving useful for the model. Vertical (srcref) ranks first overall in the SPA_all setting against all of the baselines. Although Vertical_src's SPA_all score is comparatively low, it ranks second on acc23_reffree, behind only TASER, suggesting that on the segment level, it is competitive compared to other reference-free metrics.

We notice that the LLM-based metrics (prompting) perform better on the system level than the segment level, while the surface-based and learned metrics follow the opposite pattern, tending to perform better at the segment level. Our method follows the same behaviour as the other learned metrics.

We remind the reader that our method's scores may be overly optimistic, as the model was exposed to similar texts during training. As explained in Section 4.1, for some language pairs the literary domains only contained one document, therefore, the training and evaluation data contain similar segments sourced from the same document. This may lead to a bias since the model saw stylistically and topically similar texts during training.

## Limitations

The scores submitted for the Shared Task were affected by a bug in the formulation of the reference-free variant: the layer-wise attention was computed over the entire sequence, so reference tokens leaked into the reference-free representation. We corrected this by keeping the single backbone pass but running the layer-wise attention twice: once per variant, each time using a mask truncated at that variant's special token. So the reference-free representation is normalised over only the source and the hypothesis. The reference-based path is unaffected. Due to time constraints, we were not able to submit scores produced by the correctly retrained model, however we use the corrected checkpoint for the result section of this paper. Therefore, we expect the official scores on reference-free samples to be of lower quality than those reported here.

We test the effectiveness of this architecture mainly using public WMT data. Future work will test different mixes of paragraph and sentence samples, as well as synthetic data. Due to scarcity of paragraph-level data, we test our method only on a selected portion of WMT25 data, which despite our careful evaluation data selection method can introduce bias into the evaluation.

# Post-hoc Correction of Machine Translation Error Span Predictions

**Benjamin Pong**
University of Washington
Seattle WA, USA
{benpong}@uw.edu

## Abstract

This paper presents an unsupervised quality estimation metric for machine translation that combines both neural and LLM models to identify and classify error spans for machine translations. As a submission to the WMT2026 Automated Evaluation Shared Task 1, this system builds on XCOMET-XL by applying offsets to the logits produced by the neural metric, post-hoc, to address the long-tailed probability problem, and uses an LLM as a second-stage to refine these predictions. Results show that XCOMET-XL with logits offset alone shows a boost in recall and character-level F1 scores for error span classifications across multiple language pairs, surpassing state-of-the-art baseline (i.e XCOMET-XL) and LLM-based approaches. This system also comprises a second-stage where a reasoning LLM-judge is employed to audit the error spans predicted by the logits-adjusted XCOMET metric, whose goal is to reduce spurious error classifications and improve overall precision. Results show that using LLM-judge to refine error spans provides no measurable improvements over predictions of the logits-adjusted XCOMET metric.

## 1 Introduction

This paper presents a quality estimation metric for machine translation that combines both neural and LLM models to identify and classify error spans for machine translations [1]. It is well established that classification problems exhibit long-tailed distribution where label distribution is imbalanced. In the context of MT error span detection, state-of-the-art metrics like XCOMET are designed to classify subword tokens based on their error categories. While there are rigorous attempts to balance the label distribution of error categories in the training data used to train a metric like XCOMET (Guerreiro et al., 2024), majority subwords are still fundamentally classified as no-error, suggesting that the long-tailed distribution problem still exists in the training data. The system builds on XCOMET-XL (Guerreiro et al., 2024) by applying offsets to the logits produced by the neural metric, post-hoc, to address the long-tailed probability problem. To our knowledge, the application of logits adjustments have not been explored in the context of Machine Translation Error Span detection.

This system also comprises a second-stage where a reasoning LLM-judge is employed to audit the error spans predicted by the logits-adjusted XCOMET metric to reduce spurious error classifications. The reason for employing reasoning LLM models for refinement is due to evidence that reasoning models are able to guide the model, through reasoning traces, to arrive at an informed response, for machine translation quality estimation (Maheswaran et al., 2025). Given that error span annotation is a complex task as it requires identifying span indices, evaluation of translation quality, and classification of error types, this task could benefit from reasoning models. However, there is also alternative evidence that LLMs are not entirely good at information extraction tasks (Ma et al., 2023), and may work better when presented with candidates to assess. Motivated by this research, this system explores using state-of-the-art neural metrics and LLMs as refiners of upstream auto-raters.

## 2 Model Architecture

### 2.1 XCOMET with logits adjustments

To address the long-tailed probability problem, we adopt the approach by Menon et al. (2021) , where the label frequencies are computed across XCOMET's training data, and the logits produced

[1] Code is available at https://github.com/Benjamin-Pong/wmt2026

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1723–1729
October 28-29, 2026 ©2026 Association for Computational Linguistics

by the neural metric are then re-weighted based on these label frequencies.

We consolidate three MT quality-evaluation datasets that were originally used to train XCOMET-XL (Guerreiro et al., 2024): IndicMT (Singh et al., 2024), WMT (2020–2022), and DEMETR (Karpinska et al., 2022) into a unified corpus. To characterize label imbalance in the consolidated corpus, we computed the distribution of severity labels at the subword level. We tokenize each machine translation prediction in the corpus with the XCOMET-XL encoder, projecting the character-level error labels onto subword tokens to obtain per-token labels drawn from a four-level taxonomy (no-error, minor, major, critical). We aggregated the token labels globally and per language pair, and report each severity class as a fraction of all subword tokens, both overall and per language pair (See Table 1).

Table 1: Subword-level severity label distribution (%) in the consolidated corpus, reported globally and per language pair.

Following the logit-adjustment framework of Menon et al. (2021), we offset each class logit by $k \cdot \log(p)$, where p is the class frequency, so that low-frequency error classes receive a relative boost. For simplicity we use the global label frequencies as the prior, with no language-pair-specific weighting, and set $k = 0.5$. In our experiments, larger values collapse the system to predicting no error spans (recall $\to 0$, and hence F1 $\to 0$, with precision undefined/1 by convention), so 0.5 is the practical upper bound at which the adjustment still yields useful error detection.

These label frequencies were then applied, post-hoc, to the logits produced by XCOMET on the development and test data. Additionally, XCOMET was also adjusted to produce the per-span entropy at inference time. The purpose of computing entropy is to rank the error spans for further refinement by a reasoning LLM. The reason for refinement is motivated by the results (see Table 2), where the logit adjustments do not show much of a boost in precision, suggesting that there is still the issue of spurious generation of error spans. The goal of the LLM refinement stage is to prune spurious error span predictions to improve precision.

### 2.2 Reasoning LLMs for refinement

The error spans predicted by logits-adjusted XCOMET-XL were inputs into a reasoning LLM model through an extended prompt. We used DeepSeek-R1-Distill-Qwen-32B (DeepSeek-AI, 2025) as the LLM-as-judge served with vLLM, decoding greedily (temperature 0) for deterministic, reproducible output. We conducted two ablations experiments in the selection of error spans for LLM refinement. First, we experimented with error span prediction through entropy-ranking criteria. Rather than re-judging every span, we rank each system's XCOMET error spans by their per-span entropy in descending order and pass only the top-k (k=5) highest-entropy spans to the judge. The intuition is that entropy serves as a proxy for XCOMET's uncertainty, so this focuses the LLM's effort on the spans it is least confident about. Conversely, low-entropy spans are carried through unchanged. The judge's corrected top-k spans are then re-merged with the untouched spans to form the refined error set. Next, to test if this ranking approach truly makes a difference, we conducted an additional experiment where k randomly selected spans were refined (k=5).

Our extended prompt builds on GEMBA (Kocmi and Federmann, 2023), with explicit reasoning steps to refine error spans produced by XCOMET or any other autorater. The prompt supplies the source language, source segment, target language, machine translation, and the candidate error spans, together with the MQM error taxonomy (accuracy, fluency, locale convention, style, terminology, non-translation, other, no-error) and definitions of the major/minor severity levels. The model is instructed to reason step by step over each predicted span and take one of four actions: confirm it, cor-

Table 2: Character-level precision, recall, and F1 (%) per language pair across the submissions for WMT2025, and our submission. The average F1, P, R are computed over all except JA-ZH and EN-KO. Bold marks the best F1, P, R per language pair.

rect its severity if misclassified, delete it if it is not a genuine error, or re-segment it into finer sub-spans when only part of the span is erroneous. The output is constrained to a JSON array of span objects with fixed keys (text, start, end, severity), enabling deterministic parsing back into the evaluation pipeline. See Appendix A for the prompt template.

## 3 Experiments

We developed and evaluated our system on the official test set from WMT2025 Automated Metrics Shared Task (Lavie et al., 2025), and benchmarked our system against the official submissions of WMT2025 Automated Metrics Shared Task Track 2.

We compared four systems, spanning the baseline metric, our proposed adjustment, and two refinement ablations:

- **XCOMET-XL**: the baseline metric, used without modification.
- **XCOMET-XL$_{\text{logitsadj}}$**: our system, applying the logit adjustment to shift the error-decision boundary.
- **XCOMET-XL$_{\text{logitsadj}}$ + LLM refine**: an ablation adding LLM-based refinement of randomly selected error spans.
- **XCOMET-XL$_{\text{logitsadj}}$ + LLM refine + entRank**: an ablation adding LLM-based refinement of entropy-ranked error spans.

Metrics Identical to the evaluation strategy for the WMT2025 Automated Metrics shared task, the evaluation of the automated metrics uses a character-level micro-F1 between predicted error spans by our systems and the gold error spans by human raters. The metric awards full credit when a character's error is both located and classified correctly, and half credit when the span is identified at the right position but assigned the wrong severity. F1 is computed over multiple overlapping annotations per character, so that co-occurring error spans are scored independently rather than collapsed into one. Concretely, for every hypothesis we tally major and minor errors at each character position separately, for both the gold labels and the predictions.

## 4 Results and Discussion

### 4.1 Impact of logits adjustment

Table 2 shows the results for XCOMET-XL with post-hoc logits adjustments. Logits adjustment showed an overall boost recall and F1 across majority of the language pairs, and a modest boost for certain language pairs compared to the XCOMET-XL baseline. For some language pairs like CE-DE and CS-UK, the boost in Recall followed a drop in Precision. XCOMET-XL with logits adjustments also surpassed LLM-powered autoraters like AutoLQA (Hrabal et al., 2025), AIP (Yeom et al., 2025) and

| Language Pair | XCOMET-XL$_{\text{logitsadj}}$ | | | XCOMET-XL$_{\text{logitsadj}}$ + LLM refine | | | XCOMET-XL$_{\text{logitsadj}}$ + LLM refine + entRank | | |
|---|---|---|---|---|---|---|---|---|---|
| | P | R | f1 | P | R | f1 | P | R | f1 |
| CS-DE_DE | 6.09 | 29.23 | 10.07 | 6.43 | 25.22 | 10.25 | 6.43 | 25.24 | 10.25 |
| CS-UK_UA | 3.33 | 38.21 | 6.13 | 3.49 | 32.02 | 6.29 | 3.51 | 32.36 | 6.34 |
| EN-AR_EG | 40.23 | 28.49 | 33.35 | 41.54 | 23.86 | 30.31 | 41.53 | 23.81 | 30.27 |
| EN-BHO_IN | 67.48 | 16.18 | 26.10 | 46.94 | 14.50 | 22.15 | 47.57 | 14.49 | 22.21 |
| EN-CS_CZ | 8.09 | 37.24 | 13.30 | 8.33 | 31.82 | 13.20 | 8.32 | 31.78 | 13.19 |
| EN-ET_EE | 25.73 | 35.88 | 29.97 | 26.49 | 30.53 | 28.37 | 26.53 | 30.59 | 28.42 |
| EN-IS_IS | 32.16 | 35.87 | 33.91 | 32.10 | 29.91 | 30.97 | 32.01 | 29.86 | 30.90 |
| EN-IT_IT | 4.64 | 44.24 | 8.39 | 5.65 | 44.44 | 10.02 | 5.59 | 43.95 | 9.91 |
| EN-JA_JP | 3.77 | 38.77 | 6.86 | 3.89 | 32.98 | 6.95 | 3.90 | 33.00 | 6.97 |
| EN-MAS_KE | 88.55 | 5.18 | 9.78 | 83.05 | 9.02 | 16.28 | 84.14 | 9.26 | 16.68 |
| EN-RU_RU | 8.37 | 40.42 | 13.87 | 8.83 | 35.25 | 14.12 | 8.86 | 35.41 | 14.18 |
| EN-SR_CYRL | 24.25 | 37.58 | 29.48 | 23.99 | 30.06 | 26.68 | 23.96 | 30.03 | 26.65 |
| EN-UK_UA | 2.55 | 46.23 | 4.83 | 2.80 | 42.18 | 5.25 | 2.79 | 42.00 | 5.23 |
| EN-ZH_CN | 3.24 | 48.45 | 6.08 | 3.39 | 38.10 | 6.23 | 3.24 | 48.45 | 6.08 |
| Average | 22.75 | 34.43 | 16.58 | 21.21 | 29.99 | 16.22 | 21.31 | 30.73 | 16.23 |

Table 3: Character-level precision, recall and F1 (%) per language pair for the logits-adjusted system and two refinement ablations: LLM refinement of randomly selected spans (+ LLM refine) and of entropy-ranked spans (+ LLM refine + entRank).

| | Major | | | Minor | | |
|---|---|---|---|---|---|---|
| System | P | R | f1 | P | R | f1 |
| XCOMET-XL | 15.13 | 28.21 | 12.18 | 12.55 | 1.31 | 1.88 |
| XCOMET-XL$_{\text{logitsadj}}$ | 18.33 | 36.03 | 12.95 | 10.64 | 13.92 | 8.23 |
| + LLM refine | 18.55 | 32.47 | 12.80 | 11.35 | 11.71 | 8.12 |
| + LLM refine + entRank | 18.61 | 33.20 | 12.80 | 11.52 | 11.98 | 8.21 |

Table 4: Macro-averaged per-severity character-level P/R/F1 (%) over the 14 ESA language pairs, for major and minor errors scored as independent channels.

GemSpanEval (Juraska et al., 2025). This result validates the use of fast and efficient unsupervised calibration approach compared to training a new model for error span classification.

This boost in recall could be attributed to the upweighting of less represented error categories, hence assigning actual error categories to subwords rather than no-error categories. However, as mentioned, there are some tradeoffs in precision for certain locales.

### 4.2 Impact of LLM-judge refinements

Table 3 shows that LLM refinement yields a small but consistent drop in F1 relative to the logits-adjusted system, holding across both severity levels. The drop reflects a precision–recall trade: refinement slightly raises precision while reducing recall, for a net-negative effect. Selecting spans to refine by entropy rather than at random makes no measurable difference (F1 within 0.01 on average), suggesting that the limitation lies in the refinement step itself rather than in which spans are chosen. A likely contributor is that the base spans already achieve high recall, leaving refinement more scope to alter correct spans than to recover missed ones

### 4.3 P, R and F1 by Severity Label

Aforementioned, the logits-adjusted XCOMET-XL showed a notable boost in recall. To investigate where the boost in recall is concentrated, we computed the average Precision, Recall and F1 for each severity label (minor/major). Based on the results, as seen in Table 4, the logits-adjusted XCOMET-XL achieves higher recall and F1 on major errors than on minor errors. The recall gained by the logit adjustment is therefore concentrated on the more severe, higher-priority errors rather than on minor ones. In a similar vein, we also observe a boost in precision due to logits adjustments for major errors albeit a drop in precision for minor errors.

While LLM refinement produced small gains in precision on major errors (18.33 to 18.61), consistent with the step pruning spurious spans, this came at the expense of recall (36.03 to 33.20), and the net effect on F1 was slightly negative (12.95 to 12.80). The same precision-for-recall trade holds for minor

errors, again yielding no net gain in F1. Selecting spans by entropy rather than at random produced near-identical results across both severities, indicating that the ranking provides no measurable benefit over random selection.

## 5 WMT2026 Submission

We participated in the WMT2026 task using the logits-adjusted XCOMET-XL with LLM refinements on entropy-ranked error spans, on the eight high-priority language pairs[2] that were designated by the Organizers. As the 2026 edition's gold annotations for the test set had not been released at the time of submission, the results cannot be reported. All experiments in this paper are conducted on the WMT2025 test set, in accordance with WMT2025's evaluation script.

## 6 Conclusion

This system proposes the use of logits offsets to rebalance the label distribution, addressing the long-tailed probability problem for machine translation quality estimation of error spans. Our results show that a simple post-hoc adjustment can result in a boost in F1 and recall, but dampening precision for some locales.

## 7 Limitations & Future Work

One limitation of this work is that it has yet to address language specific behavior. Deeper statistical investigation needs to be done to find out why the boost in precision and recall from logits adjustments is not uniform across all languages, and why precision benefits little from logits adjustments.

Cost in terms of high token usage is a further consideration: refining every span for every system with a 32B reasoning model is expensive, and because we already rank spans by uncertainty, refinement could be applied adaptively to only the least-confident spans, or delegated to a smaller distilled judge.

A further limitation is that entropy (computed from xcomet) was the sole metric used to rank error spans that the model is presumably least certain about. Future work could experiment with using other metrics like confidence and log-likelihood, or a combination of them, to rank error spans for refinement.

## A Prompt Template for Refinement

**Refinement Prompt**

```
You are an annotator for the quality of machine translation. Your task is to reflect on the predicted error spans produced by
an autorater given the source and target segments, and re-segment and/or re-classify these spans by severity.

source language:     {source_language}
source segment:      {source_segment}
target language:     {target_language}
machine translation: {target_segment}
predicted error spans: {xcomet_error_spans}

#### Guidelines and Error Taxonomy ####
Error categories: accuracy (addition, mistranslation, omission, untranslated text), fluency (character encoding, grammar,
inconsistency, punctuation, register, spelling), locale convention (currency, date, name, telephone, time format), style
(awkward), terminology (inappropriate for context, inconsistent use), non-translation, other, or no-error.

Each error is either major or minor. Major errors inhibit comprehension or disrupt flow. Minor errors are technically errors
but do not disrupt flow or hinder comprehension. Formatting errors alone do not hinder comprehension.

#### Your Task ####
Evaluate only the predicted error spans, given the machine translation in {target_language} and the source segment in
{source_language}. Think step by step:
1. Each entry has 'text' from the machine translation, predicted as a mistranslation. Decide whether it is a true error,
referring to the source.
2. If it is a true error but its severity is wrong, reclassify the severity.
3. If the span is not an error at all, remove its entry from the array.
4. If only part of the span is an error, re-segment it into subspans and emit those instead, each with keys: {'text': str,
'start': int, 'end': int, 'severity': str}.

Output a JSON array of objects, each with exactly the keys "text", "start", "end", "severity". 'start'/'end' are character
indices into the target translation, 'text' is the substring they bound, and "severity" is "major" or "minor". If nothing is an
error, return []. Output ONLY the JSON array, with no other text.
```

Figure 1: Reference-free refinement prompt that instructs an LLM to audit the error spans predicted by an upstream autorater.

# Leveraging Verbalized Confidence in LLM-as-a-Judge for Automated Translation Quality Evaluation

**Richard Servajean, Mohammad Golam Sohrab, Lucie Kunitomo-Jacquin, Matīss Rikters**
Artificial Intelligence Research Center (AIRC),
National Institute of Advanced Industrial Science and Technology (AIST),

## Abstract

This paper presents the AIST AIRC team's contributions to subtasks 1 (segment-level error detection and span annotation), 2 (segment-level quality score prediction) and 3 (detection of error-free segments) of the automated translation quality evaluation systems shared task in WMT 2026. Our approach to address each of the 3 subtasks relies on an LLM-as-a-judge system. Specifically, for subtasks 2, we follow an LLM-as-a-judge approach within the Multidimensional Quality Metrics (MQM) error typology, with the novel addition of prompting the large language model (LLM) to verbalize its confidence in each error type assessment. We then train a Multilayer Perceptron (MLP) Regressor on error severities with and without associated confidence ratings to predict human annotations. First, our results provide further evidence for the relevance of integrating LLMs into automated translation quality evaluation pipelines. Second, this work aims to advance ongoing efforts to make these pipelines uncertainty-aware through the integration of verbalized confidence. Our code is freely available at `https://github.com/sshrichard/WMT-Evaluation-Shared-Task-2026`.

## 1 Introduction

In the last few years, artificial intelligence (AI) systems have been applied to numerous fields such as biology (Jumper et al., 2021) and mathematics (Feng et al., 2026). In particular, since the release of GPT-3.5 in 2022 (Schulman et al., 2022), large language models (LLMs) have seen rapid and widespread adoption. In this context, a straightforward method to address any given task consists in directly prompting an LLM to perform it, an approach commonly referred to as LLM-as-a-judge (Gu et al., 2026). The LLM-as-a-judge approach has been followed in many areas, including the field of translation evaluation (Kocmi and Federmann, 2023b,a; Fernandes et al., 2023; Lu et al., 2024, 2025; Sindhujan et al., 2025; Qian et al., 2024). Accordingly, for subtask 1, we simply prompt an LLM to perform segment-level error detection and span annotation. Similarly, within subtasks 1 and 2, we follow previous work, such as Lu et al. (2024), where they implement the Multidimensional Quality Metrics (MQM; Freitag et al., 2021) framework with LLM judges. More precisely, in the current work, we prompt an LLM to assess the severity of different error types drawn from the MQM typology, with the following twist: rather than prompting the LLM solely to assess error severity, we also prompt it to report (i.e., verbalize) its confidence in each error type assessment.

*Verbalized confidence*, also referred to as *verbalized uncertainty* (Groot and Valdenegro-Toro, 2024), is one among a broad range of measures in the field of LLM uncertainty quantification (Shorinwa et al., 2025). It has also become an important focus of research on the metacognitive capabilities of AI systems (Servajean and Servajean, 2026; Liu et al., 2026a). These measures are typically evaluated on their ability to distinguish correct from incorrect responses. Importantly, it is well-established that taking into account uncertainty signals is crucial in decision-making contexts (Li and Steyvers, 2025). As an illustrative example, in a high risk, high uncertainty scenario, suspending judgment and prioritizing further data collection can help avoid committing to a decision with potentially catastrophic consequences. With regard to automatic translation evaluation, the integration of confidence signals into evaluation pipelines has recently attracted growing interest (Glushkova et al., 2021; Zerva et al., 2022). Hence, in the present paper, we aim to advance ongoing efforts to make translation quality evaluation pipelines uncertainty-aware by investigating whether taking into account verbalized confidence make LLM-based translation evaluation better.

## 2 Related Work

**Subtask 1.** Yeom et al. (2025) introduced Tagged Span Annotation (TSA), an annotation scheme designed to extract span-level information by proposing a translation error span detection system that leverages OpenAI o3[1], a state-of-the-art proprietary-based reasoning LLM, for the WMT'25 MT evaluation span-level error detection task. Building on this idea, we use an LLM with static span tagging schema.

**Subtasks 2 and 3.** Machine translation evaluation is inherently affected by multiple sources of uncertainty. As discussed by Glushkova et al. (2021), uncertainty may arise from noisy human judgments, limited inter-annotator agreement, imperfect or insufficient reference translations, complex translations, and domain mismatch between evaluation data and the model's training domain. These factors motivate the development of uncertainty-aware evaluation methods (Beck et al., 2016; Fomicheva et al., 2020; Zerva et al., 2022; Zerva and Martins, 2024; Marashian et al., 2026; Wu and Monz, 2025).

Notably, for the WMT'25 MT evaluation task, Wu and Monz (2025) leveraged the average log-likelihood assigned by an LLM as a measure of translation quality, and incorporated a calibration step in their pipeline that optimizes the Pearson correlation between this likelihood and an external quality metric to further improve its correlation with human annotations. They reported encouraging performance, sometimes exceeding that of some state-of-the-art systems.

While we focus on evaluating full translations, Marashian et al. (2026) focused on various *per-word* and *per-token* confidence measures. They especially compared methods based on verbalized confidence to methods based on internal confidence (token probabilities). Verbalized and internal methods performed comparably when evaluated on calibration and error detection. Yet, they found little to no correlation between verbalized and internal measures.

In this paper, we aim to leverage the capabilities of LLMs to explicitly assess and verbalize their own confidence.

## 3 Method

### 3.1 LLM for Segment-level Error Detection and Span Annotation

We tackle the segment-level error detection and span annotation (subtask 1) by employing `Qwen/Qwen3-32B`[2], leveraging prompt-based in-context learning for inference. The model is loaded from the Hugging Face hub. Due to time constraints to address this subtask, we mainly focus on prompt-based approaches that exploit in-context learning by providing instructions and examples rather than relying on task-specific training.

**Prompt Engineering for Error Span Detection.** Prompt engineering has become one of the most widely adopted approaches for adapting general-purpose LLMs to many domain specific tasks including text summarization, peer-review generation, and code generation. Notably, this approach does not require modifying model parameters. In a few-shot setting for translation error span detection, models are directly instructed to identify translation errors using a prompt that includes several annotated examples of error spans to guide the structure of the output.

For a given source and target languages, the task uses an error-span annotation scheme where each error span is wrapped in a static tag `<ES>.</ES>` that allows multiple errors to be annotated simultaneously within the same sentence. Therefore, each error span consists of start-token marker and a end-token marker.

For a desired JSON response format, the target schema is illustrated through few-shot examples. An example of the instructions and corresponding JSON output is provided below:

**Instruction**

You are a careful and balanced annotator for machine translation quality. Your task is to identify translation errors with appropriate confidence.
**EVALUATION GUIDELINES:**
- Be thorough but precise: Only mark errors when you are confident they are incorrect
- Consider context and domain: Some variations may be acceptable depending on context
- Distinguish between errors and acceptable alternatives: Multiple valid translations may exist
- Focus on clear, objective errors rather than subjective preferences
- Verify each potential error against the source text before marking
- When in doubt, err on the side of not marking an error

[2] https://huggingface.co/Qwen/Qwen3-32B (accessed 11 September 2026)

**Error Categories:**
- Accuracy: addition, mistranslation, omission, untranslated text
- Fluency: character encoding, grammar, inconsistency, punctuation, register, spelling
- Style: awkward phrasing
- Terminology: inappropriate for context, inconsistent use
- Other: non-translation, other issues

**Severity Classification:**
- Major: Errors that impact meaning or usability but do not render the text unusable
- Minor: Errors that do not impact meaning or usability

**Omission Classification:**
- Null: No Errors detected in the annotated text
- Major: Errors that appears in the error category as accuracy error like mistranslation, omission, untranslated text
- Minor: Errors that do not impact meaning or usability

**CRITICAL OUTPUT REQUIREMENTS:**
- Mark errors only when you have clear evidence they are incorrect
- Consider whether alternative translations could be equally valid
- Apply strict standards: better to miss a minor error than create a false positive
- Wrap error spans in the translation with tags: <ES></ES>
- NO comments, explanations, or additional text
- **Mark only the minimal substring that contains the clear error; do not include extra context**

### 3.2 Pipeline for Segment-Level Quality Score Prediction and Detection of Error-Free Segments

Here, we introduce our pipeline for subtask 2 (segment-level quality score prediction) and 3 (detection of error-free segments), in which an LLM is asked to assess the severity of different error types and to verbalize its confidence.

#### 3.2.1 Verbalized Confidence in LLM-as-a-Judge

For subtask 2 (segment-level quality score prediction), given a source and a translation, we first assess whether the translation target language coincides indeed with that of the translation using GlotLID model (Kargaran et al., 2023)[3].

If the assessed translation language is the correct one, we prompt an LLM (we tried *Qwen3.6-27B*[4] [with the recommended temperature of 1.0 and without reasoning], *Qwen3.8-27B-FP8*[5] [with a temperature of 0.7 and without reasoning; it was not included in our submission], and *Babel-83B-chat*[6] [with a temperature of 0.0]) with the source, the translation, their languages, seven error type definitions corresponding to the "seven high-level error type dimensions"[7] within MQM error typology (Lommel et al., 2024), and ask it to assess the severity of each error type by choosing among `Not applicable`, `Neutral`, `Minor`, `Major`, and `Critical`. Finally, the model is instructed (within the same prompt) to rate its confidence in each error type assessment (a confidence scale is provided [e.g., 0.6-0.8: "Highly likely"]; see the prompt available on GitHub for further details).

Based on the LLM output, we construct a $7 \times 4 + 1 = 29$-long feature vector, consisting of seven 4-dimensional blocks (one per error type) plus an additional entry indicating whether a language mismatch was detected between the translation and the target language (0 or 1). Each of the seven 4-dimensional block encodes:

Table 1: Results for all three subtasks available at Codabench[8], where our predictions are compared to the pseudo-gold-standard scores (no further details given on the official website[9]. The metrics for subtasks 1, 2, and 3 are the F-score (Perrella et al., 2026), the correlation (organizers did not specify which), and the Matthews correlation coefficient, respectively. The submission IDs are given in the second column. For subtask 1, submissions 875417 and 875796 correspond, respectively, to the settings in which omission severity was either assessed directly by the model or determined using a simple rule-based approach that checks the different errors associated with omissions (see the example in the Method section). Within subtask 2, submissions 871400 and 871401 correspond to the results obtained with *Qwen3.6-27B*, including and without including confidence ratings, respectively. Within subtask 3, submissions 871721 and 874374 correspond to the results obtained with *Qwen3.6-27B* and *Babel-83B-chat*, respectively. Empty entries (see the EN-SE column) mean that this language pair was excluded, while n/a means that we did not address this language pair.

1. Whether the considered error type is applicable or not (0 or 1),
2. Its severity taking value 0 (`Neutral`), 1 (`Minor`), 5 (`Major`) or 25 (`Critical`), where we followed standard MQM scoring model,
3. The model's confidence (float between 0 and 1), and
4. Whether a format issue occurred (0 if no issue occurred, 1 as soon as a parsing issue occurred in a single value or in the entire output). Usually, no parsing issue occurs, but this may depend on the model and on whether a strict output schema is enforced.

By default, all values are set to 0. For example, in case of an error type not applicable, the corresponding severity entry is set to 0.

Then, we stacked all vectors corresponding to all translations from the file `wmt25-genmt-humeval.jsonl`[10], and trained a Multilayer Perceptron (MLP) Regressor to predict the corresponding human annotations. We considered an MLP with two hidden layers (100 and 50 ReLU units), with scikit-learn's default settings, for up to 5000 epochs with the default convergence tolerance.

#### 3.2.2 LLM-as-a-Judge for Error-Free Translation

For subtask 3 (detection of error-free segments), a segment is considered error-free if, in subtask 2, the LLM judge considered that all error types were either not applicable or had a neutral severity (see Section 3.2.1). By default, parsing issues cause the translation to be classified as *not* error-free.

## 4 Experiments

Our implementation is based on Hugging Face transformers. During the model implementation, we use the publicly available previous year WMT ESA dataset; where the models are initialized from the publicly available checkpoints that we mentioned in the Method section. For model inference, a local machine with four NVIDIA RTX 6000 Ada GPUs with 48GB GDDR6 memory is used along with a cluster node with eight NVIDIA H200 GPUs with 141GB of HBM3e memory. To address segment-level error detection and span annotation for the official test set, we only considered eight prioritized language pairs due to time constraints. The running time for each language pair were around 30 hours where we disable the chain-of-thought thinking to non-thinking mode. Besides, we set `max_new_tokens` to 1024, which controls the maximum number of tokens generated by the model.

## 5 Results

The results obtained on the initial submission in which our predictions were compared against

pseudo-gold-standard scores are given in Table 1. For subtask 2, the correlation between human annotations and our predictions are given in Table 2. When considering the overall correlations, we can see that the impact of including confidence ratings in the regression is unclear; extremely small differences in correlation (of the order of $10^{-2}$ or $10^{-3}$) end up statistically significant (the 95% confidence interval of the paired bootstrap distribution with $n = 1,000$ of the differences in correlation excludes zero) in both directions. For a similar analysis, note that we also considered all translations from 1,000 source segments randomly drawn from the 2025 data (see the Method section) regardless of the source and translation languages, with an MLP regressor trained on *Qwen3.6-27B* assessments of the translations from a disjoint set of 1,000 source segments. With confidence ratings included in the regression, Pearson, Spearman and Kendall correlations with human scores were 0.5501, 0.4791 and 0.3459 respectively; without them, 0.5348, 0.4722 and 0.3405 (all $p < 0.001$). A paired bootstrap ($n = 10,000$) demonstrates that the improvement when including confidence ratings is significant for all three coefficients. However, the improvement is very small. Finally, for comparison, note that CometKiwi (Rei et al., 2022)[11] evaluated on the same translations yielded Pearson, Spearman, and Kendall correlations of 0.4347, 0.3308, and 0.2280, respectively (all $p < 0.001$).

Even though Table 1 and Table 2 cannot be perfectly compared as the considered translations differ (many translations from `mteval-test26.jsonl.gz` are not in `annotations_preliminary.json`; see captions for further details), we still notice significant differences. A possible explanation is that there is a varying number of human annotations per translation in `annotations_preliminary.json`, so that the presence of segments with very few annotations or even a single annotation may add noise that would degrade the correlation with our predictions, compared to the case where they are evaluated against pseudo-gold-standard scores. Similarly important differences can be noticed between Table 1 and Table 3 for subtask 3. A striking difference concerns the language pairs EN-IT (Ladin) and EN-IT (Ligurian), which were not included in the training set (i.e., last year data; see the Methods): while the Matthew correlation coefficients are near zero when our predictions are evaluated against human annotations, they remain positive when evaluated against the pseudo-gold-standard scores, although the correlations are still very moderate.

## 6 Discussion

In this paper presenting our contribution to subtasks 1 (segment-level error detection and span annotation), 2 (segment-level quality score prediction) and 3 (detection of error-free segments) of the automated translation quality evaluation systems shared task in WMT 2026, we considered an LLM-as-a-judge approach.

For subtask 1, we adopted a prompt-based in-context learning approach using few-shot examples rather than relying on task-specific training. We believe that task-specific training across all language pairs using data from previous years could further improve segment-level error detection and span annotation performance. In addition, to reduce generation time, we disabled chain-of-thought reasoning and used the model in non-thinking mode. Future work could therefore explore combining task-specific training with chain-of-thought prompting at inference time to further improve performance on subtask 1.

For subtasks 2 and 3, we followed the MQM framework, with the novel addition of prompting the LLM to verbalize its confidence in each error type assessment. More specifically, we trained a Multilayer Perceptron Regressor on error severities with and without associated confidence ratings, generated by an LLM, to predict human annotations. We find no clear evidence that including confidence ratings improves the predictions. There exist many different measures of uncertainty (Shorinwa et al., 2025). Future work could integrate alternative uncertainty measures into our pipeline and compare their effects on performance. Additionally, other regression methods could be explored, as could explicit strategies for combining error type severities with their associated confidence scores, such as a weighted sum.

An important limitation is that last year annotations, on which we performed the MLP regressions, were obtained within the ESA protocol (Kocmi et al., 2024), while 2026 data uses cESA protocol (Zouhar et al., 2026). In the latter case, annotators have access to multiple translations of the

Table 2: **Subtask 2.** Segment-level correlation between the predictions from each model and the human scores obtained within the cESA protocol (Zouhar et al., 2026), per language pair and overall (last row). When multiple human annotations are assigned to a given translation, we take the average. $r$ is Pearson, $\rho$ Spearman and $\tau$ Kendall's tau. All $p < 0.001$. The cESA scores come from the released file `annotations_preliminary.json`[12]. We only consider translation segments that are concerned by the predictions from our submission, i.e. those from `mteval-test26.jsonl.gz`[13].

same document at the same time, facilitating "more consistent and efficient judgments" (Zouhar et al., 2026). This may introduce differences between the training and testing targets.

Beyond confidence ratings, additional information could have been incorporated as regression features, such as segment length or the source and target languages (encoded as categorical variables) as there exists cross-lingual differences in human annotations (Magdy et al., 2026; Liu et al., 2026b).

Also, note that we only considered evaluating models that are publicly available at no cost or free trial to help with reproducibility, such as *Qwen3-32B*, *Qwen3.6-27B*, *Qwen3.8-27B-FP8*, and *Babel-83B-chat*. The choice of the model and parameters like the reasoning budget when applicable are likely to have a significant impact on performance.

Finally, it is worth noting that incorporating AI confidence into pipelines is becoming an increasingly prominent topic across research communities in AI.

## Acknowledgments

This paper is based on results obtained from AIST policy-based budget project "R&D on Generative AI Foundation Models for the Physical Domain," and a project, JPNP25006, commissioned by the New Energy and Industrial Technology Development Organization (NEDO).

## Limitations

In this work, we only considered evaluating open-weight models and open-access systems that are publicly available at no cost or free trial to help with reproducibility. Our code is freely available on GitHub under a permissive license at https://github.com/sshrichard/WMT-Evaluation-Shared-Task-2026.

## Ethics Statement

Our work fully complies with the ACL Code of Ethics[14]. We use only publicly available models/systems and relatively low compute amounts while conducting our experiments to enable reproducibility. We do not perform any studies on other

Table 3: **Subtask 3.** Matthews correlation coefficient between the error-free predictions from each model and the human labels, per language pair and overall (last row). A translation is labeled error-free when the human annotation marks no error spans; when multiple human annotations are assigned to a given translation, we take the majority, ties counting as containing errors. Chi-square tests of independence lead to $p < 0.001$ in all cases, with the following exceptions: for *Babel-83B-chat*, EN-ZH ($p = 2.50 \times 10^{-1}$), EN-IT (Ladin) ($p = 7.28 \times 10^{-1}$), and EN-SE ($p = 2.09 \times 10^{-3}$); for *Qwen3.6-27B*, EN-IT (Ladin) ($p = 7.50 \times 10^{-1}$) and EN-SE ($p = 2.49 \times 10^{-1}$); and for *Qwen3.8-27B-FP8*, EN-IT (Ladin) ($p = 2.42 \times 10^{-3}$). Human annotations come from the released file `annotations_preliminary.json`[15]. We only consider translation segments that are concerned by the predictions from our submission, i.e. those from `mteval-test26.jsonl.gz`[16].

# Reference-Free Consensus Evaluation of Machine Translation: Ensembling LLM Error-Span Judgments with Neutral Cross-Verification and STAPLE Reliability Fusion

Assaf Siani
assaf@lexicala.com

*Independent Submission, WMT 2026 Shared Task on Automated Translation Quality Evaluation*

**Abstract**

We present a reference-free system for the WMT 2026 automated translation-quality-evaluation shared task, covering all three subtasks: character-level error-span detection with Minor/Major severity, segment-level quality scoring on a 0–100 scale, and binary error-free classification. Rather than treating a single large language model (LLM) as an oracle, the system treats LLMs as fallible annotators. Three heterogeneous judges independently propose target-side error spans; a neutral cross-verification round converts these open-ended proposals into a complete, anonymized candidate-by-judge vote matrix; a character-level adaptation of STAPLE estimates latent error truth and per-judge reliability without references; and a two-state HMM imposes minimal span structure. Omissions are handled by a dedicated source-coverage pass rather than by scanning the target. Calibrating the single free prior against the official metric with human gold yields several findings: plain majority voting matches or beats STAPLE; the error-rate prior barely matters once outputs are schema-conformant; precision—judge over-flagging at roughly 3× the human rate—is the binding constraint; and LLM-derived silver gold cannot calibrate the prior without circularity. The system was deployed across seven language pairs with partial-failure-tolerant, resumable execution.

**Keywords:** MT evaluation; error-span annotation; quality estimation; LLM-as-a-judge; label fusion; STAPLE; consensus.

## 1 Introduction

Machine-translation (MT) evaluation increasingly requires more than a scalar system ranking. Error-Span Annotation (ESA) offers localized, severity-aware feedback while retaining a holistic score, occupying a useful middle ground between coarse direct assessment and expert-intensive MQM annotation (Kocmi et al., 2024). The WMT 2026 setting asks for three compatible views of the same segment: character error spans with severity, a 0–100 quality score, and an error-free decision. Crucially, inference is reference-free.

Reference-free inference with LLM judges is deceptively hard. A single judge can be fluent yet lenient, overconfident, prompt-sensitive, and inconsistent across severity scales. Multiple judges improve coverage but create a second problem: they propose different, overlapping intervals, and silence on an interval does not reveal whether a judge rejected it or never considered it. Naive union maximizes recall while inheriting every false positive; naive intersection is too conservative.

We resolve this by converting open-ended proposals into explicit shared decisions and then applying probabilistic label fusion. Our contributions are: (i) a two-round protocol that preserves independence during proposal generation and builds a complete, anonymized candidate-by-judge vote matrix during cross-verification; (ii) a character-level adaptation of STAPLE with MAP regularization and an HMM decoder that fuses overlapping intervals while estimating judge reliability without references; (iii) a separate source-coverage mechanism for omissions; (iv) a severity and quality layer grounded in local impact, official severity weights, and inverse-variance fusion; and (v) an empirical account, calibrated against the official metric with human gold, of what the consensus machinery does and does not buy.

## 2 Related Work

String- and embedding-based metrics such as BLEU (Papineni et al., 2002), chrF (Popović, 2015), and COMET (Rei et al., 2020) give useful external diagnostics but do not yield localized, severity-aware spans. LLM-as-a-judge evaluation scales naturally yet inherits systematic bias: position effects, superficial-quality preferences, leniency, and vulnerability to framing (Wang et al., 2024; Zhou et al., 2024; Shi et al., 2025). We observe an analogous label-framing effect—describing pooled candidates as 'flagged errors' materially increases acceptance—and therefore verify candidates neutrally. STAPLE (Warfield et al., 2004) estimates a probabilistic latent segmentation while learning each rater's sensitivity and specificity; its rater-weighting idea transfers well to target-side character masks and, unlike simple voting, lets an explicit clean judgment count as negative evidence.

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1739–1744
October 28-29, 2026 ©2026 Association for Computational Linguistics

The WMT Quality Estimation shared tasks have progressively moved toward fine-grained, reference-free evaluation, and recent findings ask whether LLMs are closing the gap to human quality estimation (Zerva et al., 2024). Our system is squarely in that line: reference-free at inference and LLM-based throughout, but departing from the single-judge paradigm by making disagreement explicit and fusing it probabilistically. The MQM framework (Lommel et al., 2013) supplies the severity vocabulary our Minor/Major labels inherit.

## 3 Task Formulation

For each source segment $x$ and system hypothesis $y$ of $N$ Unicode characters after NFC normalization, the system predicts a set of half-open target intervals $[a, b)$, each labeled Minor or Major; a quality score $Q \in [0, 100]$; and a Boolean error-free decision. Offsets are computed in the exact submitted hypothesis, satisfying $0 \le a < b \le N$. Omissions are emitted through the task's dedicated per-translation omission field rather than as target character spans. Task-1 outputs are scored by the organizers' MPP metric (Match with Partial overlap and Partial credit, micro-averaged); Task 2 by correlation with human ESA scores; Task 3 by Matthews correlation.

## 4 System Architecture

The pipeline has three online (API) stages and a deterministic offline tail. (1) Independent annotation: three heterogeneous judges—in the deployed runs Gemini 2.5 Flash, DeepSeek V4 Flash, and Qwen-Plus—each receive the source, the raw translation, language direction, domain, and a diagnostic rubric, and return zero or more target spans with a severity-oriented explanation and a holistic 0–100 score. Calls are independent and parallel; judges never see one another's proposals. (2) Neutral cross-verification: raw spans are pooled per segment into an anonymized, shuffled candidate list; every judge then votes accept/reject on every candidate and rates the benefit of correction on a bounded scale (1 slight, 2 clear, 3 dramatic), yielding a complete candidate-by-judge matrix. (3) Source-coverage: a dedicated pass detects omissions from the source side. The offline tail performs consensus fusion, quality computation, schema validation, and serialization. Resume-aware JSONL checkpoints let interrupted API runs continue without recomputing completed judgments, and partial judge failures are tolerated: a segment retaining two of three judges is still fused.

## 5 Consensus Fusion

Character projection. For judge $j$ and character $c$, $D_{jc} = 1$ when $c$ lies inside any candidate that $j$ accepted, and $0$ otherwise. Projection turns partially overlapping intervals into a common lattice and makes every explicit rejection informative.

STAPLE E-step. Let $T_c \in \{0,1\}$ be the latent truth and $\gamma = P(T_c = 1)$ the rarity prior. Judge $j$ has sensitivity $p_j = P(D_{jc} = 1 \mid T_c = 1)$ and specificity $s_j = P(D_{jc} = 0 \mid T_c = 0)$. Conditional independence gives the posterior error probability

$$W_c = \frac{\gamma \prod_j \left(p_j^{D}(1-p_j)^{1-D}\right)}{\gamma \prod_j \left(p_j^{D}(1-p_j)^{1-D}\right) + (1-\gamma)\prod_j \left((1-s_j)^{D} s_j^{1-D}\right)}$$

evaluated in log space. Abstaining or failed judges drop out of the product; they lower confidence without counting as negative votes.

MAP M-step. Maximum-likelihood estimates are unstable for short segments and three raters, so Beta-prior pseudo-counts of strength $\alpha$ regularize sensitivity toward $r_j = 0.5$ and specificity toward $s_0 = 0.95$:

$$p_j \leftarrow \frac{\sum_c (W_c D_{jc}) + \alpha\, r_j}{\sum_c (W_c) + \alpha}$$

$$s_j \leftarrow \frac{\sum_c \left((1-W_c)(1-D_{jc})\right) + \alpha\, s_0}{\sum_c (1-W_c) + \alpha}$$

The asymmetric anchors are deliberate: a high-specificity prior and small $\gamma$ break the label-swap symmetry and stop the model from painting broad clean regions as errors. EM stops when $\max_c |\Delta W_c| < 10^{-4}$.

HMM smoothing. Independent posteriors contain single-character spikes and holes. A two-state HMM uses the STAPLE likelihoods as emissions with persistence $\rho = P(T_c = 1 \mid T_{c-1} = 1) = 0.85$; to hold the stationary error mass $\gamma$, the clean→error transition is $\gamma(1-\rho)/(1-\gamma)$. Viterbi decoding yields the most probable clean/error path, and error runs shorter than two characters are pruned.

## 6 Severity, Omissions, Error-Free

Reliability-weighted severity. Each fused span inherits impact ratings from the accepting judges whose candidates overlap it. With judge reliability $\rho_j = (p_j + s_j)/2$ and weight $w_j = \max(\log[\rho_j/(1-\rho_j)],\ \varepsilon)$, the fused local impact is $Z_m = \Sigma_j\, w_j\, I_{jm} \,/\, \Sigma_j\, w_j$ over accepting judges, where $I_{jm} \in \{1, 2, 3\}$ is the impact judge $j$ assigned to span $m$ during cross-verification (1 = slight, 2 = clear, 3 = dramatic). The label is Major when $Z_m \ge 2.0$ and Minor otherwise—an absolute boundary following the prompt semantics (1 = meaning preserved, 2 = clear distortion), chosen over a corpus-relative threshold that would let unrelated batch composition flip labels.

Source-coverage omissions. An omission has no natural target span, so a dedicated pass asks each judge to align source meaning units against the unmodified translation and report uncovered units with impact. An omission is

fused when at least two judges report non-zero severity, becoming Major at fused impact 2.0, and is routed to the dedicated omission field. Treating omission as a source-coverage judgment —not as target-span scanning— avoids a category error that otherwise loses omissions on the most degraded translations.

Error-free classification. The decision is a conjunction: no fused text span, no fused omission, and median holistic adequacy at least 85. The adequacy floor guards against diffuse mistranslation or hallucination that does not localize cleanly. The serializer also exports the organizers' span-only alternative so both rules coexist transparently.

## 7 Segment-Level Quality Estimation

Two estimators are fused by inverse variance. Estimator A (debiased holistic): each judge $j$ emits a holistic 0–100 score $h_{j,s}$ on segment $s$, but judges differ systematically in leniency, so we debias before averaging. For judge $j$ we estimate a global offset $b_j$— its mean deviation, across all segments it rated, from the ensemble center $c_s$ (the per-segment mean of the judges' scores, with $|J_s|$ the number of judges scoring segment $s$):

$$b_j = mean_s\left(h_{j,s} - c_s\right), \qquad c_s = \left(\frac{1}{|J_s|}\right)\sum_j \left(h_{j,s}\right)$$

Subtracting $b_j$ places every judge on a common scale. The segment estimate $q_A$ is a reliability-weighted combination of the offset-corrected scores $h_{j,s} - b_j$, with their dispersion supplying variance $v_A$; this keeps the judges' global fluency/adequacy signal while removing persistent per-judge leniency or harshness. Estimator B (span-derived risk): with official weights 2.5 (Minor) and 10 (Major), a confidence-weighted, length-normalized penalty $P$ maps through a survival link $q_B = 100 \cdot exp(-P/\beta)$, $\beta = 5000$.

Formally, with fused span $m$ carrying confidence $conf_m$ (its posterior mass under the fusion — STAPLE's soft posterior, or vote share under majority) and official severity weight $\omega(sev_m) \in \{2.5, 10\}$, and reference length $L_0 = 500$ characters against the segment's actual length $L$:

$$P = \left(\frac{L_0}{L}\right)\sum_m \left(conf_m \omega(sev_m)\right)$$

The $L_0 / L$ term normalizes for segment length, so segments with the same density of errors receive comparable penalty regardless of raw character count; weighting by $conf_m$ lets a low-confidence span contribute partial penalty rather than an all-or-nothing count. Bootstrap resampling of span correctness gives $v_B$ (floored at 25). The fused score is

$$Q = \frac{\frac{q_A}{v_A} + \frac{q_B}{v_B}}{\frac{1}{v_A} + \frac{1}{v_B}}, \qquad v_Q = \frac{1}{\frac{1}{v_A} + \frac{1}{v_B}}$$

If holistic ratings are absent, $Q$ degrades gracefully to $q_B$; a segment whose every judge fails is marked unscorable and assigned a low, high-variance score rather than a spurious perfect one. Alongside $Q$ we also export the organizers' mechanical score $max(0,\ 100 - 10 \cdot n_{major} - 2.5 \cdot n_{minor})$, keeping the distinction between our modeling and the task-prescribed derivation explicit.

## 8 Experiments and Findings

We integrated the official Task-1 scorer and used human gold from WMT24 ESA and WMT23 MQM to calibrate the single free prior $\gamma$. Five findings stand out.

(1) Precision is the binding constraint. On genuine MT output the judges over-flag: their union covers roughly 3× the gold character mass, and per-pair precision sits at 0.13–0.24. No setting of the prior repairs this; reducing upstream over-flagging is where the remaining headroom is.

(2) $\gamma$ is a decision prior, not the corpus error rate, and it barely matters. On WMT23 he–en the gold density is 10.8% yet the F-optimal $\gamma$ is 1%, because $\gamma$ counteracts correlated over-flagging. At full scale the optimal $\gamma$ varies by pair (0.03–0.15) but $F(\gamma)$ is flat near its maximum: a single global $\gamma = 0.05$ costs at most ≈ 1.2 F-points, so per-pair tuning is low value.

| Pair | Precision | Recall | F-opt γ |
|---|---|---|---|
| cs–uk | 0.13 | 0.42 | 0.05 |
| en–ru | 0.15 | 0.39 | 0.03 |
| en–is | 0.24 | 0.31 | 0.15 |

*Table 1: Per-pair Task-1 precision/recall and F-optimal γ against WMT24 ESA gold (500 hypotheses/pair). Precision is uniformly the bottleneck; the F-optimal γ varies but the curves are flat near their maxima.*

(3) Schema conformance beats algorithm tuning. Emitting omissions through the dedicated field rather than as character spans raised F by 0.025 on average—twice the entire effect of tuning the prior—because span-encoded omissions had been pure false positives. JSON-lines formatting and Boolean labels were likewise the difference between a valid and a rejected submission.

(4) Majority voting is competitive with STAPLE. In gold ablations, character-level majority vote matched or beat the full STAPLE+HMM pipeline on both tasks (Task-1 F 0.260 vs. 0.246; Task-2 Pearson 0.538 vs. 0.491). STAPLE's complexity is not clearly earned on these three-rater segments; we therefore submit both variants.

| Variant | Task-1 F | Task-2 r |
|---|---|---|
| STAPLE + HMM | 0.246 | 0.491 |

| | | |
|---|---|---|
| Majority vote | 0.260 | 0.538 |

*Table 2: Fusion ablation on the three ESA gold pairs. Task-1 F uses the official MPP metric; Task-2 r is Pearson correlation with human ESA scores. Majority voting matches or beats STAPLE on both tasks.*

(5) Silver gold cannot calibrate the prior. Deriving gold from a strong LLM to tune $\gamma$ is circular—it is the very bias $\gamma$ must counteract—and selects $\gamma = 0.15$ where the human-gold optimum is 0.01, reporting F = 0.65 where the honest score is 0.35. For context, our F of 0.20–0.30 is competitive: the best WMT25 auto-rater averaged 13.5% micro-F1, and human–human agreement is near 47% (metrics not directly comparable).

(6) A negative result: repair-validation. An earlier design asked each judge to repair a proposed span and re-score the repaired variant under blinded batching, on the theory that a genuine error yields a positive counterfactual quality delta. In practice the filter required two unreliable events—localized repair and calibrated re-scoring. Repairs frequently changed text outside the requested interval, and absolute scores saturated or moved coarsely, so the delta was dominated by noise. We replaced this loop with the direct categorical cross-verification of Section 4, which needs no repair and produces a clean vote matrix. We report the failure because the appealing counterfactual framing is a natural trap.

Diagnostic correlation. As a sanity check, segment scores $Q$ on a 40-segment held-out set correlate positively with reference-based BLEU, chrF, and COMET despite $Q$ using no reference at inference, indicating a shared quality signal. We stress that this is diagnostic only: the sample is small and non-independent, the comparators measure different constructs, and no superiority is claimed.

(7) Task 3 (error-free), MCC. We evaluate the error-free decision against gold derived from the ESA annotations (error-free iff the human ESA score is at least 85 and there are no gold spans). The classes are imbalanced (58% error-free on cs–uk, 17% on en–is), so we report Matthews correlation (MCC). Our adequacy-gated conjunction attains MCC 0.301 (cs–uk) and 0.415 (en–is), beating the organizers' span-only baseline (0.277 and 0.399) on both pairs: the adequacy floor removes false-positive error-free labels—hallucinated or off-topic translations that produce no localizable span yet are not publishable. Error-free precision/recall are 0.73/0.61 (cs–uk) and 0.44/0.65 (en–is).

| **Pair** | **n** | **gold EF** | **MCC (ours)** | **MCC (base)** |
|---|---|---|---|---|
| cs–uk | 99 | 58% | 0.301 | 0.277 |
| en–is | 100 | 17% | 0.415 | 0.399 |

*Table 3: Task-3 error-free MCC against ESA-derived gold. Our adequacy-gated rule beats the span-only baseline on both pairs; the imbalanced classes make MCC the appropriate metric.*

(8) Isolating cross-verification from fusion. Neutral cross-verification is separable from the fuser and beneficial on its own: on 178 development candidates, framing pooled candidates neutrally rather than as 'flagged errors' raised the number rejected by all three judges from 17 to 43, removing stylistic false positives while preserving spans in heavily degraded probes. Both fusers consume this same cross-verified vote matrix, so the majority-vs-STAPLE comparison (Table 2) isolates only the fusion algorithm layered on top of it. STAPLE's marginal additions over majority are the per-judge reliability weights (reused in severity and quality), soft character posteriors, and the HMM contiguity prior; on three-rater segments these do not raise F, so we recommend majority vote as the primary submission and keep STAPLE as the second permitted variant.

## 9 Deployment and Language Pairs

The system was run on seven WMT 2026 language pairs: English–Northern Sami, Czech–German, Chinese–Japanese, English–Arabic (Egyptian and Modern Standard merged), English–Estonian, English–Indonesian, and English–Icelandic (including the GAMBITP challenge set). Direction and domain are routed per record from the item identifier, and language codes are mapped to explicit variety names so judges grade against the correct variety—critical where Egyptian Arabic and MSA are mixed. Execution is resumable and partial-failure tolerant: each stage checkpoints incrementally, and a segment losing one of three judges is still fused on the remaining two, which the source-coverage design shows is sufficient for omission. This heterogeneous-provider ensemble also proved operationally robust to per-provider quota and availability limits during large-scale runs. Table 4 reports the per-pair volume of the submitted output.

| Pair | Items | Hyps. | Spans | Omis. | Error-free | EF% |
|---|---|---|---|---|---|---|
| en–se | 493 | 13,311 | 31,750 | 5,800 | 833 | 6.3 |

## 10 Discussion

What the consensus machinery buys is epistemic bookkeeping rather than a single accuracy trick.

Independent generation separates proposal from adjudication; neutral cross-verification converts different proposal spaces into shared explicit judgments; STAPLE separates latent truth from annotator performance; the HMM imposes a minimal structural prior; and the source-coverage pass models absence in the source–target relation. No single component proves correctness, but each removes a specific ambiguity that a naive union or intersection would silently resolve the wrong way. That the far simpler majority vote is competitive (Table 2) does not negate this: the disciplined item space and neutral framing are shared by both fusers, and they are where most of the benefit accrues.

The labels reference-free and calibration-free deserve scrutiny. Inference uses no reference translation and rater weights are estimated from agreement, but the prompts encode a quality theory, providers embed training priors, and $\gamma$, $\alpha$, $s_0$, $\rho$, the pruning rule, the adequacy floor, and $\beta$ are fixed choices partly informed by development data. The honest claim is therefore reference-free inference with prior-encoded design. Finally, STAPLE assumes conditional independence across raters; heterogeneous providers reduce but do not remove correlated errors, so modeling rater correlation is a natural next step.

## 11 Limitations

Development sets are small and partly synthetic and do not substitute for blind evaluation or native adjudication. Task-1 F-scores remain low, showing that consensus and prompt design do not solve recall and boundary matching. STAPLE's conditional-independence assumption is strained when judges share training data or instruction-tuning conventions, so the vote matrix can be overconfident when all judges share a misconception, especially for low-resource pairs. Several constants are fixed design choices informed by development data; the strongest defensible claim is reference-free inference with prior-encoded design, not calibration-free evaluation. Proprietary model drift and decoding settings remain external reproducibility constraints; stored JSONL artifacts are treated as the immutable record.

## 12 Reproducibility

The judges are gemini-2.5-flash, deepseek-v4-flash, and qwen-plus, queried at temperature 0.3 for span annotation and 0 for terse single-score calls, with up to 8000 output tokens. Fixed constants: rarity prior $\gamma = 0.05$; MAP pseudo-count $\alpha = 10$ with sensitivity anchor $r_j = 0.5$ and specificity anchor $s_0 = 0.95$; HMM persistence $\rho = 0.85$ with two-character run pruning; severity cut $Z_m = 2.0$; quality $\beta = 5000$ with reference length $L_0 = 500$; adequacy floor 85. Offsets are half-open NFC character indices; runs checkpoint incrementally and are deterministic given identical model responses. Because the judges are proprietary and may drift, the stored JSONL judgments are the immutable record against which offline fusion changes should be compared.

## 13 Conclusion

We build a coherent reference-free WMT evaluation system by treating LLM outputs as noisy annotations to be verified and fused rather than as final truth. Independent generation improves candidate recall; neutral cross-verification creates a common item space and reduces framing-induced acceptance; STAPLE separates latent error from rater performance; the HMM imposes a minimal structural prior; and a source-coverage pass models absence correctly. Calibrated against the official metric with human gold, the analysis is candid about limits: precision-limited judges cap F-score, simple majority voting rivals the probabilistic model, and schema conformance outweighs parameter tuning. These lessons, more than any single component, are the contribution.

# QEbreak at WMT26: A Pre-Registered Audit of Omission and Addition Asymmetry in Machine Translation Quality Metrics

**Maksim Silchenko**
National University of Singapore
maks.silchenko.04@gmail.com

## Abstract

Reference-free quality estimation (QE) metrics see only the source and the hypothesis, so a translation that silently drops source content leaves nothing for them to flag. `QEbreak`, a pre-registered contrastive challenge set submitted to the WMT26 Automated Translation Quality Evaluation task (Subtask 4), measures this blind spot: 2,886 segments over 10 language directions, built as matched {base, omission, addition} triples, a fact-free verbosity ladder, and numeric-contradiction pairs as a positive control. Every hypothesis, endpoint, and equivalence margin was frozen in git-timestamped commits before any score existed. Scores from 31 systems confirm the deficit and refute our mechanism. Reference-free QE metrics under-penalize omission (family asymmetry $A = -0.51$; a current QE baseline scores the omission at or above its own base in 19.5 percent of matched contests, strictly above in 14.3), and the edit-direction by reference-availability interaction is significant ($\beta = -0.069$, 95% CI $[-0.081, -0.057]$). But reference-based neural metrics are asymmetric in the same direction ($A = -0.42$), outside the pre-registered $\pm 0.30$ equivalence margin, so omission under-penalization belongs to learned metrics as a class; reference access softens it but does not remove it. Every returned metric penalizes pure verbosity, and two systems score corrupted numerals above correct ones.

## 1 Introduction

A quality estimation metric that scores translations without a reference is the natural reward signal for machine translation systems: it is cheap, it needs no human reference, and it is already used to rerank candidate outputs. That role raises a structural question. A reference-based metric can notice that translated content is missing because the reference still contains it. A reference-free metric has only the source and the hypothesis, and a hypothesis that omits content is shorter, more fluent, and internally consistent. If reference-free metrics penalize omission less than they penalize a comparable amount of added content, then a best-of-$n$ reranker built on such a metric will sometimes prefer the incomplete translation. `QEbreak` was built to measure that preference directly.

`QEbreak` tests three pre-registered hypotheses. The headline hypothesis $\mathrm{H_B}$: reference-free QE metrics under-penalize meaning omission relative to fluent addition, while reference-based metrics penalize the two edit directions roughly symmetrically. $\mathrm{H_A}$: reference-free QE scores do not decrease, or even increase, as fluent, fact-free, source-unsupported material is appended to a realistic base translation. $\mathrm{H_C}$, a positive control: the reference-based neural frontier catches a single load-bearing numeric contradiction while surface and reference-free QE metrics diverge, which proves the harness can detect breaks at all.

The design choice that separates this audit from prior challenge sets is that every claim was frozen before any score existed. The hypotheses, endpoints, equivalence margin, multiplicity correction, provenance strata, and orientation manifest were committed to a timestamped git history before the challenge set was uploaded, and the three pre-score amendments are themselves logged commits (Appendix A). Whatever the organizer scores say, the reported outcome is the pre-registered one: a confirmation, or an honest negative.

We contribute three things. First, a 2,886-segment contrastive challenge set over 10 language directions, built as matched same-source triples with controlled information-unit edits and submitted blind with opaque identifiers and a private keymap. Second, a pre-registered analysis with a signed interaction primary endpoint, a reward preference-flip rate that directly measures the reranking failure, and a numeric equivalence

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1745–1756
October 28-29, 2026 ©2026 Association for Computational Linguistics

anchor for the reference-based family. Third, the findings themselves: a significant reference-availability interaction on top of an asymmetry that turns out to be shared by every learned family, a preference-flip rate that reaches one matched contest in five for a current QE baseline, a verbosity hypothesis refuted outright, and two returned systems that score corrupted numerals above correct ones.

## 2 Related Work

ACES (Amrhein et al., 2022) and its span-annotated extension (Moghe et al., 2025) established the contrastive challenge-set paradigm, including single-edit omission and addition items. `QEbreak` differs on three axes: the omission and the addition are matched on the same source at a controlled information-unit dose, the contrast is carried through the reference-availability axis, and the analysis reaches the reward-model preference flip that measures the deployment-relevant event directly. The MT-breaker line of adversarially difficult inputs (Zouhar et al., 2026) sets the rigor bar we adopt. On the length axis, prior work diagnosed QE length bias (Zhang et al., 2025) and a WMT25 challenge set measured continuation drift (CoDrift, in Lavie et al., 2025); Arm A instead isolates pure, fact-free, unsupported length as a dose curve. The pre-registered family taxonomy covers surface metrics (Papineni et al., 2002; Popović, 2015; Snover et al., 2006), reference-based neural metrics (Rei et al., 2022a; Sellam et al., 2020; Guerreiro et al., 2024; Juraska et al., 2024), reference-free QE (Rei et al., 2022b), and LLM judges in the GEMBA family (Kocmi and Federmann, 2023).

## 3 The QEbreak Challenge Set

`QEbreak` was submitted to WMT26 Subtask 4: 2,886 segments across 10 language directions, 231,582 tokens under the organizer counting rule, well under the 1M-token cap; the organizers confirmed receipt on 22 July 2026. Table 1 gives the composition.

| Direction | A | B | C | Total |
|---|---|---|---|---|
| en-de | 330 | 300 | 264 | 894 |
| en-cs | 0 | 219 | 210 | 429 |
| cs-uk | 0 | 261 | 156 | 417 |
| en-ru | 126 | 45 | 192 | 363 |
| en-zh | 0 | 66 | 188 | 254 |
| cs-de | 0 | 0 | 216 | 216 |

| en-ja | 0 | 33 | 18 | 51 |
| zh-ja | 0 | 0 | 20 | 20 |
| Total | 456 | 924 | 1,506 | 2,886 |

Table 1: Shipped segments per language direction and arm. Arm A: 76 six-step verbosity dose series (456 segments). Arm B: 308 matched {base, omission, addition} triples (924 segments). Arm C: 753 numeric minimal pairs (1,506 segments).

### 3.1 Three arms

**Arm B (headline): matched omission and addition triples.** Each of the 308 triples holds the source fixed and pairs a base translation with an omission that removes one information unit and an addition that appends one fact-free, source-unsupported unit. An information unit is one span removed or added whole and verified by the gates of Section 3.2. In the deterministic strata (S2 and S3 of Section 3.3) it is a trailing sentence or clause for an omission, and for an addition one reference segment of another source in the same language direction, appended whole and gate-verified fact-free. In the LLM-generated stratum (S1) it is one small factual detail for an omission (a modifier, name, number, date, or short phrase) and one short generic clause or sentence for an addition. Omission and addition are the two edit directions of the design. Members travel as separate rows paired by opaque group identifiers, matching the organizer-endorsed separate-segments design. The triple supports both primary endpoints: the signed edit-direction by reference-availability interaction (N1) and the reward preference-flip rate $P_{\text{flip}}$, the fraction of matched {base, omission} pairs (the contests a reranker adjudicates) in which a reference-free metric scores the omission at or above the base (N2). The two edit directions are matched on information units, not edit size: additions change a median of 2.0 times as many characters as omissions remove (whitespace-stripped characters, the unit used for the edit-size ratios and the magnitude covariate), so a length-controlled sensitivity refit accompanies the primary interaction (Section 4).

**Arm A (secondary): a verbosity dose ladder.** Each of the 76 series appends 1 to 5 fluent, fact-free filler units to a base translation on en-de and en-ru, giving six segments per series including the dose-0 base. Fillers are screened to contain no digits, dates, or named entities, and to be entailment-

neutral against both the source and the base (Section 3.2), so the ladder isolates pure unsupported length. At the maximum dose the hypothesis grows to a median of 6.4 times the base length.

**Arm C (positive control): numeric minimal pairs.** Each of the 753 pairs contrasts a correct hypothesis with a copy whose single load-bearing numeral is corrupted: digit substitution (440 pairs), transposition (213), or a magnitude shift (100). Numeral selection follows a scoring rule frozen in the pre-registration (units and separators weighted up, years penalized and never corrupted as a fallback), so the corrupted numeral is never a researcher degree of freedom. Arm C spans all 10 directions and proves the harness has teeth: if the reference-based frontier misses a flat numeric contradiction, the harness, not the metrics, is under suspicion.

### 3.2 Validity gates

Every generated item passes deterministic validity gates before it can ship; items that fail are dropped, not repaired. The omission gate requires the base hypothesis, the stem the omission was cut from (the reference itself in stratum S3 below), to entail the omitted-member hypothesis while the dropped unit stays un-entailed by the remaining text, using a natural language inference (NLI) model (mDeBERTa-v3-base-xnli, Laurer et al., 2024), which blocks omissions that merely rephrase. The addition gate requires the appended unit to carry no digit, date, or named entity (XLM-R named-entity recognition, NER) and to be entailment-neutral against both source and base (neutral $\geq 0.70$, entailment and contradiction $\leq 0.15$ each). It validates the appended delta itself whenever the addition is a clean append of the base, the base ending at a word boundary (every deterministic addition and 70 of the 89 LLM additions); for the other 19 (18 where the addition is not a verbatim extension of the base, and one en-zh append whose base ends without a boundary the rule recognizes) it checks the unit the generator itself reported as appended and requires the enlarged hypothesis to entail the base, since in those cases the base may carry small edits. Subtle LLM-generated triples obey symmetric length caps (at most 25 percent of the base's characters dropped or grown, enforced on raw character counts; realized worst cases 22.9 and 24.4 percent), and all perturbed members must be distinct from their base and from each other.

Gate survival is low by design. In the LLM-generation runs, 1,042 raw candidates were drawn, 861 parsed into complete triples, and the gates admitted 89 of those: 10.3 percent overall, between 3.2 percent (en-ja, 4 of 125) and 20.0 percent (en-ru, 6 of 30) per direction, with the full counts in Section 4. No gate reads any metric score.

### 3.3 Provenance strata

Arm B ships in three pre-declared strata, defined purely from metadata written at generation time. S1 (89 triples; the registration calls it the powered stratum): subtle perturbations generated by Llama-3.1-8B on real WMT24 system outputs under the length caps; the omission typically drops a single detail such as a street number. S2 (100 triples): deterministic whole-unit edits on real WMT24 system-output bases. S3 (119 triples): deterministic edits on reference-verbatim bases. Real-MT bases come from the median-ranked WMT24 system per direction (Kocmi et al., 2024), watermark canary lines filtered out. The pre-registered secondary prediction is a gradient, for the reference-free QE family, in the relative asymmetry $A$ of Section 4 (more negative means omission is penalized less, relative to addition) and in $P_{\text{flip}}$: $A(\text{S1}) < A(\text{S2} + \text{S3})$ and $P_{\text{flip}}(\text{S1}) > P_{\text{flip}}(\text{S2} + \text{S3})$, no prediction between S2 and S3, and no stratified test in the confirmatory family. The rationale was recorded before any score existed: a local CometKiwi pre-filter, a stand-in for the audit-target family, labeled every item with a break prediction (a prediction that a metric would score the perturbed member at or above its base; Section 4), and it already penalizes the crude deterministic omissions, so pooled dilution is a described property of the design, not a post-hoc rescue.

### 3.4 Blind submission protocol

The uploaded rows carry exactly the seven published fields; all internal metadata was stripped, identifiers are opaque hashes with no label, phenomenon, or dose token, and row order was decorrelated so the base member sits at no fixed position (base-first fell from 100 percent to 44.0 percent, against a 43.3 percent chance level). A private keymap, never uploaded, restores the pairing when scores return. Residual structure inherent to contrastive sets, such as pair members sharing a source, is disclosed in the Limitations.

## 4 Pre-Registered Analysis Plan

The full pre-registration lives in a timestamped git history frozen before the challenge-set upload and before any organizer score existed. Appendix A records the commits, the three pre-score amendments, and the post-return changes to the analysis code, which were made in one pre-analysis commit, include changes the registration did not anticipate, and are reported there as deviations. Table 2 states every registered quantity, its decision rule, its predicted sign, and where Section 5 reports it; the paragraphs below define the terms the table uses, give the anti-circularity counts, and name the two sensitivity refits, one registered and one added after the return.

**The N1 model, as fitted.** For metric $m$ and each perturbed Arm B member, the signed drop is the oriented base score minus the oriented member score, so a positive value means the metric penalized the edit; oriented means sign-adjusted so that higher is better, and since every system on this return already reported higher-is-better scores, orientation changed no sign here and the manifest's role is to fix each metric's family and reference indicator. Within each metric the drops are replaced by their average rank scaled to $(0, 1)$, so the response $y$ is a within-metric percentile and is invariant to any monotone rescaling of a metric (rank-normalization is the registered primary transform; a z-score refit is the registered sensitivity analysis). The registered three-way design (edit direction, reference availability, dose) reduces, because every shipped Arm B edit carries one information unit, to the identifiable model

$$y = \beta_0 + \beta_1 D_{\text{add}} + \beta_2 R + \beta\,(D_{\text{add}} \cdot R) + \varepsilon, \quad (1)$$

where $D_{\text{add}} = 1$ for an addition member (omission is the baseline) and $R = 1$ when the metric reads the reference. $R$ is set by the manifest, not by family: $R = 0$ pools the four reference-free QE metrics and the two reference-free LLM judges (6 metrics, 3,444 observations); $R = 1$ pools the five reference-based neural metrics, the three surface metrics, and the three reference-reading LLM judges (11 metrics, 6,776 observations). The twelve returned systems whose reference usage no public source documents (the unidentified systems of Section 5), for which $R$ is undefined, sit out of this design only. The reported $\beta$ is the coefficient on $D_{\text{add}} \cdot R$. Its point estimate is ordinary least squares (OLS) on the pooled 10,220 observations; every interval and $p$-value comes from resampling the 268 distinct source sentences with replacement ($B = 2000$ replicates) and refitting. That clustered bootstrap is the registered inference, and it carries between-source heterogeneity in intercepts and slopes alike. The registration placed this fixed part inside a mixed-effects model with random intercepts for source and for language pair; refitting that model leaves the point estimate unchanged (Appendix A). Because $y$ is a percentile, $\beta$ has a plain reading: it is the addition-minus-omission gap in mean percentile drop for reference-reading metrics minus the same gap for reference-free metrics, so $\beta = -0.069$ says the gap is 6.9 percentile points wider without a reference. Section 5.1 gives the four cell means behind it.

**The reference-based anchor.** $H_B$ is a contrast, so it needs the reference-based family to be symmetric in fact. For metric $m$, let $b_{\text{om},m}$ be the mean raw oriented drop over its omission members and $b_{\text{add},m}$ the same over its addition members, both in the metric's own units (Appendix B lists them). The scale-free relative asymmetry is

$$A_m = \frac{|b_{\text{om},m}| - |b_{\text{add},m}|}{(|b_{\text{om},m}| + |b_{\text{add},m}|)/2}, \quad (2)$$

bounded in $[-2, 2]$, with $A_m := 0$ when both drops are exactly zero; a negative value means omission is penalized less than addition. Family-level $A$ is the unweighted mean of $A_m$ over that family's returned metrics, and the teeth statistic is the mean raw drop pooled over both edit directions in the family's native units, which must be positive for the family to anchor anything. Table 2 carries the decision rules: an equivalence margin of $\pm 0.30$ tested by two one-sided tests at $\alpha = 0.05$ (equivalently, the 90% CI inside the margin, as the table states), the teeth precondition, and the refutation leg, which fires when the reference-based family's 95% CI lies entirely below $-0.30$ and thereby refutes the claim that the missing reference is what produces the asymmetry.

**Multiplicity and orientation.** Every returned metric with a declared orientation enters the confirmatory family of Table 2 mechanically, its size following from the roster before any score value is inspected, with Benjamini-Hochberg (BH) control (Benjamini and Hochberg, 1995); the harness fails closed on an undeclared name (Appendix A);

| Quantity | Definition | Registered prediction | Decision rule and inference | Outcome |
|---|---|---|---|---|
| N1 $\beta$ (Arm B, primary) | Coefficient on $D_{\text{add}} \cdot R$ in Eq. 1: the change in the addition-minus-omission penalty gap, on the within-metric percentile scale (0 to 1, so 0.01 is one percentile point), when the metric reads a reference (negative: the gap is wider without one) | $\beta < 0$ | Ordinary least squares (OLS) point estimate; source-clustered bootstrap 95% CI ($B$=2000); one test in the confirmatory family | $-0.069$ (6.9 points) $[-0.081, -0.057]$, confirmed (§5.1) |
| N2 $P_{\text{flip}}$ (Arm B, primary) | Share of matched {base, omission} pairs a metric scores at or above the base, per metric; registered for reference-free QE, exploratory for the other families | high for reference-free QE, near 0 for reference-based and LLM-judge metrics | Clustered bootstrap CI; descriptive | 0.013 to 0.195 for reference-free QE; not near 0 elsewhere (§5.2) |
| Anchor $A_{\text{ref-based}}$ | Family mean of the relative asymmetry $A_m$ of Eq. 2 for the reference-based family, whose symmetry the $H_B$ contrast needs | inside $[-0.30, 0.30]$; reference-free QE $A < 0$ | Established if the 90% CI sits inside the margin and the teeth precondition holds (pooled drop 95% CI above 0); refutes the $H_B$ mechanism if the 95% CI lies below $-0.30$; otherwise not established | $-0.42$ $[-0.49, -0.35]$: refutation leg fires; reference-free $-0.51$ (§5.1) |
| Strata gradient (secondary) | $A$ and mean $P_{\text{flip}}$ for reference-free QE within S1, S2, S3 | $A$(S1) $<$ $A$(S2+S3); $P_{\text{flip}}$(S1) $>$ $P_{\text{flip}}$(S2+S3) | Ordering of point estimates, CIs reported; below 20 pairs, point only; never in the confirmatory family | holds as an ordering (§5.5) |
| Anti-circularity strata | $\beta$, $A$, $P_{\text{flip}}$ on the 304 triples the pre-filter predicted would not break, and on the 189 real-MT-base triples | effect persists | Confirmation of $H_B$ requires both | both hold (§5.5) |
| Arm A $\rho$ | Mean over the 76 series of the per-series Spearman $\rho$ between filler dose and oriented score, per metric | $\rho \geq 0$ for reference-free QE ($H_A$) | One-sided clustered bootstrap test of $H_0$: $\rho \geq 0$, in the confirmatory family | $\rho$ from $-0.37$ to $-1.00$ for all 28 metrics: $H_A$ refuted (§5.3) |
| Arm C $\tau_b$ | Kendall $\tau_b$ of correct versus corrupted member, tie rate reported, per metric | reference-based frontier catches, reference-free trails ($H_C$) | One-sided test of $H_0$: $\tau_b \leq 0$, in the confirmatory family | holds; two MQM-LLM variants invert (§5.4) |
| Multiplicity | One test per metric on Arm A (28 metrics) and Arm C (31) plus the single pooled Arm B $\beta$; family size fixed by the returned roster | | Benjamini-Hochberg (BH) false discovery rate at $q = 0.05$, applied once | 60 tests; 58 reject at $q < 0.001$ |

Table 2: The pre-registered plan at a glance. Every quantity, its decision rule, and its predicted sign were frozen before any score existed; the last column points to where Section 5 reports it. Arm B bootstraps resample its 268 distinct source sentences with replacement; Arm A and Arm C resample their own source sentences.

and everything outside that family, the strata and the sensitivity refits included, is secondary or exploratory and is never reported as a break.

**Anti-circularity, with the numbers.** A local CometKiwi pre-filter, which belongs to the same family as the audit target, labeled every row with a break prediction but never gated selection, and there was no selection step for it to influence. The packager ran with no per-direction cap and the set came in at 231,582 tokens against the 1M budget, so every item that passed the validity gates shipped. The one exception to that shipment is a deterministic triple dropped by a metric-free rule that keeps the LLM triple when both were built on the same source, applied before any label was written. The gates themselves see no metric score; they admitted 89 of the 861 complete LLM triples of Section 3.2 (cs-uk 40 of 334, en-zh 17 of 222,

en-de 11 of 69, en-cs 11 of 81, en-ru 6 of 30, en-ja 4 of 125). The label split of the shipped set is: Arm B, 4 of 308 triples predicted to break; Arm A, 0 of 76 series; Arm C, 89 of 753 pairs. $H_B$ is reported as confirmed only if the effect also holds in the 304 Arm B triples predicted not to break and on the 189 triples whose bases are real WMT24 system outputs.

**Sensitivity refits.** Two refits of Eq. 1 qualify the primary interaction and can never rescue it: the registered z-score transform in place of the percentile transform, and a refit that adds edit magnitude (absolute whitespace-stripped character change of the member against its base) as a covariate, motivated by the measured 2.0x median edit-size imbalance between additions and omissions. The second was recorded in the decision log under 4 August; its first git timestamp is the 6 August return-ingestion commit, made before any score value was analysed (Appendix A).

## 5 Results

The organizers returned segment scores from 31 systems on 6 August 2026, scored under the task's segment-level quality-score protocol (its Task 2: one score per segment, higher is better). 28 systems cover all 2,886 segments; `cuni-v14-regression` covers three directions and the two Lexicala QE ensembles cover three of the four Arm-C-only directions (cs-de, en-ar, zh-ja). The roster is a superset: some teams submitted more than the allowed two systems, and near-duplicate submission-id variants remain because the organizers had not designated main submissions by the camera-ready deadline, so the family of 60 tests stands on the returned roster. Twelve systems carry opaque submission names whose reference usage no public source documents yet (the unidentified systems below); under the fail-closed rule they were declared with orientation only, in a pre-analysis commit, so they enter every per-metric endpoint mechanically but sit out the reference-availability axis, which is undefined for them. We write xCOMET-XL-QE and xCOMET-XXL-QE for the organizer baselines xCOMET XL and XXL Reference-free, and xCOMET-XL-ref and xCOMET-XXL-ref for their Reference-based counterparts. All ingestion checks passed: every returned segment identifier matched the private keymap, and per-system counts matched the organizers' coverage table exactly. Of the 60 confirmatory tests, 58 reject at $q < 0.001$, where rejection means the metric penalizes filler (Arm A), catches the corrupted numeral (Arm C), or shows a nonzero interaction (Arm B, two-sided); the two exceptions are the Arm C failures of the two MQM-LLM variants (Section 5.4).

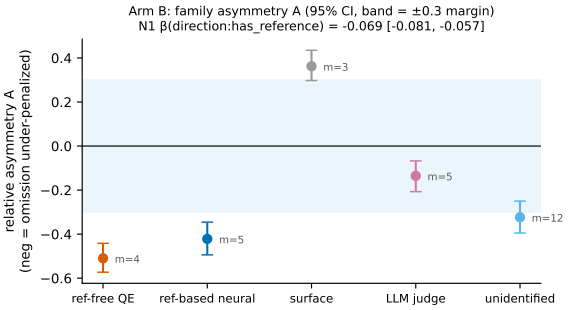

Figure 1: Family-level relative asymmetry $A$ with clustered-bootstrap 95% CIs (values in the text); the shaded band is the pre-registered $\pm 0.30$ equivalence margin for the reference-based anchor, and the reference-based family lies outside it.

### 5.1 Headline: the omission and addition asymmetry (Arm B)

The signed interaction is significant in the predicted direction: $\beta = -0.069$, source-clustered bootstrap 95% CI $[-0.081, -0.057]$, $q < 0.001$ in the confirmatory family. On its own scale (Section 4) the coefficient reads as follows. For reference-free metrics (the $R = 0$ pool, which includes the two reference-free judges) an addition sits on average at the 56.1st percentile of that metric's drops and an omission at the 43.9th, a gap of 12.2 points; for reference-reading metrics the gap is 5.2 points (52.6 against 47.4); $\beta$ is the difference of the two gaps before rounding, $-6.9$ points ($5.24 - 12.17$). Per family, the gap is 18.3 points for reference-free QE, 13.7 for reference-based neural, 3.4 for LLM judges, and $-8.6$ for surface metrics, which penalize omission more. The two sensitivity refits leave the interaction intact: $-0.24$ standard deviations $[-0.29, -0.20]$ under the z-score transform, and $\beta = -0.073$ $[-0.084, -0.061]$ with edit magnitude as a covariate, so the 2.0x character imbalance of Section 3 does not explain it.

The family asymmetries (Figure 1) tell the larger story. Reference-free QE: $A = -0.510$ $[-0.573, -0.442]$, with per-metric $A_m$ of $-1.28$ (xCOMET-XL-QE), $-0.59$ (xCOMET-XXL-QE), $-0.22$ (`cuni-v14-regression`), and

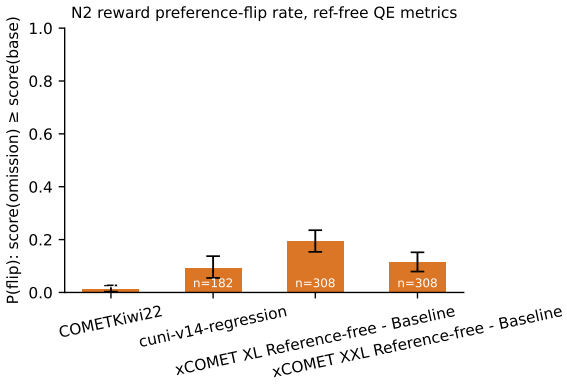

Figure 2: $P_{\text{flip}}$ per reference-free QE metric with clustered-bootstrap 95% CIs (values in the text).

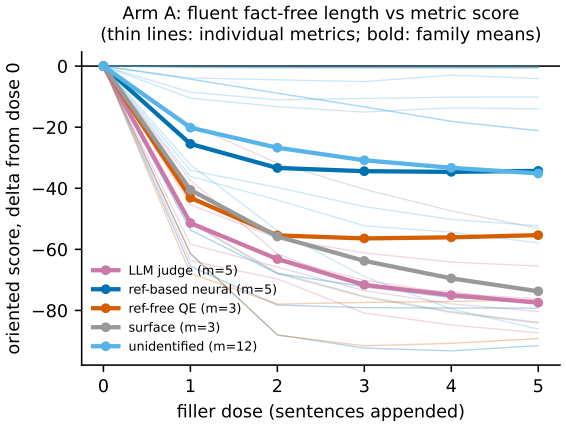

Figure 3: Oriented score against fluent fact-free filler dose (thin lines: individual metrics; bold: family means). Every family's mean falls monotonically; no returned metric rewards pure unsupported length.

$+0.05$ (COMETKiwi22). Reference-based neural: $A = -0.422$ $[-0.494, -0.346]$. LLM judges: $A = -0.135$ $[-0.207, -0.067]$. The twelve unidentified systems: $A = -0.323$ $[-0.395, -0.250]$. Surface metrics alone over-penalize omission: $A = +0.362$ $[+0.297, +0.435]$, as n-gram precision plus a brevity penalty punishes missing content twice. The anchor verdict is this paper's central honest finding. The teeth precondition holds: the pooled reference-based drop, in the family's native units and dominated by the two 0-to-100 xCOMET scales, has 95% CI $[+11.5, +13.4]$, and every member's own mean drop is positive in both edit directions (Table 4). But the reference-based 90% and 95% CIs lie entirely below the $-0.30$ margin, so the pre-registered refutation leg of Table 2 fires. $\text{H}_\text{B}$'s mechanism claim is refuted: the asymmetry appears in every learned family, so the missing reference cannot be its cause. Reference access reduces it (the significant interaction) and surface overlap inverts it.

### 5.2 The reward preference flip (N2)

$P_{\text{flip}}$ is the deployment-relevant number: the rate at which a reference-free metric scores the omission at or above its own base, which is exactly the contest a best-of-$n$ reranker adjudicates. Over 308 matched pairs (182 for the partial-coverage CUNI system), Figure 2: xCOMET-XL-QE 0.195 $[0.154, 0.235]$, xCOMET-XXL-QE 0.114 $[0.079, 0.152]$, `cuni-v14-regression` 0.093 $[0.055, 0.137]$, COMETKiwi22 0.013 $[0.003, 0.027]$. Part of the first three rates is exact ties, mostly at the scale ceiling: strictly above the base, the rates are 0.143, 0.071, 0.044, and 0.013. A reranker guided by xCOMET-XL-QE rates the translation that silently dropped content at least as high as its base in one matched contest out of five, and strictly higher in one out of seven. COMETKiwi22 almost never flips and is also the family's most symmetric member (the per-metric $A_m$ above); the deep asymmetry is carried by the xCOMET QE baselines. The failure is graded, not uniform, inside the family. The registration also expected the rate to be near 0 for reference-based and LLM-judge metrics; computed the same way for every metric (exploratory, Table 4), it is not: family means 0.088 for reference-based neural (xCOMET-XL-ref 0.208), 0.130 for LLM judges (gemba-poly 0.325), 0.074 for surface, 0.218 for the unidentified systems, against 0.104 for reference-free QE. The flip, like the asymmetry, is shared by learned metrics as a class.

### 5.3 Length bias (Arm A)

$\text{H}_\text{A}$ is refuted outright, and we report the pre-registered negative as good news for the field: every returned metric penalizes fluent fact-free filler (Figure 3), with within-source Spearman $\rho$ (the mean over series of the per-series correlation) from $-0.37$ (fluency2-gemini35-esa) to $-1.00$ (BLEU, chrF, spBLEU, YiSi-1), all $q < 0.001$ against $\text{H}_0$: $\rho \geq 0$. COMETKiwi22 reaches $\rho = -0.86$ $[-0.89, -0.83]$; xCOMET-XL-QE and xCOMET-XXL-QE $-0.65$ and $-0.70$. The length-gaming attack this arm operationalizes does not work on the modern roster. Reference-based curves are exploratory context on this arm (reference-verbatim bases inflate the dose-0 intercept), and $\text{H}_\text{A}$ conclusions are scoped to en-de and

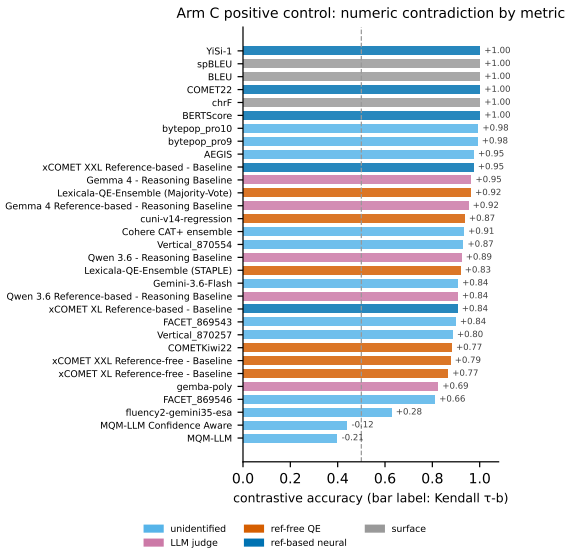

Figure 4: Numeric-contradiction contrastive accuracy, sorted; bar labels give Kendall $\tau_b$. All families sit far above chance except the two MQM-LLM variants at the bottom, which invert the control.

en-ru as registered.

### 5.4 Positive control (Arm C)

The control holds: the harness has teeth (Figure 4). The reference-based neural frontier catches the single corrupted numeral (COMET22, BERTScore, and YiSi-1 at $\tau_b = +1.00$; xCOMET-XXL-ref $+0.95$), surface metrics detect the token change deterministically ($+1.00$), and the reference-free baselines trail visibly (COMETKiwi22 $+0.77$, xCOMET-XL-QE $+0.77$, xCOMET-XXL-QE $+0.79$): reference-based catches while reference-free trails, as predicted. One cell of the frozen prediction table was wrong here and we report it rather than reframe it: surface metrics were predicted to break on this arm and instead held perfectly; Table 3 in Appendix A marks it together with the three other contradicted cells. Contrastive accuracy here counts metric ties as half credit over the same pairs, ties included, on which $\tau_b$ is computed; tie rates stay at or below 0.19 and are highest for span-derived scorers. Two participant systems invert the control: MQM-LLM ($\tau_b = -0.21$, contrastive accuracy 0.397) and MQM-LLM Confidence Aware ($-0.12$, 0.439) score the corrupted member above the correct one more often than not, the only two confirmatory non-rejections on the board. The empirical orientation cross-check (a flag whenever a metric's mean oriented correct-minus-corrupted difference

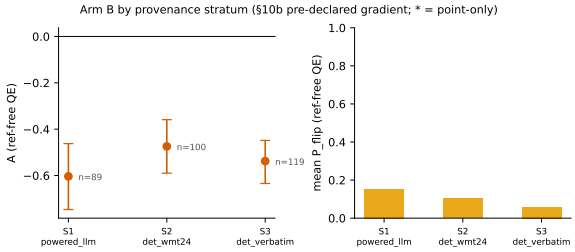

Figure 5: The pre-declared provenance-strata gradient for reference-free QE: relative asymmetry $A$ (left) and mean $P_{\text{flip}}$ (right). The LLM-generated stratum S1 cuts deepest on both readings, as pre-registered.

on Arm C is at or below $-0.05$) flags both, and their strongly negative Arm A slopes confirm the declared orientation is right, so this is a genuine system-level failure on load-bearing numerals, not a sign error in our manifest.

### 5.5 Stratified reading

The pre-declared gradient holds as an ordering of point estimates (Figure 5). In S1 (subtle LLM perturbations on real system outputs, 89 triples) the reference-free asymmetry deepens to $A = -0.604$ $[-0.747, -0.462]$ and mean $P_{\text{flip}}$ rises to 0.154 $[0.107, 0.203]$, against $-0.474$ $[-0.590, -0.359]$ and 0.104 $[0.074, 0.135]$ in S2 and $-0.538$ $[-0.634, -0.449]$ and 0.058 $[0.035, 0.085]$ in S3 (S2 and S3 pooled: $-0.510$ and 0.079); the interaction strengthens to $\beta = -0.117$ $[-0.151, -0.082]$ inside S1. The registered prediction $A(\text{S1}) < A(\text{S2} + \text{S3})$ and $P_{\text{flip}}(\text{S1}) > P_{\text{flip}}(\text{S2} + \text{S3})$ is an ordering, and it holds on both axes; the $A$ intervals overlap, so the gradient is a direction, not a separated effect. Both anti-circularity confirmation strata of Table 2 hold as well. In the 304 triples the local CometKiwi pre-filter predicted would not break: $\beta = -0.069$ $[-0.081, -0.057]$, $A(\text{ref-free}) = -0.503$, mean $P_{\text{flip}} = 0.094$. On the 189 triples with real WMT24 system-output bases: $\beta = -0.078$ $[-0.094, -0.061]$, $A(\text{ref-free}) = -0.487$, mean $P_{\text{flip}} = 0.129$. The measured deficit is not an artifact of pre-filter-guided construction, and it lives on real MT output; with the anchor refuted, these strata certify that the pervasive asymmetry the audit found is real wherever we can check it.

## 6 Human Validation Protocol

We built a blind human validation study before submission: a 270-item single-annotation sheet plus a 60-item double-annotated overlap, sampled

with a guaranteed minimum of S1 items and sealed so annotators see only an identifier, the source, and the hypothesis. The protocol targets per-direction item precision of at least 95 percent and reports Cohen's $\kappa$ and Krippendorff's $\alpha$ on the overlap (Cohen, 1960; Krippendorff, 2018). The annotation had not been carried out by the camera-ready deadline, so this paper reports the protocol and no human precision number. That is a real gap, not a formality: the machine-side gates of Section 3.2 certify entailment relations and the absence of entities, digits, and dates, but they cannot certify that a dropped unit is one a human reader would miss, or that an appended unit reads as natural, and every per-item claim in this paper inherits that limit. The sealed sheet is available with the pipeline (Appendix A) so the study can be run independently of this paper's claims.

## 7 Conclusion

`QEbreak` turns a structural suspicion about reference-free QE metrics into a falsifiable, preregistered measurement: matched same-source omission and addition contrasts, carried through the reference-availability axis, down to the reward preference flip that a metric-guided reranker would actually commit. The returned scores confirmed the deficit and refuted our favorite explanation of it. Reference-free QE metrics prefer the incomplete translation often enough to matter, but so, to a smaller degree, do the reference-based metrics that were supposed to anchor the contrast. The blind spot therefore belongs to learned metrics as a class rather than to reference-freeness, and the significant interaction shows that reference access narrows it without closing it. What we would hand next year's breakers is the discipline rather than the hypothesis: the blind protocol with a private keymap, the fail-closed orientation manifest, and the equivalence anchor with its teeth precondition, which together let a wrong mechanism story die in public while the measurement that killed it stands.

## Limitations

**Item validity rests on machine gates.** The human study of Section 6 was not run, so no per-item precision number exists; the NLI and NER gates are the operative validity evidence, with the limits stated there. Numeric pairs use Latin and Cyrillic digit contexts only; native-digit corruption for zh, ja, ar, and ko scripts was not attempted.

**Coverage, stratum sizes, edit size, and dose.** Arm B covers 6 of the 10 directions; cs-de, en-ar, en-ko, and zh-ja carry Arm C only. Sustained 8B-model generation on a fanless 8 GB machine limited S1 on some directions, so S1 is small on en-ja (4 triples) and en-ru (6); the registered small-stratum guard gives point estimates only to any stratum below 20 matched pairs, and any per-direction reading is exploratory. The omission and addition edits are matched on information units, not characters: additions change a median of 2.0 times as many whitespace-stripped characters as omissions remove (S1 1.4x, S2 2.0x, S3 2.5x), and 79 percent of triples add more characters than they remove; if a metric responds to raw edit magnitude this pushes $A$ in the predicted negative direction, which is why the edit-magnitude refit is reported beside the primary interaction. Every Arm B edit carries one information unit, so no dose-interaction claim is made. Arm A is 76 series on two directions with reference-verbatim bases: for reference-free QE, the target family, base equals reference is mechanically invisible; for reference-based metrics the dose-0 intercept is inflated, so that curve is exploratory context only, and $H_A$ conclusions are scoped to en-de and en-ru as registered.

**Circularity is disclosed, not eliminated.** CometKiwi labeled, never gated, Arm A and B items, and the confirmation rule requires the effect to survive in the stratum predicted not to break and on real system outputs; within-family corroboration is never treated as independent transfer. Members of a pair also share a source, group size correlates with arm, and control members are reference-verbatim. These properties are inherent to contrastive minimal-pair sets; an honest metric scores each row independently and cannot exploit them, but a deliberately adversarial scorer could. The blind protocol removes the fixable tells (labels, id tokens, positional order); the inherent ones are stated here.

## Acknowledgments

We thank Eleftherios Avramidis and the WMT26 Automated Translation Quality Evaluation organizers for confirming the separate-segments design and the submission logistics, and the two anonymous reviewers, whose requests for the model specification, the anti-circularity counts, and a plan section built around one table shaped

this version.

## A Pre-Registration Record

**Frozen commits.** The registration (commit `6febc4b`, 9 July 2026), a sign-gloss erratum (`b8e78f3`), the scope-and-anchor amendment (`91c19c1`), and a teeth-wording and tag-provenance clarification (`98bf78c`) all predate the 15 July upload (deadline 16 July) and the 6 August score return; the orientation manifest is frozen by content hash. The erratum corrected the verbal sign of an interpretive gloss on the interaction; it touched no endpoint, and the gloss is not used in this paper. The amendment declared the numeric equivalence bound of Eq. 2, the provenance strata, the single-dose scope of Arm B, and the two-direction scope of Arm A. The analysis code was frozen at the upload (commit `28e1706`, 15 July) apart from the post-return changes listed next; no commit lies between that upload and the return.

**Post-return changes.** The registration permits exactly one kind of change after scores return: adding an orientation pattern for a returned metric name, in a descendant commit made before any score value is inspected, with a decision-log entry. One commit (`f539810`, 6 August, 27 minutes after the return arrived and before any score value was analysed) made those additions: organizer baselines by their self-describing names and four participant systems from three teams (`gemba-poly`, the two Lexicala ensembles, `cuni-v14-regression`) by published descriptions; those pattern additions were needed because the harness raises on any returned metric name that matches no manifest pattern. The same commit went beyond what the registration anticipates, and we report those changes as deviations under its own rule. It declared the twelve unidentified systems as a fifth family with orientation only and changed the analysis code so that this family sits out the reference-availability design, where $R$ is undefined, while staying in every per-metric endpoint. It added the edit-magnitude refit of Section 4 and the code for the registered fallback that reports per-metric drops in place of a family-level $A$ when fewer than two reference-free QE metrics score Arm B; both are recorded in the decision log under 4 August with this commit as their first git timestamp, and the fallback did not fire (four scored Arm B). It added the return-ingestion code, the command-line wiring, and a plot label for the new family; plotting code changed again in the paper commit. No change touched an endpoint, a decision rule, or the confirmatory family rule. Format inspection of the return had unavoidably displayed a handful of raw rows from two files before that commit; no aggregate was computed and no declaration used score values.

| Arm | Surface | Ref-based | Ref-free | LLM judge |
|---|---|---|---|---|
| B omission | break$^\dagger$ | hold$^\dagger$ | break-hard | partial |
| B addition | hold | partial/hold | hold/partial | hold |
| A verbosity | hold | partial | break$^\dagger$ | hold |
| C numeric | break$^\dagger$ | hold | break/partial | hold |

Table 3: The frozen arm-by-family prediction table (registration section 2), verdict labels verbatim and the registration's one-phrase rationales omitted. "Break" means the family was predicted to score the perturbed member at or near the base (the pre-filter's operational rule in Section 3.3 is at or above); slashed cells were registered as either-or; the B omission reference-free cell was registered as the headline "break-hard". $^\dagger$The four cells the data contradicted: surface metrics held on Arm B omission ($A = +0.36$, Section 5.1) and on Arm C (Section 5.4); reference-free QE penalized filler on Arm A (Section 5.3); and the reference-based anchor cell fired its refutation leg (Section 5.1).

**Frozen predictions.** Table 3 reproduces the registered arm-by-family prediction table. Three of the four contradicted cells fail in the same direction, a predicted break that did not happen; the fourth, the Arm B reference-based cell, is different in kind: the registration built in the equivalence anchor precisely so that this cell could refute the mechanism claim, and it did.

**Estimator check.** The registration's mixed-effects form for Eq. 1, refitted by restricted maximum likelihood with source nested in language pair, returns $\beta = -0.069$ with Wald 95% CI $[-0.086, -0.052]$; adding random slopes for edit direction and reference availability by source gives $-0.070$ $[-0.086, -0.054]$. The registered clustered bootstrap, the least-squares point estimate, and both mixed-model refits agree, so nothing

Table 4: Per-metric Arm B quantities. $R$ is the reference-availability indicator of Eq. 1, left blank for the unidentified systems, which sit out that design. Drops are in each metric's native units, positive when the metric penalized the edit; the gap is the mean within-metric percentile of addition drops minus that of omission drops, positive when addition is penalized more; Flip is the share of matched pairs in which the metric scores the omission at or above the base ($P_{\text{flip}}$ for reference-free QE, exploratory elsewhere). $A_m$ compares mean raw drops (positive when omission is penalized more) and the gap compares mean ranks, so the two agree when their signs are opposite; a same-sign pair with a gap far from zero, as for MQM-LLM ($A_m$ near zero, gap $+13.3$), means a few large omission drops dominate the raw mean while most omissions rank low. Family $A$ in Section 5.1 is the unweighted mean of $A_m$ within each family.

turns on the estimator.

**Availability.** The build pipeline, the analysis code with its timestamped history, the labeled challenge set, the private scoring keymap, and the sealed validation sheet are available from the author on request; the organizers had not designated main submissions or a release schedule for the returned scores by the camera-ready deadline.

## B Per-Metric Arm B Results

Table 4 lists, for every returned metric that scored Arm B, the mean raw oriented drops $b_{\text{om},m}$ and $b_{\text{add},m}$ of Eq. 2 in the metric's own units, the relative asymmetry $A_m$, the addition-minus-omission gap in within-metric percentile points that Eq. 1 averages, and the flip rate (the share of matched pairs scoring the omission at or above the base, which is $P_{\text{flip}}$ for the reference-free QE family and exploratory elsewhere). The two Lexicala ensembles did not score any Arm B direction.

# SpinPop: A Fast Spin Metric for the WMT26 Metrics Shared Task

**Jia Xu**
8AI LLC

## Abstract

We describe our submission to the WMT26 Shared Task on Automated Translation Quality Evaluation. Our primary system is a per-language-pair, $z$-normalized, weight-free ensemble that combines six complementary signals: our novel metric SpinPop, COMET-22, and four large language model judges.

SpinPop is training-free, constant-cost, tokenization-agnostic, broadly multilingual, and deterministic. Within its encoder's language coverage it scores every segment, with or without a reference, using a single frozen-encoder pass that runs locally and requires no paid API calls.

Our system achieves a mean per-language-pair Pearson correlation of $0.8534$, ranking second on the WMT26 Task 2 leaderboard. The results demonstrate that a simple unsupervised ensemble of a spin-code metric, a neural metric, and multiple LLM judges can achieve top-tier performance with equal weights.

## 1 Introduction

Task 2 of the WMT26 Shared Task on Automated Translation Quality Evaluation asks systems to predict continuous segment-level translation quality scores from a source sentence and its translation, optionally using a reference translation. Systems are evaluated by the mean segment-level Pearson correlation with human cESA scores (Kocmi et al., 2024), averaged over 21 language pairs.

We submitted two closely related systems based on a simple, unsupervised ensemble of complementary evaluation signals: our lightweight byte-code metric SpinPop, the neural metric COMET-22, and multiple zero-shot LLM judges. They differ only in their use of Gemini-3.1-Pro: System 1 applies it to the nine language pairs where the base ensemble is weakest, whereas System 2 uses it for all language pairs.[1] The results show that a simple ensemble of heterogeneous evaluation signals can achieve top-tier translation quality estimation without learning combination weights.

The remainder of this paper is organized as follows. Section 2 presents the system architecture, covering the base ensemble, the judge prompting, the fusion rule, and our handling of low-resource pairs. Section 3 reports results on the WMT26 blind test together with component ablations on a WMT25 development slice. Section 4 situates our approach within prior work on quality metrics and ensembles, and Section 5 concludes.

## 2 System Architecture

**The base ensemble.** Figure 1 gives an overview of the system. Both submissions are unsupervised ensembles built from the same five per-segment signals: SpinPop, the neural metric COMET-22, and three LLM judges.

Our novel metric SpinPop, based on SPINHASH (Xu et al., 2026), represents each token by a compact code derived from a frozen multilingual encoder. Its design significantly advances prior byte-based representation work (Zhang and Xu, 2022; Li et al., 2025), which it adapts to translation quality evaluation. It requires only a single frozen encoder pass followed by a fast byte-level comparison, making it substantially more cost- and time-efficient than a learned metric or an LLM judge.

**SpinPop in detail.** SpinPop scores a hypothesis with BERTScore-style token alignment, but over compact binary codes rather than dense embeddings. Each token is embedded by a frozen multilingual mBERT encoder (Devlin et al., 2019), the `bert-base-multilingual-cased` checkpoint of $\sim$178M parameters, and its frozen layer-9

[1] Submitted to Codabench as submission 875949 for System 1 and submission 876231 for System 2, our primary submission.

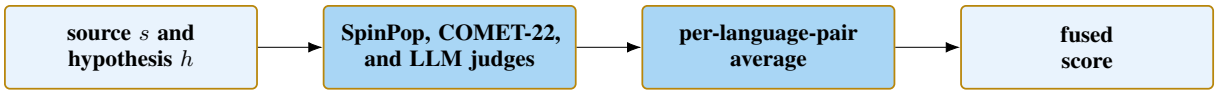

Figure 1: **System overview.** The five base signals, SpinPop, COMET-22, and three LLM judges, with an optional judge, Gemini-3.1-Pro, added on some or all language pairs, each score the source–hypothesis pair reference-based or, when no reference is present, against the source. Per language pair the present signals are $z$-normalized and averaged with no learned weights.

token embedding is converted to a binary spin code following SPINHASH (Xu et al., 2026), that is, the sign of a fixed set of random linear projections, giving a 1,024-bit code, i.e., 128 bytes per token. The projections are drawn once and never trained. Token-to-token similarity is the fraction of agreeing bits, computed by XOR and popcount, a binary analogue of cosine similarity. Given the code sequences of a hypothesis and its comparison text, each hypothesis token is greedily matched to the comparison token with the highest bit agreement, and the matched similarities are aggregated into precision, recall, and $F_1$, with $F_1$ reported as the segment score. In *reference-based* mode the comparison text is the reference; in *reference-free* (QE) mode it is the source, so SpinPop scores cross-lingually against the source whenever no reference is present. SpinPop is *training-free*, adding no learned parameters and never fine-tuned on quality-evaluation data, unlike supervised metrics such as COMET-22, its only pretrained component being the frozen encoder, exactly as in BERTScore. It is *tokenization-agnostic*, adding no metric-specific vocabulary and inheriting whatever segmentation the frozen encoder uses.

COMET-22 (Rei et al., 2022a) is a reference-based neural metric. The three LLM judges are GPT-5.4, Gemini-3.5-Flash, and GPT-5.6-luna. We selected them on a random sample of 500 WMT25 segments to achieve the best quality-to-cost trade-off, excluding higher-scoring but substantially more expensive models, including GPT-5.6-sol and GPT-5.5.

**Judge prompting.** All LLM judges receive the same system prompt: act as a professional translation quality evaluator and assign a single score from 0 to 100, where 0 denotes a completely wrong or unintelligible translation and 100 a perfect one, balancing adequacy and fluency. The prompt then provides the source sentence, the candidate translation, and the reference whenever available. We generate a single response per segment and parse the returned integer as the quality score.

All judges are used zero-shot, without in-context examples or task-specific fine-tuning. Gemini-3.5-Flash and GPT-5.6-luna are run with thinking disabled, GPT-5.4 uses its default reasoning, and Gemini-3.1-Pro additionally uses a small explicit thinking budget.

**Fusion and coverage.** The shared-task metric is Pearson correlation, which is invariant to affine transformations. We therefore combine the signals without learning weights. Intuitively, since Pearson ignores any global scale or offset, the signals' differing ranges can be aligned by $z$-normalization instead of learned weights, and the fused score needs no further calibration. For each language pair, we $z$-normalize every available signal across its segments, average the normalized scores for each segment, and linearly rescale the result. The per-signal normalization statistics, each signal's mean and standard deviation, are computed for each language pair over all of that pair's evaluated segments; because Pearson is invariant to affine transforms and no human scores enter the computation, this transductive normalization fits nothing to the gold labels. A signal missing on a segment, such as COMET-22 or any reference-based signal when no reference is available, is excluded from that segment's average, which is taken over the signals present.

Reference availability varies widely across language pairs. Some, such as CS-DE and ZH-JA, are almost entirely reference-based, whereas others, such as CS-UK, are almost entirely reference-free, with only about 3% of segments providing a reference. When a reference is available, we use COMET-22 together with the reference-based versions of SpinPop and the LLM judges. Otherwise, SpinPop and the judges operate in QE mode against the source. Because SpinPop works with or without a reference, reference availability never leaves a supported segment unscored.

**Low-resource pairs.** Three target languages, Ladin, Ligurian, and Northern Sami, fall outside

the coverage of both the multilingual encoder underlying SpinPop and COMET-22, so we exclude both signals for these language pairs. Instead, we rely on LLM judging alone: Gemini-3.1-Pro for Ligurian and Northern Sami, and Gemini-3.1-Pro combined with a SONAR-based pivot signal (Duquenne et al., 2023) for Ladin, where the hypothesis is first mapped into a supported language before scoring. As Section 3 shows, these three language pairs remain our weakest and account for most of the gap to the top-ranked system.

**The two configurations.** The submissions differ only in how widely a fourth judge, Gemini-3.1-Pro, is added to the base ensemble for the non-low-resource language pairs.

- **System 1**, submission 875949, adds Gemini-3.1-Pro only for the nine language pairs where the base ensemble was least competitive: CS-UK, EN-UK, ZH-JA, EN-TH, EN-HY, EN-DE, EN-CS, EN-RU, and CS-DE. All remaining pairs use the base ensemble alone.
- **System 2**, submission 876231, adds Gemini-3.1-Pro for every non-low-resource language pair.

Although Gemini-3.1-Pro achieved only a modest development score as a standalone judge, extending it from the nine weakest pairs to all eighteen non-low-resource pairs raised the mean Pearson correlation from 0.8496 to 0.8534 on the blind test. The two-system split was primarily operational rather than a controlled ablation. Because Gemini-3.1-Pro costs roughly four times as much as the three base judges combined, a ratio we report in Table 6, we initially applied it only to the language pairs where we trailed competing teams most on the intermediate leaderboard, yielding System 1. Once additional API quota became available, we extended the same configuration to all language pairs, yielding System 2. System 2 is our intended primary submission, while System 1 is an earlier checkpoint retained as the designated second submission.

## 3 Experiments

**Leaderboard results.** Our system is unsupervised, and nothing is fit to the blind test: the base-judge selection of Section 2 was the only choice made on development data. Table 1 reports our primary submission on the blind test. System 2 attains a mean per-language-pair Pearson of **0.8534**, ahead of 1020 Group at 0.8474 and behind ammonsh at 0.9399, while System 1 attains 0.8496. Most pairs fall in the 0.85–0.93 range. The remaining distance to the top-ranked system comes almost entirely from the three low-resource pairs: EN-LLD at 0.645, EN-LIJ at 0.701, and EN-SME at 0.741, where only LLM judging carries information. Excluding these three, System 2 rises to 0.880 and the top-ranked system to 0.948. The gap therefore narrows from 0.086 over all 21 pairs to 0.068 over the remaining 18.

| en-cs | 0.882 | en-de | 0.879 |
| en-et | 0.895 | **Mean** | **0.853** |

Table 1: **Leaderboard results.** Top: the team leaderboard. Bottom: it scores strongly across language pairs, trailing mainly on the three low-resource ones. EN-ZHTW denotes English→Traditional Chinese.

**Adding components.** Our ablations, Tables 2 through 5, all use a WMT25 development slice of 8 language pairs, English into Arabic, Korean, Serbian-Cyrillic, Japanese, Chinese, Russian, Ukrainian, and Czech, with 620 human-scored segments per pair, or 4,960 in total. Results are reported in both the task's Pearson metric and the tie-calibrated pairwise accuracy acc23 (Deutsch et al., 2023), which agree closely at $r = 0.94$. Table 2 builds the ensemble up from SpinPop, whose marginal lift is largest on the weaker signals, for example chrF from 0.263 to 0.279 and COMET-22 from 0.326 to 0.338, and small on the strongest judges. In the ensemble its main roles are broad coverage and efficiency.

**Leave-one-out.** We next drop each member from the full ensemble in turn to isolate its contribution, as reported in Table 3. On Pearson, removing Gemini-3.5-Flash hurts most, at $-0.026$, while removing SpinPop slightly *helps*, at $+0.002$. On acc23, no single member is critical, with the largest

| Ensemble | Pearson | acc23 |
|---|---|---|
| SpinPop | 0.269 | 0.569 |
| SpinPop + COMET-22 | 0.338 | 0.582 |
| SpinPop + GPT-5.4 | 0.428 | 0.611 |
| SpinPop + Flash | 0.447 | 0.623 |
| SpinPop + luna | 0.435 | 0.614 |
| Full ensemble | **0.498** | **0.634** |

Table 2: **Adding components.** Every added signal improves over SpinPop alone, building the base ensemble from 0.269 to 0.498. WMT25 slice, mean per-LP Pearson and acc23.

| Ensemble | Pearson | acc23 |
|---|---|---|
| − SpinPop | 0.500 | 0.626 |
| − COMET-22 | 0.493 | 0.628 |
| − GPT-5.4 | 0.490 | 0.630 |
| − Gemini-3.5-Flash | 0.472 | 0.626 |
| − GPT-5.6-luna | 0.481 | 0.631 |
| Full ensemble | 0.498 | 0.634 |

Table 3: **Leave-one-out.** The full ensemble (bottom row) combines all five signals, SpinPop, COMET-22, GPT-5.4, Gemini-3.5-Flash, and GPT-5.6-luna, and each row above removes one of them. No single member is indispensable: removing Flash hurts Pearson most, while on acc23 the largest drop is shared by SpinPop and Flash. WMT25 slice.

drop, $-0.008$, shared by SpinPop and Gemini-3.5-Flash. SpinPop therefore contributes little to the ensemble's headline Pearson score, serving as an efficient, low-cost member rather than the component that most raises it.

**SpinPop lifts.** When we add SpinPop to three reference-based baselines, as Table 4 shows, it lifts all three on both metrics, BLEU by $+0.043$, chrF by $+0.017$, and COMET-22 by $+0.013$ in Pearson, and more on acc23, where BLEU rises by $+0.11$. We report these as descriptive deltas on the 4,960-segment development slice and do not claim statistical significance for the sub-0.02 Pearson differences; in the full ensemble SpinPop's role is efficiency and coverage rather than a correlation gain, consistent with the leave-one-out result above.

**Combination.** Holding the full ensemble fixed, we vary only the fusion rule, with the alternatives summarized in Table 5. The $z$-normalize-then-mean rule used in our submissions reaches 0.498, versus 0.480 for an unnormalized mean and 0.480 for a median of the normalized signals, so the normalization, not only the choice of members, is what

| Ref-based metric | Pearson | acc23 |
|---|---|---|
| BLEU | 0.229 | 0.461 |
| + SpinPop | 0.272 | 0.573 |
| chrF | 0.263 | 0.578 |
| + SpinPop | 0.279 | 0.579 |
| COMET-22 | 0.326 | 0.547 |
| + SpinPop | 0.338 | 0.582 |

Table 4: **SpinPop lifts.** Adding SpinPop lifts every weaker reference-based metric on both Pearson and acc23, most on BLEU, by $+0.04$ Pearson and $+0.11$ acc23. WMT25 slice.

| Fusion rule | Pearson | acc23 |
|---|---|---|
| simple mean, no $z$-norm | 0.480 | 0.618 |
| median of $z$-normalized | 0.480 | 0.604 |
| $z$-normalize + mean, ours | **0.498** | **0.634** |

Table 5: **Combination.** The per-language $z$-normalize-then-mean fusion used in our submissions is best on both metrics, beating an unnormalized mean and a median. Full ensemble, WMT25 slice.

matters.

**Cost.** The signals differ sharply in cost, as Table 6 lays out. SpinPop needs only one pass through a frozen $\sim$180M-parameter multilingual encoder, after which each token is a 128-byte code and scoring is a fast byte-level comparison. COMET-22 is local but runs a GPU forward pass through a $\sim$0.58B-parameter model per segment, and each LLM judge costs one API call per segment, Gemini-3.1-Pro on the order of a few US dollars per thousand. SpinPop also trains nothing, whereas COMET-22 is supervised on human ratings and the judges are large pretrained models. System 2 applies Gemini-3.1-Pro on all 18 non-low-resource pairs, twice as many as System 1's nine, so it roughly doubles the Gemini-3.1-Pro cost for a $+0.0038$ mean gain.

## 4 Related Work

**MT evaluation metrics.** Automatic MT evaluation has evolved from lexical metrics such as BLEU (Papineni et al., 2002) and chrF (Popović, 2015), through embedding-based metrics including BERTScore (Zhang et al., 2020) and BLEURT (Sellam et al., 2020), to learned neural metrics such as COMET (Rei et al., 2020, 2022a), MetricX (Juraska et al., 2023), CometKiwi (Rei et al., 2022b), and xCOMET (Guerreiro et al., 2024), which currently dominate WMT evaluations (Freitag et al., 2023). In parallel, LLM judges such as

| Signal | Local? | Training | $/1k |
|---|---|---|---|
| SpinPop | yes | none | 0 |
| COMET-22 | yes | supervised | 0 |
| Gemini-3.5-Flash | no | pretrained | ∼0.1 |
| GPT-5.4 | no | pretrained | ∼0.3 |
| GPT-5.6-luna | no | pretrained | ∼0.5 |
| Gemini-3.1-Pro | no | pretrained | ∼4 |

Table 6: **Cost.** SpinPop is the only signal that is local, untrained, and free at inference time. Here, **Local** indicates on-device computation. **Training** denotes the model or training cost, ranging from none to supervised training or a large pretrained model. **$/1k** reports the approximate US cost per 1,000 segments at submission-time API prices.

GEMBA and GEMBA-MQM (Kocmi and Federmann, 2023b,a) have shown that zero-shot prompting can match or surpass learned metrics, albeit at substantially higher inference cost. SpinPop addresses the efficiency side of this trade-off. It retains BERTScore-style token alignment while replacing dense embeddings with compact byte codes, significantly advancing prior work on byte-based representations for efficient NLP (Zhang and Xu, 2022; Li et al., 2025). In our system it serves as a lightweight ensemble signal that applies to both reference-based evaluation and quality estimation.

**Ensembles of quality signals.** Ensembles are common in shared-task systems, but published work on the WMT metrics and QE task has largely focused on single learned metrics (Rei et al., 2020; Guerreiro et al., 2024) or single LLM judges (Kocmi and Federmann, 2023b,a). Our contribution is a simple unsupervised ensemble: a per-language-pair $z$-normalized average of a byte-code metric, a neural metric, and multiple zero-shot LLM judges. This approach is competitive in WMT26 Task 2.

## 5 Conclusion

We described our two WMT26 Task 2 submissions: unsupervised $z$-normalized ensembles of the byte-code metric SpinPop, the neural metric COMET-22, and zero-shot LLM judges, which require no learned combination weights. Within the ensemble, SpinPop is the lightest, broad-coverage member: it scores every supported segment at negligible cost and lifts weaker reference-based metrics by about 0.02 in correlation on average.

## Limitations

Both submissions depend on proprietary LLM judges queried through public APIs, which limits its reproducibility and makes runtime cost dominated by API calls rather than by SpinPop. Our low-resource handling is a pragmatic fallback, and the three lowest-resource pairs remain far below the rest. Finally, SpinPop's accuracy is inherited from a frozen multilingual encoder and degrades on languages that the encoder poorly supports.

# Beyond Rankings: Insights from ALTAE's PTT-MULTITAN Submission to the WMT 2026 Shared Task on Automated Translation Quality Evaluation Systems

**Lichao Zhu  Maria Zimina-Poirot  Nicolas Froeliger**

ALTAE, Université Paris Cité
{lichao.zhu, maria.zimina-poirot, nicolas.froeliger}@u-pariscite.fr

## Abstract

We describe PTT-MULTITAN, our submission to the WMT26 MT Evaluation shared task, Task 3 (error-free segment detection). The task requires a binary decision – whether a machine translation (MT) contains any error – without access to reference translations, and is scored using the *Matthews Correlation Coefficient* (MCC). Our system combines a supervised classifier trained on WMT25 human error-span annotations with three families of reference-free indicators: structural and phraseological cues, corpus-linguistic association measures computed over an LLM-as-judge model, and format/locale conformity checks. Our improved submission raises MCC from 0.159 to 0.168. We submitted six language pairs from the official WMT26 test set: English into Belarusian, German, Russian, Ukrainian, Simplified Chinese, and Traditional Chinese. Overall, TRIVE emerges as the strongest general-purpose system, with the highest full-coverage score and strong performance across European languages. *Correspondence Analysis* (CA) offers complementary insights into lexical and domain differences, while future evaluation should involve translators and translation scholars.

## 1 Introduction

### 1.1 Background

Reference-based metrics such as BLEU (Papineni et al., 2002) require a reference translation, whereas neural metrics such as COMET (Rei et al., 2020), their reference-free variants such as COMETKiwi (Rei et al., 2022), and quality estimation methods function without this requirement, but all predict a graded score. However, all of these approaches ultimately produce a *graded* quality score. In contrast, our task requires a *binary* judgment: TRUE or FALSE. This difference is consequential and directly shapes our strategy (see §4.1). At the same time, machine translations are qualitatively evaluated by human annotation protocols that differ. Direct assessment gives one number per segment, but does not indicate what is wrong. Multidimensional Quality Metrics (MQM) (Lommel et al., 2014) marks every error span with an error category and severity. ESA (Kocmi et al., 2024) offers a middle ground: annotators first mark problematic spans with a binary severity label (minor/major) and then assign an overall segment score.

### 1.2 Motivation

However, the very question "What counts as error-free, and what does not?" remains extremely complex. Translation studies have argued over it for decades and proposed systematic criteria for what qualifies as "error-free" or "publishable". Descriptive approaches, for instance, locate judgement in norms rather than in the text itself: a shift toward target-language acceptability that one evaluator marks as a deviation, another may treat as expected behaviour (Toury, 1995). Likewise, whether a translation is assessed as overt or covert changes what counts as a fault (House, 2015). To our knowledge, no substantial Natural Language Processing (NLP) study addresses these finer-grained aspects of the problem. As this is a paramount subject, although slightly outside the scope of this exercise, we feel we should go back to it in the discussion.

## 2 Related Work

A related line of research concerns phraseological features identified through corpus linguistics. Fluent production largely reuses recurrent word combinations (Sinclair, 1991), and mutual information (Church and Hanks, 1990) was the first widely adopted measure of this recurrence. The *logDice* (Rychlý, 2008) was developed for lexicographic

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1763–1771
October 28-29, 2026 ©2026 Association for Computational Linguistics

applications, designed to be independent of corpus size. A related strand asks not how strong an association is but which words are *collocational*, measuring this through the entropy of a words collocate distribution (Kilgarriff et al., 2004). We adapt this idea to assign weights to unattested *n*-grams based on the fixity of the slot they fill. To our knowledge, such measures have not previously been used as reference-free MT evaluation features before.

## 3 Task and Evaluation Settings

Task 3 is scored using the *Matthews Correlation Coefficient*, which measures the correlation between predictions and ground truth, unlike accuracy and $F_1$. Rather than treat this as an implementation detail, we took it as the starting point of the process, since two of its properties are related to what a system should aim to achieve. First, it cannot be satisfied by hedging.

## 4 Our Approach

Any constant prediction leaves the coefficient undefined, and it is conventionally assigned zero, which is also the value a random predictor attains in expectation. The second is that, being computed on hard decisions rather than on a ranking, it depends directly on where the threshold falls. If the true positive rate is $p$ and a system predicts positive at a rate $r > p$, then even a perfect ranking is capped at $\sqrt{p(1-r)/r(1-p)}$. With $p = 0.25$, predicting at $r = 0.50$ caps the score at $0.58$ regardless of how well the hypotheses are expressed. Calibration is therefore essential here. Because a segment counts as error-free only if nothing is wrong with it, the two directions of evidence are not symmetric: a single fault is enough to place a segment in the negative class, whereas placing it in the positive class would require establishing the absence of *every* fault, which no reference-free signal can do.

### 4.1 Combining MCC metrics with heuristics

The first way to identify defects relies on **heuristics** that a human annotator can use to mark errors without hesitation, such as translation in the wrong language, a verbatim copy of the source, or an empty output. The second addresses issues of meaning and linguistic norms. To this end, we added a prompted LLM judge to the evaluation framework (see Figure 2), iteratively refining its prompt by inspecting cases where its verdict diverged from that of the classifier. The iterative process was based on the assumption that disagreements between the two judgments are precisely where the two sources of evidence can provide the most information about each other.

### 4.2 The decision procedure

The asymmetry of the strategy outlined in §4.1 translates into a two-stage decision. As one fault is sufficient to disqualify a segment, while some evidence should be allowed to decide independently, we distinguish between a *veto* and a *graded score*.

#### 4.2.1 The veto

A hypothesis is disqualified, regardless of its score, if it has normative issues: its detected language is not the target language, it is empty, its most frequent token exceeds $50\%$ of its tokens, or, for Chinese, the majority of its script-discriminating characters belong to the wrong script, etc.

#### 4.2.2 Score and threshold

All remaining features are aggregated into a continuous score, thresholded separately per language pair. We use two instantiations depending on whether labelled training data covers the language pair.

**Supervised:** Where WMT25 ESA annotations cover the pair $\ell$, a calibrated classifier estimates the probability that a segment is error-free, and the threshold $\tau_\ell$ is the value maximising MCC on out-of-fold probabilities, with a global fallback where a pair has too few examples ($< 200$) or only one class is present.

**Unsupervised:** Otherwise the ranking score is `COMETKiwi`'s estimate (Rei et al., 2022) where available, and a composite of penalty terms,

$$\text{score} = -\sum_k w_k \, P_k \tag{1}$$

where $P_k$ denotes the structural and phraseological penalties, and $w_k$ are fixed weights, cut so that a target proportion is predicted error-free.

Both instantiations prioritise the veto, so the veto can only remove positives, never add them.

#### 4.2.3 Penalties

We have come across, between two submissions, the very weak performance on Chinese and Russian, which prompted us to adapt our strategy

| Pair | Prior | v1 | v2 | v3 | v4 |
|---|---|---|---|---|---|
| *Per-pair MCC* | | | | | |
| bel_Cyrl | 0.189 | **0.262** | 0.173 | 0.132 | 0.226 |
| deu_Latn | 0.255 | **0.247** | 0.182 | 0.100 | 0.126 |
| rus_Cyrl | 0.274 | 0.138 | 0.206 | 0.158 | **0.208** |
| ukr_Cyrl | 0.241 | **0.252** | 0.236 | 0.184 | 0.213 |
| zho_Hans | 0.308 | 0.055 | 0.120 | **0.183** | −0.012 |
| zho_Hant | 0.265 | −0.001 | 0.092 | **0.145** | 0.046 |
| Macro MCC | – | 0.159 | **0.168** | 0.150 | 0.134 |
| $F_1$ | – | 0.300 | **0.439** | 0.415 | 0.398 |

Table 1: All scored versions.[1] Per-pair figures are MCC, recomputed from the released confusion matrices; $F_1$ is measured against the automatic pseudo-reference (column **Prior**).

by introducing ratio, structural and phrasological penalties. The features measure conformity rather than correctness. An accurate but unusual translation is thus penalised, whereas an error shared by every system in the pool is considered as "usual".

## 5 Training Data

We used a LIGHTGBM classifier (`n_estimators=400`, `num_leaves=31`, `class_weight="balanced"`). It was recalibrated with an isotonic regression by a 3-fold cross-validation, and was fitted on the WMT25 General MT human evaluation release, which is one of the rare resources whose labels can be reconstructed for Task 3 training. Each record covers one source segment and maps every system to a list of *Error Span Annotations*, where each annotation carries a segment-level score, a list of error spans with character offsets and a `minor`/`major` severity (Kocmi et al., 2024). For the training data, where a pair carries several annotations, we adopt a *conservative* aggregation: the pair counts as error-free only if every annotation says so, as we consider the identification of a span by a single annotator sufficient to classify it as a defect.

Of the 16 pairs covered by the release, only three directly overlap with ours (`en-ru`, `en-uk`, `en-zh_CN`): Belarusian and German from English are absent, and Traditional Chinese is represented only through its simplified counterpart. Thus, supervision is in-domain for half of our language pairs and transferred to the remaining pairs.

[1] Only v2 and v3 were submitted.

## 6 Results

### 6.1 Scored submissions

We improved our system across submissions, with the MCC increasing from 0.159 to 0.168 (see Table 1). The improvement from v1 to v2 is not a uniform gain. The structural and phraseological penalties introduced in v2 raised the score of three pairs: `ukr_Cyrl` (+0.068), `zho_Hans` (+0.065) and `zho_Hant` (+0.093), while lowering it on `bel_Cyrl` (−0.089), `deu_Latn` (−0.065) and `ukr_Cyrl` (−0.016). Therefore, the penalties act like a recalibration rather than an additional filter. The two Chinese pairs behave differently from European ones, and we attribute it to the interaction between our features and character-based tokenisation. As phraseological statistics are computed over bigrams for Chinese too, the association of two Chinese characters is measured far more densely than the bigrams used in European languages, since the Chinese is space-free.

The whole system predicts positive at a rate which is above the true one – 57% to 69% of segments, compared with the true rates (priors) which range from 19% to 31%. Thresholds are fitted on WMT25 ESA, which is one of the main parameters we can act on. The gap between the calibration and evaluation distributions, rather than the ranking features themselves, seems to be the source of loss.

### 6.2 System performance evaluation and ranking

As we have explained in the introductory remarks, the benchmark we explored covers six English-to-target-language pairs: Belarusian, German, Russian, Ukrainian, Simplified Chinese, and Traditional Chinese.

In this study, translation systems with 2,451 translated segments can be compared directly, whereas systems tested on smaller subsets require separate interpretation. This distinction is essential because language coverage affects the results.

According to our evaluation, **TRIVE** provides the strongest overall result among full-coverage systems (see Table 2 and Appendix A). Its 82.6% score exceeds **Wayfinder** and **Lumen** by 0.6 percentage points and GPT 5.5 by 0.7 points. The next tier comprises **MakotoAI** at 81.3%, Gemini 3.1 Pro at 80.0%, and Qingqiu-MT-9B at 79.5%. These results suggest that several translation systems are quite close in performance, although their

language-specific profiles differ.

Based on our results, the leading systems perform particularly well on the four European language pairs. **Wayfinder** obtains the best score for Belarusian (94.1%) and the best score for Russian (91.1%). **MakotoAI** and Lumen share the lead for German at 91.1%, while **TRIVE** leads for Ukrainian at 91.6%. **TRIVE** remains consistently strong across this group, at 88.7% for Belarusian, 88.9% for German, 85.2% for Russian and 91.6% for Ukrainian. This European-language strength seems a major driver of its first-place ranking.

Our results for Chinese are quite different. **Gemma 4 - 31B** leads for Simplified Chinese at 73.0%, slightly ahead of **Cohere CAT+** at 72.6%, and also ranks first for Traditional Chinese at 80.3%. **TRIVE** is second for Traditional Chinese at 79.4% but reaches only 64.2% on Simplified Chinese. Similarly, **Wayfinder** falls from 94.1% on Belarusian and 91.1% on Russian to 59.7% on Simplified Chinese. We believe that these differences show that strong general performance does not necessarily imply uniform multilingual robustness.

The results also reveal different system profiles. **TRIVE** offers the best combination of overall performance and coverage (see Table 2 and Figure 1). **Wayfinder** and **Lumen** are exceptionally strong on European language pairs but are less competitive on Chinese. **GPT 5.5** follows a similar pattern, combining high scores for European languages with 63.8% on Simplified Chinese and 70.8% on Traditional Chinese.

By contrast, **Gemma 4 - 31B** has a lower overall score of 75.6% but a relatively balanced profile and the strongest results on both Chinese languages. According to these results, the best system may depend on whether the objective is maximum aggregate performance or more even performance across language families.

Some partial-coverage systems also have high overall scores, but these figures should not be interpreted within the full ranking results. For example, **VoxNexus_V1** reaches 84.0%, higher than every full-coverage system, yet this result is based on only 780 segments, or 31.8% of the complete benchmark, and covers two language pairs. **Yandex** reaches 82.4% on 426 segments, while **Yandex-8B** reaches 80.0% on 780 segments. These results are promising within their tested scope, but they do not reflect superior performance across the entire multilingual evaluation.

| System | Score | NSeg | Coverage |
|---|---|---|---|
| TRIVE | 82.6% | 2451 | 100% |
| Wayfinder | 82.0% | 2451 | 100% |
| Lumen | 82.0% | 2451 | 100% |
| GPT 5.5 | 81.9% | 2451 | 100% |
| MakotoAI | 81.3% | 2451 | 100% |
| Gemma 4 - 31B | 75.6% | 2451 | 100% |
| VoxNexus_V1 | 84.0% | 780 | 80% |

Table 2: Comparative performance of translation systems based on our evaluation strategy **pred_v2**.

Overall, **TRIVE** emerges as the most convincing general-purpose system in this evaluation as it combines the highest full-coverage score with strong results across the European language pairs with a leading score for Ukrainian. Nevertheless, no single system dominates every language pair. According to our results, **Gemma 4 - 31B** is the strongest option for the Chinese evaluations, while **Wayfinder**, **Lumen** and **MakotoAI** lead individual European pairs. Therefore, the core takeaway is twofold: aggregate rankings are useful to identify general-coverage solutions, yet the language-specific data and scope must continue to be crucial in determining the best system choice.

## 7 Discussion

Our results, as well as those of other systems in this shared task, rely on a particular linguistic definition of what constitutes an error and on the assumption that the source and target texts should stand in a relation of equivalence. This may be a reasonable and valid assumption in the context of automated language processing. It is not – or, at least, not systematically and no longer – the case in the actual translation profession, nor, for that matter, in translation studies, at least since the much-discussed "cultural turn" of the mid-1980s. In the outside world, quality is more and more defined first and foremost by the degree of adherence to a translation brief (Reiss and Vermeer, 2014), whether the latter is made explicit or not (and it is the translator's task to have it made explicit). Thus, the same source-language text can yield markedly different outputs in the target language, depending on its intended readers, on their backgrounds, and on the very reasons why they are to read the said output. This should, of course, be taken into account in research such as ours, and this is also one of the reasons we have started introducing a

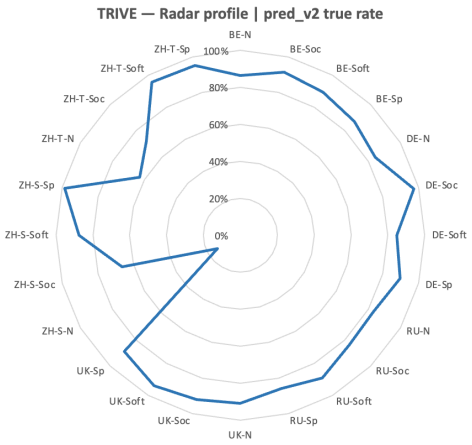

Figure 1: TRIVE's profile in different languages and domains.

prompted LLM judge, which could, with some refinement, go some way towards emulating this translation brief situation.

Within this task-dependent understanding of translation quality, *Correspondence Analysis* (CA) (Lebart et al., 1998) can provide a complementary view of how translation systems handle domain-specific lexical patterns (see Figures 4 and 5). This type of analysis allows comparing the lexical organisation of the source and machine-translated texts across the ***news***, ***social***, ***software***, and ***speech*** domains.

For example, for the English-German language pair, the **pred_v2** results are relatively balanced across the four domains, with the highest score for ***speech*** (75.1%), followed by ***software*** (71.7%) and ***social*** texts (69.7%), while news has the lowest score (62.6%). The overall score is 68.7% across 13,770 segments, suggesting greater difficulty with automatically translated news texts. The CA results provide a complementary view of these differences (see Figures 4 and 5 in the Appendix). While the source corpus shows relatively cohesive domain-specific clusters, the translated corpus exhibits greater lexical dispersion, particularly in the ***speech*** domain. Conversational items such as *hey*, *okay*, *gerade*, and *genau* are distributed across multiple regions of the CA plane, potentially reflecting weaker lexical cohesion and difficulties in preserving conversational features. At the same time, ***news*** and ***social*** texts are mapped closer together in the translated corpus than in the source corpus, suggesting increased lexical overlap between these domains.

## 8 Conclusion

We presented a reference-free system for detecting translation errors that combines a supervised classifier trained on WMT25 human error-span annotations with three complementary families of indicators: structural and phraseological cues, corpus-linguistic association measures derived from an LLM-as-judge model, and format and locale conformity checks. On the WMT26 test set, this combination yields a modest but measurable improvement over our previous submission, with the MCC increasing from 0.159 to 0.168. We evaluated the system on six language pairs, translating from English into Belarusian, German, Russian, Ukrainian, Simplified Chinese, and Traditional Chinese.

Taken together, these results suggest a gradual rather than revolutionary path toward improving machine translation. As scientific progress often proceeds through incremental steps (Kuhn, 1970, 1994), we hope our work contributes one such step. However, our findings should be interpreted with caution, as they rely on a conception of translation error based on source-target equivalence, raising broader questions about how translation quality should be defined and evaluated.

More specifically, we believe that the interpretation of our evaluation results is limited in the absence of a clearly defined translation brief (Reiss and Vermeer, 2014; Froeliger et al., 2023). Different briefs may prioritise different aspects of performance, such as terminological accuracy, fluency, consistency, speed, or cost. Within the field of translation studies, translation quality is not regarded as an unchanging concept; rather, it is evaluated based on the purpose of the translation, its intended audience, and the role of the target text (Froeliger et al., 2023). Thus, there can be no single machine translation system that is universally the best, regardless of its intended use. Instead, the suitability of a system ultimately depends on the specific translation context and the requirements of the task at hand.

Consequently, benchmark rankings should be interpreted as comparative indicators of performance rather than measures of translation quality. Their practical significance ultimately depends on how well the evaluated systems align with the requirements of the intended translation task. In this respect, CA results can help identify shifts in lexical distribution, domain differentiation, and cor-

Table 3: Percentage of correct predictions (% VRAI **pred_v2**) by language pair and domain.

pus cohesion, providing useful evidence for assessing translation quality in relation to the translation brief (Zhu et al., 2025). However, CA results should be regarded as exploratory and complementary evidence rather than as standalone measures of translation quality. This type of analysis does not directly assess adequacy, fluency, omissions, or mistranslations. These aspects require human evaluation and additional quality-estimation metrics and should be confirmed through a targeted qualitative error analysis.

In this respect, our contribution should be regarded only as a starting point, and we firmly believe that research such as ours will truly come to fruition once the service-provision dimension is fully taken into account (European Master's in Translation (EMT), 2022), that is, when professional translators and translation studies scholars are involved in the process.[2]

# RWS at WMT26 Terminology Translation Task

**Jon Cambra Guinea and Andrea Alfieri**
jcambra@rws.com
aalfieri@rws.com

## Abstract

This paper presents RWS' submission to the WMT26 terminology task: Translation-Queries-Memory (TQM), a prompt-based terminology and segment injection strategy for terminology translation across domains. We evaluate TQM on Basque to Spanish, English to Polish, and Traditional Chinese to English for WMT 2026 Terminology Shared Task 1 & 2. We demonstrate that injecting bilingual terminology and bi-text examples into recent Large Language Models' (LLM) prompts improves both overall translation quality and terminology accuracy. Our results show that strong instruction-following ability allows a system to adapt to terminology and style constraints without the need for fine-tuning.

## 1 Introduction

LLMs have become strong general-purpose translation systems, matching or outperforming previous encoder-decoder models on several language pairs (Garcia et al., 2023; Vilar et al., 2023). However, fluency alone is often insufficient for professional industry translation workflows, where accurate domain terminology is key to determine whether a translation is fit for purpose. Ensuring adherence to a set of approved term translations is therefore a long-standing concern in machine translation (MT), as evidenced by the WMT26 Terminology Translation task (Charkiewicz et al., 2026).

An up-to-date method to drive LLM translation is in-context learning. Instead of modifying the decoder, fine-tuning, or retraining the model, relevant translation information is injected into the prompt. This idea has been explored in two directions in recent times. On the one hand, terminology injection provides the model with source-target term pairs expected to be used at inference time. Moslem et al. (2023b) proved that the addition of approved terms to the prompt substantially increases the proportion of terms that appear correctly in the output. The benefit of terminology injection is not merely anecdotal. In WMT25's sentence/paragraph-level terminology translation task (Semenov et al., 2025), the first ranked system was simply OpenAI's `o3` with terminology constraints injected into the prompt. Similarly, in the document-level terminology translation task, the winning system Erlendur (Ingólfsdóttir et al., 2025) incorporated glossary information as part of the prompt.

In addition, injecting translation examples conditions LLMs on retrieved translation-memory (TM) matches, exploiting the in-context learning ability of LLMs (Moslem et al., 2023a): fuzzy matches used as few-shot examples improve translation quality over both zero-shot translation and randomly sampled examples, extending the earlier idea of integrating fuzzy matches into neural MT (Bulte and Tezcan, 2019; Cai et al., 2021); the same principle has since been carried into the fine-tuning stage, where retrieval-augmented few-shot examples are combined with instruction tuning for domain-specific MT (Zheng et al., 2024). The advantages of this approach were also demonstrated in the WMT25 terminology translation task. The submission `TiUTerm-V1` used `XGLM-7.5B` with 12 most similar in-context examples retrieved from the dev set (Semenov et al., 2025), and the system ranked fourth according to the CHRF score.

Despite these findings, terminology injection and TM example injection are typically studied in isolation and largely on high-resource and English-centric language pairs, where LLMs have been shown to perform strongly. It remains unclear how well these approaches transfer to lower-resource settings, where both term adherence and overall quality are harder to achieve.

We compare different LLMs and submit the optimal approach to WMT26 Terminology Translation Task for Spanish into Basque (es-eu), English into

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1772–1778
October 28-29, 2026 ©2026 Association for Computational Linguistics

Polish, and Traditional Chinese into English (zh-Hant-en) language pairs.

## 2 System description

TQM is our retrieval-augmented, LLM-based translation system designed to adapt to a particular style and terminology without sacrificing overall translation quality. TQM applies in-context learning: for each source segment, relevant information is retrieved and placed in the prompt before translation.

### 2.1 Terminology injection

We detect source terms with an in-house constraint-generation component. Given a source document and one or more bilingual dictionaries, it produces a set of terminology constraints for each translatable segment. At load time, each dictionary source term is tokenized and expanded into its inflected surface forms, so that the morphological variants of a term can also be matched. Detection then proceeds by greedy longest-match-first n-gram matching over the tokens of each source segment: the longest dictionary entry that fits a span is preferred, ensuring that multi-word terms take precedence over their constituent words, and overlapping candidates are resolved by a priority score. Each match yields the source span together with its prescribed target translation. These detected source-target term pairs are subsequently injected into the prompt.

### 2.2 Sample sentence injection

When translation memories (TM) are available, we condition the model on retrieved parallel translation examples extracted from them. This differs from terminology injection: while term pairs guide lexical choices, full segment pairs serve as in-context examples of a given domain which can inform the vocabulary, style, grammar, register and patterns of the output. The user can therefore benefit from the in-context learning ability of LLMs.

For each source sentence in a text fragment to translate, we retrieve the $k$ most similar source sentences from the TM by dense embedding similarity. Each source sentence in the TM is encoded into a multilingual vector using `paraphrase-multilingual-MiniLM-L12-v2` from sentence transformers (Reimers and Gurevych, 2019, 2020), a multilingual sentence encoder that maps semantically similar sentences close together in a shared embedding space across languages. We embed the TM source side offline, and store the resulting vectors in a vector index to allow efficient search. At inference time, we encode the source sentence to translate with the same model and compute its cosine similarity against the TM vectors. The $k$ TM entries with the highest scores are retrieved, and the corresponding translation pairs are injected into the prompt as few-shot examples.

### 2.3 Model selection

For the task, we analyze the behavior of three LLMs across all settings.

**LW Research Pro**. RWS' private research model finetuned for translation.

**TranslateGemma-27B**. Google's Gemma3 finetuned for translation (Finkelstein et al., 2026), in a GGML 4-bit quantized version.

**Qwen35-35B**. Alibaba's open-source Qwen3.5-35B-A3B Instruct model (Qwen Team, 2026), in a GGML 8-bit quantized version.

## 3 WMT submissions

We used TQM for both Document-Level Translation with Dictionaries (Track 1) and Document-Level Translation with Sample Sentences (Track 2)

### 3.1 Track 1: Document-Level Translation with Dictionaries

Track 1 involves document translation in Spanish-Basque (es-eu) for the energy and automation domains, and English-Polish (en-pl) for the medical and mechanical engineering domains. For each domain, a glossary is available to correctly translate terms when present in input documents. The solution needs to detect relevant terms in source segments and produce high-quality translations that use the correct term translation. To fully evaluate these abilities, three glossary modes are tested: `noterm` (no glossary provided), `random` (random, irrelevant terms provided), and `proper` (relevant, domain-specific terms provided).

#### 3.1.1 Data pre-processing

Input documents differ between language pairs. In the es-eu data, each document is a concatenation of short paragraphs, sentences, and/or titles, whereas in the en-pl data, documents consist of concatenated long paragraphs. We segment the documents into the above units for each language, respectively.

| | medical (en→pl) | | | mech.-eng. (en→pl) | | | energy (es→eu) | | | automotion (es→eu) | | |

Table 1: Per-domain, per-language-pair comparison of systems in proper, random, and noterm modes. Best value per column *within each mode* in **bold**; term accuracy is undefined in no-terminology mode (–). TA = term accuracy (↑), MetX = MetricX-24-XL-QE (↓), CK = WMT23-CometKiwi-DA-XL (↑).

#### 3.1.2 Results

In the absence of reference data, we estimate translation quality using reference-less metrics: MetricX-24-XL-QE (Juraska et al., 2024) and WMT23-CometKiwi-DA-XL (Rei et al., 2023). We also estimate term accuracy using an in-house implementation of a term-accuracy metric inspired on WMT25's terminology translation metric.[1]

Table 1 shows the performance of all systems across all modes. In term injection modes, TranslateGemma-27B leads the ranking in term accuracy in both es-eu domains. This aligns well with the language coverage in the training data. Indeed, the amount of Basque data in LW Research Pro training is scarce compared to a system like TranslateGemma-27B.

This is no longer the case for en-pl, LW Research Pro outperforms the other systems in 3 out of 4 cases according to term accuracy and is state-of-the-art in translation quality according to the reference-less metrics. Therefore, we submit translations with the winning system for each language pair: **TranslateGemma-27B in es-eu and LW Research Pro in en-pl.**

We note a clear degradation in translation quality for the random mode for all systems and language pairs. We hypothesize that injecting huge amounts of irrelevant terminology could be damaging translation quality.

### 3.2 Track 2: Document-Level Translation with Sample Sentences

Track 2 involves document translation in es-eu for the machine-tool and railways domains, en-pl for the mechanical-engineering and medical domains, and Chinese-English (zh-Hant-en) for finance-domain data. For each domain, a sample bi-text file with in-domain translation examples is available, from which the system has to learn the terminology and translation style.

#### 3.2.1 Data pre-processing

The data is also heterogeneous across languages. In the source documents, we observe the same discrepancies between es-eu and en-pl as in Track 1 and apply the same segmentation. Additionally, the zh-Hant-en document does not contain any clear paragraph separator; therefore, at inference time, we split the zh-Hant-en source documents into sentences to simplify the task.

In the sample bi-text files, translation pairs are sentence-level for es-eu and en-pl, but document-level for zh-en. We therefore pre-process the zh-en sample file to convert it into aligned parallel sentences: we divide the source and target documents into sentences, then ensure alignment by embedding the source and target sides with LaBSE (Feng et al., 2022) and maximizing the corresponding cosine similarity. The resulting sample segments can then be retrieved and injected into the prompts as described in Section 2.2. Figure 3 shows the similarity distribution for Track 2 between the source segments and the retrieved sample segments.

#### 3.2.2 Results

Figure 1 shows translation quality for all systems and $k$ values. Since translation-memory sample injection has a strong language-pair and system-dependent effect on quality, we select the optimal configuration separately for each language pair submission according to MetricX-24-XL-QE scores.

[1] https://github.com/wmt-conference/wmt25-terminology

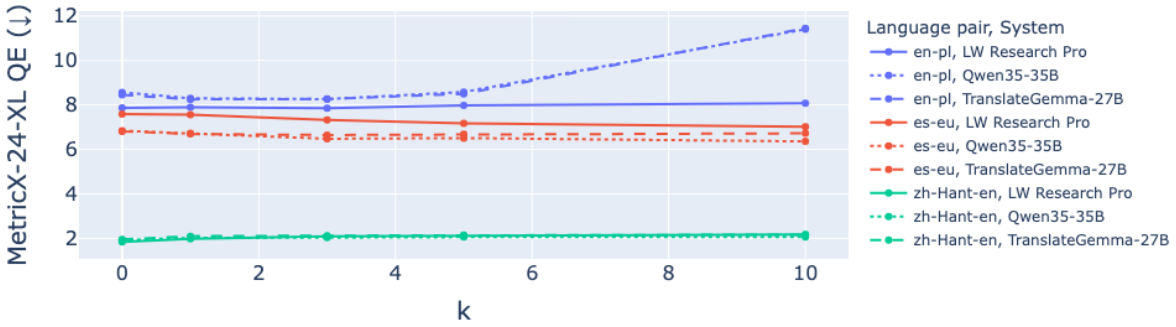

Figure 1: Effect of translation-memory sample injection on MetricX-24-XL QE (↓). Increasing the number of injected examples $k$ does not uniformly improve quality: gains appear for zh-en and es-eu but en-pl degrades with larger $k$, indicating a strong language-pair and model dependence.

As measured by MetricX-24-XL-QE, generally, we observe similar behavior and translation quality across systems and language pairs.

- **es-eu** Quality improves monotonically with $k$ for all 3 systems. As in Track 1, LW Research Pro lags behind the open-source systems given the low amount of Basque data it was trained on. Qwen35-35B reaches the best scores for all values of $k$. We therefore **select Qwen35-35B with k=10**.

- **zh-Hant-en** Translation quality is almost identical across systems for each value of $k$, and the quality curve is almost flat. However, as shown in Figure 3, identical or near-identical segments were included in the prompt, and the presented technique increases translation quality on exact matches, as discussed in Figure 2. This suggests that our metric may not fully capture the domain-specific requirements of this file. As a trade-off, **we submit Qwen35-35B with k=3** to ensure the LLM is extensively exposed to Chinese data and to sufficient translation style and terminology.

- **en-pl** Behavior differs drastically from the other pairs: adding more than 3 examples can harm MetricX-24-XL-QE scores, with the sole exception of LW Research Pro. We attribute this general degradation to input length. As described in Section 3.1.1, translation units correspond to paragraphs, but the $k$ examples are injected per sentence, resulting in extremely long prompts for long paragraphs. Open-source LLMs are less able to adequately handle this long context to adapt style and terminology at the paragraph level. The best configuration in terms of translation quality is achieved with LW Research Pro at $k = 3$. However, we could not submit that last result on time for the competition. As a consequence, **we submit a suboptimal solution, i.e. TranslateGemma-27B with k=3**.

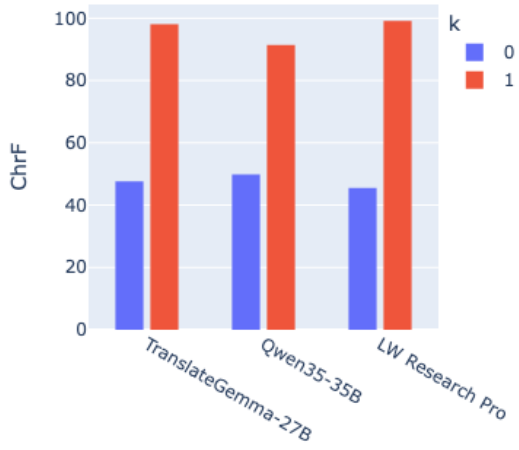

Figure 2: ChrF scores by model at k=0 vs. k=1 for segments with source–sample similarity > 0.99 (sample used as reference). Suggesting that the method is able to inject correctly the translation information from the bitext samples.

## 4 Conclusion

We investigated terminology quality in MT by submitting two methods of in-context prompt injection: for Track 1, approved terminology to force term translation, and for Track 2, retrieved translation examples to improve overall quality. We evaluated this approach in different domains and language pairs. For Track 1, we submit TranslateGemma-27B in es-eu and LW Research Pro in en-pl with term injection; for Track 2, we

submit TranslateGemma-27B with $k = 3$ in en-pl and Qwen35-35B with $k = 10$ and $k = 3$ for es-eu and zh-Hant-en respectively. We show that this technique, applied to different types of LLMs, can lead to high quality results.

## Limitations

Our RAG-based solution has several limitations. First, it depends heavily on the LLM's language pair coverage, its accuracy on instruction-following tasks, and prompt format used. Secondly, this ability might not generalize to some domains or language pairs. Additionally, the search for the optimal $k$ was implemented at the document level but could be better adjusted at the segment level based on similarity thresholds. Another avenue for improvement is the exploration of more recent embedding models and alternative similarity metrics. Finally, in the absence of reference or human-labeled data, our evaluation and configuration selection relied on reference-less metrics, which may not fully reflect in-domain style and terminology precision.

## Acknowledgments

We thank Amos Kariuki for providing the terminology detection component used for this work. We are grateful to William Tambellini, Justin Beavers and Matias Lin for the efficient open-source LLM versions used for the experiments.

# A Prompts

The prompts used for terminology injection (Track 1) and sample sentence injection (Track 2) are shown below.

## A.1 Track 1: Terminology Injection Prompt

```
You are a professional {source_lang} to
{target_lang} translator. Your goal is to
accurately convey the meaning and nuances of
the original {source_lang} text while
adhering to {target_lang} grammar,
vocabulary, and cultural sensitivities.
Produce only the {target_lang} translation,
without any additional explanations or
commentary. Please translate the following
{source_lang} text into {target_lang} where
'{source_term_1}' translates into
'{target_term_1}',
'{source_term_2}' translates into
'{target_term_2}',
...,
'{source_term_n}' translates into
'{target_term_n}':

{source_segment}
```

## A.2 Track 2: Sample Sentence Injection Prompt

```
You are a professional {source_lang} to
{target_lang} translator. Your goal is to
accurately convey the meaning and nuances of
the original {source_lang} text while
adhering to {target_lang} grammar,
vocabulary, and cultural sensitivities.
Produce only the {target_lang} translation,
without any additional explanations or
commentary. Please translate the following
{source_lang} text into {target_lang} where
'{source_match_1}' translates into
'{target_match_1}',
'{source_match_2}' translates into
'{target_match_2}',
...,
'{source_match_k}' translates into
'{target_match_k}':

{source_segment}
```

## B Cosine similarity distribution in Track 2

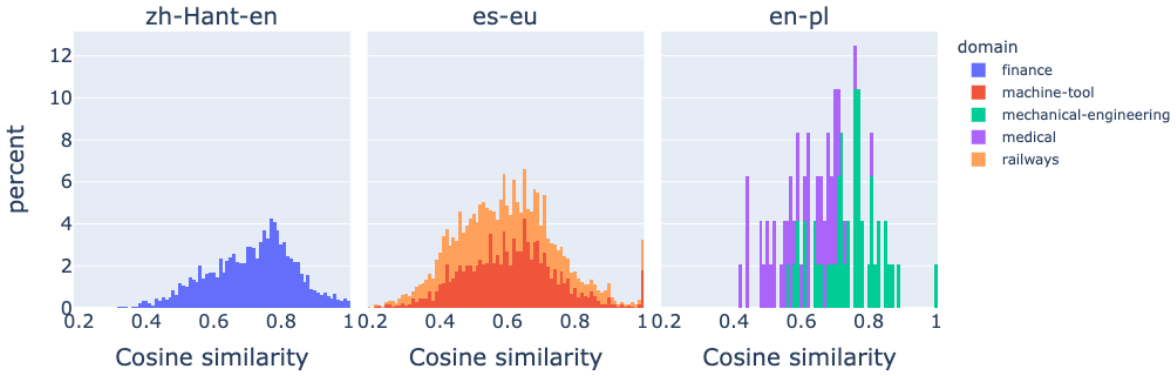

Figure 3: Cosine similarity distribution across language pairs between source segment and most similar source sample.

# UniOR-MT: An Agentic Pipeline for Terminology Translation

**Antonio Castaldo[1,2], Giulia Speranza[1], Maria Carmen Staiano[3], Petra Giommarelli[1,2], Johanna Monti[1], Maria Pia Di Buono[1]**

## Abstract

We present UniOR-MT, an agentic terminology-aware machine translation pipeline developed for the WMT 2026 Terminology Translation Shared Task. We compare five progressively enriched translation paths, each adding one component to isolate its individual contribution. We additionally submit a mixed system that selects, among the five candidate paths, the best candidate using a combined measure of terminology accuracy and document-level quality estimation. Evaluation results show that incorporating a bilingual glossary provides the most consistent benefit, while additional post-editing steps yield limited improvements, and can even degrade translation quality for Spanish–Basque in the official evaluation. The final system, which includes iterative QA feedback and a stronger fallback model, achieves the highest docCOMET scores in our internal evaluation.

## 1 Introduction

The translation of specialised terminology has been studied for decades, dating back to early work in the 1960s (Dunne, 2013). Regardless of whether the users are domain experts or professional translators, the primary objective is the accurate transfer of specialized knowledge (Pavel and Nolet, 2001). Consequently, translation-oriented terminology work focuses on ensuring consistency and accuracy (Prieto Ramos, 2021), enabling specialised information to be conveyed clearly to the end user. Meeting these requirements remains a major challenge for machine translation (MT) systems. Despite substantial advances in MT research, terminology-heavy domains remain far from being fully resolved. While general-purpose systems have achieved near-human performance for many high-resource language pairs, high-stakes domains such as science, engineering, medicine, and finance continue to pose significant challenges. Modern MT systems often demonstrate strong sentence-level performance, but ensuring terminological consistency across documents remains an open research problem (Semenov et al., 2025).

These challenges provide the motivation behind the fourth edition of the WMT 2026 Terminology Translation Shared Task (Charkiewicz et al., 2026), which focuses on document-level translation performed under explicit terminology constraints. Extending the scope of previous editions, this year's task broadens the evaluation to include lower-resourced, morphologically rich languages, offering a more challenging benchmark for terminology-aware machine translation systems. The WMT 2026 Terminology Task includes two tracks:

- **Track 1:** Document-Level Translation with Explicit Dictionary covers Spanish–Basque in the Engineering and Technology domain, as well as English–Polish in the Engineering and Technology and Medicine domains.
- **Track 2**: Document-Level Translation with Sample Bitexts covers Traditional Chinese–English in the Finance domain.

We focus on Track 1, which targets document-level translation with an explicit terminology dictionary. For each language pair, the input is provided as a JSON file of document-length source chunks (~2,000 words each), accompanied by a corpus-level bilingual dictionary in JSON format, mapping source terms to their target-language equivalents.

Systems are evaluated under three modes of terminology translation: i) no terminology (plain document translation, with no dictionary supplied), ii) proper terminology (translation guided by the correct domain dictionary), and iii) random terminology (translation guided by a control dictionary of the same format and size as proper, but populated with words sampled arbitrarily from the input

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1779–1790
October 28-29, 2026 ©2026 Association for Computational Linguistics

rather than domain terms). This three-way setup isolates the causal contribution of accurate terminology from the effect of simply providing any additional lexical input.

For Track 1, we propose a modular translation pipeline made up of a sequence of progressively enriched systems. Starting from a zero-shot translation baseline (ZS), the pipeline incrementally introduces bilingual terminology constraints (ZS+T), Post-editing (PE), Rule-guided Post-editing (Rule PE), and iterative Quality Assurance (QA). By adding a single module at each stage, the proposed architecture enables a controlled ablation of the contribution of each terminology-aware intervention, as presented in Table 1.

Internal analysis shows that additional stages can optimize the system on specific automatic metrics, with terminology injection (ZS+T) providing the most benefit. The official blind evaluation shows that this increased complexity does not necessarily translate into better performance, with ZS+T achieving the strongest performance among our submitted systems. Terminology injection emerges as the most robust strategy across language pairs, while additional post-editing produces small improvements for English–Polish but substantial degradation for Spanish–Basque, resulting in worse overall performance.

## 2 Related Work

Research on terminology-aware machine translation has been approached with a variety of methods aimed at improving the consistent use of domain-specific terminology. These methods are traditionally grouped into two strategies that differ in how strongly terminological choices are imposed on the model: hard and soft terminology constraints. Hard constraints intervene directly in the decoding process of the model to ensure that a given set of terms appear in the generated translation. These methods have been shown to achieve high terminological accuracy (Huang et al., 2024), but they often negatively affect overall translation quality and fluency (Hasler et al., 2018; Zhang et al., 2021). For this reason, they are often followed by a refinement stage, as seen in Wu et al. (2025). A more flexible alternative is offered by soft constraints, where terminology is provided as guidance during the generation process. In this methodology, bilingual glossaries and dictionaries are incorporated into the model's input, allowing the model to be guided by the given terminology without modifying the generation process itself (Briva-Iglesias and Ferre-Fernández, 2026; Hauhio and Friberg, 2024; Moslem et al., 2023).

Recent work has increasingly combined terminology-aware translation with refinement stages. Translate–then–refine approaches employ constrained re-decoding or LLM-based post-editing to improve terminology adherence while preserving translation quality (Bogoychev and Chen, 2023; Jaswal, 2025).

A paradigm that has become increasingly popular in MT is the use of collaborative agentic pipelines. Depending on the workflow design, these systems employ different collaboration strategies, including reflection-based refinement, where an LLM iteratively critiques and improves its own translation (Ng, 2025); role-based collaboration, in which specialised agents such as translators, reviewers, proofreaders, or domain experts sequentially refine translations (Wu et al., 2025; Sin et al., 2025; Briva-Iglesias, 2025); and consensus-based architectures, where multiple models or agents generate alternative translations that are subsequently reconciled by an arbitration mechanism (Staiano et al., 2026). These approaches use specialised agents to improve translation quality through iterative refinement, collaboration, or agreement before producing the final output.

A common design pattern in these systems is the generation of multiple translation candidates followed by a selection stage that balances overall translation quality against terminology accuracy, rather than optimising a single objective (Guttmann et al., 2025; Grubišić and Korencic, 2025). However, such selection is not without risks: a selector driven by a single utility metric may prefer candidates that omit the required terms, a form of metric interference (Pombal et al., 2025). These systems generate their candidates in parallel and do not isolate which stage of terminology intervention drives the trade-off between adherence and quality.

Our work addresses this limitation by adopting an incremental pipeline in which terminology-aware components are introduced progressively. This design enables a controlled evaluation of each intervention, allowing us to isolate its individual contribution to terminological accuracy and translation quality.

## 3 Methodology

We developed a modular MT pipeline, composed of five progressively enriched paths and relying primarily on `gpt-4o-mini` as the underlying language model. For each source segment, the pipeline generates five translations from five different paths, each corresponding to the system configurations described in Section 3.1. Each system builds directly upon its predecessor by the addition of a single component, allowing the isolated effect of each intervention to be assessed while holding all other factors constant. Using a relatively small model, the proposed architecture allows us to investigate whether structured terminology-aware interventions can achieve strong performance without requiring larger language models throughout the pipeline. Figure 1 provides an overview of the final agentic pipeline.

### 3.1 System Configurations

**Path 1: ZS.** The baseline system consists of a single language model acting as a translation agent (GPT-4o-mini), prompted to produce a direct translation of the source text with no auxiliary resources. This condition serves as the lower-bound reference against which the contribution of subsequent components is measured.

**Path 2: ZS+T.** Path 2 extends Path 1 by supplying the translation agent with the domain-specific bilingual dictionary provided by the workshop organisers. The dictionary is injected into the prompt as terminological constraints, with the aim of improving lexical accuracy and terminological consistency without altering the underlying translation process.

**Path 3: PE.** Path 3 introduces a second agent, a post-editor, which receives the output of Path 2 (translation agent + dictionary) and operates under a general instruction to improve the fluency, accuracy, and overall quality of the translation, without being given explicit editing criteria.

**Path 4: Rule PE.** Path 4 retains the architecture of Path 3 but replaces the generic post-editing instruction with an explicit set of post-editing rules (see Appendix A). These rules were designed by drawing on established principles from terminology theory and translation studies (Fernández-Parra, 2025; Bowker, 2015; Cabré, 2010; Scarpa, 2001). In particular, we selected rules to instruct the model to verify the consistent use of terms throughout the translation (ISO 11669:2024, 2024; ISO 17100:2015, 2015), ensure compliance with terminological databases (Risku, 2006), evaluate whether the selected terms are appropriate for the given domain and context (Lušicky and Wissik, 2015; Chiocchetti and Ralli, 2013; ISO 704:2009, 2009), use only synonyms and acceptable term variants (Lavagnino, 2010), and avoid common translation errors such as literal renderings and false friends (Lomaka, 2017). Rather than providing generic editing suggestions, Path 4 therefore equips the model with terminology-aware revision criteria grounded in established terminology management practice. Overall, this configuration tests whether structuring the post-editor's task with explicit, actionable criteria yields measurable gains over unconstrained post-editing.

**Path 5: Rule PE + QA.** Path 5 extends Path 4 with a Quality Assurance (QA) agent positioned downstream of the rule-guided post-editor. Quality assurance is, in fact, considered one of the main goals of terminology work (Schmitz and Straub, 2010). Terminology plays a role at every stage of the translation QA process, since it is one of the elements that must be checked against established standards (Popiolek, 2015). The QA agent verifies whether the post-editor applied all the rules and the glossary constraints. If all checks pass, the translation is accepted as the final translation for S5. If not, the post-edited translation is passed to the Supervisor agent, which provides textual feedback explaining to the post-editor what should be modified and how. The post-editor thus adjusts the translation based on the supervisor's feedback. This feedback paraphrase loop is repeated for a maximum of three iterations. At the end of the loop, a final attempt to repair the translation output is performed using a Post-Editor agent, originally powered by `gpt-4o-mini` and later replaced with `gpt-5.6-luna`.

This configuration tests the added value of an explicit, iterative self-correction mechanism over a single-pass rule-guided revision. The proposed multi-agent translation pipeline was inspired by the roles, activities, and workflow typically found in a professional translation setting. Rather than modelling agents as arbitrary computational components, each agent was designed to emulate a specific participant in the translation workflow. The Editor provides terminology resources or glossaries and the general translation guidelines and require-

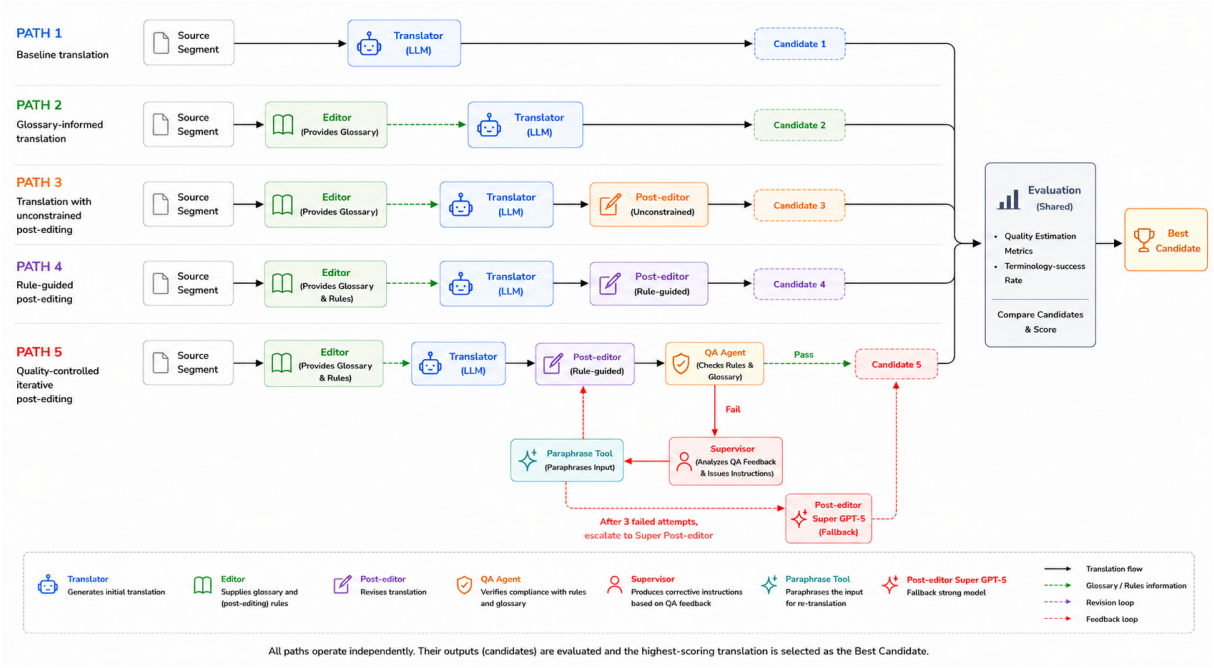

Figure 1: The UniOR-MT agentic pipeline. The pipeline is composed of five progressively enriched paths. For the mixed system submission, the best candidate is selected from the five paths in order to maximize quality estimation metrics.

ments; the Translator Agent corresponds to the professional translator responsible for producing the initial translation; the Post-Editor performs linguistic revision; the Quality Assurance Agent verifies compliance with predefined linguistic and terminological requirements; the Supervisor generates structured corrective feedback when quality issues are detected; and the Paraphraser Agent reformulates this feedback to facilitate subsequent refinement.

Consequently, the overall architecture reproduces the iterative nature of human translation workflows, where translation, revision, quality control, and feedback operate as complementary stages aimed at progressively improving translation quality. Although implemented through language models, the interaction among agents mirrors the collaborative practices commonly adopted in professional translation and localization environments.

### 3.2 System Implementation

The pipeline was implemented in Python using DSPy (Khattab et al., 2023), a framework for constructing modular programs powered by LLMs, through declarative task specifications. The translation, post-editing, and quality-assurance agents were implemented as separate DSPy modules, with `gpt-4o-mini` configured as the underlying language model through the OpenAI API, with temperature equal to 0.3. Prompts and module specifications were designed independently for each agent role and are reported in full in Appendix B.

### 3.3 Systems Submission

We submitted four systems: three individual configurations, namely i) ZS+T, ii) PE, and iii) Rule PE, and iv) one mixed system. The choice of individual submissions was based on development experiments conducted using the original pipeline implementation, in which all agents were powered by `gpt-4o-mini`. Under this implementation, the Rule PE+QA configuration did not provide sufficiently consistent improvements over the simpler paths and was therefore not selected as an individual submission.

Our primary system, called mixed, followed a broader candidate selection strategy. For each source segment, it selected the most suitable candidate that maximized a combined quality measure based on terminology accuracy and a document-level approximation of COMET-Kiwi (Rei et al., 2022), adapted to document-level evaluation, as described in Section 4.

Since the source documents exceed COMETKiwi's maximum context length, document-level quality estimation is approximated

by partitioning each document into contiguous windows containing approximately the same number of tokens. COMETKiwi is applied independently to each window, and the resulting scores are averaged to obtain a single quality estimate for the entire document. This last mixed system, therefore, combines the outputs of Path 1 to Path 5 in order to maximize the estimated quality.

After the standalone submission set had been determined, the final repair agent in the Rule PE+QA path was upgraded from `gpt-4o-mini` to `gpt-5.6-luna`. The stronger performance of Rule PE+QA in our internal evaluation therefore reflects the improved final configuration, whereas the individual submissions reflect the development results obtained with its original implementation.

Table 1: Results for the English–Polish and Spanish–Basque language pairs.

We evaluate the proposed agentic paths internally using three metrics. TermAcc measures terminology adherence, while docCOMET (Vernikos et al., 2022) and SLIDE (Raunak et al., 2024) provide estimates of the overall translation quality at the document level. This analysis is conducted on a held-out test set derived from the training data and is intended to examine the contribution of the individual stages of the pipeline.

Table 1 reports results across the three terminology conditions and five agentic paths. The proper glossary produces the clearest gains in TermAcc for both language pairs. However, adding further processing stages after glossary injection does not result in proportional improvements. Differences among ZS+T, PE, and Rule PE are generally small, and the additional post-editing steps occasionally lead to lower scores for some translation quality metrics. This pattern suggests that the largest benefit is obtained from providing the correct terminology at translation time, while increasing the complexity of the subsequent revisions does not necessarily improve terminology adherence or overall translation quality across language pairs and evaluation metrics.

Rule PE+QA emerged as the strongest configuration according to docCOMET, consistently outperforming the other agentic paths across both language pairs and all terminology conditions. However, the same pattern is not consistently reflected by SLIDE. For English–Polish, Rule PE+QA obtains substantially higher docCOMET scores but lower SLIDE scores than the other configurations, whereas for Spanish–Basque the differences in SLIDE are smaller and less systematic. This divergence indicates that the two document-level metrics respond differently to the changes introduced by the QA stage, particularly for English–Polish.

Finally, the `random` condition shows that simply providing additional lexical information is not enough to improve performance. The gains observed with `proper` terminology appear to depend on the relevance and correctness of the supplied terms, while irrelevant terminology may even have a negative effect on translation quality.

The official evaluation on the blind test set is presented in Table 3 and 4 of Appendix C, and it supports the limited contribution of the additional processing stages. Overall, ZS+T achieves the strongest performance among our submitted systems, obtaining the best average scores for terminology success, COMET-22, XCOMET-XXL,

and MetricX-24, while Rule PE obtains a higher chrF++ score. The effect of post-editing appears to vary substantially across language pairs. For English-Polish, Rule PE and generic PE yield small improvements over ZS+T on some metrics. In contrast, for Spanish-Basque, both post-editing paths lead to lower terminology success and lower translation quality scores. Taken together, these results indicate that additional refinement stages may improve specific metrics or language pairs, but these gains are local and do not translate into a consistent advantage across evaluation conditions. Terminology injection therefore emerges as the most robust intervention in the proposed pipeline.

The greater degradation observed for Spanish–Basque after post-editing interventions may be related to the lower-resource nature of the Basque language. While additional post-editing can introduce useful revisions for a better-resourced target language such as Polish, the same generative interventions may be less reliable for Basque and may actually degrade the translations produced under direct terminology constraints.

## 5 Conclusions

In this paper, we presented UniOR-MT, an agentic pipeline for terminology-aware machine translation developed for the WMT 2026 Terminology Translation Shared Task. Our main contribution is an incremental evaluation framework that isolates the effect of successive terminology interventions within a unified translation workflow. This design allows us to quantify how each stage contributes to terminology success rate and overall translation quality, providing insights into the trade-offs between increasingly sophisticated terminology-aware strategies.

Our experiments show that providing a bilingual glossary substantially improves terminology adherence, whereas generic and rule-guided post-editing yield comparatively smaller gains. This indicates that increasing the number of processing stages after glossary injection does not necessarily translate into proportional improvements in either terminology adherence or document-level translation quality. In our internal evaluation, the largest improvements in docCOMET are achieved by introducing an explicit quality assurance stage with iterative feedback. However, these gains are not consistently reflected by SLIDE, highlighting that additional refinement may improve some dimensions of translation quality while negatively affecting others. The official blind evaluation further shows that ZS+T achieves the strongest overall performance among our submitted systems. While post-editing produces small improvements for English–Polish on some metrics, it substantially degrades performance for Spanish–Basque. Notably, these results were obtained with a pipeline relying primarily on `gpt-4o-mini`, suggesting that structured terminology-aware workflows can achieve strong performance without relying on larger language models throughout the pipeline.

Overall, our findings suggest that the effectiveness of terminology-aware MT depends not only on the availability of lexical resources but also on how these resources are integrated into a structured revision workflow. Increasing pipeline complexity does not consistently lead to better performance: while accurate terminology resources provide clear benefits, subsequent refinement stages yield more limited, metric-dependent, and language-pair-dependent gains. By progressively introducing terminology-aware components within a unified pipeline, our evaluation framework provides a more interpretable analysis of their individual contribution to terminology adherence and overall translation quality than evaluating complete end-to-end pipelines alone.

## 6 Limitations

The proposed pipeline was evaluated exclusively on the WMT 2026 Terminology Translation Shared Task (Track 1), covering two language pairs and a limited number of specialised domains. Consequently, the observed improvements may not generalise to other languages, domains, or translation settings. Furthermore, the pipeline was implemented using only a small selection of language model, meaning that the reported gains primarily reflect the contribution of the agentic workflow and prompting strategy rather than model diversity. Finally, our internal quality estimation relied on an approximation of COMETKiwi obtained by averaging scores over fixed-length context windows. Although this enabled document-level comparison across systems, it may not fully capture discourse phenomena spanning longer contexts. Future work should validate these findings through human evaluation and investigate stronger specialised agents and long-context quality estimation methods.

## Acknowledgments

This work has been funded by the Italian National PhD programme in Artificial Intelligence, partnered by University of Pisa and University of Naples "L'Orientale", through a doctoral grant (ID 39-411-24-DOT23A27WJ-6603) to the first author, established by Ex DM 318, of type 4.1, cofinanced by the National Recovery and Resilience Plan. This work was also partially supported by the PhD programme in Humanities and Technologies funded by the University of Macerata under D.R. No 253/2023. This work has been partially supported by the 4MLP Project, funded by the University of Naples "L'Orientale" under the University Research Projects funding scheme (PRA 2025) - CUP C66125002860005.

## A Explicit Post-Editing Rules

1. **Glossary conformity.** Every glossary pair must be respected. Wherever a source term appears in the source sentence, the translation must use the corresponding target term exactly, allowing only the grammatical inflection required by the target language. If the draft uses a synonym or paraphrase, replace it with the prescribed glossary term.

2. **Terminological consistency.** Use the same target term for the same concept throughout the sentence. Do not alternate between the glossary term and a synonym.

3. **Domain adequacy.** Use renderings appropriate to the relevant domain, such as enterprise software or technical documentation. Prefer established domain-specific terminology to general-language wording.

4. **Correct grammatical variants.** Inflect glossary terms correctly according to the grammar of the target language. Case, number, gender agreement, orthographic variants, abbreviations, and acronyms must all be well formed. Adapting the grammatical form of a glossary term to fit the sentence is required and does not constitute a violation of Rule 1.

5. **Do-not-translate terms.** Terms that must remain in the source language, including product names, brand names, user-interface commands, code identifiers, and file paths, must be preserved exactly as they appear in the source. If the glossary maps a term to itself, treat it as a do-not-translate term.

6. **Avoidance of word-for-word literalism.** Except for constrained glossary terms, translate the meaning rather than the surface form. Restructure the sentence whenever required by the target language so that the translation reads naturally and fluently.

7. **Avoidance of false friends.** Check words that are formally similar across the source and target languages but differ in meaning. Ensure that each term conveys the intended source meaning rather than that of a misleading look-alike.

8. **Minimal editing.** Make only the changes required by the preceding rules or those necessary to correct clear problems of accuracy, grammar, or fluency. Do not rewrite acceptable phrasing, and do not add or omit information relative to the source.

## B Prompts Configuration for the Agents

**Path 1: Baseline Translator**

**Translator agent**

Translate the source sentence while enforcing every terminology pair exactly, allowing only grammatical inflection. If no terminology is provided, produce an accurate and fluent translation.

**Path 2: Translator with Glossary**

**Translator agent**

Translate the source sentence into the target language. You MUST use the provided terminology: for every source-term-to-target-term pair, the translation must render the source term using exactly the specified target term, inflected only as required by target-language grammar. If the terminology is "(none)", translate the sentence accurately and fluently. Output only the translation.

**Path 3: Translator and Generic Post-Editor**

**Post-editor agent**

Post-edit the draft translation. Ensure that every terminology constraint is respected exactly, allowing only grammatical inflection, and correct any accuracy, grammar, or fluency issues. If no terminology is provided, focus exclusively on translation quality. Keep edits minimal and output only the final translation.

**Path 4: Translator and Rule-Based Post-Editor**

**Rule-based post-editor agent**

Revise the draft translation by applying the complete rule set in addition to enforcing the glossary. The rules require glossary conformity, terminological consistency, domain adequacy, correct grammatical inflection, preservation of protected terms, natural target-language phrasing, avoidance of false friends, and minimal editing. Output only the final translation.

**Path 5: Full Agentic Pipeline**

**Quality-assurance agent**

Verify that the translation complies with every rule in the rule set and with every terminology constraint. Check the rules individually against the translation. Set `passed=True` only if all requirements are satisfied. If any requirement is violated, set `passed=False`; in the feedback, identify each violated rule and state concretely how the translation should be revised to enforce it.

**Supervisor agent**

Diagnose why the translation fails the QA check and produce concrete, actionable feedback for a post-editor to fix it. Ground every point in a specific rule or terminology constraint and state exactly what to change.

**Paraphrase agent**

Rephrase and sharpen the guidance instead of repeating it verbatim, calling out whatever the earlier wording likely left ambiguous or the post-editor missed.

Table 2: Prompt configurations used in the proposed translation pipeline

## C Official Shared Task Evaluation

Table 3 reports the official WMT 2026 evaluation scores for our submitted systems across the three terminology conditions.

| | Proper | | | Random | | | Noterm | | |

# AGENTEAK: A Multi-Agent Pipeline for Terminology-Constrained Spanish–Basque Translation

**Jurgi Giraud[1,2] and Andrew Gargett[2]**
[1]School of Informatics, University of Edinburgh, Edinburgh, UK,
[2]School of Languages and Applied Linguistics, The Open University, Milton Keynes, UK
jgiraud2@ed.ac.uk andrew.gargett@open.ac.uk

## Abstract

This paper describes the OpenU's submission to the WMT26 Terminology Translation Task for Spanish into Basque (Track 1), covering the automotive and energy domains. We present AGENTEAK, a multi-agent system built on LANGGRAPH in which three compact open-weight models (4–8B parameters) cooperate: a reasoning model that selects and disambiguates the terminology relevant to each segment, a domain fine-tuned translation model, and a verification model that checks and repairs terminology in the draft translation. To adapt the translator, we mined in-domain Spanish–Basque bitext from Wikipedia using multilingual sentence embeddings and complemented the data with in-domain synthetic parallel paragraphs generated by an instruction-tuned Basque LLM. Domain-tagged fine-tuning improves the base model by up to 10.4 BLEU and 3.9 COMET points on our in-domain test sets. On the shared task data, supplying the pipeline with correct terminology raises terminology success rate from 0.613 to 0.757 (automotive) and from 0.601 to 0.774 (energy).

## 1 Introduction

Terminology control is one of the clearest cases where Machine Translation (MT) quality is judged by more than adequacy and fluency. In technical and industrial settings, a translation that renders a term inconsistently is unusable regardless of how natural it reads. The WMT terminology tasks have made this requirement explicit by pairing test documents with domain term bases and evaluating systems on whether the prescribed target terms appear in the output (Alam et al., 2021; Semenov et al., 2023).

Our submission addresses Track 1 of the WMT26 Terminology Translation Task, Spanish into Basque, in the automotive and energy domains. Basque makes the problem markedly harder than the language pairs typically studied. It is a language isolate with agglutinative, suffix-based morphology: nouns inflect for number, definiteness and case within a single word form. Constraint mechanisms that copy a target string verbatim, such as lexically constrained decoding (Hokamp and Liu, 2017; Post and Vilar, 2018), are therefore a poor fit as enforcing the citation form produces ungrammatical output, while allowing free inflection removes the guarantee that motivated the constraint in the first place. Basque is also comparatively low-resourced, and in-domain Spanish–Basque parallel data for the automotive and energy domains is essentially unavailable off the shelf.

We tackle both problems with a modular pipeline[1], AGENTEAK,[2] that separates terminology reasoning from translation. Rather than a single prompted model, AGENTEAK distributes the work across three compact open-weight models orchestrated with LANGGRAPH, none larger than 8B parameters, so that the whole system is able to run on a single consumer-grade GPU. Our contributions are:

1. a domain-targeted Wikipedia bitext mining procedure for Spanish–Basque;
2. an in-domain synthetic data generation procedure using an instruction-tuned Basque LLM;
3. domain-tagged parameter-efficient fine-tuning of Latxa-Llama-3.1-8B-Instruct, improving translation quality over the base model in the two domains;
4. a three-agent terminology-aware translation pipeline, and an analysis contrasting correct and randomly substituted term constraints that quantifies how far the system actually follows the terminology it is given.

## 2 Background

**Terminology-constrained MT.** Early approaches enforced terminology at decoding time, either by extending beam search to track unsatisfied constraints (Hokamp and Liu, 2017) or by allocating beam capacity dynamically to keep the cost tractable (Post and Vilar, 2018). Because hard constraints interact badly with reordering and inflection, a second line of work moved the constraint into the training data, teaching the model to use inline target-term annotations supplied at inference time (Dinu et al., 2019). Bergmanis and Pinnis (2021) showed that annotating target *lemmas* rather than surface forms is markedly more effective for morphologically rich languages, since it leaves the model free to inflect the term correctly. Our approach is a soft variant of this idea: terminology is injected into the prompt of an instruction-tuned model, and a downstream agent, rather than the decoder, is responsible for checking that it was used.

**LLMs and agentic translation.** LLMs are competitive with dedicated NMT systems for high-resource pairs and exploit instructions and in-context examples well (Hendy et al., 2023; Vilar et al., 2023), including glossary entries supplied at inference time (Moslem et al., 2023); targeted fine-tuning closes much of the remaining gap (Xu et al., 2024). A parallel line of work decomposes translation into a generate–critique–revise loop (Madaan et al., 2023): Feng et al. (2025) show that systematic error identification followed by targeted repair beats undirected self-correction, and Wu et al. (2024) assign distinct roles to separate model instances for literary translation. The closest precedent for our submission is IRB-MT at WMT25 (Grubišić and Korencic, 2025), which entered the terminology task with an agentic translation-revision workflow over several small open-weight LLMs, deliberately avoiding fine-tuning and selecting a final candidate with a terminology-aware quality metric. AGENTEAK differs on both counts: we fine-tune the translation agent on mined in-domain data, which we consider necessary rather than optional for a target language with no strong general-purpose translator, and we run a single bounded verification pass instead of a metric-guided search over candidates, accepting a lower ceiling for a fixed inference budget.

**Basque MT and terminology.** Basque NLP has been transformed by open resources such as BasqueGLUE (Urbizu et al., 2022) and Latxa, a family of Llama-based models continued-pretrained on a large Basque corpus (Etxaniz et al., 2024), which we use as our backbone. Dedicated ES–EU systems exist but are general-domain, and massively multilingual systems such as NLLB-200 (NLLB Team, 2022) cover Basque without domain adaptation or terminology control. The most direct precedent for terminology-aware Basque MT is clinical: Soto et al. (2019) report that injecting bilingual clinical terminology, combined with back-translation of monolingual health records, roughly doubled BLEU on health record templates in the absence of any in-domain parallel corpus, and the same group examined the benefits and limits of terminology-driven domain adaptation for Basque at WMT20 (Soto et al., 2020).

**Parallel data mining.** Where in-domain parallel data does not exist, it can be mined. Margin-based retrieval over multilingual sentence embeddings (Artetxe and Schwenk, 2019) underpins large-scale corpora extracted from Wikipedia (Schwenk et al., 2021), and LaBSE (Feng et al., 2022) provides strong cross-lingual sentence representations for over 100 languages, Basque among them. Since embedding similarity alone admits many near-parallel but unusable pairs, filtering is needed to remove problematic pairs which might introduce noise in the data. We additionally follow the observation that LLM-generated in-domain text is a useful substitute for authentic domain data when the latter is scarce (Moslem et al., 2022), a synthetic-data strategy in the tradition of back-translation (Sennrich et al., 2016).

## 3 Data

### 3.1 Domain bitext mining from Wikipedia

We built in-domain Spanish–Basque parallel data[3] by mining comparable Wikipedia articles. For each domain we defined a set of Spanish root categories and traversed their subcategory graph to collect candidate articles. For the automotive domain we used *Vehículos*, *Industria automotriz*, *Automoción*, *Componentes del automóvil*, *Tecnologías del automóvil*, *Tecnologías del transporte* and *Motores*

[3]Datasets available on Hugging Face: https://huggingface.co/jurgiraud/datasets with the name tag eseu-wmt26

| | Automotive | Energy |
|---|---|---|
| *(a) Mined bitext* — sentence pairs | | |
| Candidates (cos. $\geq 0.80$) | 3,054 | 4,348 |
| Retained (Bicleaner AI $\geq 0.50$) | **2,447** | **3,297** |
| *(b) Synthetic* — paragraph pairs | | |
| Retained (Bicleaner AI $\geq 0.50$) | **1,189** | **1,129** |
| *equivalent sentences* | *3,567* | *3,387* |

Table 1: In-domain Spanish–Basque data. The two sources are counted in different units: mined bitext is aligned at the sentence level, synthetic data at the level of three-sentence paragraphs. The italicised row converts (b) to sentences for scale only.

*de combustión interna*; for the energy domain, *Energía*, *Fuentes de energía*, *Tecnología energética*, *Energías renovables*, *Generación de energía eléctrica*, *Ingeniería eléctrica* and *Combustibles*.

This produced 7,788 Spanish candidate articles for the automotive domain and 3,874 for energy. Articles were linked to their Basque counterparts through Wikipedia interlanguage links, leaving 704 comparable article pairs in each domain. Both sides were sentence-split and cleaned, and every Spanish sentence was compared against every Basque sentence within the same article pair using LaBSE embeddings (Feng et al., 2022), retaining pairs with cosine similarity $\geq 0.80$[4]. Restricting candidate generation to within-article pairs keeps the search tractable and reduces false positives relative to corpus-wide retrieval.

The resulting 3,054 (automotive) and 4,348 (energy) candidate sentence pairs were then further filtered using Bicleaner AI (Zaragoza-Bernabeu et al., 2022) at the recommended threshold of 0.50, discarding roughly 20% and 24% of pairs respectively. This double-filtering approach is supported by evidence that corpus quality outweighs quantity for Basque and other low-resource languages (Artetxe et al., 2022). Table 1 summarises data and filtering pipeline.

### 3.2 Synthetic in-domain data

To complement mined Wikipedia parallel sentences, and to to increase terminological density and coverage which may not have been fully captured by encyclopaedic texts, we generated additional parallel data[5] with Latxa-Llama-3.1-8B-Instruct (Sainz et al., 2025). To do so, we prompted the model to produce three-sentence Basque paragraphs together with their Spanish translations, with explicit instructions to employ correct bilingual terminology for the target domain taken from the bilingual dictionary provided as part of Track 1 of the shared task. Generating short paragraphs rather than isolated sentences yields text with intra-paragraph coreference and connectives, which is closer to the document-level test data than mined sentence pairs are.

Generated pairs were passed through the same Bicleaner AI filter, leaving 1,189 automotive and 1,129 energy pairs.

### 3.3 Out-of-domain data and splits

Both mined and synthetic in-domain data are small, and fine-tuning on them alone can cause over-fitting to domain-specific data. We therefore combined them with EusParallel,[6] a general-domain Spanish–Basque parallel corpus, as an out-of-domain component. All in-domain data was split into training and development portions at the article level, so that no development sentence originates from an article seen in training. The resulting datasets have been released on the Hugging Face Hub.

## 4 Translation Agent

**Setup.** We selected the translation agent against four criteria: the model should be (i) openly available, (ii) pre-trained or adapted on Basque data, (iii) instruction-tuned, and (iv) compact, below 10B parameters. Our choice fell on Latxa-Llama-3.1-8B-Instruct (Sainz et al., 2025), a Llama-3.1 model adapted to Basque on the Latxa corpus (Etxaniz et al., 2024), which meets all four criteria. We fine-tuned it[7] with LoRA (Hu et al., 2022) on an instruction-formatted version of our data. Each training example carries an explicit domain tag (`[automotive]` or `[energy]`) in the instruction, so that a single set of adapters serves both domains and the domain can be selected at inference time. We train two configurations: (i) mined bitext plus

[4] Feng et al. (2022) used a threshold of 0.60 for translation retrieval which included partial translations. We used a more stringent threshold to retain only good quality parallel sentences

[5] Datasets available on Hugging Face: https://huggingface.co/jurgiraud/datasets with the name tag eseu-wmt26 and synthetic

[6] https://huggingface.co/datasets/HiTZ/EusParallel

[7] The fine-tuned model is available on Hugging Face: https://huggingface.co/jurgiraud/latxa-eseu-wmt26-augmented

out-of-domain data, and (ii) mined bitext plus out-of-domain plus synthetic data. Fine-tuning configuration and parameters are provided in Appendix A.

**Evaluation.** We report BLEU (Papineni et al., 2002) and TER (Snover et al., 2006) through sacreBLEU (Post, 2018), chrF2 (Popović, 2015), which is better suited to agglutinative targets because it credits partially correct word forms, and COMET (Rei et al., 2020) on our held-out in-domain development sets.

**Results.** Table 2 shows that domain fine-tuning improves translation quality as measured by automated metrics. Against the base model, the first configuration gains 5.4 BLEU and 3.5 COMET in the automotive domain and 9.7 BLEU and 3.3 COMET in energy, with TER falling by 12.6 and 19.7 points. Adding synthetic data gives a further consistent improvement in every metric and in both domains (+1.6 and +0.7 BLEU), confirming that terminology-conditioned generation from the same backbone supplies a signal the mined data does not. The gains are largest for energy, where more mined data was available.

## 5 The AGENTEAK Pipeline

The submitted system is a five-stage workflow implemented with LangChain and LangGraph,[8] of which three stages are model-driven agents and two are deterministic, as seen in Figure 1. Documents are processed chunk by chunk, with the domain tag fixed for the whole document.

**Step 1: Candidate term matching (deterministic).** The source chunk is matched against the term base provided with the task data. Matching is performed on the Spanish side, where morphological variation is limited to number and gender agreement, using normalised surface forms and a small set of inflectional rules. This stage is high-recall by design: it over-generates candidates, including spurious matches inside longer expressions, and leaves disambiguation to the next stage.

**Step 2: Terminology agent.** The candidate list and the source chunk are passed to Qwen3-4B (Yang et al., 2025) operating with reasoning/thinking mode enabled. The agent fulfils three tasks: to discard candidates that are not genuine domain uses of the term, to recover terms the matcher missed, and to resolve entries with multiple admissible Basque equivalents by choosing the one appropriate to the context.

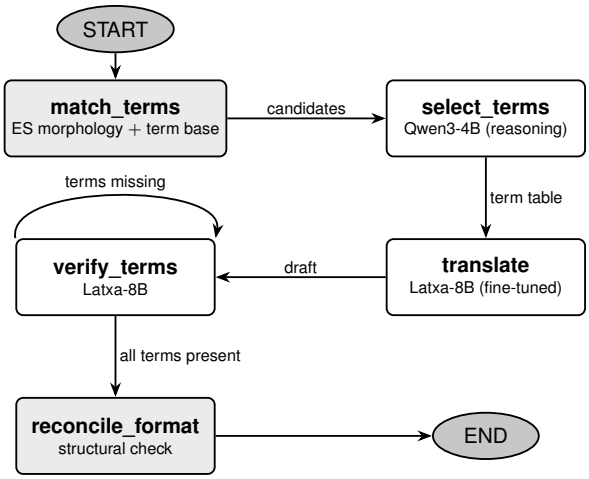

Figure 1: The AGENTEAK graph. Shaded nodes are deterministic, white nodes are LLM agents. Documents are processed chunk by chunk; the state carried between nodes comprises the source chunk, the document's domain tag, the selected term table, the current draft and the verifier's flags.

The prompt states the task explicitly and includes few-shot examples covering each of these cases. The agent returns a per-chunk table of source terms and selected target terms, which is carried forward. We use a small reasoning model here rather than the larger translator because the task is classification and selection, not generation, and because keeping this component separate means the term table can be inspected and, in principle, overridden by a human.

**Step 3: Translation agent.** The fine-tuned model from §4 receives the source chunk together with the selected term pairs. The prompt makes both the domain and the required terminology explicit. Crucially, the terminology is presented in citation form and the instruction states that the terms must be inflected as the Basque sentence requires; we do not ask the model to copy them verbatim. This is the soft counterpart of the lemma-annotation strategy of Bergmanis and Pinnis (2021) and is what makes the approach viable for an agglutinative target.

**Step 4: Verification agent.** The draft translation and the term table are passed to a verification agent, in the current pipeline Latxa-Llama-3.1-8B-Instruct, which checks, for each required term, whether an admissible inflected form is present,

| System | Automotive | | | | Energy | | | |
|---|---|---|---|---|---|---|---|---|
| | BLEU↑ | chrF2↑ | TER↓ | COMET↑ | BLEU↑ | chrF2↑ | TER↓ | COMET↑ |
| Latxa-8B-Instruct (no fine-tuning) | 20.36 | 56.82 | 82.05 | 80.73 | 17.62 | 58.46 | 87.12 | 82.96 |
| + FT (mined + OOD) | 25.76 | 62.27 | 69.44 | 84.21 | 27.33 | 63.64 | 67.38 | 86.21 |
| + FT (mined + OOD + synthetic) | **27.39** | **62.65** | **67.36** | **84.58** | **28.01** | **64.50** | **65.79** | **86.48** |

Table 2: Translation agent performance on the in-domain development sets. OOD denotes the out-of-domain EusParallel component. Best scores in **bold**.

and repairs the translation where it is not. The prompt includes few-shot examples of correct and incorrect realisations, with particular attention to the failure mode in which a repair strips a case ending and leaves the term grammatically stranded. Only flagged segments are rewritten, which limits the collateral edits that undirected self-refinement tends to introduce (Feng et al., 2025).

**Step 5: Formatting reconciliation (deterministic).** The edited translation is checked against the source for structural correspondence, including segment count, paragraph boundaries, and pass-through of symbolic or numeric-only chunks, before the final output document is assembled.

## 6 Results

### 6.1 Conditions and metrics

We evaluate under three terminology conditions: **noterm**, where the pipeline receives no terminology and the term-matching and verification stages are inactive; **proper**, where the pipeline receives the correct term base entries; and **random**, where the target side of each entry is replaced by a randomly chosen alternative. The **random** condition is a control since a system that simply ignores its terminology input would score identically across conditions, whereas a system that blindly copies would follow arbitrary terms as readily as correct ones.

We measure overall quality with the reference-free metric CometKiwi (Rei et al., 2022), and terminology usage with terminology success rate (TSR). The term base entries matched on the source side of a segment define its required target terms, and TSR is the proportion of those realised in the hypothesis, micro-averaged over all (segment, term) pairs. Since required terms almost never surface in citation form (§1), exact string matching is unusable. We instead match stems with a left word-boundary anchor and unconstrained suffixation, adapting the scorer released with the WMT25 task (Semenov et al., 2025). Appendix B gives the procedure in full.

| Terminology given | Automotive | Energy |
|---|---|---|
| None | 0.7598 | 0.8097 |
| Random | 0.7618 | 0.8125 |
| Proper | **0.7662** | **0.8138** |

Table 3: Reference-free translation quality (CometKiwi) of the full pipeline under the three terminology conditions.

### 6.2 Overall translation quality

Table 3 reports CometKiwi. Quality is ordered **proper** $>$ **random** $>$ **noterm** in both domains, but the spread is small: $0.0064$ for automotive and $0.0041$ for energy. Adding a constraint-and-repair loop on top of a fine-tuned translator does not degrade general translation quality, which is the usual price of hard constrained decoding, and even the **random** terminology does not push quality below the unconstrained baseline as the verification agent integrates the imposed term into a well-formed sentence rather than pasting it in. The absolute gap between domains ($\approx 0.05$ CometKiwi) is much larger than any effect of terminology, and mirrors the development-set gap in §4.

### 6.3 Terminology success rate

Table 4 crosses the terminology supplied to the pipeline with the term set against which success is measured. Three observations stand out.

First, the pipeline uses the terminology it is given. Supplying proper terms raises proper-term success from $0.6128$ to $0.7570$ in the automotive domain ($+14.4$ points, $+23.5\%$ relative) and from $0.6013$ to $0.7736$ in energy ($+17.2$ points, $+28.7\%$ relative). The same holds in the control: supplying random terms raises random-term success from $0.6314$ to $0.6896$ and from $0.6721$ to $0.7434$.

Secondly, the interference between conditions is asymmetric and mild. Feeding random terms costs little proper-term accuracy ($-1.2$ points automo-

| Domain | Terms given | Evaluated against | |
|---|---|---|---|
| | | Proper | Random |
| Automotive | None | 0.6128 | 0.6314 |
| | Random | 0.6013 | **0.6896** |
| | Proper | **0.7570** | 0.6315 |
| Energy | None | 0.6013 | 0.6721 |
| | Random | 0.6025 | **0.7434** |
| | Proper | **0.7736** | 0.6902 |

Table 4: Terminology success rate. Rows indicate the terminology supplied to the pipeline; columns indicate the term set against which success is measured. Diagonal cells (in bold) are the compliance figures of interest.

tive, $+0.1$ energy, i.e. within noise), meaning the system largely falls back on its own preferences. Conversely, feeding proper terms leaves random-term success at or slightly above baseline ($0.6315$ and $0.6902$), which we attribute to stem overlap between the true and substituted entries in a fair number of cases; this also indicates that the absolute success-rate values carry some measurement noise from stem-level matching.

Finally, the **noterm** baselines are already high ($0.60$–$0.67$). The fine-tuned translator produces a majority of the required terms unprompted, a direct return on the in-domain mined and synthetic data of §3: terminology injection is refining an already domain-adapted model rather than compensating for a generic one.

## 7 Official Shared Task Results

Table 5 reports the official Track 1 scores released by the task organisers (Charkiewicz et al., 2026). AGENTEAK was entered for Spanish–Basque only, and all figures below are for that direction, pooled over the automotive and energy domains. We show our own row alongside the reference translations and three contrasting submissions; the full ranking over all systems and both language directions is available from the leaderboard.

Among the nineteen systems submitted for Spanish–Basque in Track 1, AGENTEAK places 13th on term success under both the surface and the lemmatised variant, and between 10th and 11th on the quality metrics (chrF++, COMET-22, CometKiwi-22, XCOMET-XXL and both MetricX-24 variants). Terminology compliance is thus the weaker side of our submission relative to the field, which is consistent with the ceiling we anticipated in §2 for soft, prompt-level constraint injection with a single bounded verification pass: the systems above us on term success cluster tightly at $89$–$90\%$ surface success, a band that a fixed one-shot repair stage does not reach.

Two further observations follow from the official figures. First, the organisers' term success is computed with their own source-side matcher and their own lemmatiser, and is therefore *not* comparable with the stem-level TSR of §6; the official figure is the higher of the two, which suggests our deterministic matcher (Step 1) marks more source occurrences as requiring a target term than the official scorer does, so our own numbers are measured against a stricter denominator. Second, the gap between surface and lemmatised term success is $10.3$ points for AGENTEAK, against a median of approximately $7.5$ points across the nineteen es–eu submissions. This is direct external evidence for the argument of §8: our failures are disproportionately failures of *form* rather than of lexical selection, with the prescribed term present but realised in a way that surface matching rejects.

## 8 Discussion

**Morphology is the residual error source.** The gap between what the terminology agent selects and what appears in the final output is largely morphological rather than lexical. In our development work the dominant failure mode was not a missing term but a term realised in citation form where the syntax required an inflected one, or conversely a repair that stripped a case ending. It also suggests that terminology success rate, computed over stems, systematically overstates usable accuracy for Basque considering that a term counted as present may still be ungrammatical in context. A task-appropriate metric for agglutinative targets would need to check morphosyntactic well-formedness, not only presence.

**Why separate the agents.** Ablating the pipeline into a single prompted model would be simpler, but the separation buys two things. The term table produced at Step 2 is an inspectable intermediate artefact, which matters in professional settings where terminology decisions are auditable. And the division of labour lets each component be sized to its task: a 4B reasoning model suffices for selection, while the 8B fine-tuned model is reserved for generation. The entire system uses no model above 8B parameters and requires no proprietary API.

| | chrF++ | | Term success | | COMET | | MetricX-24 XL | |
|---|---|---|---|---|---|---|---|---|
| System | doc↑ | para↑ | surface↑ | lemma↑ | COMET-22↑ | Kiwi-22↑ | ref↓ | QE↓ |
| *gold* (references) | 100.0 | 100.0 | 98.7 | 99.1 | 96.5 | 75.4 | 1.82 | 3.47 |
| COZY (best overall) | 75.3 | 70.1 | 89.5 | 96.4 | 88.8 | 75.0 | 3.24 | 3.77 |
| Agentic-OPUS | 73.5 | 67.5 | 89.9 | 96.0 | 87.6 | 75.1 | 3.53 | 3.84 |
| SalamandraTA | 73.3 | 67.5 | 86.0 | 95.2 | 87.0 | 74.6 | 3.66 | 4.01 |
| MASC-Dec | 72.7 | 67.1 | 82.1 | 86.8 | 84.5 | 72.2 | 4.61 | 4.71 |
| AGENTEAK (ours) | 68.8 | 61.3 | 78.4 | 88.7 | 84.6 | 72.5 | 4.71 | 4.67 |

Table 5: Official WMT26 Track 1 results for Spanish–Basque (Charkiewicz et al., 2026), pooled over both domains. XCOMET-XXL is omitted for space (75.7 for AGENTEAK, 83.2 for the best system). *gold* is the reference translation, not a participant, and bounds each metric. Comparison systems are shown for calibration only and are not an exhaustive ranking: nineteen systems were submitted for this direction.

## 9 Conclusion

We described AGENTEAK, the OpenU's submission to the WMT26 Terminology Translation Task for Spanish into Basque. The system combines targeted in-domain data creation (Wikipedia bitext mining and prompted synthetic generation) with a three-agent pipeline that separates terminology selection, translation and verification across compact open-weight models. Domain-tagged fine-tuning improves the backbone by up to 10.4 BLEU, and terminology injection raises terminology success rate by 14–17 points at negligible cost to reference-free quality. Our analysis with randomised terminology shows that the system follows correct constraints considerably more readily than arbitrary ones, characterising both the robustness and the limits of soft, prompt-level terminology control for a morphologically rich low-resource target language. In the official evaluation (Charkiewicz et al., 2026), AGENTEAK placed mid-field among the nineteen Spanish–Basque submissions to Track 1 (§7), with the surface/lemma term-success gap confirming that its residual terminology errors are predominantly morphological.

## Limitations

We report no human evaluation, and CometKiwi has not been validated specifically for Basque, so absolute values should be treated with caution, further evidenced by Falcão et al. (2024) who find that COMET-family metrics transfer unevenly to Spanish–Basque. Terminology success rate is computed by stem-level matching, which both over-counts (crediting morphologically ill-formed realisations) and potentially under-counts (missing legitimate allomorphy).

It is also worth noting that while the translator agent was fine-tuned on in-domain data and translation instruction, the verification agent was not, and the pipeline relies on its instruct-based nature and on the few-shot examples provided at inference to define the task and output required. A natural follow-up would be to fine tune a verification agent specifically on the task of verifying and editing Basque terminology alongside proper declension, and to evaluate this agent.

## A Fine-Tuning Setup

**Prompt.** The system prompt (Figure 2) is written in Spanish and carries the domain as an explicit `Ámbito:` line. It is wrapped in the Llama-3.1 chat template that Latxa inherits (Figure 3). Prompt tokens are masked and the loss is computed on the Basque completion only. The same system prompt, with the same `Ámbito:` value, is used at inference inside the pipeline.

**Model and adapter.**

- bf16, no quantisation; SDPA attention; gradient checkpointing.
- LoRA $r = 16$, $\alpha = 32$, dropout $0.1$, bias none.
- Targets: `q`, `k`, `v`, `o`, `gate`, `up`, `down`.
- 41.9M trainable parameters

**Optimisation.**

- Max length 1024, packing disabled, seed 42.
- LR $1e{-4}$, cosine schedule, warmup ratio $0.03$, weight decay $0.01$.
- Batch 4 per device $\times$ 4 accumulation steps (effective 16).
- Evaluate and checkpoint every 100 steps; best combined dev loss restored;

## B Computing Terminology Success Rate

Figure 4 summarises the procedure. Required terms are determined by matching the term base against the *source* segment with the same deterministic matcher used at Step 1 of the pipeline (§5), so the scorer and the system see identical source-side matches; repeated occurrences of an entry within a segment count once. Each required target term is lowercased and reduced to the invariant prefix its inflected forms share, and counts as realised if that stem occurs in the hypothesis preceded by a word boundary and followed by anything. TSR is the ratio of realised to required terms, pooled across the test set and reported per domain and per condition.

Our scorer adapts the one released with the WMT25 task (Semenov et al., 2025); the stem reduction and boundary anchoring are our additions, so our figures are *not* directly comparable with those of the unmodified official scorer. Two biases follow from the design. The measure overcounts, because a stem match certifies presence but not grammaticality since a term left morphologically stranded still scores as a success (§8). It is also noisy, because proper and random entries sometimes share a stem, which inflates success rates measured against the term set that was not supplied.

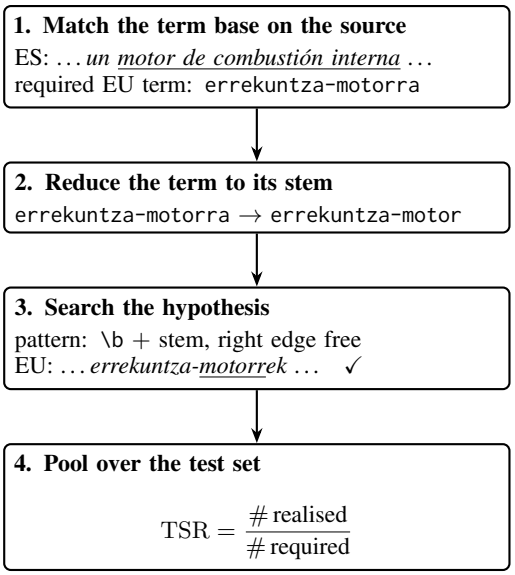

Figure 4: Terminology success rate, computed for one required term. The left word boundary stops a stem being credited inside an unrelated word.

## Abstract

We describe HW-TSC's submissions to both tracks and all language pairs of the WMT26 Terminology Translation Shared Task. Our primary system uses Qwen3.7-Max for source-term extraction, bilingual term alignment, and document translation. In Track 1, it matches the current document or translation chunk against the supplied dictionary and places at most 200 applicable term pairs in the translation prompt. In Track 2, it first induces a bilingual glossary from the seed bitexts and then reuses the Track 1 translation module. Induction combines open source-term extraction with seed-source expression matching, followed by LLM alignment to the seed targets. We optimize the extraction prompt with SkillOpt (Yang et al., 2026) on a train/validation/test split of the WMT25 English–Chinese finance data and use Qwen3.7-Max to rewrite it for directions without labeled optimization data. Extraction recall rises from 0.6250 to 0.6344 on validation and from 0.6451 to 0.6674 on the held-out test split. On the same held-out test documents with Qwen3.7-Max, glossary induction raises TSR from 0.5212 (no glossary) to 0.7910 with the initial prompt and to 0.8026 after SkillOpt, with chrF++ of 57.45, 67.05, and 67.36; the official glossary yields TSR 0.9019 and chrF++ 63.94.

## 1 Introduction

Specialized translation requires more than selecting the right target lemma. A system must reuse terminology consistently across a document while realizing prescribed terms grammatically in context, a particular concern for lower-resource, morphologically rich target languages. Earlier WMT terminology tasks established evaluations that combine general translation quality with term-centered criteria (Alam et al., 2021; Semenov et al., 2023, 2025). Methods have included terminology-aware training, source annotations, constrained decoding, and, more recently, glossary-conditioned LLM generation and quality–terminology reranking (Dinu et al., 2019; Ailem et al., 2021; Bergmanis and Pinnis, 2021; Guttmann et al., 2025; Zhu et al., 2025).

WMT26 changes the operational setting in two important ways (Organizers, 2026). Both tracks are document-level. Track 1 supplies corpus-level dictionaries and requires no-, proper-, and random-terminology modes. Track 2 supplies seed bitexts rather than a dictionary, so the system must recover or otherwise exploit their terminology before translating related documents. The directions are Spanish→Basque and English→Polish in both tracks, plus Traditional Chinese→English finance in Track 2. Evaluation jointly considers overall quality, terminology success rate (TSR), document-level consistency, and grammaticality of term realizations; the organizers frame comparison in terms of the quality–terminology Pareto frontier.

Our submission is an LLM pipeline for this setting. It contributes (i) one translation module that locally matches an optional glossary and admits at most 200 pairs per document or chunk, and (ii) a Track 2 induction stage that combines two source-term discovery channels with seed-grounded target alignment. For Channel A extraction, we use SkillOpt (Yang et al., 2026), a text-space skill optimizer that treats a natural-language skill/prompt document as the trainable external state of a frozen language model, proposes bounded edits from scored rollouts, and accepts an edit only when it improves a held-out validation score. We apply SkillOpt to the WMT25 English–Chinese finance setting and transfer the resulting prompt to the remaining WMT26 directions with Qwen3.7-Max.

## 2 Task Coverage

HW-TSC submitted to both tracks and all available directions (Table 1). Track 1 provides source documents and domain-level proper and random dictionaries; the same source documents are also translated without terminology. Track 2 provides

| Track | Direction | Domain | Term resource |
|---|---|---|---|
| 1 | Es→Eu | Eng./Tech. | Supplied |
| 1 | En→Pl | Eng./Tech.; Med. | Supplied |
| 2 | Es→Eu | Eng./Tech. | Induced |
| 2 | En→Pl | Eng./Tech.; Med. | Induced |
| 2 | Zh-Hant→En | Finance | Induced |

Table 1: Submission coverage. Track 1 uses the supplied proper or random dictionary, or omits it in the no-term mode. Track 2 derives a glossary from seed bitexts.

terminology-rich parallel seeds and related source documents, with no explicit dictionary (Organizers, 2026).

## 3 System Description

Figure 1 separates Track 2 glossary induction from the translator shared by both tracks. Qwen3.7-Max (Yang et al., 2025) is the primary backbone for extraction, alignment, prompt transfer, and translation. Qwen3.7-Max is also used to rewrite the optimized extraction prompt for new language/domain settings.

### 3.1 Shared Translation Module

**Local glossary matching.** The supplied Track 1 dictionaries and Track 2 induced glossaries are corpus-level resources and can contain entries irrelevant to a particular input. Before translation, we match source entries against the current source span and retain only applicable pairs. We cap the matched glossary at 200 pairs per document or chunk to control prompt length and reduce interference from irrelevant terminology. If more than 200 entries match, the implementation truncates the matched set to 200 using its selection heuristic. A short document receives at most 200 matched pairs, while a long document is first divided into chunks and each chunk is matched independently to obtain its own set of at most 200 pairs. Because matching is local to the current span, the effective terminology budget scales with the number of chunks rather than requiring a single unbounded glossary for an entire long document.

**Prompted translation.** The prompt specifies the source and target languages, domain, source span, and matched `source => target` pairs. It asks the model to use applicable target renderings consistently while adapting morphology and agreement to the target context. Proper and random Track 1 modes use the same matching procedure and prompt template; only dictionary content changes. Local matching is applied uniformly to both proper and random terminology settings to filter out entries that do not occur in the current source span. The no-term mode removes both the glossary block and glossary-specific instruction. Long-document chunking is invoked only when required by the input length.

The translation prompt template is as follows:

```
You are a professional translator.
Translate the following SOURCE document
from {SRC} to {TGT} in the {DOMAIN}
domain.

Requirements:
- Use the GLOSSARY entries consistently
throughout the translation.
- Adapt morphology and agreement as
required by {TGT} grammar.
- Preserve document structure,
formatting, numbers, and codes.
- Output only the translation.

GLOSSARY (source => target):
{term1 => translation1
term2 => translation2
...
}

SOURCE:
{document_or_chunk}
```

### 3.2 Track 2 Glossary Induction

Track 2 turns the supplied seed bitexts into a bilingual glossary before calling the shared translator. The pipeline first discovers source candidates through two channels, merges and filters them, and then asks Qwen3.7-Max to align retained candidates to target expressions evidenced in the seed translations.

#### 3.2.1 Channel A: open source-term extraction

Channel A asks Qwen3.7-Max to extract source-language domain terms from the document to translate, without proposing translations. We optimize this extraction instruction offline with SkillOpt (Yang et al., 2026). As introduced above, SkillOpt keeps the target model frozen and updates only the skill document under validation gating. We optimize the Channel A extraction prompt on the WMT25 English–Chinese finance split using source-term recall as the validation objective, while keeping the remaining pipeline unchanged. The resulting skill replaces the hand-written extraction prompt used at inference for that setting. The optimization data are the WMT25 Track 2 English–Chinese finance data (Semenov et al., 2025), partitioned into train, validation, and held-out test subsets. Training and validation information is used

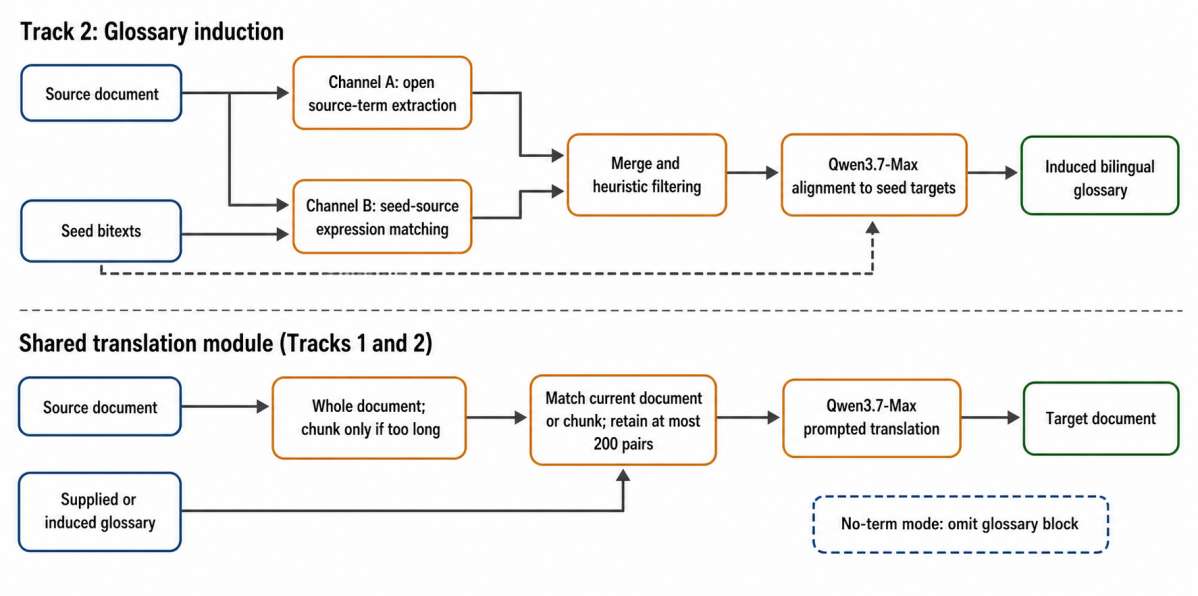

Figure 1: HW-TSC pipeline. Track 2 first induces a seed-grounded bilingual glossary. The shared translator matches only entries relevant to the current document or chunk and places at most 200 pairs in the prompt.

during prompt optimization and selection; the held-out test subset is reserved for the reported final comparison.

The optimized prompt is used for the English/Chinese finance setting. For the remaining WMT26 directions, Qwen3.7-Max adapts the optimized prompt using the target language pair, domain, and seed examples, without additional labeled optimization.

The initial prompt broadly prioritizes finance-related terms, proper names, complete multiword expressions, translation-sensitive core terms, and both abbreviations and their long forms. SkillOpt retains this task definition but makes the search procedure and span policy substantially more explicit (Table 2). In particular, it instructs the model to exhaust four candidate classes in sequence and to retain independently useful nested terms in addition to complete expressions. These edits mainly change which source spans enter the candidate pool: denser coverage of abbreviations, short core terms, and nested constituents tends to yield a slightly larger, more complete pseudo-glossary after alignment. Section 4 measures that effect as extraction recall and as downstream TSR/chrF++ under an otherwise fixed translator.

| Aspect | Initial prompt | SkillOpt prompt |
|---|---|---|
| Search order | Broad priorities listed in parallel | Four mandatory passes: abbreviations; 1–2 word core terms; complete expressions/entities; other terms |
| Coverage | Important core terms and long/short forms | Exhaustive emphasis on abbreviations and short domain-core terms |
| Span policy | Prefer complete multiword entries; avoid redundant variants | Also emit independent nested terms and coordinated components |
| Surface form | No dedicated rule | Preserve quoted, punctuated, versioned, or year-qualified names; retain useful core forms separately |
| Capacity policy | General relevance criteria | If limited, favor abbreviations and short core terms over descriptive phrases; never fill with generic words |

Table 2: Qualitative changes introduced by SkillOpt between the initial and optimized prompts.

#### 3.2.2 Channel B: seed-source expression matching

Channel B compares the source document with the source side of the seed bitexts. It extracts expressions that are identical or differ only slightly in form, thereby recovering candidates directly connected to bilingual evidence. This channel complements open extraction: Channel A can propose domain terms from the document, whereas Channel B emphasizes expressions attested in the seeds. The exact and near-match decisions are made by Qwen3.7-Max, which identifies exact and near-

| Stage | Model | Output |
|---|---|---|
| Prompt transfer | Qwen3.7-Max | Rewritten extraction prompt |
| Open extraction | Qwen3.7-Max | Source-term candidates |
| Seed matching | Qwen3.7-Max | Shared/near expressions |
| Alignment | Qwen3.7-Max | Bilingual term pairs |
| Translation | Qwen3.7-Max | Target span |

Table 3: Model roles in the primary submission pipeline.

matching expressions against the seed sources.

#### 3.2.3 Merge, filtering, and bilingual alignment

We merge both candidate lists and apply heuristic filtering to remove duplicates and candidates that are not usable as terms. Qwen3.7-Max then inspects the relevant seed bitexts and identifies the seed-attested target realization for each retained source candidate. Candidates for which a target cannot be grounded in the seed translations are discarded. The surviving source–target pairs form the pseudo-glossary supplied to the shared module in Section 3.1, where they are matched again against the current document or chunk and capped at 200.

**Evidence boundaries.** Both discovery channels generate source-side candidates. Channel A receives the document to translate and emits source candidates; Channel B compares that document with seed sources and emits shared or lightly varying source expressions. Target-side seed translations are introduced only during bilingual alignment, where each candidate is mapped to a seed-attested target expression; candidates without sufficient bilingual evidence are discarded.

## 4 Implementation and Evaluation

### 4.1 Implementation Summary

The primary submission uses Qwen3.7-Max for prompt transfer, Channel A extraction, Channel B matching and bilingual alignment, and final translation. Term discovery operates over the document, while chunking is a translation-time length safeguard. For every translation call, matching is rerun on the actual source span and limits the terminology block to at most 200 pairs.

Table 3 summarizes model responsibilities.

### 4.2 SkillOpt Extraction Recall

Table 4 reports source-term extraction recall before and after SkillOpt on our WMT25 English–Chinese finance split. Recall increases by 0.0094 on the validation subset and by 0.0223 on the held-out test subset. The additional candidates that survive filtering and seed-grounded alignment become extra glossary constraints for the shared translator in Section 3.1.

| Split | Initial prompt | SkillOpt prompt |
|---|---|---|
| Validation | 0.6250 | 0.6344 |
| Held-out test | 0.6451 | 0.6674 |

Table 4: Source-term extraction recall on our split of the WMT25 Track 2 English–Chinese finance data. Validation participates in prompt selection; the test subset is held out.

### 4.3 Downstream TSR and chrF++

We further evaluate Qwen3.7-Max translation on the same held-out WMT25 English–Chinese finance test documents, reporting terminology success rate (TSR) and chrF++. Table 5 compares four terminology conditions under the shared translation module: no glossary; a glossary induced by the initial Channel A prompt followed by seed-grounded alignment; a glossary induced after SkillOpt optimization of Channel A; and the official shared-task glossary.

Relative to the no-glossary baseline, the initial induced glossary raises TSR from 0.5212 to 0.7910 and chrF++ from 57.45 to 67.05. SkillOpt yields a further gain to TSR 0.8026 and chrF++ 67.36, consistent with the higher extraction recall in Table 4: a modestly richer seed-grounded glossary improves both term realization and surface overlap with the reference. The official glossary attains the highest TSR (0.9019) but a lower chrF++ (63.94) than either induced glossary. One possible explanation is that denser exact-term constraints can displace otherwise fluent phrasings or encourage locally awkward insertions, which would lower character $n$-gram overlap even when term hits improve. By contrast, induced glossaries are sparser and filtered by seed evidence; they recover much of the terminology benefit while leaving the translator more freedom on non-term spans, yielding higher chrF++ at a lower TSR. These results highlight a trade-off between strict terminology realization and overall surface similarity. These results are development measurements on our WMT25 English–Chinese split rather than official WMT26 scores across all submitted directions.

| Terminology condition | TSR | chrF++ |
|---|---|---|
| No glossary | 0.5212 | 57.45 |
| Induced (initial prompt) | 0.7910 | 67.05 |
| Induced (SkillOpt prompt) | 0.8026 | 67.36 |
| Official glossary | 0.9019 | 63.94 |

Table 5: Qwen3.7-Max TSR and chrF++ on our held-out WMT25 Track 2 English–Chinese finance test split under different terminology conditions.

## 5 Design Considerations

The unified interface reduces Track 2 to obtaining a glossary that the Track 1 translator can consume. This simplifies implementation and makes the cap and matching behavior identical across tracks, but it also creates an error path from source-term discovery through alignment to translation. Seed-grounded alignment is intended to limit unsupported target constraints; Table 5 shows that induced glossaries already improve TSR and chrF++ over a no-glossary baseline on our WMT25 development split.

The 200-pair cap keeps each translation call within a manageable prompt budget while preserving local relevance. With per-chunk rematching, long documents are not forced to compress an entire corpus dictionary into one call; each span only competes for its own 200-pair allotment. For Basque and Polish, a further consideration arises between preserving the prescribed target lemma and producing a grammatically licensed surface form. The prompt therefore requests morphological adaptation rather than literal string copying, consistent with prior work on lemma-level terminology control (Bergmanis and Pinnis, 2021) and with the shared task's grammaticality criterion (Organizers, 2026).

**Retrieval and truncation.** Local matching reduces exposure to irrelevant dictionary entries. When the 200-pair cap is active, the matched set is truncated by an implementation heuristic. In the random terminology setting, local matching prevents unmatched dictionary entries from entering the translation prompt, thereby reducing potential interference.

**Induction.** Channel A can propose domain expressions that are not recoverable from the seeds, while Channel B can capture surface variations. The seed-grounded aligner requires evidence in the seed translations and can discard unsupported candidates. On our WMT25 English–Chinese finance split, SkillOpt acts upstream of this aligner by changing the source-candidate distribution; the downstream TSR/chrF++ gains in Table 5 are therefore an indirect effect of better Channel A coverage under a fixed translator.

**Document segmentation.** Matching every chunk against the same glossary makes prescribed pairs available wherever their source form is detected. Chunks are translated in separate model calls, so discourse choices and term realizations may vary across boundaries.

## 6 Conclusion

HW-TSC participated in both WMT26 terminology tracks and all language pairs with a Qwen3.7-Max-centered document translation system. Track 1 locally matches the supplied dictionary; Track 2 combines open extraction and seed-source matching, aligns candidates to seed targets, and feeds the induced glossary to the same translator. Every translation call receives at most 200 locally matched term pairs, with chunking only for overlong documents. On our WMT25 English–Chinese finance split, SkillOpt improves held-out source-term extraction recall from 0.6451 to 0.6674 and, after glossary induction and translation, raises TSR/chrF++ from 0.7910/67.05 (initial prompt) to 0.8026/67.36, compared with 0.5212/57.45 without a glossary.

## Limitations

Quantitative analysis in this paper focuses on a partition of the WMT25 English–Chinese finance data; we do not report corresponding TSR/chrF++ breakdowns for the Basque, Polish, or Traditional Chinese WMT26 directions, nor official shared-task leaderboard scores. Validation data participates in SkillOpt prompt selection. Prompt rewrites used to transfer the SkillOpt skill across languages are not evaluated on labeled extraction sets. We likewise do not provide a measured comparison of Track 1 proper versus random dictionaries; the discussion of random-mode noise is qualitative and relies on local matching as a filter. API model versions and decoding settings may affect reproducibility. The full production prompts are not reproduced; Table 2 records their principal methodological differences.

## Acknowledgments

We thank the WMT26 terminology organizers for the task design and data, and colleagues at HW-TSC for discussion and engineering support.

## Abstract

Terminology-aware translation asks for more than a correct translation: the output must use the exact terms a glossary prescribes. The standard recipe, fine-tuning on glossary-annotated translation pairs, hides an inefficiency: for most examples the glossary prescribes exactly what the model would have produced anyway, so they teach nothing about following a glossary. We therefore keep only the examples where the model's own translation contradicts the glossary. In a controlled study at fixed data volume, this selection alone raises term accuracy from 78.7% to 89.9%. The filtered data, built by a two-way synthetic pipeline on open models, is part of the instruction-tuning mixture of our public release SALAMANDRATA-7B-INSTRUCT v3.0, which, used exactly as released and wrapped in a document-level inference pipeline, forms the BSC submission to the WMT26 Terminology Shared Task Track 1. At the official WMT26 evaluation, our system achieves 94.2% term success at 74.6 chrF++, with only two of the twenty-two submissions outperforming it on both metrics. On last year's benchmark, it also surpasses our GRPO-based system, despite being trained solely with ordinary supervised fine-tuning.

## 1 Introduction

A translation can preserve the meaning perfectly and still fail its audience. A Spanish-speaking developer who opens a *pull request* will call it exactly that, yet a generic machine translation (MT) system may render the phrase as *solicitud de extracción*. Both are understandable, but only the English term matches what developers read every day in their interfaces and documentation. Terminology-aware translation addresses this gap: beyond producing a correct translation, it must produce the prescribed one, whether the prescription comes from a client's glossary or from the usage of a community.

A common way to teach this behaviour is to fine-tune the model on glossary-annotated translation pairs. Much of this supervision, however, is redundant: for a large share of training examples the glossary prescribes exactly what the model would have produced anyway, so the example can be answered correctly without consulting the glossary at all. The useful signal is concentrated in the cases where the prescribed term differs from the model's default choice. This observation suggests a simple data selection rule: keep for training only those where at least one term is hard for the model and comes out wrong (Figure 1). Our controlled experiment confirms that the rule matters. Holding the training budget and every other ingredient fixed, we vary only the proportion of these hard examples in the terminology data, and term accuracy climbs from 78.7% with none of them to 89.9% with all of them (Figure 2).

Figure 1: Data selection: train only on what SALAMANDRATA-7B-INSTRUCT gets wrong.

This paper describes the Barcelona Supercomputing Center (BSC) submission to the WMT26 Terminology Translation Shared Task Track 1,

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1807–1818
October 28-29, 2026 ©2026 Association for Computational Linguistics

document-level translation with an explicit dictionary. Our system is our latest public release, SALAMANDRATA-7B-INSTRUCT v3.0,[1] used exactly as released: its instruction-tuning mixture already includes terminology data built with this recipe, generated by a two-way synthetic pipeline on Gemma-4-31B (Team, 2026) and filtered against our previous release. At inference time, documents are translated chunk by chunk with per-chunk glossaries and lightly post-edited under a guard that protects prescribed terms. At the official WMT26 evaluation, our system achieves 94.2% term success at 74.6 chrF++, with only two of the twenty-two submissions outperforming it on both metrics. On last year's benchmark, it also surpasses our GRPO-based system, despite being trained solely with ordinary supervised fine-tuning.

In summary, we make three contributions. First, we show that a lot of glossary-annotated training data is redundant, and that a simple remedy, keeping only the examples where the glossary contradicts the model's default translation, yields an eleven-point term-accuracy gain at fixed data volume. Second, we describe a two-way synthetic pipeline built on open models, which turns glossaries into documents and documents into glossaries, and whose output trains the terminology component of the public release SALAMANDRATA-7B-INSTRUCT v3.0. Third, we present the BSC Track 1 submission: the released model, unmodified, wrapped in a document-level inference pipeline with per-chunk glossaries and a post-editing guard that protects prescribed terms.

## 2 Related work

**Making models follow glossaries.** The terminology constraint was earlier imposed at decoding time, through lexically constrained beam search (Hokamp and Liu, 2017), at a cost in speed and fluency. Dinu et al. (2019) moved it into training, annotating source terms with their prescribed translations so the model learns to copy them in context. The WMT terminology shared tasks (Alam et al., 2021; Semenov et al., 2023, 2025) record the field's shift to LLMs. Our own previous submission moved the constraint into the reward, optimising models with GRPO under a joint adherence and quality objective (Garcia Gilabert et al., 2025). This year the recipe is simpler: ordinary supervised fine-tuning, targeting longer document inputs. What is new is not how we train but what we train on: only the examples whose terminology the model gets wrong.

**Synthetic terminology data.** LLM-generated parallel text now rivals web-crawled corpora in quality (Finkelstein et al., 2024), and strong WMT25 terminology systems already relied on curated synthetic data and LLM post-editing (Jaswal, 2025; Semenov et al., 2025). Our pipeline differs in shape and in openness: it runs in both directions, expanding glossaries into documents and mining documents for glossaries, and is built entirely on openly licensed models and data.

**Choosing what to train on.** That some examples teach more than others is a recurring observation. In MT, selection began as domain adaptation (Axelrod et al., 2011), later made dynamic during training (van der Wees et al., 2017); curriculum learning orders examples by difficulty instead of filtering them (Bengio et al., 2009; Kocmi and Bojar, 2017; Platanios et al., 2019). The instruction-tuning era sharpened the point that a small, well-chosen set can beat a large undifferentiated one (Zhou et al., 2023; Chen et al., 2024; Liu et al., 2024), and, closest to us, Kocmi et al. (2025) filter MT data by difficulty before preference tuning. Concentrating supervision where the current model falls short is also the animating idea of active learning (Settles, 2009), long used in MT to decide what to annotate (Haffari et al., 2009; Zhao et al., 2020). In our case, we select from an already-labelled pool, so no annotator is queried; and where prior selection relies on a continuous score, however obtained, our notion of hardness is self-referential and binary: an example is hard exactly when the model's own unconstrained output contradicts the prescribed term. The filter itself has no scores to threshold, and §4 measures its individual contribution.

## 3 Data: two synthetic pipelines

The terminology component of SALAMANDRATA v3's instruction-tuning mixture is built by two synthetic pipelines that run in opposite directions. One starts from terminology and generates text: bilingual medical glossaries (MeSpEn; Villegas et al., 2018) seed Gemma-4-31B[2] (Team, 2026), which writes parallel texts around them. The other starts from text and extracts terminology: Gemma-4-31B

[1] https://huggingface.co/BSC-LT/salamandraTA-7b-instruct

[2] https://huggingface.co/google/gemma-4-31B

extracted aligned term pairs from the EMEA parallel corpus[3] (Tiedemann, 2012), whose sentences we then assemble into documents. Both pipelines share one selection step, described in §3.3, that keeps only what our own model gets wrong. Together they yield 33,615 instances covering 94 directed pairs across 29 languages (12,479 from MeSpEn, 21,136 from EMEA); Appendix A documents cleaning rules, generation prompts, and filtering thresholds (Figure 3 gives an overview).

### 3.1 MeSpEn: terminology → text

After cleaning the raw glossaries, we keep only the hard terms, those our model mistranslates in isolation (§3.3), and use them as seeds. Gemma-4-31B writes a parallel text around small groups of seeds, grouped by semantic similarity so that co-occurring terms are plausible together, at lengths ranging from a single sentence to multi-paragraph documents. In document-length samples the main term must appear at least twice and be translated identically each time, mirroring the consistency requirement of the shared task. A sample survives only if every annotated term actually appears on both sides, and term and sentence pairs exceed LaBSE (Feng et al., 2022) similarity thresholds.

### 3.2 EMEA: text → terminology → documents

Gemma-4-31B extracts aligned term pairs from each EMEA sentence pair, and sentences on which our model already produces every gold term are discarded (§3.3). After quality filtering, deduplication, and LaBSE filtering, consecutive sentences are concatenated into a mixture of granularities: single sentences, paragraphs, and multi-paragraph documents with literal newline breaks, each document's glossary being the union of its sentences' term pairs. Finally, glossary entries are reduced to lemma form while the text is left untouched, so the model must learn to inflect prescribed terms in context rather than copy surface strings.

### 3.3 The hard-example filter

Both pipelines rely on the same selection step, and it is the step this paper is about. Every candidate, a glossary term in MeSpEn or a sentence in EMEA, is translated by SALAMANDRATA-7B-INSTRUCT v2.0 *without* any terminology in the prompt, and the output is checked against the gold terms with a lenient matcher that forgives casing, punctuation, and spacing differences. If every required term already appears, the model needs no help on this example and it is discarded; only candidates with at least one missed term survive. We call the discarded examples *easy* and the surviving ones *hard*. The filter is computed once, against our previous public release.

[3] https://opus.nlpl.eu/datasets/EMEA

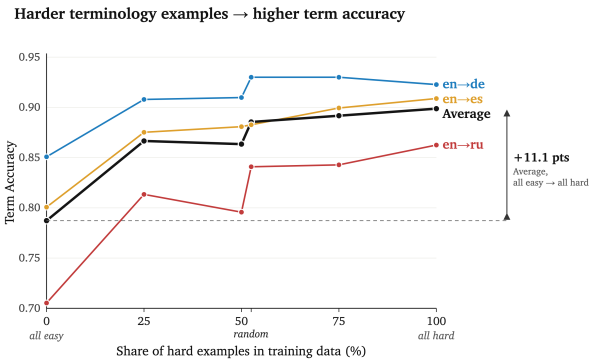

Figure 2: Term accuracy against the share of hard examples in the terminology data.

## 4 Controlled study: does hardness matter?

The filter of §3.3 discards nearly half of the corpus (47.5%; Appendix B). This section asks whether that is actually a good idea. We hold everything about training fixed and vary a single quantity, the share of hard examples in the terminology data, from 0% to 100% in five steps plus a random baseline, and trace term accuracy along the way (Figure 2).

### 4.1 Setup

**Training runs.** In Figure 2, each point on the curve is a complete instruction-tuning run. Starting from the SALAMANDRATA-7B base model (the continually pre-trained translation checkpoint), we fine-tune on the fixed-background mixture of the public SALAMANDRATA-7B-INSTRUCT v2 release recipe (see data datails in Appendix C). All runs use identical hyperparameters: one epoch, learning rate $10^{-5}$ with cosine decay and 3% warmup, context length 8,192, and an effective batch size of 32.

**The six mixtures.** Into this background we insert a terminology component, the only ingredient that changes between runs. It spans the 19 directions the EMEA branch produces, with a fixed per-direction budget of up to 4,000 examples, identical across mixtures. Six compositions are tested: 0%,

25%, 50%, 75%, and 100% hard examples, plus a *random* baseline sampled from the unfiltered pool, which inherits the corpus's natural per-direction proportion of hard examples. Easy examples and hard examples pass the same cleaning, quality, and semantic-similarity gates, so the two pools differ only in difficulty.

**Evaluation.** We evaluate on the WMT2025 Terminology Track 1 test set (Semenov et al., 2025): en→de, en→es, and en→ru.[4] None of the three occurs as a training direction in the terminology component, so any gain on them already reflects transfer. We report the official term accuracy, micro-averaged over all 1,589 term occurrences, together with chrF (Popović, 2015) as a check that translation quality does not silently degrade; confidence intervals and $p$-values come from a clustered paired bootstrap over source segments (95%, 10k resamples).

**Relation to the released model.** These runs do not reproduce the v3.0 recipe. The background mixture follows the earlier v2.0 release recipe and does not include the additional tasks introduced in v3.0 (structured-text translation, register control, paraphrasing, and further post-editing and gender data). The terminology component also differs from the released one: v3.0 is trained on MeSpEn and EMEA data together, whereas each run here uses EMEA data only, at a fixed volume of 76,000 instances, so that the hard-example ratio is the only moving part across runs. The curve should accordingly be read as evidence for the selection principle, not as a decomposition of v3.0's gains.

### 4.2 Results

Selection alone is worth eleven points. Figure 2 shows the result, with per-direction numbers in Appendix D: averaged over the three directions, term accuracy climbs from 78.7% with no hard examples to 89.9% with only hard examples, a gain of 11.2 points (95% CI $[+9.5, +12.8]$, $p < 0.0001$) at identical data volume. The easy examples are not noise; they passed exactly the same cleaning, quality, and similarity gates as the hard ones.

Accuracy generally follows the dose of difficulty across every mixture we tested. Hard examples are potent: a quarter dose already delivers 71% of the full effect. The small dip at 50%, traced to the en→ru direction, lies within noise on the average (25% vs. 50%: $+0.3$ points, 95% CI $[-0.6, +1.3]$, $p = 0.55$, paired bootstrap). A forced 50/50 split trails the fully filtered set by 3.5 points. An unfiltered random sample of the same size comes closer, but for a revealing reason: EMEA is naturally rich in hard sentences, so a random draw is itself a moderately hard mixture, and it lands where its hard share predicts. Even against this lucky corpus, filtering adds a significant $+1.3$ points ($p = 0.003$); on a corpus with fewer hard cases, random sampling would inherit correspondingly less, while the filter turns the dose of difficulty into a guarantee.

The strongest evidence that difficulty is what does the teaching comes from the direction the training data covers worst. For en→ru, with no Russian anywhere in the terminology data, the easy-to-hard gain is the largest of the three ($+15.7$ points). The en→es curve climbs strictly with the hard share ($+10.8$), and en→de, the direction closest to the training languages, saturates earliest, with 75% hard and the random mixture edging past pure-hard (93.0 vs. 92.3).

Hardness costs nothing in quality. Across the five mixtures that contain hard examples, average chrF stays within half a point (67.0–67.4), and the all-easy mixture is the weakest on chrF as well (66.5). The gains are not bought with translation quality.

## 5 Document-level submission pipeline

The WMT26 Track 1 test sets are full documents, each paired with a corpus-level glossary that mixes entries relevant to the document with distractors from the whole collection. The 8,192-token context window of our system must hold the document, its glossary, and the translation as it is generated, so full documents invite truncation and repetition; and oversized glossaries dilute attention over entries that never occur in the text. The submission therefore translates each document in three stages.

**1. Layout-preserving chunking.** A document is split only at line breaks into chunks of roughly 500 source words, translated chunk by chunk with the terminology prompt of the model card (beam search, beam size 5), and re-joined into documents. A chunk spans several lines, and the model reproduces its line structure directly, having been trained on exactly these granularities (§3). An automatic check verifies every chunk, and the few that call for it are re-translated line by line, so the submitted

[4] https://github.com/wmt-conference/wmt25-terminology

layout matches the source by construction.

**2. Glossary filtering.** Each chunk receives only the glossary entries whose source term actually occurs in it. A term counts as present if it appears verbatim or if its lemmas match. This shrinks the corpus-level glossary to the handful of entries the model must act on.

**3. QE-guided post-editing.** Chunk translation leaves occasional local defects: dropped clauses, agreement errors, spelling noise. We therefore score every segment with CometKiwi (Rei et al., 2022) and let the same released model post-edit the low-scoring ones, using the post-editing prompt from its instruction tuning, so that the submission comes entirely from one model.

The risk is that fluency and terminology disagree about repetition. The test documents often name one concept several ways while the glossary maps every name to the same target, so faithful translations repeat themselves: *a steel wheel (or steelie)* becomes *koło stalowe (lub koło stalowe)*. The post-editor does what any writer would and smooths the repetition away. Sometimes this is harmless, because the document keeps enough copies of the term; sometimes it deletes an occurrence that term accuracy still needed, or replaces the prescribed wording altogether. CometKiwi rewards all three alike. An edit is therefore applied only if it raises CometKiwi and does not lower document-level term accuracy. Most edits that survive fix grammar, spelling, or punctuation, or remove a genuinely surplus repetition.

## 6 Results

### 6.1 Official WMT26 results

Table 1 places SALAMANDRATA-7B-INSTRUCT v3.0, used exactly as released and wrapped in the pipeline of §5, among the WMT26 Track 1 submissions (Charkiewicz et al., 2026). The system reaches 94.2% lemmatised term success at 74.6 document chrF++, only 2.2 points of term success below the human reference. Of the twenty-two submissions, only COZY and Agentic-OPUS improve on both axes at once; four further systems reach higher term success at lower chrF++.

### 6.2 Comparison with our GRPO submission

Our WMT25 system optimised the same model family with GRPO under a joint adherence and quality reward (Garcia Gilabert et al., 2025). It operates only at the sentence level, so the two can only be compared on last year's benchmark (Table 2). The released v3.0 model improves on both axes, from 67.3 to 69.4 average chrF and from 91.3% to 94.0% average term accuracy, with no reinforcement learning, no task-specific adaptation, and no access to the test-time domain. The comparison is not fully controlled, however. The two systems differ not only in their terminology data, but also in the broader instruction mixture. We therefore view this as a system-level comparison rather than a controlled ablation. Nevertheless, the result does show that a general-purpose translation model, given our terminology data as part of ordinary instruction tuning, can outperform a dedicated RL pipeline on this task.

## 7 Discussion

**Many-to-one glossaries make quality and adherence disagree.** The test glossaries are not injective: *boot lid* and *trunk lid* share the single prescribed target *klapa bagażnika*. When a source document deliberately enumerates synonyms, a faithful translation must repeat that target: "both the boot lid and the trunk lid" can only become *zarówno klapa bagażnika, jak i klapa bagażnika*, text any human editor would immediately smooth out. Quality estimation sides with the editor: CometKiwi scored the smoothed variant, ... *jak i pokrywa bagażnika*, 0.13 higher, and across our post-editing stage it consistently assigned positive deltas to the very edits that damage adherence. We suspect this tension generalises: any system that optimises a quality metric on top of a terminology task needs an explicit adherence constraint, because the two objectives are locally adversarial on some many-to-one entries. What the translations of these sentences should ideally look like, and how they should be scored in the terminology task, remain open questions.

**What the filter buys.** The controlled study suggests the value of hard examples is not the term pairs they contain but the behaviour they force: reading the glossary when the model's default would have been something else. This also suggests the filter should transfer to other adherence-flavoured tasks (style guides, register constraints, do-not-translate lists) where most naturally occurring supervision is similarly redundant. Whether this behavioural account holds up mechanistically,

| System | Term success | | | chrF++ | | |
|---|---|---|---|---|---|---|
| | Avg | en-pl | es-eu | Avg | en-pl | es-eu |
| *gold* | *96.4* | *93.6* | *99.1* | *100.0* | *100.0* | *100.0* |

and what in the model implements it, we leave to future work.

## 8 Conclusion

We described the BSC submission to WMT26 Terminology Translation Track 1: the public release SALAMANDRATA-7B-INSTRUCT v3.0, whose terminology training data is built by a two-way synthetic pipeline on open models and filtered by a single rule, keep only what the model gets wrong, together with a document-level inference pipeline with per-chunk glossaries and QE-guided post-editing. A controlled study shows the filter is responsible for an eleven-point term-accuracy gain at fixed data volume, and the released system reaches 94.2% term success at 74.6 chrF++ in the WMT26 official evaluation. Hard examples, it turns out, are better teachers.

## Limitations

The WMT25 test set provides per-sentence terminology, so its errors are all genuine adherence failures. The WMT26 setting differs: a corpus-level glossary must first be narrowed to each chunk by surface and lemma matching (§5), and a term whose inflected form escapes the match never reaches the model at all. Our submission's errors will therefore mix adherence failures with retrieval failures. The controlled study is deliberately narrow: one data source, three test directions, one data volume, and a single reference model defining hardness. The filter is also static, computed once against v2.0 before training; a dynamic variant that re-estimates difficulty during training might select better but was out of scope. Our terminology data is biased toward the medical domain of its seed resources, while the test domains this year differ. Finally, the base model was continually pre-trained on sentence-level parallel data only. Document-level translation behaviour comes primarily from instruction tuning, and very long documents must be chunked at inference, which can lose cross-chunk context such as antecedents for consistent term choice. We are currently extending continual pre-training to document-level parallel corpora, which we expect will improve document-level context modeling.

## A Synthetic-data pipeline details

Figure 3 gives an overview of the two pipelines. MeSpEn starts from terminology and generates text around it, while EMEA pipeline starts from the EMEA corpus after cleaning with ParaCLEAN (Mash et al., 2026) and extracts terminology out of it. Both contain the same two quality gates: a *hard-case selection* step, where SALAMANDRATA itself decides what is worth training on, and a *semantic filter* based on LaBSE similarity.

### A.1 MeSpEn: generating text from terminology

**1. Glossary cleaning.** The raw MeSpEn glossary files contain formatting noise: numbered variant lists, domain markers, phonetic transcriptions, part-of-speech tags, and occasional swapped columns. A single cleaning pass fixes these, splits multi-variant entries into pipe-separated alternatives, and deduplicates rows.

**2. Hard-term selection.** SALAMANDRATA-7B-INSTRUCT v2.0 translates every glossary term on its own, and the output is compared to the gold entry with a lenient matcher, so that casing, punctuation, or spacing differences do not count as errors. Terms the model already translates correctly are discarded; only genuine mismatches are used as seeds.

**3. Semantic grouping.** Each synthetic text is generated around a small group of glossary terms, so the terms in a group must plausibly belong to the same text: sampling them at random produces absurd combinations (e.g., an obstetrics term next to a dental one). We therefore cluster the glossary into medical sub-domains with LaBSE, and draw the terms of each group mostly (80% of the time) from a single cluster.

**4. Text generation.** Gemma-4-31B receives a term group and writes the source text and its translation in one pass, at lengths ranging from a single sentence (25%) over short passages and paragraphs (58%) to multi-paragraph documents (17%); short texts carry 1–3 terms, documents more. Two tricks keep the output realistic. First, the model must invent a one-sentence scenario before writing (e.g., "a discharge summary after knee surgery"), which anchors the text in a concrete setting instead of a vague list of facts. Second, in document-length samples the main term has to appear at least twice and be translated the same way each time. The model finally reports which surface form each term actually took (say, the plural *células* rather than the glossary form *célula*); the next step depends on these.

**5. Filtering.** Two kinds of errors slip through generation. Sometimes a reported term does not actually appear in the text it claims to be in; simple rule checks catch these, and also drop degenerate samples (extreme length ratios, source copied as target, duplicates). Sometimes both source and target read fluently, yet they quietly say different things; LaBSE similarity catches these, by requiring each term pair and the full text pair to score at least 0.80. Surviving records are formatted as prompt–answer pairs, with document-form records oversampled ($\approx 10\times$) to strengthen multi-paragraph layout.

### A.2 EMEA: extracting terminology from text

**1. Term extraction.** Gemma-4-31B reads each aligned sentence pair and extracts the domain-specific term pairs it contains. Numeric "terms" (dosages such as *720 IU/kg*) are removed.

**2. Normalization.** EMEA text carries detokenization artifacts that would otherwise end up inside glossary terms: "*Parkinson' s*", "*13, 6 mg*", "*mg/ ml*". A conservative pass repairs these ("*Parkinson's*", "*13,6 mg*", "*mg/ml*").

**3. Hard-sentence selection.** SALAMANDRATA translates every source sentence *without* any glossary in the prompt, and we check which gold terms appear in its output. If all of them do, the model needs no help on this sentence, so only sentences with at least one missed term are kept.

**4. Filtering and audit.** The same two error types as in MeSpEn are checked. Sometimes Gemma reports a term that is not literally in the sentence (e.g., one it inferred rather than read), so we look up every extracted term in its own sentence and drop the record when it is missing, along with truncated or length-distorted samples. Sometimes the two sides quietly diverge in meaning; LaBSE similarity catches these, by requiring the sentence pair to score at least 0.88.

**5. Document construction.** EMEA sentences arrive in corpus order, so consecutive sentences from the same document section can simply be concatenated back into longer units. Each training instance is sampled from a length profile, that is, a single sentence, a short space-joined paragraph, or

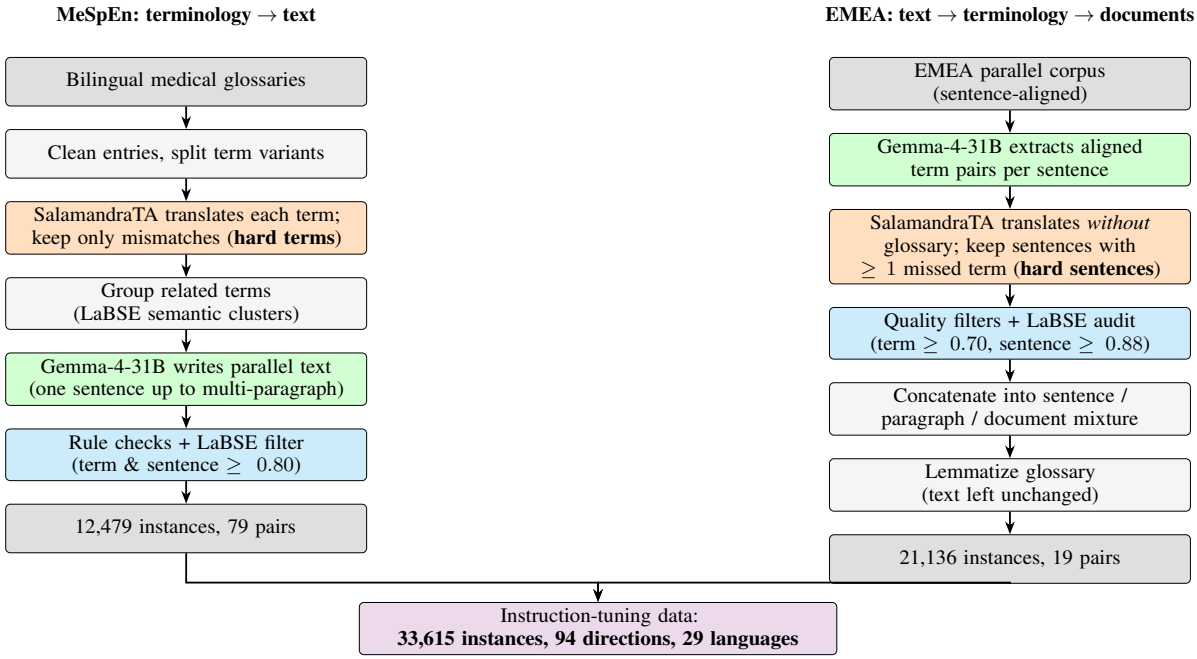

Figure 3: The two synthetic-data pipelines.

a document of several hundred to ≈1,000 source words with newline layout, so that the model sees every granularity. A document's glossary is the union of its sentences' term pairs.

**6. Glossary lemmatization.** Finally, every glossary entry is reduced to its lemma form with Stanza (Qi et al., 2020) and deduplicated. The glossary thus advertises *apple* → *manzana* even where the text contains *apples*/*manzanas*, and the model must learn to inflect prescribed terms in context rather than copy surface strings. We verified that the longest formatted instances stay within the 8,192-token training context.

### A.3 Data profile

Figure 4 summarizes the two corpora. MeSpEn contributes short, term-dense texts in 79 language pairs (median 45 source words, usually 1–2 glossary entries), while EMEA contributes long documents in 19 pairs (median 645 source words, median 83 glossary entries).

## B Hard/easy pool sizes per direction

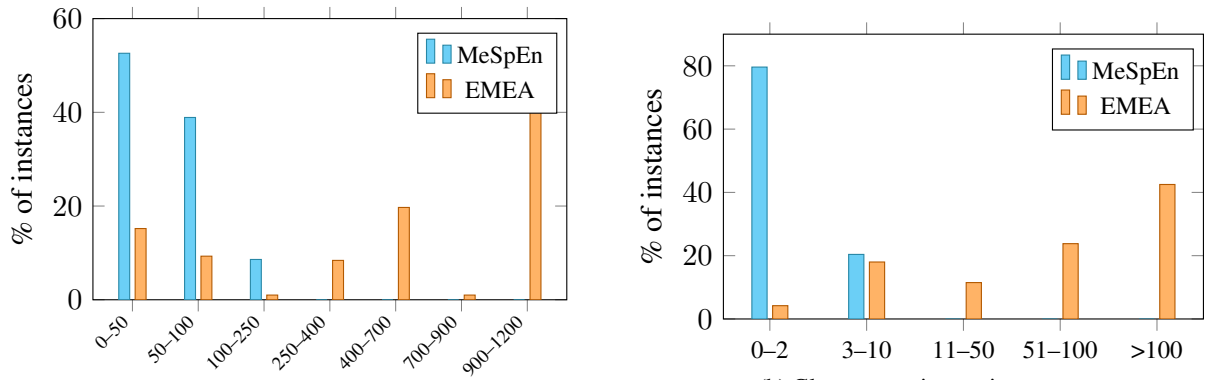

Table 3 gives, for every direction, the size of the hard pool (v2.0 misses at least one term) and the easy pool (v2.0 already produces every term), counted after the quality and LaBSE audit gates and before any subsampling. Every ratio-curve run of §4 draws 4,000 records per direction from these pools; the *random* baseline draws them from the union of the two, which is why its hard share tracks the corpus's natural one.

| Direction | Hard | Easy | %Hard |
|---|---|---|---|
| cs-de | 7,291 | 7,929 | 47.9 |
| cs-en | 15,187 | 30,291 | 33.4 |
| de-en | 14,835 | 30,886 | 32.4 |
| en-et | 17,348 | 12,457 | 58.2 |
| en-pl | 20,404 | 18,558 | 52.4 |
| es-bg | 32,219 | 32,839 | 49.5 |
| es-cs | 36,281 | 28,473 | 56.0 |
| es-da | 34,639 | 30,472 | 53.2 |
| es-el | 23,646 | 23,587 | 50.1 |

## Abstract

This paper describes the GRIAL-TA team's submission to the WMT2026 Terminology Translation Shared Task. We participated in both tracks for the English-Polish language pair. Our core translation architecture relies on an instruction-aligned Gemma 4 model fine-tuned on highly curated, domain-specific corpora. To address the specific evaluation modes of Track 1, we constructed specialized datasets to train the model to adapt to prompts featuring no terminology, proper domain terminology, and random terminology. For Track 2, where explicit dictionaries are absent, we extracted the required glossary from the provided seed bitexts prior to translation using TBXTools, a tool for automatic terminology extraction. We merged the unique terms extracted independently by a BERT-based methodology and a linguistic part-of-speech pattern extractor, to mitigate a significant performance drop observed in the Polish data. Ultimately, while our approach maintained competitive general translation quality, the evaluations reveal that extensive fine-tuning degraded the model's instruction-following capabilities, reducing its adherence to terminology constraints. We discuss these limitations and propose future strategies to balance domain adaptation with prompt sensitivity.

## 1 Introduction

With the creation of large language models (LLMs), machine translation (MT) has reached cutting-edge performance (Ataman et al., 2025); nonetheless, they have shown some struggles when it comes to multilingual machine translation (MMT) compared to traditional approaches (Zhu et al., 2024). Moreover, LLM translations of terminology-heavy texts are far from the desired outcome (Semenov et al., 2025). At the document-level, LLMs tend to be inconsistent or eliminate terminology (especially in low-resource languages), which is detrimental for the quality of the overall translated text.

With this background in mind, the GRIAL-TA team participated in the Terminology Shared Task of WMT26, in both Track 1 (document-level MT with an explicit dictionary) and Track 2 (document-level translation with sample bitexts) for English and Polish in the fields of Medicine, and Engineering and Technology. We fine-tuned an instruction-tuned Gemma 4 model for both tracks. To extract terms from the Track 2 data we used the term extraction tool TBXTools[1], using both BERT-based and linguistic methodologies (Oliver and Vàzquez, 2015; López-Sánchez et al., 2026).

## 2 Resources

In this section, we specify the resources used to fine-tune the translation model used in Tracks 1 and 2. We compiled a term reference list in the domains specified by the task organizers: Medicine, and Engineering and Technology. We decided to search for large resources with multiple subdomains related to the main domains. Additionally, we added bilingual corpora in order to enhance translation. All resources were obtained from reliable sources, such as institutions, international agencies, published dictionaries, and official databases. It is worth mentioning that all the resources used for this shared task, except for the European Medicines Agency and European Union's (2026) corpus, are open access.

### 2.1 Corpora

We used EuroPat and EMA (Heafield et al., 2022; European Medicines Agency and European Union, 2026) with the purpose of training the translation models described in Section 2.4. We chose only English-Polish as the language pair for this task,

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1819–1829
October 28-29, 2026 ©2026 Association for Computational Linguistics

meaning that the unique segments mentioned in this section only apply for these two languages.

EMA and EuroPat are multilingual medicine and technical corpora, respectively. The former was constituted by documents from the European Medicines Agency and has 348,236 unique segments. The latter is the compilation of patent-specific parallel data, with 332,120 unique segments. We also created a general bilingual corpus based on NLLB[2] (NLLB Team et al., 2022) (74,065,994 unique segments) and Paracrawl v9[3] (Bañón et al., 2020) (40,082,037 unique segments) corpora. To do so, both corpora are deduplicated, concatenated, and deduplicated again. The resulting corpus is published in Hugging Face[4].

Since the alignment for the three corpora does not have the quality we desired (namely, segments that did not match exactly with their corresponding counterparts), we applied the rescoring algorithm[5] proposed by Oliver and Álvarez (2023) to improve it. It uses `lid.176.bin` (Joulin et al., 2016), a language identification model based on fastText. It is trained on large multilingual datasets and supports 176 languages. As for the selection of rescored segments, we took into account language detection confidence and similarity between segments key metrics (both with a minimum score set at 0.75). After rescoring, they sized down to 162,091 segments for EMA-en-pl, 292,768 for EuroPat-en-pl, and 76,478,046 for the general corpus.

### 2.2 Terminological databases

We used the IATE (InterActive Terminology for Europe) database (Translation Centre for the Bodies of the European Union, 2018) to compile specialized terminology. This resource is used for the translation of official documents and legislation within the EU. Its website enables customized terminology extraction through structured download requests, requiring users to specify parameters such as language, domains, term types, file formats, and reliability levels. In total, we collected 22,201 terms between the three domains. Table 1 shows the parameters used to obtain them for both domains of the shared task. It is divided by languages, IATE domains, term type, reliability, evaluation[6], and total number of terms. In Section 3.4.1, the parameters used for terminology extraction are specified.

### 2.3 Bilingual dictionary

For the selection of random terms in the creation of the fine-tuning sets (see Section 3.2) we have used the Wikdict dictionaries[7]. In our repository, a script to convert Wikdict TEI dictionaries to tabtxt is provided. The English-Polish Wiktionary has a total of 99,394 entries.

### 2.4 Base models

The Gemma 4 models (El Abd et al., 2026), developed by Google DeepMind and hosted on Hugging Face, are a set of open-weights multimodal models, delivering state-of-the-art performance in several tasks and with high multilingual capabilities, covering over 140 languages.

- **`google/gemma-4-12B-it`**: A lightweight, instruction-tuned 12B model that directly projects audio and visual inputs into the language embedding space, removing standalone encoders to minimize latency and memory usage on standard GPUs (8–16 GB VRAM).

- **`google/gemma-4-31B-it`**: A dense 30.7B parameter model optimized for complex reasoning, multi-turn agentic tasks, and software engineering, featuring native video processing and adjustable visual token budgets.

We selected these models for this shared task due to their ideal balance of high-throughput efficiency, strong instruction-following capabilities, and robust multilingual pre-training across over 140 languages. Terminology-aware translation demands precise adherence to domain-specific glossaries and complex contextual constraints, making Gemma 4's native system prompt support and configurable thinking modes particularly advantageous for controlled decoding and constrained generation. Furthermore, evaluating both the 12B and 31B variants enables a direct comparative analysis between lightweight, low-latency architectures suitable for practical edge deployments and high-capacity models capable of mastering subtle morphological inflections in terminology-heavy texts.

## 3 Methodology

### 3.1 Prompts

We designed a set of prompts to fine-tune the translation models under several conditions. These prompts can be found in appendix A.

### 3.2 Creation of the sets for fine-tuning Gemma

We developed a Python script (`createSet.py`) that, provided a parallel corpus, a general dictionary in tab separated format and a terminological database in TBX format, and specifying the names and codes of the source and target languages, can create a JSONL file that contains: the source segment, the target segment, the proper terms of both segments, and the random terms of both segments (up to three, if there are more, only the longest are selected). What follows is an example of the output:

```
{"en": "32 Metformin Non-clinical data for
    metformin reveal no special hazard for
    humans based on conventional studies of
    safety pharmacology, repeated dose toxicity,
     genotoxicity, carcinogenic potential,
    toxicity to reproduction.", "pl": "
    Metformina Dane niekliniczne dla metforminy
    nie wykazały specjalnych zagrożeń dla ludzi
    na podstawie tradycyjnych badań bezpieczeń
    stwa farmakologicznego, toksyczności po
    podaniu wielokrotnym, genotoksyczności,
    rakotwórczości, toksycznego wpływu na
    rozrodczość.", "proper_terms": {"clinical
    data": "dane kliniczne", "safety
    pharmacology": "farmakologia bezpieczeństwa
    ", "repeated-dose toxicity": "toksyczność po
     podaniu wielokrotnym", "genotoxicity": "
    genotoksyczność"}, "random_terms": {"
    metformin": "metformina", "special": "
    specjalny", "safety": "bezpieczeństwo"}}
```

To create these sets, we used the EMA, Europat, and the general corpus presented in Section 2.1 and the terminological databases presented in Section 2.2. As the process is slow, the task creation of sets from the general corpus was stopped before the end. Table 2 details the size of the created sets.

| Subject | Category | Total |
|---|---|---|
| Medical | EMEA | 103,178 |
| | General | 59,160 |
| Technical | Europat | 51,644 |
| | General | 137,754 |

Table 2: Size of the fine-tuning datasets.

### 3.3 Fine-tuning of Gemma

We used the `transformers` library to fine-tune `gemma4-12b-it` and `gemma4-31b-it` for medical texts with two different settings: early stopping with patience of 3, and 2 epochs. All these variants were evaluated and compared with the base models. The best performing option was used to fine-tune a model for technical texts. All the fine-tuning scripts can be found in the repository[8], so all the different parameters can be observed and the experiments can be reproduced.

In Table 3 we can observe the evaluation results of the base models and of the fine-tuned models. Overall, the data shows that fine-tuning enhances model performance in most metrics, with the two-epoch (FT 2 Ep.) configuration standing out as the most effective approach across both model sizes. Completing two training epochs yields improvements in standard quality metrics (BLEU, chrF, and COMET) while markedly reducing the Translation Error Rate (TER). For instance, the 12b model's BLEU score jumps from approximately 28.5 in its base state to over 53 after two epochs, outperforming the Early Stopping (E.S.) strategy. Interestingly, while the 31b base model initially exhibits a slight

[8] https://github.com/grial-research-group/WMT26-SharedTask-Terminology-GRIAL-TA

| Size | Model | Prompt | Terms | BLEU | chrF | TER | COMET | T.P. % |

| 31b | FT 2 Ep. | Medical | No terms | 53.87 | 70.90 | 46.87 | 89.28 | 77.05 |
| 31b | FT 2 Ep. | Medical | Random | 55.63 | 72.46 | 44.65 | 89.60 | 76.69 |
| 31b | FT 2 Ep. | Medical | Proper | 53.79 | 71.22 | 46.30 | 89.51 | 79.11 |

Table 3: Evaluation results for medical texts (FT: fine-tuned; E.S.: early stopping; 2 Ep.: 2 Epochs).

edge over its 12b counterpart, this capacity-related advantage virtually dissipates after full fine-tuning. Both models converge at remarkably similar performance levels, achieving a BLEU score of roughly 53.8 and a COMET score of around 89 to 90 when utilizing proper terminology.

Furthermore, analyzing the prompt and terminology configurations reveals nuanced model behaviors. Although the application of a domain-specific "Medical" prompt provides only marginal gains over a "General" baseline, injecting "Proper" terms dramatically boosts Terminology Precision (T.P. %) in the base models. This is clearly evidenced in the 31b Base model, where T.P. surges from 74.93% to 88.64%. However, this terminology injection effect is noticeably less pronounced in the fine-tuned (2 Epochs) models, suggesting that the extended training process already enables the models to internalize the requisite domain vocabulary robustly.

In Table 4, we can observe the evaluation results of the 31b model in its base state compared to its fine-tuned counterpart after two training epochs (FT 2 Ep.). Mirroring the trends seen in the medical domain, fine-tuning improves lexical quality metrics across all prompt and terminology settings. Specifically, the BLEU score increases by over six points (rising from approximately 29.0 to 35.7–36.9), accompanied by a four-point gain in chrF and a notable reduction of over five points in the Translation Error Rate (TER). Interestingly, neural evaluation via COMET displays a slight divergence from the lexical metrics: COMET scores remain exceptionally stable, experiencing a minor drop from around 85.36 in the base model to roughly 84.90–85.03 in the fine-tuned model. This suggests that while fine-tuning aligns the model's outputs much more closely with reference $n$-grams, its underlying semantic quality remains consistently high across both states. Regarding prompting and terminology injection, the domain-specific 'Technical' prompt yields negligible differences compared to the 'General' baseline when no terms are provided. However, the inclusion of 'Proper' terminology again demonstrates a clear benefit for target term preservation. In the Base model, providing proper terms drives Terminology Precision (T.P.) up from 74.49 % to 86.14 %. While this boosting effect persists in the fine-tuned model—raising T.P. from 78.06 % to 82.39 %—it is comparatively less pronounced, reinforcing the observation that fine-tuning inherently embeds domain vocabulary while slightly dampening the model's sensitivity to external terminology prompts.

| Size | Model | Prompt | Terms | BLEU | chrF | TER | COMET | T.P. % |
|---|---|---|---|---|---|---|---|---|
| 31b | Base | General | No terms | 29.50 | 60.13 | 58.69 | 85.38 | 75.16 |
| 31b | Base | Technical | No terms | 29.03 | 59.93 | 59.20 | 85.36 | 74.49 |
| 31b | Base | Technical | Random | 31.40 | 61.58 | 56.30 | 85.21 | 75.16 |
| 31b | Base | Technical | Proper | 29.85 | 60.64 | 58.27 | 85.29 | 86.14 |
| 31b | FT 2 Ep. | General | No terms | 35.70 | 64.21 | 53.65 | 84.94 | 78.58 |
| 31b | FT 2 Ep. | Technical | No terms | 35.72 | 64.15 | 53.47 | 84.86 | 78.06 |
| 31b | FT 2 Ep. | Technical | Random | 36.91 | 65.13 | 52.37 | 85.12 | 78.91 |
| 31b | FT 2 Ep. | Technical | Proper | 35.90 | 64.22 | 53.99 | 85.03 | 82.39 |

Table 4: Evaluation results for technical texts (FT: fine-tuned; 2 Ep.: 2 Epochs).

Appendix B details the hardware specifications of the server, alongside the time and energy consumption of all the fine-tuning processes that were carried out.

### 3.4 Terminology extraction

Track 2 of the shared task required term extraction from a sample of parallel sentences. For this, we initially used the BERT methodology of the term extraction tool TBXTools (Oliver and Vàzquez, 2015; López-Sánchez et al., 2026). This methodology models automatic terminology extraction as a token-level sequence labeling task using BIO tagging. A pre-trained BERT-based model is fine-tuned on an automatically annotated corpus to predict terms. We empirically evaluated several well-established models for this task. Following extensive hyperparameter tuning for each candidate, for our final implementation we selected the base variant of XLM-RoBERTa (Conneau et al., 2020), a multilingual version of RoBERTa pre-trained on 100 languages, which allowed us to seamlessly process the bilingual data. Although the larger (`xlm-roberta-large`) variant achieved a higher F1-score on a validation split of the data, a qualitative manual inspection of the actual predictions revealed no significant differences. Consequently, we prioritized the base model in favor of computational efficiency.

#### 3.4.1 Resources for terminology extraction

In order to generate the training labels to be used during the fine-tuning of our terminology extraction model we needed a list of terms and a corpus for the tool to automatically annotate. For this, we compiled reference term lists using the IATE database. We downloaded lists in Polish and English for the specific domains of the task. These lists are different from those used in the dataset generation for the fine-tuning of the translation model. We aimed to maximize number of terms, so we did not filter the download query as much as previously, as we wanted the same model to predict terms in both languages across both domains. A detailed overview of our download requests is illustrated in Table 5. Once we obtained the files, we performed some additional processing. We decided to keep only terms containing fewer than five elements and no punctuation or special characters such as parentheses, to ensure the model learned mainly to identify terms not containing them. The resulting reference lists' sizes across domains and target languages are summarized in Table 6.

| | English | Polish |
|---|---|---|
| **Eng. & Tech.** | 138,905 | 16,227 |
| **Medicine** | 77,186 | 15,807 |

Table 6: Number of terms in the terminology reference lists by domain and language.

We also created the required specialized corpora using the tool `corpus-from-wikipedia`[9] (Segués et al., 2026), designed for compiling specialized monolingual and parallel corpora from Wikipedia. Building on prior success with highly curated data, our objective was to evaluate whether a widely accessible platform like Wikipedia can serve as a viable source of specialized training data for our terminology extraction model. For each language, we built two separate corpora based on Wikipedia categories, one for Medicine and another one combining Engineering and Technology, the domains specified by the tasks organizers. We also performed extra filtering on this output to handle cross-lingual noise. This is particularly common in non-English Wikipedia articles, which often include English titles of books, films, or proper nouns. To address this problem we used the `lid.176.bin` language detector of fastText (Joulin et al., 2016). Only sen-

### 3.4.2 BERT extraction

Once the corpora and reference term lists were compiled, we provided them as inputs to TBXTools to automatically annotate the data and fine-tune our model. The tool first lemmatized, using spaCy[10], both the corpora and the term lists, executing the annotation process separately by language and domain. The lemmatized data were used exclusively for label generation and the resulting labels were then aligned to the original, unlemmatized corpora. The model was fine-tuned on a combined dataset of both languages and domains using the default optimization setup of the Hugging Face Trainer API, with a learning rate of $4.5 \times 10^{-5}$, a batch size of 32, a weight decay of 0.028, and a warmup ratio of 0.016 for 1.7 epochs. Hyperparameters were chosen based on the highest F1-score on a validation split of the training data.

Afterwards, we used the fine-tuned model to perform the extraction of the terms on the sample sentences given by the task organizers. The data contained 214 parallel sentences for Engineering and Technology and 70 for Medicine. While the fine-tuned model managed to extract a high number of terms in English, we observed that in Polish it extracted a considerably smaller number of terms. To address this issue we decided to perform an additional extraction using linguistic methods.

### 3.4.3 Linguistic extraction

Linguistic terminology extraction is another extraction methodology supported by TBXTools. It is based on the search of certain combinations of POS tags in a text. We used the same corpora and lists of terms as used in the extraction described in section 3.4.2. The tool automatically annotated the data with part-of-speech tags, using spaCy, and retrieved the underlying POS patterns directly from the reference terminology separately by language and domain. Thus, we had four distinct lists of linguistic patterns alongside their frequency in the corpus. To reduce noise, we discarded patterns with a frequency of 2 or less. Additionally, we filtered out single-tag patterns consisting of any of the following POS tags: PUNCT, X, AUX, DET, ADP, NUM, INTJ, CONJ, and PART. We then used these lists to perform the term extraction, limiting candidate terms to unigrams, bigrams, trigrams and quadgrams. This process yielded a greater number of Polish terms. After a qualitative analysis of the results, we decided to combine the unique terms extracted by both the BERT and linguistic methodologies. Table 8 details the results of both methodologies and their combined result.

### 3.4.4 Terms alignment

In order for the machine translation system to use the extracted terms, they first had to be matched to their translation equivalent. Although we lemmatized all the data, it should be noted that

[10] https://spacy.io/

| Methodology | Domain | English | Polish |

Table 8: Extracted terms from the sample sentences by methodology, domain, and language.

we intentionally restricted the lemmatization of Polish multi-word terms with nominal modifiers, e.g. *wału rozrządu*, to maintain standard citation forms and our fine-tuning data format. In these cases, the head noun was lemmatized to the nominative case (*wał*) and the modifier retained the grammatical inflection (*rozrządu*). Afterwards, we generated vector embeddings using LaBSE (Feng et al., 2022), a BERT based multilingual embedding model supporting 109 languages, via the `sentence-transformers` (Reimers and Gurevych, 2020) library. By mapping terms into a shared vector space, LaBSE enables the computation of semantic similarity via cosine similarity. We computed pairwise cosine similarity scores across all vector pairs, which produced separate similarity matrices for the Engineering and Technology, and Medicine domains. In these matrices each cell represents the semantic similarity score between a Polish term and an English term. We subsequently applied the linear sum assignment function from the `SciPy` (Virtanen et al., 2020) library to each matrix to extract the optimal one-to-one alignments, therefore maximizing the total semantic similarity. After a qualitative analysis of the results, we decided on a minimum similarity threshold of 0.80 to filter out low-confidence pairs. In the end, we obtained 391 aligned pairs for Engineering and Technology along with 98 for Medicine.

## 4 Participation in Track 1: Document-Level Translation with Explicit Dictionary

For both tracks of the task, we fully fine-tuned `gemma4-31B-it` for two epochs. We trained two separate models: one specialized in medical texts and another in mechanical engineering, as described in Section 3.3. As required by the task, we evaluated three distinct translation setups based on the provided resources: (1) given no terminology, (2) given random terminology, and (3) given proper terminology.

Initially, we attempted full-document translation; however, this resulted in incomplete or truncated translations. Adjusting generation parameters to generate longer outputs did not resolve the issue. This limitation was likely due to the fact that the fine-tuning process was conducted at the segment level. Consequently, we adopted a segment-by-segment translation approach after segmenting each document. When incorporating terms, only the terms explicitly present in the given segment were included in the prompt. Segments without any associated terms were translated using the standard domain-specific prompt. This strategy successfully allowed us to retrieve complete translations for all documents.

### 4.1 Results

Our system's performance demonstrates competitive surface-level translation quality, though it struggles with strict terminology enforcement. As shown in Table 9, our system achieved a chrF++ score of 71.0, closely aligned with the average system score (72.2). However, the neural metrics scores indicate a wider gap in semantic quality compared to the average.

The most significant holdup was term success. Under the *proper* dictionary condition, our system achieved only a 57.3% term success rate, significantly below the 85.5% system average. Despite this, the ablation across different prompt conditions somewhat validates our fine-tuning, since injecting the correct terminology improves term precision, as detailed in Table 10.

## 5 Participation in Track 2: Document-Level Translation with Sample Bitexts

For this track, the task organizers provided a group of sample sentences, that could be used by our system in different ways to extract the relevant terminological information, and a document to translate, from which the sample sentences were retrieved. We divided this task in two different processes:

- Extraction of relevant terms in both languages and subsequent alignment, described in detail in Section 3.4.
- Using these extracted terms to carry out the same procedure as done for Track 1, described in Section 4.

Data sourced from task organizers. The remaining systems were averaged into one single row (Avg. system) for conciseness.

### 5.1 Results

The results of this track highlight the challenges faced in the term extraction from the sample bitexts. As detailed in Table 11, our system achieved scores below the average system. Terminology success, shown in Table 12, reached 32.1%, significantly below of the 74.8% average system baseline.

The most revealing insight from this track is the performance inversion. The *noterm* setting, where the model translated without the help of the extracted glossary, actually outperformed the *sample* setting accross all metrics. This drop in performance when using the glossary correlates with the difficulties detailed in Section 3.4.

## 6 Conclusions and future work

In this work, we presented the GRIAL-TA submission to the WMT26 Terminology Shared Task for the English-Polish language pair across both Track 1 and 2. A major challenge of our approach was constructing a specialized training corpus to fine-tune Gemma 4, explicitly teaching the model to follow terminology-constrained prompts structured for the task. Although the algorithm developed for corpus creation—which extracts random terms from a dictionary and proper terms from a terminology database—leaves room for improvement (particularly regarding morphological inflection handling in highly inflectional languages like Polish), our experimental results demonstrate the suitability of this strategy.

However, our approach faced certain limitations. First, due to time constraints inherent to the Shared Task schedule, our experiments were strictly limited to two model sizes of a single architecture, preventing a broader comparative analysis across other open-weight large language models. Second, because our fine-tuning dataset was compiled exclusively at the segment level, the fine-tuned models exhibited document truncation issues when attempting zero-shot full-document translation, necessitating a segment-by-segment decoding approach during inference.

In addition, the shared task's results suggest that the performance gap compared to the average system primarily stems from the model's reduced sensitivity to prompt constraints. As observed during internal evaluations, the fine-tuning degraded the model's instruction-following capabilities, making it less receptive to the provided glossary of terms—a significant limitation, given that this was a fundamental requirement of the task.

Regarding terminology extraction, the BERT-based methodology proved highly effective for English but significantly underperformed in Polish. This imbalance in the quantity of the predicted terms negatively impacted the subsequent alignment phase, although we managed to partially mitigate it using linguistic methods. While multilingual models offer strong baseline cross-lingual transfer, their ability to extract highly specialized terminology was noticeably degraded in the Polish data. This degradation may be attributed to the 'curse of multilinguality' described in Conneau et al. (2020). Under this phenomenon, model capacity is diluted across languages, that is, while low-resource languages benefit from shared representations, moderate-to-high resource languages, like Polish, can be hindered. In addition, because English outweighs Polish in XLM-RoBERTa's pretraining data, it is probable that the model simply lacked sufficient exposure to specialized Polish terminology.

In future work we plan to investigate whether dedicated monolingual BERT-based models mitigate these issues, and further analyze the impact of the quality of the data, especially in languages other than English. Likewise, regarding the training phase of the translation model, we plan to refine the dataset creation algorithm to better account for complex target-language morphology. Regarding prompt sensitivity, we intend to explore alternative fine-tuning strategies to ensure the model retains its ability to adhere to external glossaries. Furthermore, we aim to expand the generation of these enriched datasets to paragraph and document levels, as well as to additional language pairs and specialized domains.

## Abstract

To assess the progress in terminology-aware machine translation, the Terminology Shared Task is hosted alongside the Conference on Machine Translation (WMT). In this paper, we describe our submission to the shared task: STaR-MT. This is a three-step pipeline composed of (S)election, (T)ranslation, (a)nd (R)evision, focused on terminology-aware machine translation (MT). Our methodology adopts a lightweight agent-based design that selects relevant entries or examples and presents them to the translation agent, which uses a general-purpose LLM with a large context window to produce the initial output. Next, the revision agent uses language-specific models to improve translation quality for selected target languages. Experiments on the FLORES+ dataset with different model sizes in the pipeline suggest that machine translation pipelines can benefit from combining large general-purpose translation models with language-specific revision models, at least in some language pairs. While simple in architecture, this approach allows us to generate translations at the document level, with no need for pre-processing or paragraph splitting, and with minimal errors across most languages.

## 1 Introduction

The performance of Large Language Models (LLMs) in machine translation tasks has significantly improved in recent years (Lyu et al., 2024). Despite this progress, important challenges remain. One such challenge is terminology-aware machine translation, in which systems must not only produce fluent, accurate translations but also preserve domain-specific terminology consistently across sentences and documents. This requirement is especially important in professional translation settings, as economy, precision, and adequacy are three basic principles of Terminology (Cabré, 1999) even when the overall translation is understandable. Recent findings from the WMT Terminology Shared Task show that terminology-aware translation still lags behind standard sentence-level translation, particularly in more complex document-level scenarios (Semenov et al., 2025). This is understandable, considering that terminology relies to a large extent on conceptualization systems, with which LLMs still struggle.

To assess progress in this area, the Terminology Shared Task is organized as part of the Conference on Machine Translation (WMT). In its fourth edition (Charkiewicz et al., 2026), the shared task expanded its language coverage to include two lower-resourced languages, Basque and Polish, in addition to English and Traditional Chinese. Participants could submit systems to two tracks. The first track focused on sentence-level translation with access to an explicit terminology dictionary, while the second track addressed document-level translation with only a small number of translation examples per language pair.

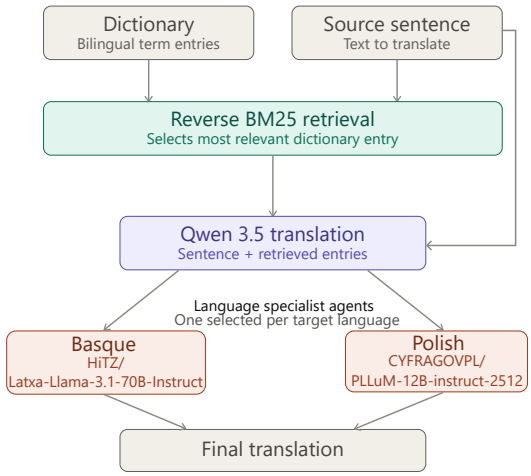

Figure 1: Diagram of the STaR-MT pipeline, comprised of three steps: Select, Translate, and Revise.

In the first track, the goal was to perform sentence-level terminology-aware translation us-

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1830–1839
October 28-29, 2026 ©2026 Association for Computational Linguistics

ing a provided dictionary. The track included two translation directions: Spanish→Basque and English→Polish. For each language pair, the input sentences were divided into two subject domains. The Spanish→Basque pair covered Automation and Energy, while the English→Polish pair covered Mechanical Engineering and Medicine. Each language-domain combination had its own terminology dictionary, containing approximately 1,000 to 3,000 entries. To evaluate whether systems could correctly use the intended terminology, the dictionaries also included a "random" translation alongside the correct one. Participants were required to generate three translations for each sentence: one using the correct terminology entry, one using the random terminology entry, and one without any terminology information.

The second track introduced two changes that substantially increased the task's difficulty. First, the input texts were much longer. While the first track focused on sentence-level translation, the second track required translating at the document level, with several texts exceeding 20,000 words. Second, the explicit terminology dictionaries were removed. Instead, participants were given only a few translation examples from the relevant domain. This made it necessary for systems to identify and reuse useful translation patterns without direct access to a complete term base. The second track also introduced a third translation direction, Traditional Chinese→English. The subject domains for this track were Mechanical Tools and Railways for Spanish→Basque, Mechanical Tools and Medicine for English→Polish, and Finance for Traditional Chinese→English.

In this paper, we describe our submission to the shared task: STaR-MT, a terminology-aware machine translation pipeline composed of three stages (i.e., Selection, Translation, and Revision). Motivated by findings from the previous edition of the shared task, where LLM-based approaches were used in the majority of submissions (Semenov et al., 2025), we focus exclusively on open-weight models. The pipeline first selects the most relevant terminology entries or translation examples using a BM25 index. It then prompts a multilingual LLM to generate an initial translation conditioned on the selected information. Finally, when beneficial for the target language, a language-specific model revises the initial translation to improve its adequacy in the target language. The same general architecture is used for both tracks, with the selection component adapted to the available resources in each setting (i.e., the translation dictionary for track 1 and translation examples for track 2).

Our internal evaluation on the FLORES+ dataset (NLLB Team et al., 2024; Burchell et al., 2024; Dale et al., 2025) shows that this is a promising architecture. By comparing different model sizes and revision configurations across the language directions included in the shared task, we find that language-specific models can improve translations produced by more general-purpose models in some settings. It is interesting to note that although the larger language-specific models produce the best revisions, the general-purpose model can still benefit from revisions made by smaller specialist models, albeit to a reduced degree. This is especially relevant for lower-resourced or morphologically rich target languages, where dedicated models may provide linguistic knowledge that complements the broader multilingual capabilities of large LLMs.

## 2 Related Work

Several approaches have been proposed to improve the performance of LLMs in machine translation. Although these approaches are often discussed separately, they are not mutually exclusive and can be combined within a single translation pipeline.

Prompt engineering methods rely on LLMs' ability to follow natural-language instructions. In MT, such instructions can specify the desired style, register, domain, target audience, or degree of structural preservation. These methods are attractive because they do not require updating the model parameters and can therefore be applied directly to general-purpose LLMs. However, prompt engineering also requires substantial experimentation, since small changes in prompt wording may lead to unpredictable changes in the final output. Despite this limitation, previous work has shown that explicitly providing information about the translation purpose and target audience can improve translation quality (Yamada, 2023).

A closely related strategy is in-context learning, also referred to as few-shot prompting (Brown et al., 2020). Instead of modifying the model parameters, this approach includes translation examples directly in the prompt, allowing the model to infer the expected translation pattern from the provided context. Prior work has shown that translation examples can steer LLM outputs and improve translation behavior (Alves et al., 2023). Be-

yond sentence-level examples, prompts can also include terminology constraints, style guidelines, or domain-specific instructions. This is particularly relevant for specialized translation tasks, where preserving terminology is often as important as producing fluent target-language text. In-context information has also been shown to help lower-resource languages, for example, through the use of loanword or terminology constraints (Ali et al., 2025).

More recently, LLMs have also been used as components of agent-based systems. This line of work has gained popularity as LLMs have become increasingly capable of instruction following, reasoning, planning, and tool use (Gao et al., 2024; Arora et al., 2023). In translation, agent-based methods enable decomposition of the process into multiple stages, with different agents responsible for distinct aspects of the workflow (Wu et al., 2024). For example, one agent may generate translation guidelines, another may enforce terminology and localization constraints, and a third may revise or proofread the output. This structure resembles professional translation workflows, where translation and revision are typically performed as separate steps.

Our methodology follows this general direction, but adopts a lightweight agent-based design. Rather than relying on a large number of interacting agents, we use a three-step pipeline composed of selection, translation, and revision. The selection step retrieves relevant terminology entries or translation examples, connecting retrieval-augmented generation with in-context learning. The translation step uses a general-purpose LLM with a large context window to produce the initial output from a terminology-enriched prompt. Finally, the revision step uses language-specific models to improve translation quality for selected target languages. In this way, the proposed STaR-MT pipeline combines concepts from prompt engineering, retrieval-augmented generation, and agent-based translation, while keeping the architecture simple.

## 3 Methodology

Our STaR-MT methodology is composed of three different steps (Figure 1):

**Selection.** The pipeline first selects the terminology entries or translation examples that are most relevant to each source sentence. We implement this selection using a reverse BM25 retrieval strategy. Rather than building the BM25 index over the translation dictionary, we index the source-language sentences that need to be translated. Each dictionary entry is then treated as a query and searched against this sentence index. If a dictionary entry ranks a given source sentence highly, the entry is considered relevant to that sentence. For each sentence, we keep the top-ranked dictionary entries according to their BM25 scores and include them in the prompt provided to the translation agent.

**Translation.** The initial translation is produced by a single LLM-based agent. This agent receives a code-switched prompt: the main instructions are written in English, while the selected terminology entries and translation examples are preserved in their original languages, as shown in Figure 2. The model is instructed to translate the input while preserving, as much as possible, the original sentence and paragraph structure.

We use a model from the Qwen 3.5 family (Qwen Team, 2026). This choice is motivated primarily by its large context window of approximately 262k tokens, which allows the model to process the long documents from Track 2 alongside retrieved terminology and translation examples without splitting the input into multiple smaller prompts. In addition, models from this family support all target languages considered in this work, including Basque, although performance for Basque is comparatively lower.

```
Using the provided term dictionary,
translate the following text from {
source_lang} to {target_lang}. The paragraph
 structure should be mantained as close as
possible to the original. You should output
only the generated translation.
Dictionay: {dict}
Text: {text}
```

Figure 2: Prompt used for the initial translation using few-shot examples and code-switching. The {dict} parameter will be replaced by either pair of words from track 1, or the translation samples from track 2. The {text} parameter contains the text to be translated from the source language.

**Revision.** The final step revises the initial translation generated by the Qwen model. For this stage, we employ language-specific models for each target language. These models were further trained by their respective teams on curated datasets. For

Basque, we use a model from the Latxa family (Sainz et al., 2025); for Polish, we use a model from the PLLuM family (Kocoń et al., 2025). English translations were revised using the Gemma 4 family only during development, as our evaluation showed that this step decreased translation quality in English, as discussed in Section 3.1.

Each revision agent uses a prompt written in the corresponding target language, ensuring that all text presented to the model is in a single language. The revision prompt was originally written in English and translated using the DeepL platform[1]. Figure 3 contains the original revision prompt in English, while Figures 4 and 5 depict the Basque and Polish versions, respectively.

```
This text was originally translated from
Chinese. Its structure and wording should be
 checked for compliance with standard {
subject} sector terminology. The structure
of the original paragraphs should be
preserved. Output only the revised version.
Text to be checked: {translation}.
```

{translation}
```

Figure 5: Prompt for the Polish revision. Note that the {subject} and the {translation} placeholders will be replaced with their respective content in Polish.

Based on the evaluation described in Section 3.1, we selected the following model configuration for the final task submissions:

- Initial translation: Qwen 3.5 27B[2]
- Basque revision: Latxa 70B[3]
- Polish revision: PLLuM 12B[4]
- English revision: none (Gemma 4 family used during evaluation only)

Even though the PLLuM 70B performed better than the 12B variant, given the time-sensitive nature of producing the final translations, we have selected the 12B variant, as it showed very similar performance with a shorter generation time. Both revision models use beam-search decoding with three beams and no sampling.

### 3.1 Evaluation

Since the shared task did not include a held-out test set, we evaluated our pipeline using the FLORES+ dataset (NLLB Team et al., 2024; Burchell et al., 2024; Dale et al., 2025). FLORES+ provides parallel evaluation data for all language pairs considered in the task, making it suitable for measuring general translation quality across the required directions. However, the dataset does not include task-specific terminology annotations or terminology constraints. Therefore, this evaluation does not measure the effectiveness of the terminology selection component described in Section 3. Instead, it focuses on the two generative stages of the pipeline: the initial translation step and the subsequent revision step.

For this evaluation, we employed the development split of FLORES+, with 997 source sentences per language direction. We evaluated the same translation directions required by the shared task: Spanish→Basque, English→Polish, and Traditional Chinese→English. For each language pair, the source sentence was translated by the initial translation model and passed to a second model for revision. The revised output was then compared against the FLORES+ reference translation.

Translation quality was measured using sentence-level chrF++ (Popović, 2017) and SacreBLEU (Post, 2018) averaged over sentences. We evaluated three variants from the Qwen 3.5 family for the initial translation: a small 9B variant, a 27B variant, and a 35B Mixture-of-Experts

Table 1: Translation quality achieved by different pipeline configurations, measured by sentence-level chrF++ and SacreBLEU averaged over sentences on the FLORES+ dataset. The t-value columns contain the results from the paired-samples t-test (997 samples), along with their respective p-values. A positive t-value represents an improvement over the unrevised translation. The highest score for each language is noted in bold.

variant with 3B active parameters. For the revision step, we experimented with two model variants for each target language, yielding 6 pipeline configurations evaluated per language. In addition to the aggregated average value for each metric, we also performed a paired-samples t-test, using the unrevised translation as the baseline, to determine whether the revisions offered any benefit to the translation. The experiments' results are shown in Table 1.

To further investigate the contribution of specialized revision models, we also include a Self-Revision (Madaan et al., 2023) configuration in Table 1. In this setting, the revision step is performed by a Qwen 3.5 27B model rather than a language-specific model, since it consistently generated the

best initial translation. This comparison allows us to distinguish between two possible sources of improvement. The first is the revision process itself, which may improve quality simply by giving the model a second chance to revise the translation with a monolingual target-language prompt. The second is the use of specialized models, which may provide additional benefits because they were trained on or adapted to the target language. If Self-Revision improves over the initial translation, this suggests that the revision setup alone is beneficial. Otherwise, this indicates that language-specific models offer additional gains.

The results reveal several relevant patterns. First, the performance of the initial translation models suggests that the number of active parameters is more important than the total parameter count alone. This can be observed by comparing the Qwen 3.5 variants used for the initial translation step. Although the 35B A3B variant has a larger total parameter count than the other evaluated models, it performs among the lowest across the tested language pairs. In contrast, the Qwen 3.5 27B model consistently achieves stronger results across the initial translation configurations. This suggests that, for this task, a dense model with more active parameters may be preferable to a larger mixture-of-experts model with fewer active parameters during inference.

Second, the revision step improves translation quality for the two lower-resource target languages when performed by specialized language models. For Spanish→Basque, the Latxa-based revision model improves the output generated by the initial Qwen translation model. Similarly, for English→Polish, the PLLuM-based revision model also increases translation quality, but to a smaller degree. It is interesting to note that for these two language pairs, both model sizes positively affected the initial translation, although the larger models showed greater improvement. This suggests that even smaller, target-language-specialized models can complement larger general-purpose models to some extent, particularly when the target language benefits from dedicated linguistic knowledge or language-specific adaptation.

The opposite trend is observed in Traditional Chinese→English translation. In this direction, revision with smaller models consistently reduces translation quality. This is likely because English is already well represented in the pretraining and instruction-tuning data for most general-purpose LLMs. As a result, the smaller revision models do not provide additional target-language expertise, introducing unnecessary edits that degrade the translation. Based on this observation, we removed the revision step for the Chinese→English direction in the final task submissions.

### 3.2 Manual evaluation on the Shared Task dataset

Since there is no evaluation split in the shared task dataset, we evaluated quality through manual inspection of samples from the generated translations (2 from the Chinese→English, 10 from Spanish→Basque, and 6 from the English→Polish) and the validation script provided by the organizers, which only validates paragraph structure. Even through this simple evaluation method, we gathered some interesting insights.

Starting with the English translations, we observed that these had the fewest issues. The only issue detected was paragraph structure when compared with the reference. As the original Chinese texts employed no line breaks and the translated text included some paragraphs to follow more standard English newspaper article conventions, the validation identified a misalignment of paragraphs, which were easily corrected by manually excluding line breaks. Content-wise, while we lack the required expertise to evaluate financial terminology, all sampled translations seemed coherent and on topic.

In the Polish translations, we noticed greater divergences from the reference texts, particularly in paragraph structure and notation styles. The first major difference we observed in the translation process was a tendency to standardize the usage of line breaks (‘\n’). While the reference texts employed a mixture of single and double ‘\n’ to differentiate between new lines and paragraphs, the translated text used a single variant: some translations used only single ‘\n’, while others used only double ‘\n’. Another noticeable change introduced by the translation process concerns paragraph headers. The reference texts appear to be book chapters or report sections, particularly those used for translations in the Medicine domain. The translation process tended to include ‘**’ markers before the numbers denoting new chapters, report sections, or document titles, whereas the reference text used only numbers. While these divergences do not cause any semantic differences in the generated translation, they could negatively affect n-gram-based auto-

matic metrics. These alterations may result from language models attempting to conform the translated text to the standards used in certain markup languages. An example of these changes is illustrated in Figure 6.

Figure 6: Example of markup notation included in the Polish translation for one of the entries from the track 1 dataset from the shared task. The top sentence fragment is from the English reference text, and the bottom is the generated Polish translation.

Finally, the Basque translation offered the biggest challenge for our pipeline. Unlike the previous languages, where line-break behavior differed from the reference text but was consistent, the behavior in the Basque translations was less predictable. We observed instances in which the translations replaced commas with line breaks, introduced semicolons to split long sentences where none existed in the reference, and made other structural changes. Besides these structural changes, we observed more concerning alterations, specifically with generation length. While we are not able to assess the fluency or grammatical quality of the Basque text, we identified several instances in which the translated texts were significantly longer than the original reference, more than could reasonably be attributed to grammatical differences between Spanish and Basque. This leads us to conclude that the models tended to expand sections of the text to include new information, which can be particularly problematic in translation. Interestingly, these anomalous behaviors were mostly observed in translations from track 1, with a single instance from track 2 (out of 5 inspected) showing a significant generation error: a word-repetition loop at the tail end of the text. These observations of error generation led us to exclude the Basque translations from our track 1 submission.

| STaR-MT (ours) | 68.6 | 44.9 |

Table 2: Track 1 results for the English-Polish language pair of the STaR-MT system, compared with similarly ranked systems and the top-performing one.

### 3.3 Shared Task overall performance

After the Shared Task submission concluded, the organizer provided us with the official results for all submitted systems. As mentioned before, we have not submitted translations for the Spanish→Basque language pair for Track 1, so we report results only for the English→Polish pair, as shown in Table 2. The Track 2 results, which include evaluations for all three language pairs, are shown in Table 3. In both tables, we have also included the results for the track's top-performing system for comparison.

When comparing only automatic quality metrics, our system performed in line with other submissions. While the final quality is lower than that of the top performer, it does not deviate from the average observed in the submitted systems, reported in Charkiewicz et al. (2026). On the other hand, our system performed poorly when evaluated using the term success metric.

Comparing the results from Tracks 1 and 2, it is possible to see that the term success rate for the English→Polish pair dropped. This drop in performance is expected, as it is easier for LLMs to leverage explicit dictionaries than for them to generalize from translation examples. Interestingly, performance across languages in Track 2 varies widely. While we have achieved less than 50% term success in English→Polish and Spanish→Basque pairs, term success surpassed 80% for the Chinese→English pair. While the root cause of this change in behavior is unclear, it may result from differences in instruction-following capabilities when targeting specific languages or from errors introduced during the revision process for lower-resource languages. In either case, this significant change in performance warrants further exploration.

| System | chrF++ | | | | Term Success (lemma) | | | |
|---|---|---|---|---|---|---|---|---|
| | Avg | enpl | eseu | zhen | Avg | enpl | eseu | zhen |
| CUNI-UFAL | 78.1 | 81.3 | 76.9 | 76.1 | 89.2 | 90.4 | 88.5 | 88.7 |
| VNFusion | 73.8 | 75.1 | 76.3 | 70.1 | 73.4 | 66.4 | 75.8 | 78.0 |

Table 3: Track 2 results for all language pairs of the STaR-MT system, compared with similarly ranked systems and the top-performing one.

## 4 Conclusion

The performance of LLMs on machine translation tasks has improved significantly in recent years (Lyu et al., 2024), but they still struggle in some settings. This is particularly the case for terminology-aware translation, where terminological consistency across long documents is critical in technical and scientific settings.

In this paper, we present our submission to the WMT 26 Terminology shared task. Our methodology adopts a lightweight agent-based design, using a three-step pipeline composed of selection, translation, and revision. The selection step retrieves relevant entries or examples. The translation step uses a general-purpose LLM with a large context window to produce the initial output from a terminology-enriched prompt. Finally, the revision step uses language-specific models to improve translation quality for selected target languages.

Overall, our results from testing the pipeline on the FLORES+ dataset suggest that machine translation pipelines can benefit from combining large, general-purpose translation models with language-specific revision models, at least for some language pairs. The large model provides strong multilingual translation capabilities and can handle long prompts, while the specialized model acts as a targeted post-editor for languages where dedicated adaptation improves fluency, adequacy, or morphological correctness. It is interesting to note that although employing larger language-specific models produces better revisions, the general-purpose model can still benefit from revisions made by smaller specialist models, albeit to a reduced degree. This effect is not universal, as shown by the Chinese→English results, but it appears to be beneficial for lower-resource or morphologically richer target languages, such as Basque and Polish.

Conversely, this pipeline style has some drawbacks. Since there is no specific step to validate the intermediate generation, errors can easily propagate downstream. Some of these error propagations were observed during the generation of the Basque translations for track 1 of the shared task. Moreover, the term success rate was significantly lower than that achieved by other participating systems. While our system performed well for the Chinese→English pair, its performance dropped considerably for the other two. Future work will focus on exploring alternative pipeline architectures to mitigate the identified errors and investigating approaches to reduce the performance gap between language pairs.

## Limitations

Due to hardware limitations, we did not evaluate the pipeline with models larger than 70B, as even with 4-bit quantization, they exceeded our memory budget. We expect that employing the larger Qwen3.5 122B A10B and 397B A17B in the initial translation could significantly improve the pipeline's final translation quality, or alter the impact of employing specialized models.

## Abstract

We describe **TARL** (Terminology-Aware Agentic Repair Loop), our submission to the WMT26 Terminology Translation Task, which targets document-level, terminology-constrained translation for morphologically rich and lower-resource directions (Spanish→Basque, English→Polish) and Traditional Chinese→English. Our system performs no fine-tuning: it is a sequential pipeline of four role-specialized LLM agents (translate, verify, review, and post-edit) in which a required target term, once inserted, is treated as locked so that later agents improve the translation around the terminology rather than altering it. Relevant glossary terms are retrieved per sentence by an exact, fuzzy $n$-gram matcher (with substring matching for CJK source), and for the sample-only Track 2 we first induce a glossary by extracting bilingual term pairs from the provided parallel data. The agents' instructions are optimized automatically with GEPA (Genetic-Pareto), an automated prompt optimization framework that uses natural language reflection and multi-objective Pareto evolutionary search to tune LLM prompts, rather than being hand-written. On the official WMT26 Track 1 evaluation, TARL attains the highest lemmatized terminology success rate of any submitted system ($95.7\%$, averaged over English→Polish and Spanish→Basque), while remaining competitive on translation quality (COMET-22: 88.3, XCOMET-XXL: 83.6). On Track 2, TARL achieves $80.4\%$ term success and 85.8 COMET-22 across three directions. A terminology-mode analysis confirms that the gains come from genuine use of the supplied dictionary rather than from instruction-following alone.

## 1 Introduction

Machine translation of specialized text often has to respect a fixed vocabulary. In domains such as medicine, law, finance, and engineering, a source term is expected to be rendered with one specific target term, and a translation that is otherwise fluent can still be unusable if it translates a term inconsistently or incorrectly. The WMT terminology translation task targets this setting: systems are given source text together with a bilingual glossary and are expected to produce translations that both read well and use the required terms (Semenov et al., 2025a).

Large language models now produce fluent translations across many language pairs, but they do not automatically follow a supplied glossary. A term may be paraphrased, inflected into a different form, or dropped, especially when the required target term does not fit naturally into the sentence the model would otherwise produce. This is the core difficulty of the task: satisfying a hard terminology constraint while keeping the translation accurate and natural.

Our submission, **TARL** (Terminology-Aware Agentic Repair Loop), addresses this difficulty entirely at inference time: we do not fine-tune any model. Instead, we treat terminology-aware translation as a short pipeline of four agents, each of which performs one narrow job: translating the sentence, making the required terms appear exactly, reviewing the result for remaining errors, and post-editing to fix those errors. The agents share a single rule throughout the pipeline: once a required target term is in place it is treated as locked, so later steps improve the translation around the terms rather than changing them. The pipeline is implemented with DSPy (Khattab et al., 2023), which lets us define each agent by its inputs, its output, and its instructions.

The task is organized into two tracks. In Track 1 the glossary is provided, so terminology is used as given. In Track 2 only parallel data is provided, so we first build a glossary by extracting bilingual term pairs from the parallel texts with an LLM, and then apply the same translation pipeline.

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1840–1848
October 28-29, 2026 ©2026 Association for Computational Linguistics

This paper describes TARL and its components. We first explain how terminology is obtained in each track and how relevant terms are retrieved for a given sentence, then describe each of the four agents in the pipeline, and how the agents' instructions are optimized with GEPA (Genetic-Pareto)(Agrawal et al., 2026), an automated prompt optimization framework. We develop and tune on the WMT25 terminology benchmark, whose document-level dictionary setting mirrors WMT26 Track 1, and we submit to the live WMT26 tracks (Charkiewicz et al., 2026). On the organizers' official WMT26 evaluation, TARL attains the highest lemmatized terminology success rate of any submitted system in Track 1 ($95.7\%$), while remaining competitive on translation quality (COMET-22: 88.3).

## 2 Related Work

**Terminology-constrained MT.** Terminology-constrained machine translation has been studied through a series of WMT shared tasks (Alam et al., 2021; Semenov et al., 2023, 2025b), which have driven progress from sentence-level constraint injection toward document-level terminology consistency. Early neural approaches enforced term constraints by training the model to copy provided translations rather than altering the decoder (Dinu et al., 2019), and evaluation converged on character-level quality metrics (Popović, 2015, 2017) alongside dedicated terminology success-rate and consistency measures (Semenov and Bojar, 2022). In the industrial localization setting, Rosa (2026) propose a multi-agent orchestration framework for terminology-constrained translation, showing that structured agent coordination can reliably enforce domain glossaries at scale. A central finding of the WMT25 edition is that an accurate dictionary helps most for already-strong systems, and that document-level terminology remains substantially harder than the near-saturated sentence-level setting (Semenov et al., 2025b).

**Systems for the WMT25 terminology task.** The strongest WMT25 entries were LLM-based and fall into a few families. One line fine-tunes or reinforcement-tunes translation models toward term adherence, including dual-stage NMT-plus-LLM post-editing (Jaswal, 2025) and GRPO-based training against a terminology-adherence reward (Garcia Gilabert et al., 2025). A second line leaves model weights fixed and works at inference time, generating multiple candidate translations and reranking them with quality and terminology metrics via Pareto-optimal decoding (Guttmann et al., 2025). A third line arranges several LLMs into a workflow in which some models translate and others revise, selecting a final output with a terminology-aware quality metric (Grubišić and Korenčić, 2025). The document-level track winner combined modular source analysis, fuzzy glossary filtering, and context-carrying chunked translation over a single swappable backbone (Ingólfsdóttir et al., 2025); our terminology-retrieval design follows its fuzzy $n$-gram matching recipe. Our submission is inference-time and fine-tunes nothing, but unlike the generate-and-select multi-agent approach of Grubišić and Korenčić (2025), our agents are *role-specialized* (translate, verify, review, post-edit) and refine a single translation sequentially rather than serving as interchangeable candidate generators.

**Multi-agent and iterative-refinement translation.** A broader line of work improves LLM outputs at inference time through a generate–critique–revise loop. Self-Refine shows a single model can iteratively critique and improve its own output without additional training (Madaan et al., 2023), and Reflexion frames verbal self-feedback as a form of reinforcement (Shinn et al., 2023). In machine translation, multi-agent systems assign specialized roles to distinct agents: TRANSAGENTS mimics a human translation company for long-form literary translation (Wu et al., 2025), TACTIC organizes cognitively-motivated agents (Li et al., 2025), and MAATS decomposes quality assessment along MQM error dimensions including terminology (Wang et al., 2025). Our four-agent pipeline follows this lineage while keeping terminology strictly locked once inserted, so downstream agents refine the translation *around* the required terms rather than altering them.

**Prompt optimization.** Rather than hand-crafting prompts, a growing body of work treats the prompt as a learnable parameter. APE frames instruction generation and selection as a black-box search over LLM-proposed candidates (Zhou et al., 2023), while OPRO uses the LLM itself as an optimizer that iteratively proposes improved prompts conditioned on past prompt–score pairs (Yang et al., 2024). DSPy (Khattab et al., 2023) generalizes this by treating an LLM pipeline as a declarative program whose modules are compiled against a

downstream metric, with MIPROv2 jointly tuning instructions and demonstrations for multi-stage programs (Opsahl-Ong et al., 2024). We optimize our agents' instructions with GEPA , a reflective, evolutionary optimizer that reflects on execution traces and natural-language feedback and evolves a Pareto front of prompt candidates, a natural fit for the task's Pareto objective of translation quality against terminology success. Because GEPA optimizes natural-language instructions rather than weights, an instruction tuned with one backbone can be executed by another; we exploit this to optimize with a smaller model and deploy on a stronger one. As an in-loop quality signal we draw on reference-free LLM-as-judge evaluation (Kocmi and Federmann, 2023).

## 3 Approaches

### 3.1 Inflection-Aware Term Anchoring

Glossary-injection techniques control which terms appear, but not the *form* they take in context. This matters for morphologically rich targets: glossary entries are given in citation form, but their use in context may require case marking, agreement, or agglutinative suffixation. We therefore add **Inflection-Aware Term Anchoring (ITA)**, a single-pass prompting technique that treats each glossary entry as a *lexical* constraint rather than an exact surface-string constraint, targeting the WMT26 grammaticality axis (Xu and Carpuat, 2021). It needs no fine-tuning, constrained decoding, or post-editing: the guidance is placed in the document-level context given to the model. The required target lexeme must appear whenever its source term occurs, with the same lexical choice kept across repetitions while the surface form varies with local grammar. The prompt makes this explicit for the target language: it states that entries are citation forms, summarizes the language's case and affixation system and the contexts that trigger each form, and asks the model to inflect the head of a multi-word term while keeping agreement. ITA only affects output on morphologically rich targets. Analytic languages such as Chinese do not inflect glossary terms for case or agreement, so ITA reduces to plain exact-match term injection there. Chinese thus cannot distinguish ITA from a term-injection baseline on the grammaticality axis. We therefore treat ITA as a targeted contribution for morphologically rich targets and use the agentic pipeline (§3.2) as our primary, language-agnostic system for evaluation.

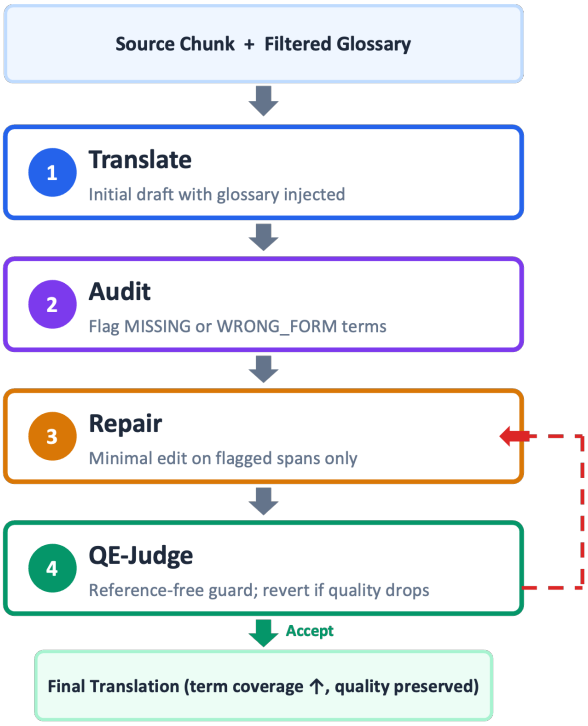

Figure 1: The four-agent terminology-aware translation pipeline. Each source chunk, together with its filtered glossary, passes through Translation, Terminology Verification (Audit), Reviewer, and Post-Editor (Repair) agents; a reference-free quality gate reverts a repair if it degrades quality. Required terms are locked once inserted, so later agents refine the surrounding text without altering them.

### 3.2 TARL: Agentic Terminology-Aware Translation

We approach terminology-aware translation as a pipeline of four agents that run in sequence (Figure 1). Each agent handles a specified task in the pipeline. The first agent produces a translation, the second makes sure the required terms are present, the third looks for remaining errors, and the fourth fixes those errors. The output of one agent is passed as input to the next. All four agents are implemented with the DSPy framework.Before the pipeline runs, we retrieve the terminology that applies to each source sentence and pass it to the translation agent as a list of source-to-target term pairs.

#### 3.2.1 Terminology Retrieval

For each source sentence we look up which glossary terms it contains and build a list of (source term, target term) pairs. Retrieval is exact-match and does not use the language model. We support

two matching strategies depending on the language:

- For space-delimited languages (for example English, Spanish, Polish), we tokenize the sentence on whitespace, generate $n$-grams up to a fixed length, and keep any $n$-gram that matches a glossary key exactly. Longer matches are preferred over shorter ones, and matched spans are not allowed to overlap.

- For CJK languages (Chinese, Japanese, Korean), where text has no spaces, we match glossary keys directly as substrings of the source sentence. Longer keys are tried first so that more specific terms take priority, and matched spans are again kept non-overlapping.

When a source term maps to more than one target term, we use the first one. The result is an ordered list of term pairs formatted as "source → target", which is the form the agents receive.

#### 3.2.2 The Four Agents

Each agent receives the source sentence and the retrieved terminology pairs, andthey run in sequence (Figure 1). The **Translation Agent**produces an initial translation that is fluent and accurate and uses each exacttarget term without paraphrasing it. The **Terminology Verification Agent**then makes minimal edits so that every required target term appears verbatim,driving the Term Success Rate toward 1.0 while preserving meaning and fluency.The **Reviewer Agent** inspects the result for remaining problems(mistranslations, omissions, grammatical errors) but treats the required terms as*locked*: it may only flag issues that do not involve them, and reports noneif every issue would require touching a locked term. Finally, the**Post-Editor Agent** applies the reviewer's fixes to produce the finaltranslation, again keeping every required term exactly as-is; terminologycompliance takes priority over other corrections.

### 3.3 Terminology Extraction for Track 2

Track 1 supplies a glossary as input; Track 2 gives only parallel data (source documents and their human translations). For Track 2 we therefore build the glossary ourselves before any translation takes place.We process one parallel pair at a time, prompting the LLM (Claude on Amazon Bedrock, temperature 0) with both texts and asking for the domain-specific term pairs it finds. The prompt names the domain and both languages, and requires the model to keep only domain-specific or technical terms, named entities, and multi-word terms of art (skipping generic and function words); to copy the source and target terms verbatim from their respective texts, preferring base forms and excluding surrounding punctuation or articles; and to invent nothing absent from either text. Responses are returned as a JSON array of source/target objects and parsed; pairs are processed in parallel across the corpus with a thread pool.Each pair is then validated with a loose case-insensitive substring check against the corresponding text, discarding hallucinated or reformulated terms. Surviving pairs form a glossary mapping each source term to the set of target terms observed for it.The glossary optionally passes through two filters shared with our word-alignment extraction pipeline, so both extractors produce comparable output: a *noun-phrase filter*, which POS-tags source terms with Stanza and keeps only noun phrases (a noun or proper noun with a nominal head), dropping verb-only entries; and a *deduplication filter*, which removes a shorter term subsumed by a longer term with the same target and merges source terms sharing an identical target set.The result is written in the provided-glossary format, so the rest of the pipeline treats both tracks identically from this point on.

## 4 Experimental Setup

**Data.** We report official WMT26 Terminology Shared Task (Charkiewicz et al., 2026) scores. *Track 1* supplies a bilingual dictionary and covers English→Polish (medical, mechanical-engineering) and Spanish→Basque (automotive, energy). *Track 2* provides only sample parallel bitexts and adds Traditional Chinese→English (finance). All data is document-level. We tuned on the WMT25 release, whose dictionary setting mirrors WMT26 Track 1.

**Terminology modes.** Track 1 is evaluated under PROPER (correct dictionary), RANDOM (decoy dictionary), and NOTERM (no dictionary); Track 2 under SAMPLE (with bitexts) and NOTERM. The PROPER−NOTERM contrast isolates the causal effect of terminology; RANDOM detects blind term insertion.

**Metrics.** Five metrics are reported: document-level chrF++ (Popović, 2017); lemmatized exclusive term success rate (TSR, %); and three

**Track 1** (PROPER mode: en→pl, es→eu)

| | NOTERM | 68.1 | 73.2 | – |

Table 3: **Track 2** mode analysis: with sample bitexts (SAMPLE) and without (NOTERM).

neural metrics on aligned segments—COMET-22, XCOMET-XXL, and MetricX-24 XL (↓). Systems are ranked by Pareto domination over (chrF++, TSR) per direction (Semenov et al., 2025b).

**Configurations.** We submit two configurations, both using Claude Opus on Amazon Bedrock with no fine-tuning: **TARL** (hand-tuned prompts) and **$\text{TARL}_{\text{GEPA}}$** (prompts optimized with GEPA (Agrawal et al., 2026) against a combined quality-plus-terminology objective). Both run on Track 1 and Track 2; for Track 2 the glossary is induced from parallel data (§3.2). In the tables, *gold* is the reference ceiling. Neural metrics for $\text{TARL}_{\text{GEPA}}$ are unavailable as they are computed exclusively through the WMT26 portal scorer API.[1]

## 5 Results

Table 1 reports the main metrics; Tables 2–3 the mode analyses.

**Terminology adherence.** On Track 1 (Table 1), TARL achieves 95.7% lemmatized term success—the highest of any submitted system, ahead of $\text{COZY}_{\text{flash}}$ (95.4%) and HW-TSC (95.3%)—consistent across morphologically rich en→pl (95.4%) and surface-transparent es→eu (96.0%). The locked-term invariant prevents downstream agents from paraphrasing required terms. On Track 2, TARL reaches 80.4%, strongest on zh→en (85.5%, near the gold ceiling of 86.3%). $\text{TARL}_{\text{GEPA}}$ improves both axes on Track 2: term

[1] $\text{TARL}_{\text{GEPA}}$ was evaluated locally with the released `wmt26-terminology` toolkit, which computes chrF++ and lemmatized term success but not the neural metrics.

success rises to 86.7% (+6.3) and chrF++ to 74.8 (+1.1), indicating optimized instructions help most on the harder glossary-induction setting. On Track 1 the trade-off reverses: chrF++ rises (75.8 vs. 75.3) but term success dips slightly (94.1% vs. 95.7%).

**Quality cost.** TARL's COMET-22 of 88.3 on Track 1 is within 1 point of the leaders COZY and CUNI-UFAL (89.2), and its XCOMET-XXL (83.6) and MetricX (3.92) are mid-pack. The quality cost of term-locking is modest, placing TARL on the chrF++/TSR Pareto frontier that the task ranks on.

**Causal check.** On Track 1 (Table 2), TARL's term success jumps from 68.6% (NOTERM) and 66.8% (RANDOM) to 95.7% (PROPER)—a 27-point gain attributable only to the supplied dictionary. The small RANDOM–NOTERM gap (1.8 pts) confirms no blind insertion. $\text{TARL}_{\text{GEPA}}$ shows the same pattern (69.3/68.2→94.1). On Track 2, sample bitexts lift TARL from 68.7% to 80.4% and $\text{TARL}_{\text{GEPA}}$ from 68.1% to 86.7%, while noterm baselines stay comparable—confirming GEPA affects glossary *use*, not baseline quality (Semenov et al., 2025b).

## 6 Conclusion

We presented **TARL**, our submission to the WMT26 Terminology Translation Task: a fine-tuning-free system that treats terminology-aware translation as a short pipeline of four role-specialized LLM agents (translate, verify, review, and post-edit) in which a required target term, once inserted, is locked so that later stages refine the translation around the terminology rather than altering it. Relevant terms are selected per sentence by an exact fuzzy $n$-gram retriever (with substring matching for CJK source), and for the sample-only track we induce a glossary from the provided parallel data before translating. The agents' instructions are optimized automatically with GEPA (Genetic-Pareto) against a combined quality-plus-terminology objective rather than being hand-written. On the official WMT26 Track 1 evaluation, TARL attains the highest lemmatized terminology success rate of any submitted system (95.7% on average), while remaining competitive on translation quality (COMET-22: 88.3). On Track 2, GEPA-optimized prompts improve both term success (86.7% vs. 80.4%) and chrF++ (74.8 vs. 73.7), demonstrating that automated prompt optimization is particularly effective when the task is hardest. A mode analysis confirms the gains come from genuine use of the supplied dictionary rather than from instruction-following alone.

## A Agent Prompts

This appendix documents the DSPy signatures (instructions and field descriptions) for each of the four agents in the agentic terminology-aware translation pipeline.

### A.1 Agent 1: Translation Agent

**Instruction:**

> You are a professional translator. Translate the source sentence from the source language into the target language with the following strict requirements:
>
> 1. **TRANSLATION**: Produce a fluent, natural, and grammatically correct translation in the target language that preserves the full meaning of the source sentence.
> 2. **TERMINOLOGY ADHERENCE**: You MUST use the exact target terms from the provided terminology pairs wherever the corresponding source term appears in the sentence. Do NOT paraphrase, substitute, or modify these terms. This is a strict requirement.
> 3. **QUALITY**: The translation must be high-quality, idiomatic, and read naturally to a native speaker of the target language. Do not produce literal or awkward translations.
> 4. **LANGUAGE**: The entire output MUST be in the target language. Do NOT leave any words in the source language except for the required terminology terms.

**Input Fields:**

- `source_sentence`: The source sentence to translate.
- `source_language`: The language of the source sentence.
- `target_language`: The language to translate into.
- `terminology_pairs`: Terminology pairs (source → target). You MUST use these exact target terms in your translation when the source term appears in the sentence.

**Output Field:**

- `translation`: The high-quality translated sentence in the target language that strictly incorporates all applicable terminology.

### A.2 Agent 2: Terminology Verification Agent

**Instruction:**

> You are a terminology compliance editor. Your task is to edit the given translation so that the required target terminology terms appear EXACTLY as-is in the translation.
>
> Rules:
>
> 1. For each terminology pair provided, the TARGET term MUST appear verbatim in the edited translation.
> 2. Make MINIMAL edits to the translation — only change what is necessary to include the exact target terms.
> 3. Preserve the overall meaning and fluency of the translation as much as possible.
> 4. Do NOT add, remove, or change content beyond what is needed for terminology compliance.
> 5. If a target term already appears correctly in the translation, leave it unchanged.

**Input Fields:**

- `translation`: The initial translation that may not contain all required terminology.
- `source_sentence`: The original source sentence for context.
- `terminology_pairs`: Required terminology pairs (source → target). Each target term MUST appear exactly as-is in the output.

**Output Field:**

- `edited_translation`: The edited translation where ALL required target terms appear verbatim. TSR (Term Success Rate) must be 1.0.

### A.3 Agent 3: Reviewer Agent

**Instruction:**

> You are a professional translation reviewer. Analyze the translation for inaccuracies, errors, or quality issues.
>
> Rules:
>
> 1. Compare the translation against the source sentence for semantic accuracy.
> 2. Check for mistranslations, omissions, additions, or grammatical errors.
> 3. **CRITICAL CONSTRAINT**: You MUST NOT suggest any changes to the required terminology terms listed in the terminology pairs. These terms are LOCKED and cannot be modified, rephrased, inflected differently, or removed under any circumstance — even if they appear grammatically awkward.
> 4. Only suggest changes to parts of the translation that do NOT involve the required terminology terms. Everything else (word order, non-terminology vocabulary, grammar of surrounding words, style) is fair game.
> 5. If the only issues you find involve the required terminology, state 'No actionable issues found.' since those terms cannot be changed.
> 6. Be specific and actionable in your feedback — clearly state what can be changed and confirm that terminology must remain untouched.

**Input Fields:**

- `source_sentence`: The original source sentence.
- `translation`: The current translation to review.
- `terminology_pairs`: Required terminology pairs (source → target). The TARGET terms are LOCKED — you MUST NOT suggest changing, inflecting, or removing them.

**Output Field:**

- `review`: Review listing issues that can be fixed WITHOUT touching the required terminology terms. State 'No actionable issues found.' if all issues involve locked terminology.

### A.4 Agent 4: Post-Editor Agent

**Instruction:**

> You are a professional translation post-editor. Fix the identified inaccuracies in the translation while STRICTLY maintaining terminology compliance.
>
> Rules:
>
> 1. Address the issues identified in the review.
> 2. NEVER remove, modify, or paraphrase any of the required target terminology terms. TSR must remain 1.0.
> 3. Improve fluency, accuracy, and naturalness where possible.
> 4. If fixing an issue would require changing a required terminology term, do NOT fix that issue — terminology takes absolute priority.
> 5. The output must be the final, polished translation.

**Input Fields:**

- `translation`: The current translation with potential inaccuracies.
- `source_sentence`: The original source sentence for reference.
- `terminology_pairs`: Required terminology pairs (source → target). These MUST appear exactly as-is in the output — never modify them.
- `review`: Review feedback identifying inaccuracies to fix.

**Output Field:**

- `final_translation`: The corrected translation that fixes inaccuracies while strictly preserving all required terminology terms.

# CUNI-ÚFAL at the WMT26 Terminology Translation Task

**Aleš Manuel Papáček and Tomáš Sourada**

{papacek,sourada}@ufal.mff.cuni.cz

## Abstract

This paper describes the CUNI-ÚFAL submission to the WMT26 Terminology Translation Task. We present a model-agnostic pipeline that selects document-relevant terminology for a general-purpose LLM, instantiated with GPT-5.6-Sol for both tracks. For Track 1 (explicit dictionary) we compare glossary placement, inline annotation, dictionary filtering, and terminology-aware revision: filtering the dictionary per document improves judged coverage and, slightly, translation quality. Inline term insertion buys a small coverage gain at the cost of fluency. For Track 2 (in-domain seed bitexts) we compare presenting them as translation history, extracting a dictionary and reusing the Track 1 pipeline, and their hybrid. Lacking development references, we evaluated with surface- and lemma-based term matching plus an LLM judge. Among submitted systems in the official evaluation, our Track 1 submission ties for the highest COMET-22 score and obtains the best XCOMET-XXL and MetricX-24 XL scores, and our primary Track 2 submission achieves the highest term success.

## 1 Introduction

The WMT26 Terminology Translation Task (Charkiewicz et al., 2026) studies document-level machine translation in specialized domains. Track 1 provides an explicit bilingual terminology dictionary, whereas Track 2 provides in-domain seed bitexts that can be used to infer relevant terminology.

The WMT24 General Translation Task findings described machine translation as entering the LLM era (Kocmi et al., 2024); by WMT25, most participants used LLMs (Kocmi et al., 2025). The trend also appeared in the WMT25 Terminology Translation Task (Semenov et al., 2025). We therefore design a model-agnostic pipeline for general-purpose LLMs rather than rely on a translation-specific architecture. Under our budget, we compare approaches with the relatively inexpensive Gemini 2.5 Flash (Google DeepMind, 2025) and use the stronger, newer GPT-5.6-Sol (OpenAI, 2026) for the final submissions.

For Track 1, we study how to present a potentially large bilingual dictionary to an LLM. We compare filtering and prompt placement strategies, and test a multistep variant in which a separate model flags terminology errors for the translation model to revise.

For Track 2, the main question is whether a general-purpose LLM can infer and apply relevant terminology from seed bitexts alone, without an explicit dictionary. We compare presenting the seed pairs directly to the model as a translation history, extracting a dictionary from them and reusing the Track 1 pipeline, and a hybrid of both.

## 2 Related Work

Terminology constraints can be enforced during decoding or supplied as model input. Dinu et al. (2019) trained an NMT system to apply runtime glossary constraints, avoiding the overhead and brittleness of constrained decoding. For morphologically rich translation, Jon et al. (2021) found that agreement errors accounted for almost half of the errors from a constrained English–Czech baseline and showed the benefit of input-side guidance. Bogoychev and Chen (2023) similarly annotated source terms and applied LLM refinement after detecting constraint violations. We also use input-side guidance, but filter the glossary per document and use off-the-shelf LLMs without fine-tuning.

Recent WMT systems combine LLMs with terminology selection, extraction, or post-editing. Ingólfsdóttir et al. (2025) select relevant glossary entries and include dictionary lookup results in an LLM prompt. For the WMT25 document-level evaluation, Semenov et al. (2025) use GPT-4o to extract bilingual terminology from document pairs.

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1849–1859
October 28-29, 2026 ©2026 Association for Computational Linguistics

Jaswal (2025) combine terminology-aware NMT with LLM post-editing, whereas Garcia Gilabert et al. (2025) optimize terminology adherence and translation quality through Group Relative Policy Optimization (GRPO). In contrast, our Track 2 experiments compare direct use of seed bitexts, glossary extraction, and their hybrid without model training.

## 3 Task and Data

We summarize below the parts of the setup our system depends on; Charkiewicz et al. (2026) give the full task description, data statistics, and evaluation protocol.

Track 1 provides an explicit dictionary and requires translations in three modes: without terminology (`noterm`), with the domain dictionary (`proper`), and with a random dictionary (`random`). The `random` dictionary has the same format but holds words drawn at random from the input texts rather than domain terms. Track 1 covers Spanish–Basque (Es–Eu) in the automotion and energy domains, and English–Polish (En–Pl) in mechanical engineering and medical.

Track 2 provides in-domain seed bitexts instead of a dictionary and has two modes: `sample`, with seed bitexts, and `noterm`, without. It covers five domains over three language pairs: En–Pl in the same two domains as Track 1, Es–Eu in machine tools and railways, and Traditional Chinese–English (Zh–En) in finance.

The released data contains 87 Track 1 documents and 129 Track 2 documents. Across the Spanish–Basque and English–Polish datasets, the mean document lengths range from approximately 1,000 to 1,800 words. Track 2 contains much larger outliers, including a 16,549-word Spanish railway document.

## 4 System Description

Our model-agnostic pipeline sends each complete document, translation instructions, and mode-specific terminology resources to an LLM. Figure 1 summarizes both tracks. The implementation is available at `https://github.com/ampapacek/wmt26-terminology-mt`, with further details and prompts in Appendices A and C.

### 4.1 Track 1

**Dictionary Prompting.** For the `proper` and `random` modes, the system first identifies dictionary source terms that occur in the current document. We use Stanza (Qi et al., 2020) to lemmatize both the source document and each dictionary source term. An entry is selected when either its surface tokens or its lemma sequence occurs as a contiguous whole-token span in the document. Only the selected entries are then shown to the LLM, including all acceptable target options provided by the task.

Our default prompt places the filtered dictionary before the source document. We compare it with placing the dictionary after the document and inserting source–target annotations directly into the source text. In the inline variant, a matched span is rendered, for example, as ⟪`Turbinas eólicas [dict: turbina eólica] -> haize-sorgailu`⟫. This keeps the inflected source form while also showing its dictionary entry and prescribed target at the point where it occurs.

We test three diagnostic variants: merging the `proper` and `random` dictionaries, adding the other domain's dictionaries for the same direction, and supplying the complete mode-specific dictionary without document filtering. The first two test robustness to larger, noisier resources. The third isolates the contribution of per-document selection and is also relevant to potentially noisy Track 2 dictionaries.

**Document Structure Validation.** The official validator requires the output to preserve the source structure, treating blank-line-separated text as paragraphs and otherwise counting individual lines. We state the expected count in the prompt and verify it after generation. Mismatches trigger up to two whole-document retries, remaining failures are translated in batches of at most 25 paragraphs and reassembled with the original delimiter. For the weaker models, a little over 10% of documents needed repair, and some of those reached the batched fallback, whereas GPT-5.6-Sol needed it for about 1% of documents, all of which were resolved on the first retry.

**Judge-Gated Terminology Revision.** The complete Track 1 pipeline works as follows: After the initial translation, deterministic surface and lemma matchers check the output. An LLM from a different model family then examines only the terms not detected by either matcher and determines whether the translation contains a valid inflected form, an incorrect translation, or a genuinely missing term. If no revision is performed, these judgments are used

to compute the final judged coverage (Section 5.3).

In the optional revision phase, the translation model receives the source document, its initial translation, the same filtered dictionary used during the first phase, and the issues identified by the judge. It is instructed to correct the terminology while leaving the remainder of the translation unchanged.

### 4.2 Track 2

Track 2 provides seed bitexts rather than an explicit dictionary. We build three systems from them: (1) *end-to-end*, which shows the seed bitexts as a multi-turn translation history, (2) *dictionary*, which extracts a dictionary from them and then runs the Track 1 pipeline, and (3) *hybrid*, which does both. The three share the same `noterm` configuration, because they differ only in how they use the seed bitexts.

Document structure validation (Section 4.1) is applied unchanged, with the seed history carried along on every retry.

**End-to-End Translation.** Selected seed pairs form a multi-turn conversation: each source is a `user` turn, its gold translation the next `assistant` turn, and the document the final `user` turn. We cap this history at 80,000 source-plus-target characters per document[1]. All pairs fit in four of the five domains and are shown in file order. The exception is `finance.zhen` (Traditional Chinese → English translation), whose 15 seed pairs are document-level bitexts with essentially zero verbatim overlap with the test documents, so we first re-align them into sentence pairs with a length-based dynamic-programming alignment (Gale and Church, 1993). Under the budget, pairs are then ranked by IDF-weighted cosine overlap between the seed source and the document for translation (character bigrams for Chinese, IDF estimated over that domain's own document collection) and selected greedily, but still presented to the model in corpus order. Two alternatives scored slightly worse on a small random subset and were not adopted: placing the most relevant pair immediately before the document, and ignoring the character budget entirely (which affected only `finance.zhen`).

When a seed source occurs verbatim in the document, the system prompt additionally asks the model to reuse its approved translation. For more details on the prompt, see Appendix C.4.

[1]The threshold was selected ad hoc

**Extract Dictionary, Then Apply Track 1 Pipeline.** As an alternative, we extract a dictionary from the seed bitexts and translate with the Track 1 pipeline.

The term dictionary is obtained by prompting an LLM[2] once per seed pair (once per ten aligned sentence pairs for `finance.zhen`), asking for both the source and target term in citation form (singular, dictionary form, no case or agreement marking) together with the verbatim source span the term was taken from. The verbatim span is checked against its sentence and used to drop hallucinated entries; a frequency-based check additionally repairs entries whose key turns out to be written in the target rather than the source language, and duplicate entries are merged by surface form and lemma.

The dictionary is extracted with the same model that then translates with it, and is consumed by the Track 1 pipeline; the seed bitexts themselves are not shown to the translation model in this mode (prompt in Appendix C.5).

**Hybrid.** The hybrid system combines both: the document is translated with the end-to-end prompt described in Section 4.2, and the extracted dictionary's glossary block is appended to that prompt's system message, so the model sees the seed pairs as conversation history and the terms of the current document as an explicit glossary at the same time.

## 5 Experimental Setup

### 5.1 Track 1

**Models and Variants.** We use Gemini 2.5 Flash (Google DeepMind, 2025) for the controlled comparison of Track 1 prompt variants, so that each experiment changes the terminology presentation while keeping the translation model fixed. We then compare the chosen default configuration for Gemini 2.5 Flash, Gemma 4 31B (Google DeepMind, 2026), and GPT-5.6-Sol.

**Primary System.** Our final Track 1 submission uses GPT-5.6-Sol (OpenAI, 2026) with temperature 0.2 and medium reasoning effort. It translates each document in one pass using the document-filtered dictionary placed before the source text. We do not apply the optional revision phase to the submitted output. We mark the submission by the identifier `cuni-ufal-gpt-56-sol`.

[2]We have also experimented with non-LLM extraction, but in preliminary experiments it led to worse results than the LLM extraction

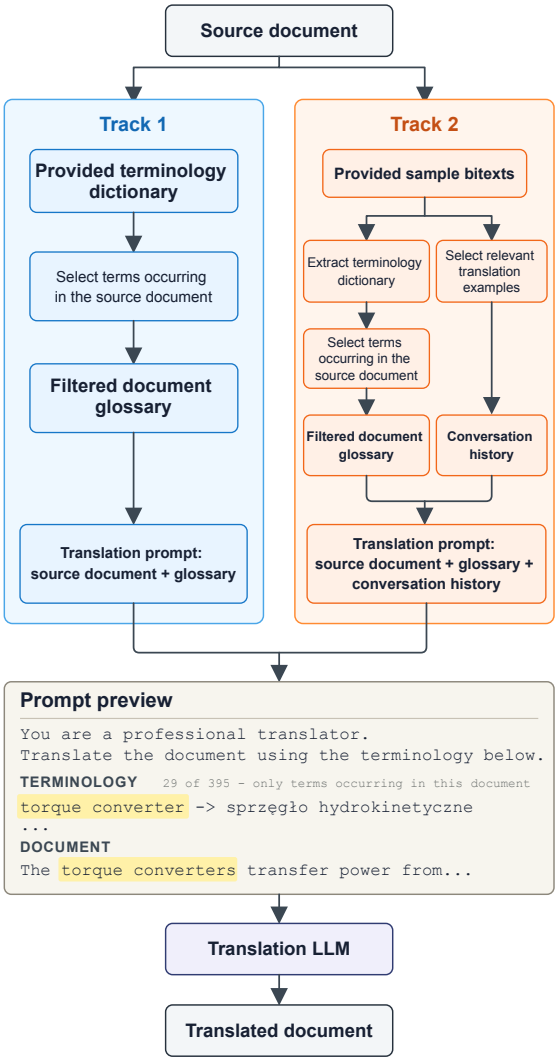

Figure 1: Overview of our primary Track 1 and Track 2 (hybrid) translation pipelines. The dictionary extraction in Track 2 is done with an LLM.

### 5.2 Track 2

**Models and Systems.** As in Track 1, we first compared the three systems on Gemini 2.5 Flash and only then verified them on the submission model, GPT-5.6-Sol.

**Primary System.** Based on the development-stage comparison (Section 6), we submit all three systems on GPT-5.6-Sol at temperature 0.2 and medium reasoning effort, each using the seed budget and dictionary-extraction mode selected on the development model: end-to-end with the default 80,000-character seed budget (`cuni-ufal-gpt-56-sol-e2e`), dictionary, extracted with an LLM (`cuni-ufal-gpt-56-sol-dict-llm`), and hybrid (`cuni-ufal-gpt-56-sol`), which is our primary Track 2 submission (sharing the primary Track 1 identifier); end-to-end and dictionary are submitted as contrastive systems.

### 5.3 Reference-Free Evaluation

The task provides no development references, so we cannot compute reference-based translation metrics locally and instead use three complementary measurements. *Surface recall* checks whether any allowed target option occurs as a contiguous whole-token sequence. *Lemma recall* lemmatizes both the translated text and the dictionary target options before applying the same matching rule, using the same Stanza-based procedure as for source-side filtering with the corresponding Basque and Polish models. *Judged coverage* then combines these deterministic matches with inflected forms confirmed by an LLM judge, DeepSeek V4 Pro (DeepSeek-AI, 2026), which reviews only the terms neither matcher found. Judged coverage is our main terminology measure; we reserve *term success* for the official metric.

The judge also scores each document on a 1–5 scale: fluency and adequacy in Track 1, and fluency, adequacy, and terminology consistency in Track 2, where there is no dictionary to match against. In Track 2 it additionally lists the terminology problems it found, and for the four Es–Eu and En–Pl domains the gold translations of any seed sentences occurring verbatim in the document are attached as terminology evidence.

Surface recall is low for all systems because both target languages inflect heavily, and it should not be read as a quality measure on its own. It is informative in combination with lemma recall. A system whose surface recall is close to its lemma recall is reproducing dictionary forms as written rather than adapting them to context, which in a morphologically rich target language usually indicates an error.

Track 1 terminology metrics are micro-averaged over all required document–term pairs and judge scores averaged over documents; because the four domain–direction subsets range from 6 to 41 documents, this weights each subset by the amount of data it contributes. Track 2 scores are macro-averaged over the five domains, with failed judge calls excluded from the mean.

The judge is not deterministic. Four Track 2 `sample` files were judged twice on byte-identical input, as a by-product of a comparison that changed only `finance.zhen`. The repeated scores agree to

| Variant | Surf. | Lem. | Cov. | Flu. | Adeq. |
|---|---|---|---|---|---|
| No terminology | .394 | .658 | .764 | 4.26 | 4.39 |
| Default | .645 | .894 | .973 | 4.37 | **4.49** |
| Text first | .654 | .898 | .972 | **4.39** | 4.38 |
| Inline | **.700** | **.904** | **.983** | 4.08 | 4.18 |
| Proper + random | .618 | .889 | .967 | 4.32 | 4.38 |
| All dictionaries | .609 | .874 | .959 | 4.24 | 4.39 |
| No filtering | .585 | .843 | .930 | 4.29 | 4.32 |
| Revision: errors only | .568 | .837 | .924 | 4.25 | 4.28 |
| Revision: glossary + errors | .642 | .900 | .974 | 4.38 | **4.49** |

Table 1: Reference-free Track 1 results for prompting variants in the `proper` condition. Surf., Lem., and Cov. denote surface recall, lemma recall, and judged coverage, micro-averaged over the 2,477 required document–term pairs; Flu. and Adeq. are judge scores on a 1–5 scale, averaged over the 87 documents. The first row is the `noterm` baseline, scored against the same dictionary.

within 0.06 on the two largest domains but differ by up to 0.29 on `mechanical-engineering.enpl` (7 documents) and `medical.enpl` (6). We therefore treat per-domain differences below 0.3 on those two domains as noise and rank systems by the macro-average.

These measurements are development proxies, not reproductions of the official evaluation, which reports document-level chrF++, exclusive lemmatized term success, and COMET-22, XCOMET-XXL, and MetricX-24 XL on aligned segments, aggregated by file and direction. Judged coverage is closest to official term success, but our deterministic matching and LLM adjudication differ from the official *exclusive* matching, in which each target-term occurrence is credited to at most one source occurrence.

## 6 Results and Analysis

### 6.1 Track 1

**Selecting the Prompt Configuration.** We first use Gemini 2.5 Flash in the `proper` condition to select the terminology-prompting configuration. Table 1 compares dictionary placement, inline insertion, dictionary selection, and revision variants. Across the four files, the evaluation contains 2,477 required document–term pairs. Supplying a filtered dictionary raises judged coverage from .764 to .973. Inline annotations produce the highest surface and judged coverage, but receive lower fluency and adequacy scores. Changing whether the dictionary appears before or after the document produces nearly identical scores.

We experiment with additional settings, *Proper + random* joins the `proper` and `random` dictionaries within a single domain. *All dictionaries* joins both domains and both modes. Both still apply the document-level filter before the glossary reaches the LLM, *no filtering* setup omits it. The `proper` dictionaries contain 374–761 entries, and the `random` dictionaries 642–816, of which 18.8–64.3 and 111.7–313.9, respectively, remain per document on average after filtering. Across all document prompts, filtering retained 20.8% of the random-dictionary entries, compared with 4.2% of the proper-dictionary entries, consistent with the random dictionaries containing more broadly occurring terms.

Removing the filter reduced judged coverage in every file: by 1.8–6.7 percentage points for the proper dictionaries and 1.0–3.2 points for the random dictionaries. Fluency and adequacy changed only slightly and without a consistent direction. These results suggest that filtering helps the model focus on terminology relevant to the current document.

**Terminology-Aware Revision.** Both revision variants receive the source, initial translation, and judge-identified errors. The *errors only* variant includes only flagged terms, whereas *glossary + errors* retains the original filtered glossary. The former reduced judged coverage from .973 to .924 by changing some correct terms; the latter restored it to .974 but did not improve on the initial translation. Revision therefore provides little benefit for already strong translations.

**Selected Configuration.** Based on these experiments, we select the document-filtered dictionary placed before the source document and do not apply revision. A comparison of this configuration across models and an analysis of document-level terminology consistency are provided in Appendix B.

### 6.2 Track 2

Our reference-free comparison preferred the end-to-end system with Gemini 2.5 Flash, whereas the hybrid received the highest terminology-consistency score with GPT-5.6-Sol. The full comparison is reported in Appendix B.

### 6.3 Official Results

Table 2 reports the official main-metric results for our submissions, as computed by the task organizers (Charkiewicz et al., 2026). In Track 1, the

| System | Term | chrF++ | COMET | XCOM. | MX ↓ |
|---|---|---|---|---|---|
| *Track 1: proper* | | | | | |
| Primary | 93.4 | 74.4 | 89.2 | 85.9 | 3.55 |
| *Track 2: sample* | | | | | |
| Hybrid (primary) | 89.2 | 78.1 | 88.7 | 86.0 | 3.22 |
| End-to-end | 87.1 | 78.1 | 88.9 | 86.5 | 3.14 |
| Dictionary | 89.0 | 74.9 | 88.5 | 85.9 | 3.25 |

Table 2: Official main-metric results for our Track 1 `proper` and Track 2 `sample` submissions. Term is exclusive lemmatized term success (%). XCOM. and MX denote XCOMET-XXL and MetricX-24 XL. Higher is better except for MetricX-24 XL.

primary system obtains 93.4% term success, ties for the highest COMET-22 score, and obtains the best XCOMET-XXL and MetricX-24 XL scores among submitted systems. Compared with the `noterm` condition, the proper dictionary improves term success by 22.1 percentage points, chrF++ by 1.3 points, and COMET-22 by 0.6 points. The random condition does not improve term success against the proper dictionary (69.3% versus 71.3% for `noterm`).

In Track 2, the primary hybrid system achieves the highest submitted term success, at 89.2%. The end-to-end contrastive system has lower term success but slightly better neural scores, indicating a small terminology–quality trade-off. Relative to `noterm`, seed bitexts improve the hybrid by 15.5 term-success, 4.7 chrF++, and 1.2 COMET-22 points.

## 7 Illustrative Downstream Use Case

Terminology-aware translation can also support multilingual retrieval. In the CZDEMOS4AI project, Czech user queries are translated for retrieval from an English-language collection on digital addictions. For the query *Hraní her*, general-purpose MT translated it as *gambling*, whereas translation aligned with the collection terminology used *gaming*. In this example, the relevant document ranked first with the collection-aligned query, compared with seventh and outside the context passed to the generation model with the general translation.

## 8 Conclusion

We presented a model-agnostic prompting system for both tracks of the WMT26 Terminology Translation Task. Across both tracks, a general-purpose LLM follows terminology well when the terminology it is shown is filtered to the current document. Our Track 1 submission achieves the strongest or joint-strongest neural scores among submitted systems, and our Track 2 hybrid the highest term success. In both tracks terminology information also improves chrF++ and COMET-22.

## Limitations

- **Evaluation.** Our development evaluation is reference-free, using neither an established quality-estimation metric nor human validation of the judge; we therefore cannot report human agreement (including for Basque) or precision and recall for terminology adjudication, and a target-term occurrence may occasionally be attributed to the wrong source occurrence. A different model family reduces direct self-preference but not evaluator bias, and we did not systematically measure judge stability, so we report deterministic matches separately and treat small judge-score differences as noise.
- **Generality.** We test few models with one shared prompt, without model-specific tuning. Most comparisons use Gemini 2.5 Flash and may not transfer to other models.
- **Revision.** The same judge identifies revision issues and scores the revised output, potentially favouring revision; these rows are therefore not directly comparable to the others.

## AI usage statement

**Research code.** A substantial part of the experimental code base was written with Claude Code during July 2026, working from task descriptions, design decisions, and review comments provided by the authors. The authors specified what each component should do, reviewed the generated code, and are responsible for its correctness; the design decisions the code implements are the authors' own and are documented in the paper.

**Writing.** Parts of the manuscript were drafted with Claude Code from the authors' notes, logs, and result files, then checked and edited by the authors, who take full responsibility for all content, claims, and numbers.

## Acknowledgments

This work was supported by the project "Human-centred AI for a Sustainable and Adaptive Society" (reg. no.: CZ.02.01.01/00/23_025/0008691),

co-funded by the European Union, and partially by the SVV project number 260 821. ## A Implementation and Reproducibility

All LLM calls were made through the OpenRouter v1 API in July 2026. We used the models (ID on OpenRouter) google/gemini-2.5-flash, google/gemma-4-31b-it, openai/gpt-5.6-sol, and deepseek/deepseek-v4-pro for evaluation. Translation used temperature 0.2 and a default output limit of 32,000 tokens. GPT-5.6-Sol used medium reasoning effort.

Terminology evaluation uses the Stanza `eu_bdt` and `pl_pdb` models for lemma matching, followed by DeepSeek V4 Pro review of unmatched terms.

The final GPT-5.6-Sol Track 1 sweep covered 261 document–mode instances, of which three required an automatic paragraph-count repair. The completed sweep cost approximately $28.46 for translation and $3.11 for evaluation. All 12 output files passed the official task validator.

The three final GPT-5.6-Sol Track 2 sweeps covered 129 documents in each of the two modes per system. The `noterm` condition is configuration-identical across the three systems, so it was translated once with the end-to-end system and copied to the other two; 516 document–mode instances were therefore generated in total, of which seven required an automatic paragraph-count repair and none failed. Translation cost approximately $47.31 for the end-to-end system ($15.62 of that the shared `noterm` files and $31.69 its own `sample` files), $31.00 for the hybrid system and $15.90 for the dictionary system, $94.21 in total. Extracting the GPT-5.6-Sol dictionary over all five domains cost a further $24.24, and the reference-free evaluation of the three systems' `sample` outputs cost $5.41. All ten output files of every system passed the official task validator.

| Direction | No term | Proper | Random |
|---|---|---|---|
| *Gemini 2.5 Flash* | | | |
| Es–Eu | .795 / 4.23 | **.967 / 4.36** | .874 / 4.14 |
| En–Pl | .701 / **4.43** | **.985** / 4.07 | .876 / 4.21 |
| *Gemma 4 31B* | | | |
| Es–Eu | .510 / 2.32 | **.974 / 2.48** | .918 / **2.48** |
| En–Pl | .620 / **4.00** | **.989 / 4.00** | .921 / 3.14 |
| *GPT-5.6-Sol* | | | |
| Es–Eu | .846 / 4.60 | **.975 / 4.63** | .908 / 4.30 |
| En–Pl | .780 / **4.50** | **.989 / 4.50** | .900 / 4.36 |

Table 3: Track 1 judged coverage and fluency by translation direction, reported as coverage / fluency. Coverage is micro-averaged over required document–term pairs and fluency over documents within each direction. Bold marks the highest value for each measure within a row, including ties.

## B Additional Local Results

### B.1 Track 1: Comparison Across Models

Table 3 compares the selected document-filtered dictionary configuration across models and under the three terminology modes. The `noterm` and `proper` conditions are evaluated against the proper dictionary, while `random` is evaluated against the random dictionary and is therefore not directly comparable.

GPT-5.6-Sol receives the highest fluency scores in both directions and reaches near-ceiling judged coverage with the proper dictionary. Gemma 4 31B also obtains high proper-dictionary coverage, but its fluency differs sharply by direction: 2.32–2.48 for Spanish–Basque, compared with 3.14–4.00 for English–Polish. The gap is also present without a dictionary, so dictionary bias alone cannot explain it. We additionally observed one degenerate repetition loop during generation. Because all models use the same prompt without model-specific tuning, these results characterize performance under our fixed configuration rather than each model's best achievable quality.

### B.2 Track 1: Document-Level Consistency

We measure whether Gemini 2.5 Flash uses the same target option for repeated occurrences of a source term. For multi-option entries, only 41 of 1,210 recognized occurrences (3.4%) in the `proper` condition use an option other than the document's most frequent one. The rates are 2.9% for `noterm` and 3.4% for `random`. The calculation uses deterministic lemma matches.

| Domain | E2E | Dict. | Hybrid |
|---|---|---|---|
| *Gemini 2.5 Flash (development)* | | | |
| Finance | **4.91/4.64** | 3.81/3.60 | 4.26/3.91 |
| Machine tool | 4.37/3.80 | 4.14/3.91 | **4.43/4.14** |
| Mech. eng. | 3.43/3.00 | **3.71**/3.00 | 3.43/**3.14** |
| Medical | 4.00/3.17 | 3.83/**3.50** | **4.17/3.50** |
| Railways | **4.32/3.86** | 4.04/3.48 | 4.25/3.46 |
| *Macro* | ***4.21/3.69*** | *3.91/3.50* | *4.11/3.63* |
| *GPT-5.6-Sol (submitted)* | | | |
| Finance | **5.00**/4.76 | 4.94/**4.79** | **5.00**/4.74 |
| Machine tool | **4.66**/4.43 | 4.37/4.03 | 4.60/**4.63** |
| Mech. eng. | 3.57/2.57 | **4.14/3.43** | 3.43/**3.43** |
| Medical | 4.33/3.83 | **4.50**/4.00 | 4.17/**4.17** |
| Railways | **4.61/4.50** | 4.48/4.00 | 4.54/4.25 |
| *Macro* | *4.43/4.02* | ***4.49***/*4.05* | *4.35*/***4.24*** |

Table 4: Track 2 judge scores by domain. Each cell gives fluency/terminology consistency (1–5, higher is better). The macro rows average the five domains equally. The numbers of judged documents are 53, 35, 7, 6, and 28 in the displayed domain order. Bold marks the highest value for each measure within a row, including ties.

### B.3 Track 2: Reference-Free Development Results

We compare the end-to-end, dictionary, and hybrid systems, first on Gemini 2.5 Flash and then on GPT-5.6-Sol. Table 4 reports the DeepSeek V4 Pro judge fluency and terminology-consistency scores by domain and their five-domain macro-average at both stages.

On Gemini 2.5 Flash, the end-to-end system receives the highest macro-average score on both reported axes. That ranking does not transfer to GPT-5.6-Sol, for which the dictionary system receives the highest fluency and the hybrid the highest terminology-consistency score. The per-domain results are more mixed for both models: no system consistently performs best across domains, so no single system is uniformly superior.

## C Prompt Templates

The templates below reproduce the operational instructions while replacing dynamically inserted values such as language names, paragraph counts, documents, translations, and glossary entries with placeholders. Repeated delimiter-specific wording is condensed. The same translation template is used with all supported LLMs.

### C.1 Track 1 Translation Prompt

The system message begins with the following instructions:

> You are a professional *[source]*-to-*[target]* translator specializing in technical, engineering, medical, and scientific documents. Translate the document below from *[source]* into *[target]*.
>
> **Rules:**
>
> 1. Translate the entire document faithfully and fluently.
> 2. The source has exactly *[count]* paragraphs separated by blank lines, or exactly *[count]* lines separated by single line breaks. Output the same number in the same order and do not merge, split, add, or drop them.
> 3. Keep brand names, product codes, and proper nouns untranslated unless a translation is standard.
> 4. Do not add explanations, notes, or commentary.
> 5. Output only the translated text.

In the default setting, the following block is appended to the system message before the source document:

> **Terminology glossary (use these target translations):**
> *[source term]* → *[target option 1]* | *[target option 2]*
>
> For each glossary entry, when the source concept appears in the text, render it using the given target term, inflected or agreed as the target-language grammar requires. When several options are listed, pick the one that best fits the context and use it consistently. Prefer natural, fluent phrasing over a literal or forced insertion. If a term genuinely cannot fit grammatically, translate the concept faithfully instead.

The `noterm` mode uses the same translation instructions without this block. The `proper` and `random` modes differ only in the dictionary from which the displayed entries are selected. In the text-first variant, the same block follows the source document. The inline variant instead marks a matched span as ⟪*source span* → *target option*⟫ and asks the model to remove the marker while using an appropriately inflected target form.

### C.2 Terminology Evaluation Prompt

The judge receives the source document, its translation, and only the dictionary entries missed by the surface and lemma matchers. Its system message contains the following tasks:

> **Task 1:** For every listed dictionary entry, choose exactly one verdict:
>
> - `correct-inflected`: an acceptable target option is present but was missed because it is inflected, declined, agglutinated, or has a minor orthographic variation;

- `wrong-sense-or-mistranslated`: the source concept is rendered, but not with an acceptable option;
- `genuinely-missing`: the source concept is absent from the translation.

In the note, quote a short relevant translation fragment when one exists.

**Task 2:** Rate the complete translation for fluency and adequacy from 1 to 5. For fluency, 1 denotes broken or unreadable text and 5 natural, native-quality text. For adequacy, 1 denotes meaning that is mostly wrong or omitted and 5 a complete and precise translation.

Return strict JSON only: `{"fluency": [int], "adequacy": [int], "terms": [{"source": [source term], "verdict": [verdict], "note": [evidence]}]}`. The terms array must contain exactly one entry for every supplied dictionary entry, in the same order.

The user message contains the source document, the translation, and the unmatched dictionary entries with all acceptable target options.

### C.3 Revision Prompt

The revision model receives the source document, the initial translation, the full filtered glossary used for the initial translation, and the terminology issues identified by the judge. Its system message gives the following rules:

1. Check each reported issue against the draft. If the draft already uses an acceptable target option in an appropriate inflected form, treat the issue as a false positive and leave it unchanged.
2. Return a revised translation of the complete document, correcting only issues that are genuinely wrong or missing.
3. For each real issue, use one of the acceptable target terms and inflect or agree it as required by the target-language grammar. Prefer natural phrasing over forced insertion.
4. Keep all wording and style not affected by a genuine issue unchanged.
5. Preserve exactly the source number and ordering of paragraphs or lines.
6. Do not add explanations, notes, or commentary; output only the revised translation.

### C.4 Track 2 End-to-End Translation Prompt

The end-to-end system message opens like the Track 1 prompt (Appendix C.1), but its third rule refers to the provided examples rather than to a glossary:

> You are a professional *[source]*-to-*[target]* translator specializing in technical and financial documents. Translate the document below from *[source]* into *[target]*.
>
> **Rules:**
>
> 1. Translate the entire document faithfully and fluently.
> 2. The source has exactly *[count]* paragraphs separated by blank lines, or exactly *[count]* lines separated by single line breaks. Output the same number in the same order and do not merge, split, add, or drop them.
> 3. In `sample` mode: follow the terminology and style of the reference translations you have been given. In `noterm` mode (no examples given): render every domain-specific term consistently throughout the document.
> 4. Do not add explanations, notes, or commentary.
> 5. Output only the translated text.

In `sample` mode, the selected seed pairs are then sent as alternating `user`/`assistant` turns preceding the document, which forms the final `user` turn:

`system:` *the instructions above*
`user:` *[seed source 1]*
`assistant:` *[seed target 1]*
...
`user:` *[document to translate]*

When a seed source occurs verbatim in the document, an additional system-message rule asks the model to reuse that seed's approved translation for the matching span. For the dictionary and hybrid systems, the terminology glossary block from the Track 1 prompt (Appendix C.1) is instead built from the terms extracted for the current document. The dictionary system shows this block with no example history, in an otherwise unchanged Track 1 system message; the hybrid system appends it to the end-to-end system message above, so both the example history and the glossary are present at once.

Whenever the history is non-empty, the system message also appends one line stating how many previously approved translations follow and instructing the model to treat them as reference material – reuse their terminology and register – rather than text to translate again.

### C.5 Term Dictionary Extraction Prompt

This is the prompt used to build the dictionary consumed by the `dict` and `hybrid` systems (Section 4.2): one call per seed pair (per ten aligned pairs for `finance.zhen`).

> You build a *[source]*-to-*[target]* terminology dictionary from aligned sentence pairs.
> Extract only *[domain]* DOMAIN TERMINOLOGY: the specialised terms of the subject field. Do not extract general-language vocabulary, function words, everyday verbs and adjectives, dates, or plain numbers.
>
> **Rules:**

1. Give both sides in their dictionary (citation) form: singular, nominative/absolutive, no case suffix, no attached article, no possessive, verbs in the infinitive.
2. Citation form applies to the phrase as a whole, never word by word: every modifier must agree with the head noun again in the citation form, on both the source and the target side.
3. Also report, in *source_surface*, the exact substring of the source sentence the term was taken from, copied character for character.
4. The target must render the source term as the target sentence does (same sense, same register), in its own citation form.
5. One entry per distinct source term; alternative target renderings go in the same entry's target list.
6. Terms are words or short phrases, never whole sentences; if a pair has no extractable terminology, return no entries for it.

Output strict JSON only: `{"terms": [{"pair": [int], "source": [citation form], "source_surface": [verbatim source substring], "targets": [[citation form], ...]}, ...]}`.

The user message lists the batch's sentence pairs, numbered. Two worked examples are included in the system message to illustrate the phrase-as-a-whole agreement rule (rule 2) on both the source and the target side, since this is where the model most often reverts to per-word citation forms instead. *source_surface* is what the hallucination guard checks (Section 4.2): an entry whose reported span does not occur verbatim in its own source sentence is dropped before merging.

# Tilde's Submission for the WMT2026 Shared Task on Terminology Translation

**Mārcis Pinnis[1,2], Martins Kronis[1], Emīls Grims[1], Ervīns Jakovelis[1], Roberts Rozis[1], Toms Bergmanis[1,2]**

## Abstract

This paper describes Tilde's submissions to the WMT 2026 Shared Task on Terminology. For both subtasks, we use TildeOpen-30B, which we instruction-tune for translation using terminology glossaries and translation memories, and we detail the construction of the training data augmented with these resources. For Task 1, we compare three term recognition methods aimed at reducing large term collections to subsets relevant for translation: fuzzy search, stemming with exact-match search, and stemming with fuzzy search. For Task 2, we compare extracting a glossary from the provided translation memory and integrating it in context against using retrieved translation-memory entries directly as few-shot examples. As the shared task provides neither reference translations nor a development set, we validate our design decisions with an LLM-as-a-judge protocol. In-domain term collections reduce translation errors by up to 22% relative to translating without terminology, whereas out-of-domain collections yield only marginal gains, and glossaries extracted from the translation memory outperform few-shot translation with retrieved entries.

## 1 Introduction

Accurate and consistent use of domain terminology is essential in technical translation. Even an otherwise fluent translation may alter the meaning if specialised terms are mistranslated or used inconsistently. Such errors can lead to misunderstandings and, in sensitive domains, potentially serious consequences. Maintaining consistency is a particular challenge in document-level translation. However, translation is rarely performed on whole documents because the quadratic complexity of the transformer's attention mechanism makes whole-document translation computationally impractical for large documents and webpages. Translating in chunks restores tractability but can reintroduce inconsistencies in the translation of terms, brand language, and named entities. Translation informed by user-provided terminology, translation memories, or even previously machine-translated paragraphs from the same document can help reduce these inconsistencies.

Terminology integration in machine translation has been well studied for encoder–decoder neural machine translation models. For instance, (Dinu et al., 2019) proposed annotating source sentences with target-side term constraints during training, enabling terminology-aware neural machine translation models to accept term translation suggestions at inference time. (Bergmanis and Pinnis, 2021b) extended this approach with target-language lemma annotations, making it suitable for morphologically rich target languages. With the emergence of large language models, researchers have explored terminology-constrained post-editing of machine-translated hypotheses (Bogoychev and Chen, 2023; Moslem et al., 2023b), automatic bilingual terminology extraction (Moslem et al., 2023a), parameter-efficient instruction tuning on in-domain, terminology-augmented data (Rios, 2025), and direct terminology-aware translation through in-context learning (Moslem et al., 2023a; Lackner et al., 2025). The latter is particularly attractive in practice because it requires no model retraining and allows terminology to be updated dynamically during inference.

The WMT 2026 Shared Task on Terminology enables evaluation of methods that integrate terminology and translation memories into machine translation systems. We participate in both tasks with TildeOpen, a 30B large language model instruction-tuned for several translation scenarios, including terminology-aware translation through in-context learning and translation-memory integration through few-shot prompting. In Task 1, relevant entries are selected from the provided term collection and included in the translation prompt. In

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1860–1872
October 28-29, 2026 ©2026 Association for Computational Linguistics

Task 2, we investigate both terminology extracted from the provided translation memory and the direct use of retrieved translation-memory entries as few-shot examples. In both tasks, we participate with translations for the English-Polish translation direction.

In this paper, we describe the construction of the terminology- and translation-memory-augmented training data and the fine-tuning of the base TildeOpen model (Bergmanis et al., 2026). We further document the translation pipelines used for Tasks 1 and 2, including the evaluated term-recognition methods and the strategy for integrating translation memory.

## 2 Instruction-Tuning of TildeOpen

We follow Bergmanis et al. (2026) in adapting the TildeOpen-30B foundation model for general translation and introduce two additional tasks: translation with terminology glossaries and translation with translation memories. Below, we first describe the general translation data, then the other two data types, and finally the fine-tuning procedure.

### 2.1 General Parallel Data

The instruction-tuning corpus includes translation directions for all 34 languages supported by TildeOpen. It is compiled from publicly available sources: OpenSubtitles (Lison and Tiedemann, 2016), TED talks (Salesky et al., 2021) from OPUS (Tiedemann, 2012), and newly recrawled EUR-Lex[1] parallel data. We use document-level versions of these datasets and select consecutive segments so that each source and target text contains no more than 3,000 space-separated words. Additionally, we collect monolingual news articles in all supported languages from HPLT-v2 and back-translate them into English using the Gemma 2 27B IT model (Gemma Team et al., 2024). Note that we do not use domain-specific data to fine-tune TildeOpen. Domain adaptation will be solely achieved during inference through in-context learning.

We apply several filters to ensure data quality. For OpenSubtitles and TED, we retain only segments with average COMET quality-estimation scores at least 25% higher than the average FLORES dev-set score for each language pair (Rei et al., 2022; NLLB Team, 2024). LangID filtering removes texts with low language confidence or identical source and target segments. For back-translated data, we verify that the generated English maintains paragraph structure, numerals, and terminal punctuation. Each sentence or text appears only once as a translation target across all language pairs.

From the filtered data, we sample 2 million documents, balancing target-language tokens so that each language serves as the target about 3% of the time. Parallel data is formatted using simple English instructions: "{source text}\n\nTranslate the given text from {source language} to {target language}.{target text}". The final dataset contains approximately 462 million tokens: 65% back-translated news, 25% OpenSubtitles, 5% TED, and 5% EUR-Lex. The data is further wrapped in a chat template so that the trained model supports the prompt structure shown in Appendix B and Figure 2.

### 2.2 Terminology Data

To train the model to translate text using a user-provided term glossary, we created parallel training data in which sentence pairs are annotated with bilingual terminology suggestions. Producing such data requires (i) a parallel corpus, (ii) bilingual term collections, and (iii) a procedure for identifying term occurrences in both the source and the target side of the corpus. We describe each in turn.

**Parallel Corpus and Term Collection** We build on our previous work and reuse the parallel data prepared for TildeOpen, as described in Bergmanis et al. (2026). Among other corpora, this data includes EUR-Lex, TED Talks (Cettolo et al., 2012), and OpenSubtitles (Lison and Tiedemann, 2016). The European legal data includes terms from the Interactive Terminology for Europe (IATE) database (Zorrilla-Agut and Fontenelle, 2019), while the two conversational corpora are likely to include entries from the Microsoft Terminology Collection.

**Text and Term Normalisation** Matching glossary terms against running text requires abstracting away from surface form variation. We therefore normalised terms and corpus text with a shared pipeline that combined lemmatisation using the Stanza toolkit (Qi et al., 2020) and stemming with our in-house rule-based stemmer, originally based on the Snowball stemmer (Porter, 2001).

**Term Indexing** For efficient lookup, we organised each term collection in a trie structure over lemmatised words: terms were split into words,

[1] https://eur-lex.europa.eu/

and each term was inserted in a left-to-right pass, so that the first level of the trie holds the first words of all terms, the second level – the second words, and so on. Terms sharing lemmatised prefixes thus collapse into common paths, keeping the trie compact and making term search fast. Importantly, every term carries an identifier that links its equivalents across languages. Terms with multiple meanings but matching surface forms share the same source identifier, allowing us to additionally build a translation alternative lookup. We later use this to provide ambiguous terms with several meanings and translation alternatives.

**Term Matching and Selection** We processed each document paragraph by paragraph, scanning the source and target sides independently. In each paragraph, we matched terms greedily from left to right, extending a match word by word as long as the running word sequence remained on a path in the trie. We then retained only those candidates whose identifiers were present on both the source and target sides.

The resulting term annotations sometimes contained overlapping terms. We selected longer multiword terms over single-word terms so that the model learns to use them. When terms from different collections overlapped, IATE was given priority over the Microsoft Terminology Collection; remaining ties were broken at random. Finally, we deduplicated the selected source–target term pairs so that no annotation appears twice in a training example. As above, the data is processed using a chat template so that the trained model supports the prompt structure shown in Appendix B and Figure 3.

### 2.3 Translation Memory Data

To teach the model to translate using translation memory examples, we created a dataset in which training samples are augmented with example translations. We use the EUR-Lex corpus to obtain document-level and corpus-level translation examples. For document-level translation examples, we randomly selected up to 20 examples from either the beginning or the end of the document. To obtain corpus-level examples, we created a translation memory index and queried it to retrieve sentences similar to the text being translated.

**Translation Memory Index** To implement the translation memory, we use Apache Lucene[2]. Instead of documents, we indexed aligned source–target sentence pairs, so that querying the index with a source sentence returns lexically similar sentences together with their translations. We indexed our entire EUR-Lex dataset, amounting to almost 18 million sentence pairs. For each source sentence, we queried the index for up to 1k candidate examples and kept only those whose Levenshtein similarity ratio to the query, computed on the source side, exceeded 0.7. To expose the model to exact matches, we sampled up to 20% of examples from the document itself for 10% of the documents. The data was further formatted so that the trained model supports the prompt structure given in Appendix B and Figure 4.

### 2.4 Finetuning

We instruction-tune the model in a supervised manner using a custom fork of GPT-NeoX framework[3] (Andonian et al., 2023) on 512 AMD MI250x GPUs of the LUMI supercomputer. The model is trained in 600 updates for a total of ∼2.4B tokens. Our starting learning rate of $8 \cdot 10^{-6}$ matches the final cool-down value in the foundation model's pre-training schedule and is further cooled to 1% using `1-sqrt` cooldown schedule.

Automatic evaluation results on standard test sets are given in Table 1. The results show that the model achieves overall translation quality that is competitive with current open-weight models of similar size.

## 3 Task 1: Translation with Terminology

Task 1 analyses three translation scenarios: translation without a term collection (`No terms`), translation with an in-domain term collection (`Proper`), and translation with an out-of-domain or mixed-domain collection that may contain terms among other words and phrases (`Random`). We participate in Task 1 with the TildeOpen translation model, which has been instruction-tuned for translation with terminology, along with other capabilities.

To translate the evaluation data, we first perform term recognition to identify term entries present in each paragraph. Then, for each paragraph, we form a translation prompt that, for the `No terms` scenario, skips terms (an example prompt is provided

| NTREX | 53.03 | **54.44** | 50.48 | **0.8805** | 0.8738 | 0.8659 |

Table 1: ChrF++ and COMET scores across test sets for the English→Polish translation direction. We compare TildeOpen 30B, Gemma 4 31B, and Qwen 3.5 27B. FLORES-200 (Costa-Jussà et al., 2022) and NTREX (Federmann et al., 2022) test translation of news articles, NTEU (García-Martínez et al., 2021) – legal (EU policy) documents, and WMT24++ (Deutsch et al., 2025) represents a mix of news, fiction, social media communications, and speech transcripts. The best result for each test set and metric is shown in bold.

in Appendix B; Figure 2), and for the other scenarios includes the recognised terms (Appendix B; Figure 3). Finally, we generate a translation with the instruction-tuned TildeOpen model by setting the temperature and frequency penalty to 0.

For term recognition, we analyse three methods:

- **Fuzzy Search**: We lowercase both the translatable text and source terms, followed by a three-level term recognition method. First, we try to match term occurrences exactly. Then, we check whether a prefix of the term matches a token found in the text (or vice versa), with a minimum overlap of 0.7. Finally, we use the `rapidfuzz` library to calculate a fuzzy match score between the term and tokens in the text. If the score is 90% or higher, we accept the term as a match. The first and third methods are applied for both single-word and multi-word terms. The second method is applied only for single-word terms. This method can handle inflectional changes and typographical errors; however, it is prohibitively slow in practice with large term collections (see Appendix A for performance analysis).

- **Stemming and Exact Match Search**: First, both the translatable text and source terms from the term collection are lowercased and stemmed using a stemming tool[4]. Then we search for term occurrences in the text using a trie lookup algorithm. Stems are matched exactly. This method handles most inflectional changes and is efficient for practical application with large (1M+ entries) term collections; however, it does not address changes that occur at the root of a word and fails with typographical errors.

- **Stemming and Fuzzy Search**: Here we combine the first two ideas. First, all text and terms are stemmed. Then we build a trie from the term collection to support multi-word term recognition, as in the second method. Finally, matching at each trie node is performed using fuzzy search rather than an exact hash table lookup. For this method, we perform fuzzy search using the `SymSpell` library[5]. This method can handle inflectional changes and typographical errors, and, thanks to the efficient fuzzy lookup provided by SymSpell, it can be applied in production workflows.

The methods are designed to reduce the original term collection to a manageable subset for each paragraph, rather than recognising only truly valid term entries. That is, we aim for high recall rather than high precision, because the translation model can handle disambiguation.

Since the organisers did not provide a development set with reference translations and terminology for each paragraph, on which we could analyse the model's performance across different translation scenarios, we performed an automatic LLM-as-a-judge evaluation. For each paragraph, we prompted the GPT-5.6-luna[6] model to generate a list of all minor and major errors that could be identified in the hypothesis, using the given source

[4]For English, we use a slightly optimised C# port of the Porter2 stemming algorithm from Snowball(https://snowballstem.org/). The exact source code is available on GitHub (https://github.com/pmarcis/dict-filtering/blob/master/FilterGizaDictionary/Stemmers.cs).

[5]https://github.com/wolfgarbe/SymSpell

[6]https://developers.openai.com/api/docs/models/gpt-5.6-luna

text and a term collection as context (an example of the evaluation prompt is given in Appendix B; Figure 6). Since each term recognition method recognises only a subset of possible terms, we unified all subsets for each paragraph and used the resulting set for evaluation. This does not ensure that all valid term entries are provided as context; however, this ensures that all term recognition scenarios are evaluated using the same term collection.

The results of the LLM-as-a-judge evaluation are provided in Table 2. Across both domains, using the `Proper` terminology for term recognition consistently reduces translation errors compared with translating without terminology, whereas the `Random` terminology yields only marginal or inconsistent improvements. Differences among the three term recognition methods are relatively small, although `Fuzzy search` generally achieves the strongest results with the `Proper` terminology, while the stemmer-based methods show comparable but slightly lower results. For the shared task, we made two submissions: `Fuzzy search` as our primary submission (named `to+fuzzy_tr`), as it achieved the highest error reduction for the proper term collection, and `Stemming and fuzzy search` as our secondary submission (named `to+stem_fuzzy_tr`).

## 4 Task 2: Translation with a Translation Memory

Task 2 analyses two translation scenarios: translation without a term collection (`No terms`) and translation with a translation memory (translation memory) that features in-domain terminology. We participate in Task 2 with the TildeOpen translation model. However, we split the translation memory scenario into two further scenarios – one where we automatically construct a term collection from the provided translation memory and translate the documents using terminology integration through in-context learning (similarly to Task 1), and the other where we perform translation memory integration using few-shot translation.

To create the term collections from the translation memories for the two domains, we use Gemma 4 31B. The model is prompted to extract term pairs in canonical forms and surface forms from translation memory entries. An exact prompt example is provided in Appendix B (Figure 5). The extraction process resulted in term collections of 418 and 956 terms for the medical and mechanical engineering domains, respectively.

For the `No terms` scenario and the terminology integration scenario, we use the same methods for translation generation as described in Section 3. For the translation memory integration scenario, we split each translatable paragraph into sentences and extract the N most similar sentences from the translation memory (where N equals 5, 10, or 15). Then, in a round-robin manner, we select the topmost similar candidates for each sentence till N candidates are selected. If N is larger than the number of sentences in the paragraph, some sentences will have more than one translation memory entry assigned. If N is smaller, then some sentences will lack assigned translation memory entries. We use Levenshtein distance as the similarity metric. Once translation memory entries are selected, we form a few-shot translation prompt (see Appendix B; Figure 4 for an example), and generate the output.

Similar to Task 1, we perform an LLM-as-a-judge evaluation to identify which scenario yields better translations. However, this time we do not have access to a reference term collection. Therefore, we prompt the GPT-5.6-luna LLM with only the source text, the hypothesis translation, and the domain name (see Appendix B; Figure 7 for an example). Given the limited context, we expect the evaluations to be noisier than those for Task 1.

The results of the LLM-as-a-judge evaluation are provided in Table 3. Across both domains, incorporating information from the translation memory consistently reduces translation errors compared with translating without additional context. However, automatically extracting terminology from the translation memory and integrating it as an in-context glossary generally yields larger improvements than few-shot translation using retrieved translation memory examples. That being said, the results may indicate a capability deficiency in the instruction-tuned TildeOpen model that we will have to address in a future run. For the shared task, we made three submissions - `Top 15 candidates` few-shot translations (named - `to+tm_top15`) as our primary submission, and `Top 5 candidates` few-shot translations (named - `to+tm_top5`) and `Fuzzy search` (named - `to+g4terms`) as our secondary submissions.

## 5 Official Results

Table 4 summarises the official results of our English→Polish submissions to the WMT 2026

| Domain | Terms | Term recognition method | Errors | | | Reduction (%) vs. no terms |
|---|---|---|---|---|---|---|
| | | | Minor | Major | Total | |
| Medical | No terms | | 4.2 | 1.0 | 5.2 | |
| | Proper | Fuzzy search | 3.8 | 0.7 | 4.5 | 13.5% |
| | | Stemmer + exact search | 4.1 | 0.8 | 4.9 | 5.8% |
| | | Stemmer + fuzzy search | 4.0 | 0.6 | 4.6 | 11.5% |
| | Random | Fuzzy search | 4.4 | 0.8 | 5.2 | 0.0% |
| | | Stemmer + exact search | 3.8 | 1.2 | 5.0 | 3.8% |
| | | Stemmer + fuzzy search | 4.0 | 1.0 | 5.0 | 3.8% |
| Mech. eng. | No terms | | 4.6 | 3.0 | 7.6 | |
| | Proper | Fuzzy search | 4.3 | 1.6 | 5.9 | 22.4% |
| | | Stemmer + exact search | 4.4 | 1.9 | 6.3 | 17.1% |
| | | Stemmer + fuzzy search | 4.5 | 1.6 | 6.1 | 19.7% |
| | Random | Fuzzy search | 4.8 | 2.6 | 7.4 | 2.6% |
| | | Stemmer + exact search | 4.6 | 2.4 | 7.0 | 7.9% |
| | | Stemmer + fuzzy search | 4.4 | 2.5 | 6.9 | 9.2% |

Table 2: LLM-as-a-judge evaluation results for Task 1 (English→Polish translation direction).

Terminology Translation Task (Charkiewicz et al., 2026). For Task 1, fuzzy search achieves the highest scores among our submissions on all four metrics. It outperforms stemming and fuzzy search by 2.8 percentage points on the term success metric; however, the differences in paragraph-level chrF++ and COMET are comparatively small.

For Task 2, no single configuration performs best across all metrics. Few-shot translation with 15 retrieved translation-memory examples achieves the highest term success and paragraph-level ChrF++, while using five examples yields the highest COMET score. The glossary-based configuration achieves the highest lemmatised term success. Both few-shot configurations outperform glossary integration on ChrF++ and COMET, in contrast to the overall preference for glossary integration in our LLM-as-a-judge evaluation.

The results suggest that term success improves with in-context learning via a glossary or a translation memory by up to 28.7 percentage points (e.g., from 52.1% without terms to 80.8% with proper terms and fuzzy search in Task 1). However, the results also show that there is still room for improvement, as in 19.2% of cases the model decided not to follow the glossary entries and mistranslated. The results indicate a need for deeper analysis of the mistranslation cases. However, we leave this for future work.

## 6 Conclusions and Discussion

We described Tilde's submissions to the WMT 2026 Shared Task on Terminology. For both tasks we used TildeOpen-30B, instruction-tuned for terminology-aware translation through in-context glossaries and for translation-memory integration through few-shot prompting, and we detailed the construction of the terminology- and translation-memory-augmented data used for this instruction-tuning. For Task 1, we compared three term recognition methods – fuzzy search, stemming with exact search, and stemming with fuzzy search – as means of reducing a large term collection to a per-paragraph subset. For Task 2, we compared two ways of exploiting the provided translation memory: extracting a glossary from it and integrating that glossary in context, or using retrieved translation-memory entries directly as few-shot examples.

Lacking a development set with reference translations, we evaluated all scenarios with an LLM-as-a-judge protocol. In-domain term collections reduced errors by 13.5–22.4% relative to translating without terminology, while out-of-domain collections yielded only marginal gains. Differences among the three recognition methods varied, but pointed towards a preference for methods that have high recall. In Task 2, glossaries extracted from the translation memory outperformed few-

| Domain | Scenario | Configuration | Errors | | | Reduction (%) vs. no terms |
|---|---|---|---|---|---|---|
| | | | Minor | Major | Total | |
| Medical | No terms | | 4.2 | 0.8 | 5.0 | |
| | Term int. | Fuzzy search | 3.5 | 0.7 | 4.2 | 16.0% |
| | | Stemmer + exact search | 3.1 | 0.6 | 3.7 | 26.0% |
| | | Stemmer + fuzzy search | 3.8 | 0.6 | 4.4 | 12.0% |
| | TM int. | Top 5 candidates | 3.8 | 0.6 | 4.4 | 12.0% |
| | | Top 10 candidates | 3.8 | 0.3 | 4.1 | 18.0% |
| | | Top 15 candidates | 3.6 | 0.5 | 4.1 | 18.0% |
| Mech. eng. | No terms | | 4.6 | 3.0 | 7.6 | |
| | Term int. | Fuzzy search | 3.6 | 2.0 | 5.6 | 21.1% |
| | | Stemmer + exact search | 3.5 | 2.2 | 5.7 | 19.7% |
| | | Stemmer + fuzzy search | 3.0 | 2.4 | 5.4 | 23.9% |
| | TM int. | Top 5 candidates | 3.9 | 2.6 | 6.5 | 8.5% |
| | | Top 10 candidates | 3.6 | 2.8 | 6.4 | 9.9% |
| | | Top 15 candidates | 3.7 | 2.7 | 6.4 | 9.9% |

Table 3: LLM-as-a-judge evaluation results for Task 2 (English→Polish translation direction). Note that the test sets for Task 1 and Task 2 differ; therefore, the *No terms* results are slightly different in both experiments.

| Configuration | Term success | Term success (lemmatized) | ChrF++ (paragraph) | COMET |
|---|---|---|---|---|
| **Task 1** | | | | |
| Fuzzy search | **77.8%** | **80.8%** | **71.8** | **0.881** |
| Stemming and fuzzy search | 75.0% | 78.0% | 71.5 | 0.880 |
| **Task 2** | | | | |
| Fuzzy search | 77.4% | **79.8%** | 71.5 | 88.5 |
| Top 15 candidates | **80.4%** | 78.7% | **77.2** | 89.7 |
| Top 5 candidates | 73.2% | 73.7% | 75.4 | **89.9** |

Table 4: Official results of our submissions. The best result for each task and metric is shown in bold.

shot translation using retrieved entries, which may point to a capability gap in the current instruction-tuned model rather than a limitation of few-shot translation-memory integration per se.

The practical value of terminology-aware machine translation has long been limited by the quality of the term collections themselves. In Bergmanis and Pinnis (2021a), we documented the noise typical of term collections repurposed for machine translation: entries where the source and target are not translations of each other, several possible translations with no indication of which one to use, unrelated terms and spelling variants collapsed into a single entry, terms listed in inflected rather than dictionary forms, and entries that explain a concept in a full sentence instead of naming it. We argued that reformatting human-oriented term collections into machine-readable files does not make their content machine-usable, and that collections intended for machine translation must therefore meet a higher standard than those intended for humans – unless substantially more intelligent translation systems emerge, a condition that, in 2021, sounded akin to waiting for artificial general intelligence.

Ironically, no general intelligence was required: the caveat now simply describes the present. The systems described in this work interpret ambiguous entries in context, select among competing translation equivalents, and inflect dictionary forms as required by the target morphosyntax; definition-style

entries, once noise to be filtered out, could now even serve as useful context. While terminology-aware neural machine translation systems demanded cleaner term collections, terminology-aware translation with language models can now meet collections where they are. This reversal suggests that the burden of quality has shifted: rather than curating collections to suit rigid systems, the remaining challenge is selecting, from imperfect collections, the entries worth showing to a model that can handle the rest.

## Limitations

The primary limitation of this work stems from the Shared Task competition-like setting, which understandably leads to working without reference translations. The shared task did not provide a development set either. Participants were therefore left without any means of validating design decisions against ground truth: every choice we report – which term recognition method to use, how many translation-memory candidates to retrieve, whether to extract a glossary or prompt with retrieved entries – had to be made on the basis of an LLM-as-a-judge protocol applied on the test set itself. This is a shortcoming of the task design rather than of any individual submission, and it limits what the shared task as a whole can conclude about terminology integration: without development sets and references, participants cannot reliably compare methods, and system rankings rest solely on the organisers' evaluation. Our own conclusions consequently depend on the judge model's sensitivity to terminological adequacy, a property we could not verify. The Task 2 evaluation is weaker still: lacking a reference term collection, the judge received only the source text, the hypothesis, and the domain name, so terminological errors had to be recognised from its domain knowledge alone. We consider those results correspondingly noisier.

## Acknowledgments

The research leading to these results has received funding from the project "Competence Centre of Information and Communication Technologies for Research" of the Recovery and Resilience Facility, contract No. 5.1.1.2.i.0/2/24/A/CFLA/007 signed between IT Competence Centre and Central Finance and Contracts Agency, Research No. 2.6 "European Large Language Models for Ensuring Digital Content Accessibility".

We acknowledge that this work also benefited from the EuroHPC JU computing award, granting access to LUMI HPC in Finland; project number EHPC-AI-2024A06-029.

## A Term Recognition Efficiency Analysis

The three different term recognition methods analysed in our work differ not only in term recognition recall, but also in efficiency. Figure 1 shows that the trie-based method that uses a stemmer and

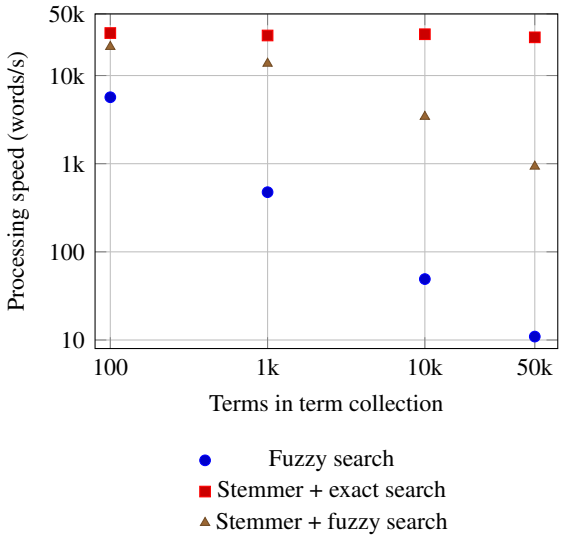

Figure 1: Term-recognition throughput for different term-collection sizes. Both axes use logarithmic scales.

exact match search is the most efficient and is applicable for large term collections. The Trie-based method that uses fuzzy search is applicable for term collections of up to 1k entries; beyond that, its performance degrades. The fuzzy search method is not applicable in practice.

## B Prompt examples

Figures 2, 3, 4, 5, 6, and 7 provide prompt examples used for translation generation, terminology extraction, and automatic translation evaluation.

# UniVie-HAITrans at WMT26 Terminology Translation Task: Terminology-Guided Data Filtering and Few-Shot Fine-Tuning for Lightweight LLMs

**Miguel Rios**
Centre for Translation Studies, University of Vienna, Austria
miguel.angel.rios.gaona@univie.ac.at

## Abstract

Specialised domain translation using Large Language Models remains challenging due to terminology constraints, scarce in-domain parallel data, and the tendency of fine-tuning to degrade in-context learning performance. We present our submission for the English–Polish and Spanish–Basque translation in the Medical and Engineering & Technology domains. Our method follows three stages: i) We extract in-domain terms from a terminology database and prompt a multilingual LLM to generate contextual sentences for each term. ii) We build an efficient search index over large-scale, unconstrained web-crawled and medical parallel corpora. Using the synthetic sentences as queries, we retrieve and filter the most semantically relevant pairs to build an in-domain fine-tuning dataset. iii) We structure our training instances with a mixture of 0-shot and semantically retrieved 5-shot prompts, and fine-tune lightweight multilingual LLMs (Gemma-3-4B, and Tiny-Aya-Global) via QLoRA. Fine-tuned Gemma-3 achieves the best results on held-out data across all metrics on English–Polish (Medical) and on Spanish–Basque (Engineering & Technology), showing that few-shot fine-tuning enhances specialised domain translation quality and preserves in-context adaptation.

## 1 Introduction

Machine Translation (MT) based on Large Language Models (LLMs) has achieved impressive zero-shot and few-shot general-domain translation quality (Moslem et al., 2023a; Bawden and Yvon, 2023; Gaona et al., 2026). However, translating specialised domains, such as Medical guidelines or Engineering & Technology specifications, remains a major challenge. Specialised domain translation requires adherence to terminology and exact contextual information, areas where general-purpose LLMs frequently produce mistranslations or hallucinated terminology (Moslem et al., 2023b; Gaona et al., 2023; Gaona, 2025). While supervised fine-tuning (SFT) on in-domain parallel data can adapt models to technical domains, acquiring high-quality parallel sentence pairs for specialised domains is costly and sparse. Furthermore, standard SFT often causes models to over-fit to strict direct-translation or few-shot templates, degrading their in-context learning (ICL) performance when presented with different few-shot example prompts at inference time.

Using a terminology database to filter parallel corpora is a highly effective strategy for domain adaptation and fine-tuning MT models (Lohar et al., 2022; Nayak et al., 2023; Imamura and Utiyama, 2026). On the other hand, Alves et al. (2023) examine the trade-offs between instruction fine-tuning and ICL in LLMs for MT. To address this over-specialisation, they introduce a strategy that incorporates few-shot examples directly into the fine-tuning process, effectively preserving in-context adaptation.

To overcome these challenges, we present a system for sentence-level MT that integrates synthetic sentence generation, efficient vector search with filtering over large-scale parallel corpora for domain adaptation, and few-shot fine-tuning (Alves et al., 2023) for lightweight LLMs. We evaluate our system for the English-Polish (**en-pl**) and Spanish-Basque (**es-eu**) language pairs for the Medical and Engineering & Technology domains.

We few-shot fine-tune two lightweight LLMs: Gemma-3-4B-it (Team et al., 2025) and Tiny-Aya-Global (Salamanca et al., 2026) using Quantised Low-Rank Adaptation (QLoRA) (Dettmers et al., 2023). Our contributions are:

- We provide a scalable methodology to convert terminology databases into domain extraction filters for large web corpora.
- We use a method to structure our training instances into a mix of 0-shot instructions and

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1873–1880
October 28-29, 2026 ©2026 Association for Computational Linguistics

5-shot in-context examples.

- We evaluate the translation quality of lightweight LLMs across across Medical and Engineering & Technology domains for both en-pl and es-eu language pairs with automatic metrics, while preserving their ICL performance.

## 2 Experimental Setup

We use a domain-adaptation framework for en-pl (Medical, and Engineering & Technology) and es-eu (Engineering & Technology). By leveraging a terminology database, we generate synthetic context sentences via an LLM and extract relevant parallel segments from large corpora with an efficient index. Finally, we fine-tune two lightweight LLMs on a mixed 0-shot and 5-shot dataset to preserve both instruction-following and ICL translation performance.

### 2.1 Terminology

The Interactive Terminology for Europe (IATE)[1] is a terminology management system from EU institutions that covers different domains (e.g., economics, law, health, medical). We extracted terminology entries from IATE across domains associated with Medical and Engineering & Technology. Specifically, we selected terms under the following domain categories from the IATE system: *Health*, *Economics*, *Finance*, *Science*, *Production, Technology & Research*, and *Industry*. We only use terms with quality: 2 (minimum reliability), 3 (reliable), and 4 (very reliable) stars (human annotated quality scores). The resulting amount of terms for each domain and source language is as follows: 178,309 *Engineering & Technology* terms for English, 58,862 *Medical* terms for English, and 120,137 *Engineering & Technology* terms for Spanish.

### 2.2 Data

To build our domain-specific datasets, we use raw parallel pairs from two parallel sentence-level corpora: CCMatrix and EMEA.

**CCMatrix** A large-scale parallel corpus extracted from Common Crawl web data using multilingual sentence embeddings (LASER) (Schwenk et al., 2021). Because it covers a broad, unconstrained web-crawled texts, it serves as a candidate pool for extracting specialised Engineering & Technology segments for both en-pl and es-eu language pairs. We use 30M segments for en-pl, and 6.5M segments for es-eu.

**EMEA** A domain-specific parallel corpus derived from the European Medicines Agency documents (ELG, 2020). It contains official medical, pharmacological, and clinical guidelines, providing high-quality, in-domain target sentence pairs for en-pl (Medical). The EMEA corpus contains 762,904 segments.

Before the semantic filtering and fine-tuning, we pre-processed all raw parallel corpora with standard text cleaning using the Moses[2] toolkit scripts to remove noisy or corrupted sentence pairs: **Length Filtering**: Sentence pairs are pruned if either the source or target sequence exceeds a maximum length of 200 tokens or falls below a minimum length of 1 token. **Length Ratio Filtering**: To eliminate misaligned sentences or alignment artefacts, we remove sentence pairs where the source-to-target and target-to-source length ratio of 1.5 times longer than the other sentence. **Deduplication**: duplicate sentence pairs across the raw datasets are removed to prevent data leakage and avoid biassing the fine-tuning process.

Following this initial cleaning step, the preprocessed corpora are passed to the filtering stage. We split a held-out sample dataset of 1,000 sentence pairs per language pair/domain combination, used strictly for evaluation. The remaining sentence pairs form the training pool.

### 2.3 Models

**Aya Expanse** To generate domain-specific contextual data, we use Aya-Expanse-32B [3]. This 32-billion parameter multilingual LLM is explicitly optimised for robust cross-lingual reasoning across 23 languages (Dang et al., 2024). Because of its advanced instruction-tuning and performance, we use it to generate fluent sentences from the IATE terminology, effectively bootstrapping our in-domain fine-tuning dataset.

**Tiny-Aya** Our first lightweight LLMs is Tiny-Aya-Global[4]. This 3.35 billion parameter multilingual model is optimised specifically for balanced, high-quality performance across non-English and

[2] https://github.com/moses-smt/mosesdecoder/blob/master/scripts/training/clean-corpus-n.perl

[3] CohereLabs/aya-expanse-32b

[4] CohereLabs/tiny-aya-global

low-resource language pairs. Its lightweight size and strong baseline language representation make it a good candidate for adaptation on the en-pl and es-eu language pairs.

**Gemma-3** As our second lightweight LLM, we use Gemma-3-4B-it[5]. Gemma-3 is a 4 billion parameter model that integrates a 128K token context window and widespread multilingual support, spanning over 140 languages. Despite its size, it produces reasoning and strict instruction-following outputs, providing a highly competitive baseline for our few-shot fine-tuning method.

### 2.4 Few-Shot Fine-Tuning

Our method follows *three stages*:

**Synthetic Seed Generation** We extract terms for English and Spanish from the IATE terminology database, filtered specifically for the target domains (Medical, Engineering & Technology). Because the raw terminology lacks contextual information, or examples. We generate synthetic context sentences for each term. Using Aya-Expanse, we prompt the system to produce one natural, domain-appropriate sentence for each term. The synthetic data generation prompt is defined in Section A. For example, with the English Medical domain term "*drug injection*" the LLM generates: "*The patient required a drug injection to alleviate the severe pain in their lower back.*".

**Semantic Embedding Filtering** We compute vector representations for all synthetic sentences and the source-side corpus using a dense text encoder with a multilingual model[6] from sentence-transformers (embedding size, $d = 384$). To efficiently mine domain-relevant samples from our large parallel corpora, we use a scalable vector index based on Facebook AI Similarity Search (FAISS) (Douze et al., 2025).

To overcome the memory size and search speed related to brute-force comparisons over millions of sentences, we index the corpus embeddings using an Inverted File with Product Quantisation (IVFPQ) index optimised for $L2$ Euclidean distance. The embedding space is partitioned into $N$ Voronoi cells via $K$-means clustering. During retrieval, the search is restricted only to the inverted lists corresponding to the nearest centroid clusters, this drastically narrows the search space. To minimise memory, each $d$-dimensional embedding vector is split into $M$ sub-vectors. Each sub-vector is independently quantised into a cluster centroid via $K$-means, converting high-dimensional floating-point vectors into lightweight codebooks. The index hyper-parameters depend on the size of the pool corpus. The values of the FAISS index hyper-parameters for each language pair are defined in Section C.

For each seed synthetic domain sentence, we query the IVFPQ index to retrieve the nearest neighbour corpus source sentence within $L2$ distance. Corpus sentence pairs falling within the *top-1* are extracted and deduplicated to build the final fine-tuning dataset.

**Few-Shot Example Retrieval** To retain both 0-shot performance and few-shot adaptability, we format the data into a mixed structure. Following (Alves et al., 2023), we build a hybrid fine-tuning dataset where instances randomly alternate between **0-shot** (direct translation instructions) and **5-shot** configurations (instructions with 5 example pairs). The 5 examples are retrieved from the remaining pool of segments using the previous FAISS index, ensuring that the in-context prompts are domain-relevant.

For Track 2 of WMT26, the organisers do not provide a terminology database. Instead, they supply two sets of texts. *Seed Bitexts*: Sentence and paragraph pairs designed for systems to extract and learn relevant domain terminology. *Source Documents*: Texts containing the terminology established in the seed. We use an in-context learning strategy. The 0-shot baseline incorporates no target terms (bitexts) for prompting, whereas the 5-shot approach incorporates semantically retrieved seed bitexts into the prompt. The few-shot fine-tuning prompts are defined in Section B.

Sampling instances from both formats during fine-tuning ensures the model learns to output clean translations without over-generating, while remaining responsive to few-shot prompts. The final fine-tuning data split contains a total of $269,152$ segments: 129,173 (Engineering & Technology), 48,834 (Medical) segments for en-pl, and 91,145 (Engineering & Technology) segments for es-eu.

We fine-tune two lightweight LLMs to evaluate translation quality: **Gemma-3**, and **Tiny-Aya**.

| Gemma-3 FFT | **71.6*** | **85.7*** | **0.9108*** |

Table 2: Evaluation of base LLMs and few-shot fine-tuned models (FFM) on the es-eu language pair for the Engineering & Technology domain in 0-shot and 5-shot configurations. Bold denotes top results, and asterisks (*) denote statistical significance ($p < 0.05$) for comparisons between the baseline and FFT models.

Both models are fine-tuned on the mixed few-shot dataset using QLoRA (Dettmers et al., 2023). We apply adapters to the query, key, value, and projection layers to optimise parameter efficiency while maintaining baseline model performance. The values for QLoRA and SFT hyper-parameters are defined in Section D.

**WMT26 Submission** Our submission is the fine-tuned Gemma-3 model for the WMT Track 2 terminology task, covering English–Polish (Medical, Engineering & Technology) and Spanish–Basque (Engineering & Technology). We process both the supplementary few-shot candidate pool and the target documents at the sentence-level using our system. For Track 2 document-level translation, we submit MT outputs with both 0-shot (*no terminology*) and 5-shot (*bitext*) setups.

To replicate our experiments, we are releasing our scripts on GitHub[7].

## 3 Results

For automatic translation evaluation on the held-out test set, we report BLEU (Papineni et al., 2002; Post, 2018), chrF (Popović, 2015), and COMET (Rei et al., 2020). For COMET, we specifically use the `Unbabel/wmt22-comet-da` model. We evaluate the base instruction-tuned LLMs as baselines and compare their performance against the few-shot fine-tuned models (**FFM**) across both 0-shot and 5-shot configurations.

Table 1 shows the performance of the baseline lightweight LLMs (Tiny-Aya and Gemma-3) compared to the FFT models on the en-pl language pair. The asterisks denote statistical significance ($p < 0.05$) between the baseline and the FFM models for automatic metrics based on bootstrap resampling (Post, 2018).

The results for the en-pl language pair show that fine-tuning with our few-shot adaptation approach produces significant improvements across models and domains, with Gemma-3 FFT outperforming in all the setups. The FFT models outperform the baselines in almost all scenarios. Gemma-3 FFT with 0-shot achieves a high improvement in BLEU in the Medical and Engineering & Technology domains. Similar improvements are observed in chrF.

Our few-shot training strategy preserves and enhances ICL performance. Across all models, moving from 0-shot to 5-shot evaluation produces

Table 4: **WMT26 Track 2**: lemmatized term success (%), document chrF++ and COMET-22 under with and without the sample bitexts. Random and noterm are scored against the proper dictionary.

noticeable score improvements. Gemma-3 FFT achieves the highest performance in the 5-shot configuration, reaching top scores on BLEU, chrF, and COMET. While Tiny-Aya FFT achieves consistent improvements in BLEU and chrF over its baseline, its COMET scores show a decrease after FFT (0-shot Medical). In contrast, Gemma-3 FFT scales well, improving simultaneously across BLEU, chrF, and COMET (Medical), indicating that larger model capacity combined with in-domain few-shot examples, plays a role in translation quality.

Table 2 shows the performance of base LLMs against the FFT models on es-eu language pairs within the Engineering & Technology domain. The results for es-eu show improvements following the few-shot fine-tuning, highlighting the necessity of domain and language adaptation for low-resource languages like Basque. The baseline models struggle significantly in the 0-shot setting.

This shows that base lightweight LLMs lack sufficient pre-training data for Basque without ICL guidance or targeted adaptation. In the 0-shot setup, Gemma-3 FFT shows an increase in BLEU, followed by chrF and COMET. ICL provides further improvements when combined with fine-tuning. Moving from 0-shot to 5-shot evaluation improves all models, Gemma-3 FFT achieves the overall highest scores of BLEU, chrF, and COMET. Fine-tuning for es-eu produces statistically significant improvements across all three metrics for both FFT LLMs.

**WMT26 Results** The organisers evaluated all submissions using chrF++, lemmatised **Term** Success percentage, COMET, XCOMET, and MetricX (Charkiewicz et al., 2026). We compare our system's performance with the runner-up submission (CUNI-UFAL) (Charkiewicz et al., 2026). Table 3 shows the comparison between our model and CUNI-UFAL, while Table 4 details the performance across 0-shot and 5-shot configurations. The fine-tuning few-shot approach shows consistent gains over the baseline, however it does not surpass the top-performing CUNI-UFAL system.

## 4 Conclusions and Future Work

In this work, we presented a system for domain adaptation in specialised MT using lightweight LLMs, without compromising their ICL performance. We evaluate across en-pl and es-eu for specialised domains (Medical and Engineering & Technology). Our findings indicate: The few-shot fine-tuning method (Gemma-3 FFT) shows statistically significant improvements over base LLM baselines across automatic metrics. The FFT approach effectively preserves and enhances ICL. Evaluating models in a 5-shot configuration consistently produces the top performance across all metrics.

Building on these findings, we identify promising directions for future work: Studying lexical retrieval-based (e.g., BM25, fuzzy-match) selection for filtering and few-shot prompting could further improve the interaction between the fine-tuned adapter parameters and prompt context. While automatic metrics show high translation quality performance, conducting human evaluations (e.g., MQM framework) will help assess terminology consistency, and potential hallucinations in the fine-tuned LLMs (Lommel et al., 2013; Gaona et al., 2023; Kocmi et al., 2024).

## Limitations

Relying on the synthetic generated sentences for filtering, potentially perpetuates or amplifies underlying biases of the LLM while failing to capture complex in-domain examples. In-house computing resources force trade-offs in LLMs size, restricting overall MT capacity during training and testing. The system's terminology database (IATE) is heavily based on EU institutions, potentially leading to coverage gaps and lower precision when translating non-EU text.

## A Synthetic Seed Generation Prompt

The synthetic seed data generation prompt is as follows:

```
Produce one sentence in {src} using the following term from the {domain-str} domain: "{term}"
```

with *src* source language (*English* or *Spanish*), *domain-str* domain name (*health* or *engineering and technology*), and *term* source test segment.

## B Few-shot Fine-tuning Prompts

The 0-shot and 5-shot prompts are as follows:

**0-shot** prompt:

```
Translate the {src} source text to {tgt} in the {domain-str} domain.
Rules:
Output strictly the {tgt} translation.
Do NOT repeat the {src} text.
Do NOT include labels like "{src}:" or "{tgt}:".
Do NOT add quotation marks, explanations, or any extra text.
Now translate the following:
{src}: {src-segment}
{tgt}:
```

**5-shot** prompt:

```
Translate the {src} source text to {tgt} in the {domain-str} domain.
Rules:
Output strictly the {tgt} translation.
Do NOT repeat the {src} text.
Do NOT include labels like "{src}:" or "{tgt}:".
Do NOT add quotation marks, explanations, or any extra text.
Examples from the {domain-str} domain:
{src}: {example-segment}
{tgt}: {example-segment}
...
{src}: {example-segment}
{tgt}: {example-segment}
Now translate the following:
{src}: {src-segment}
{tgt}:
```

with *src* source language (*English* or *Spanish*), *tgt* target language (*Polish* or *Basque*), *domain-str* domain name (*health* or *engineering and technology*), *example-segment* source or target retrieved examples, and *src-segment* source test segment.

## C FAISS Index Hyper-parameters

Instead of searching through all dataset vectors, FAISS uses *IndexFlatL2* to store and search the coarse cluster centroids that partition your vector space into $k$-means clusters. The IndexFlatL2 uses Euclidean distance (L2) to perform vector searches. When the index is trained FAISS runs $k$-means clustering on the a sample of the training data to learn $N$ global centroids/clusters. The FAISS index hyper-parameters are as follows:

| Language pair | Training size | *N* clusters | *M* sub-quantisers | *nbits* |
|---|---|---|---|---|
| en-pl | 20M | 30000 | 64 | 8 |
| es-eu | 4M | 1000 | 16 | 8 |

Table 5: FAISS index hyper-parameters with a *IndexFlatL2* coarse-quantiser and embedding dimensionality of $d = 384$.

## D QLoRA and SFT Hyper-parameters

The hyper-parameter values for both LLMs are as follows:

| Hyper-parameter | Value |
|---|---|
| r | 32 |
| $\alpha$ | 64 |
| Dropout | 0.1 |
| Target modules | q_proj, k_proj, v_proj, o_proj, gate_proj, up_proj, down_proj |
| Epoch | 2 |
| Max sequence length | 1024 |
| Batch size | 2 |
| Gradient accumulation | 4 |
| Learning rate | $2e-4$ |
| Warm-up steps | 0.03 |
| Scheduler type | cosine |

Table 6: FFT hyper-parameter values. The upper section contains the 4-bit QLoRA hyper-parameters, and the lower section contains the overall SFT.

# STRA-MT: Deterministic Terminology Control for Document-Level Machine Translation

## Abstract

STRA-MT is a translation pipeline with deterministic terminology control built around small open weight language models. The pipeline (1) reuses exact repetitions and guides near-duplicates using translations from earlier occurrences, (2) maintains a growing terminology ledger initialized from either the provided glossary or a termbase mined from sample bitext, and (3) verifies every required term and, when one is missing, regenerates the paragraph once with the missing terms named. On the WMT25 zh-Hant→en development sets, STRA-MT improves mean terminology success over glossary prompting from 87.3 to 92.4 under the official WMT25 evaluation, while maintaining competitive BLEU, chrF++, and COMET scores. Official WMT26 test sets shows that term delivery on en→pl comes close to the reference ceiling while the translation quality depends on the backbones.

## 1 Introduction

Recent developments in large language models (LLMs) have significantly advanced the state of the art in machine translation (MT). In terms of fluency and naturalness, LLMs have rapidly narrowed the gap with dedicated MT systems and are increasingly used for general purpose translation. However, in specialist domains like medicine or finance, accurate and consistent terminology remains an open problem. WMT25 terminology task (Semenov et al., 2025) found that provided terminology helps, especially for systems that already translate well .

Previous work controls terminology through mechanisms such as constrained decoding (Hokamp and Liu, 2017; Post and Vilar, 2018) or by providing required terms as part of the input to instruction-following LLMs (Moslem et al., 2023). Recent LLM translation agents extend this approach with document-level memory maintained in the prompt (Wang et al., 2025), building on mechanisms that page memory through the prompt (Packer et al., 2023). In these approaches, terminology and document context are provided to the model as part of translation.

STRA-MT keeps translation choices consistent through explicit steps in the translation process. It uses at most two small open weight models for each translation direction. Before translation, an offline planning step finds exact repeated paragraphs and reuses their earlier translations. For near-duplicate paragraphs, it provides the earlier translation as a guide while generating a new translation. During translation, a term ledger stores the provided glossary and the terms chosen by the system in earlier paragraphs. After each paragraph is generated, a verifier checks whether every required term appears in the output. If a required term is missing, the system translates the paragraph one more time with the missing terms provided in the prompt. A cached classifier checks whether a term can appear in an inflected form. Short notes record recurring entities and are included in later prompts while they remain relevant. Final checks look for untranslated source text, repeated or looping text, and malformed headings.

## 2 System Architecture and Pipeline

### 2.1 Overview

The WMT26 Terminology Translation Task consists of two tracks. In Track 1, every document comes with a terminology dictionary in two versions. The *proper* version lists the real domain terminology, and the *random* version is a control set of ordinary words with their reference translations. Each document is translated three times, once with no terminology, once given the proper version, and once given the random version. In Track 2 only sample bitext per do-

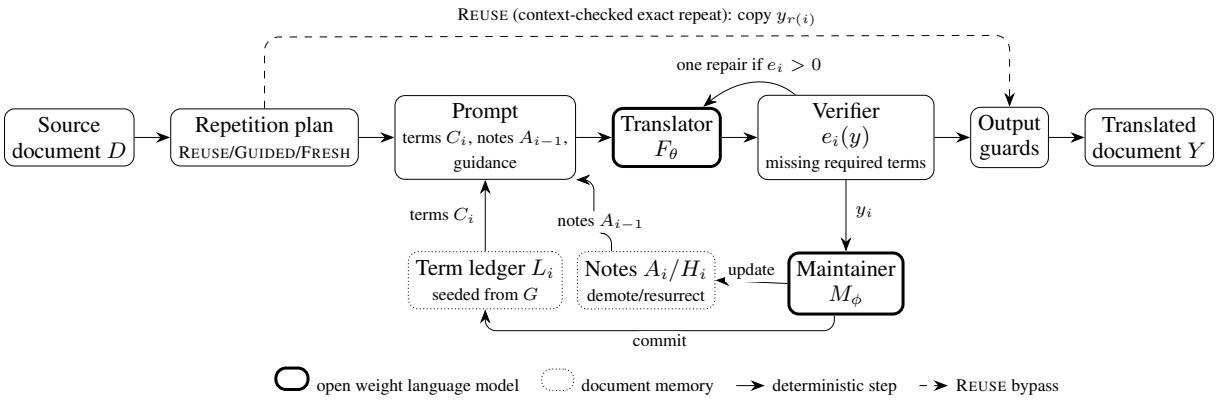

Figure 1: The STRA-MT pipeline. The plan routes each paragraph, translation is conditioned on the ledger and notes with at most one repair, and the maintainer updates both memories.

main is supplied, and documents are translated without terminology and given the bitext. Both tracks cover es→eu (Spanish→Basque), en→pl (English→Polish). Track 2 additionally covers zh-Hant→en (Traditional Chinese→English). We submitted to every cell, that is every direction and domain, of both tracks.

STRA-MT is built around a translator and a maintainer model. Technical documents are usually repetitive. We therefore resolve repetition with a deterministic plan built before any translation begins (§2.3). Translation then proceeds paragraph by paragraph under a growing term ledger with a verify-and-repair loop (§2.4). While it runs, the maintainer writes short discourse notes that are paged in and out of the prompt (§2.5). Finished outputs pass three guards before staging (§2.6). The key prompts are given in Appendix A.

The components play different roles across the two tracks. The ledger, together with its verification and repair mechanisms, directly addresses the task. In Track 1, it is seeded from the provided dictionary, whereas in Track 2, it is seeded from a termbase mined from the sample bitext. For en→pl, the inflection check further allows the system to accept declined forms. The repetition plan, discourse notes, and output guards are intended more generally for long technical documents. On the development sets, these components do not affect term success (§3), while on this year's blind documents, the repetition plan is triggered only rarely (Appendix B.2). We nevertheless retain them as inexpensive safeguards for repetitive or entity-dense documents.

Figure 1 summarizes the pipeline. Throughout, the source document is $D = (x_1, \ldots, x_N)$ with translation $y_i$ for paragraph $x_i$, and $r(i)$ is the index of the earlier paragraph most similar to $x_i$. $G$ is the provided glossary or the mined termbase, $L_i$ the term ledger after paragraph $i$, $C_i$ the set of ledger terms enforced on paragraph $i$, $e_i(y)$ the number of those terms missing from a candidate output $y$, $A_i$ and $H_i$ the active and archived discourse notes, $F_\theta$ the backbone translator, and $M_\phi$ the maintainer model. We call zh-Hant→en and en→pl the *instruct directions*. Their translator is an instruction-following model that reads the ledger and the notes from the prompt. On es→eu the translator is a specialist model, and the maintainer applies the ledger by post-editing (§2.2).

| Direction | Backbone | BLEU | chrF++ |
|---|---|---|---|
| zh-Hant→en | **Gemma-4-E2B** | 25.8 | 53.7 |
| | NLLB-1.3B | 25.9 | 52.4 |
| | TranslateGemma-4b | 21.9 | 51.2 |
| es→eu | Gemma-4-E2B | 2.0 | 26.1 |
| | **NLLB-1.3B** | 12.8 | 46.9 |
| | TranslateGemma-4b | 4.2 | 35.2 |
| en→pl | **Gemma-4-E2B** | 20.7 | 48.2 |
| | NLLB-1.3B | 21.1 | 48.6 |
| | TranslateGemma-4b | 16.9 | 45.9 |

Table 1: Backbone screening on FLORES-200 devtest. Bold marks the selected backbone.

## 2.2 Backbones

We select one base translator per direction by evaluating each candidate on the FLORES-200 devtest (NLLB Team, 2022) with BLEU (Papineni et al., 2002) and chrF++ (Popović, 2017) as the evaluation metrics. We choose instruction-following Gemma-4-E2B (Gemma Team, 2026), the multilingual specialist NLLB-1.3B (NLLB Team, 2022),

| Direction | Translator | Maintainer | Ledger seed |
|---|---|---|---|
| zh-Hant→en | E2B | shared E2B | mined termbase |
| en→pl | E2B | E4B | dictionary / mined |
| es→eu | NLLB + E4B | E4B | dictionary / mined |

Table 2: Submitted configuration per direction. On es→eu the E4B maintainer also post-edits the NLLB draft.

and TranslateGemma-4b (Finkelstein et al., 2026) as our candidates. We select Gemma-4-E2B for zh-Hant→en and en→pl (Table 1). It is competitive and follows an in-prompt glossary. On es→eu, Gemma-4-E2B collapses into pseudo-Basque with Spanish intrusions (for FLORES "…tenemos ratones de cuatro meses…" it produces "*Aktualean*, urtekatarretarren *ratonek* dituztegi" where NLLB gives "lau hilabeteko saguak ditugu"), therefore we use NLLB-1.3B as the translator. Because NLLB cannot utilize any prompt, the maintainer takes a second role as the *corrector*. After NLLB drafts a paragraph, the same loaded Gemma-4-E4B instance post-edits the draft so that the required terms appear. The edit is accepted only if it loses no term and does not drift toward the source language (Appendix A.3). E2B and E4B are the two smallest Gemma-4 instruction-tuned variants, with about 2B and 4B effective parameters. On zh-Hant→en the E2B translator serves as its own maintainer, which delivers more terms than a separate E4B (§3). On en→pl and es→eu we use a separate 4-bit Gemma-4-E4B maintainer. Table 2 lists the resulting configuration per direction. The pipeline is identical across directions. The plan thresholds, ledger policy, verification, note paging, guards, and prompts are shared. Only the models in the translator and maintainer slots differ.

### 2.3 Offline repetition plan

Before any translation, a deterministic pass scans the document for repetition. Paragraphs are compared after lowercasing and collapsing whitespace. For each paragraph $x_i$ the pass finds the most similar earlier paragraph $x_{r(i)}$ and assigns one of three modes. Similarity is the `difflib` SequenceMatcher ratio over characters, $2M/T$, where $M$ is the number of matched characters and $T$ is the combined length. Pairs whose lengths differ by more than a factor of two are skipped. The pass runs on the CPU and makes no model call.

REUSE applies when the paragraph repeats an earlier one exactly and the paragraph immediately before it also matches. We call this the *context check*. The earlier translation $y_{r(i)}$ is then copied with no model call. If the preceding paragraphs differ, the exact repeat is not copied and is handled as a near-duplicate instead.

GUIDED applies when the two paragraphs are similar but not identical, with a similarity ratio of at least 0.7. The paragraph is translated by the model, but the prompt shows the earlier paragraph and its translation as an example, together with an instruction derived from the difference (Appendix A.3). When only values differ, such as numbers or dates, the instruction is to keep the example's wording and substitute the new values. When the wording itself differs, the instruction is to translate the changed part faithfully. This guidance requires a translator that follows prompts, so it applies on the instruct directions only. On es→eu, where NLLB translates the bare segment, a near-duplicate is translated as fresh and only the reuse of exact repeats operates.

FRESH applies to everything else, and the paragraph is translated normally.

### 2.4 Term ledger with verify and repair

**Ledger** The system maintains a growing term ledger as external memory for terminology. The ledger can be initialized from a provided glossary or from a termbase mined from sample bitext. Unlike the soft proper-noun records used by DelTA (Wang et al., 2025), ledger entries are treated as fixed translation choices. After each paragraph, the translator identifies the proper nouns and fixed technical terms it used, and these source–target term pairs are added to the ledger under a first-commitment policy. Glossary entries always take priority, existing ledger entries remain unchanged, and only previously unseen terms receive a new translation.

When a ledger term appears again, its committed translation is provided to the translator as the required rendering. Without a glossary, the system's first translation of a recurring term therefore becomes the translation used for later occurrences. The ledger does not assess whether a committed translation is correct. This means an incorrect entry is propagated just as consistently as a correct one.

**Termbase mining** In Track 2, we build a small termbase from the provided sample bitext using SimAlign (Jalili Sabet et al., 2020). We keep a source-target pair when it is aligned at least twice and the most frequent target accounts for at least 60

percent of that source term's alignments. We then remove pairs where two nearby content words align to the same target token, as well as pairs containing a digit or function word.

**Inflection-aware enforcement** Enforcement applies to all terms in the ledger, whether they were seeded from a termbase or added by the system. For each paragraph $x_i$, the system first identifies the ledger terms that occur in that paragraph and stores them in an enforcement set $C_i$. Recognition is based on surface matching. Both the paragraph and the ledger keys are lowercased before matching. Keys containing Latin letters must occur as whole tokens, while keys in unspaced scripts, such as Chinese, are matched as substrings. Only the matched terms are included in the prompt, and the complete glossary is never provided. The system does not perform sense disambiguation (see Limitations).

The system then applies two cached checks provided by the maintainer $M_\phi$. The proper-name check removes a term if its occurrence is part of a larger company, brand, or organization name. The term is still enforced when it occurs independently in another paragraph. The inflection check determines whether a term must be used in its committed form or can be inflected (Bergmanis and Pinnis, 2021). Fixed-form terms must be reproduced exactly. For example, the acronym *ERTMS* must appear verbatim. Inflecting terms can appear in different grammatical forms. For Polish *karcynogeneza*, for example, *karcynogenezy* is accepted because each word in the committed rendering matches an output token by stemmed prefix (Appendix B.4).

Both checks use only local models. The final set of requirements is then added to the translation prompt as instruct directions. For es→eu, the E4B corrector also applies these requirements when post-editing the NLLB draft.

**Verify and repair** After each paragraph, a deterministic verifier counts the required terms missing from the output, $e_i(y)$. If any is missing, the system regenerates the paragraph once with the missing terms named (Appendix A.2) and keeps whichever of draft and repair misses fewer, with ties resolved for the repair. Regeneration is thus bounded to one extra model call and can never increase the number of violations.

### 2.5 Paged discourse notes

**Notes** While translating, the maintainer writes short notes about the entities in the current document, recording who did what (Appendix A.3). Notes about recently mentioned entities are kept in the prompt so that later references stay coherent. Nothing is retrieved from outside the document, and the maintainer must use the same renderings the ledger enforces in every note and alias.

**Demote and resurrect** Because the context window is limited, note paging is deterministic. A note unmentioned for 8 paragraphs is demoted to the archive $H_i$, and at most 12 notes stay active in $A_i$. Before each paragraph is translated, every archived note is tested against the source paragraph. The test is the same surface match used for ledger terms (§2.4). It is applied to the note's entity name, its object, and every alias the maintainer recorded, and a note with any hit is resurrected into $A_i$. It is tagged with the number of paragraphs since it was last seen, so the translator can tell old context from current context. Demotion archives rather than deletes, so a paged-out note can always return. The match is exact at the string level. It costs no model call and never resurrects a note for an unrelated entity. It misses a mention that appears only as an inflected form, a pronoun, or a paraphrase. The maintainer must also have recorded the alias for it to count. We did not measure the recall of this trigger against a gold standard (see Limitations).

### 2.6 Output guards

We add postprocessing guards over every finished output before it is staged as a submission file. The first two guards check every document and fire only on the failure they target. The third is switched on per cell. An LLM-based repair is accepted only when it improves the metric that flagged it. The guards are not part of the development harness, so all development results are measured without them. Appendix B.2 reports how often each fired on the blind test. The *target-language identity guard* flags output still in the source language via per-direction function-word and script rules and retranslates it with the direction's repair prompt. The *repetition guard* flags a paragraph when any word trigram repeats four or more times and retranslates it, falling back to a deterministic collapse that keeps the first occurrence if the backbone keeps looping. The *heading guard* recases mangled all-caps headings through a minimal-edit pass. It runs only on the en→pl medical documents, a switch set by inspecting the released sources.

Table 3: zh-Hant→en WMT25 dev years. TS is WMT25 term success, $TS_{26}$ the WMT26 measure. Both glossary-fed configurations run the proper-name check, answered by E4B in the glossary column and by E2B in the STRA-MT column (see the proper-name check paragraph). Bold marks the best Avg.

## 3 Results

**Evaluation setup** WMT26 provides no development references for es→eu or en→pl, so reference-based validation is possible only for zh-Hant→en. We use the five zh-Hant→en years of the WMT25 Terminology Task development data (finance). We compare against the bare Gemma-4-E2B translator and the same translator with the glossary in the prompt (Appendix A.1). STRA-MT uses Gemma-4-E2B as translator and maintainer. The metrics are BLEU (Papineni et al., 2002), chrF++ (Popović, 2017), COMET (Rei et al., 2020) with the `wmt22-comet-da` checkpoint (Rei et al., 2022), and term success (TS), the share of required dictionary terms whose allowed rendering appears in the output. For zh-Hant→en we also report $TS_{26}$, the WMT26 lemmatised exclusive term success from the organisers' scorer[1] (Charkiewicz et al., 2026). It is stricter than TS, because it requires a separate output span for every source occurrence of a term, so its ceiling lies below 100. The development data has no occurrence annotations, so we annotate each source paragraph with the dictionary entries it contains that pass the WMT25 reference filter, one per occurrence. BLEU and chrF++ score each document as one segment. COMET is averaged over aligned paragraphs. BLEU, chrF++, and TS use the official WMT25 implementation[2].

**Findings** Table 3 shows the zh-Hant→en results. Showing the model the glossary brings the largest improvement, from 43.3 to 87.3 term success, in line with the WMT25 finding that instruction-following models exploit provided terminology (Semenov et al., 2025). STRA-MT improves term success by a further 5.1 points to 92.4 and is the best of the three configurations in every year. The proper-name check paragraph below gives the like-for-like comparison. The cost is about one BLEU point, because a repaired paragraph is regenerated whole and kept when it delivers more terms. Translation quality is inherited from the backbone. Qualitative examples are in Appendix B.

| Configuration | BLEU | chrF++ | COMET | TS | $TS_{26}$ |
|---|---|---|---|---|---|
| Bare translator | 27.6 | 66.0 | 0.843 | 43.3 | 41.0 |
| + glossary in prompt | 33.7 | 69.6 | 0.858 | 87.3 | 70.0 |
| Ledger + verify/repair | 33.6 | 69.7 | 0.857 | **92.4** | **72.6** |
| + plan (no notes) | 33.7 | 69.7 | **0.861** | **92.4** | **72.6** |
| + notes (no plan) | 33.7 | 69.7 | 0.857 | **92.4** | **72.6** |
| Full pipeline (STRA-MT) | 33.7 | 69.7 | **0.861** | **92.4** | 72.5 |
| Full, mined termbase | 26.2 | 65.1 | 0.845 | 40.6 | 38.8 |
| Full, same-corpus mined | 26.9 | 66.1 | 0.848 | 42.0 | 42.9 |

Table 4: Component ablation and termbase seeding, zh-Hant→en five-year means, same setting as Table 3. Each "+" row adds one component to the ledger row. Bold marks the best in the upper block.

**Ablation** The upper block of Table 4 adds one component at a time. *Glossary in prompt* lists the terms found in the paragraph as mandatory, without verification. *Ledger + verify/repair* adds the ledger of §2.4, together with its two checks and single repair. The + *plan* and + *notes* variants do not further improve term success. Neither changes BLEU, chrF++, or COMET. The output guards are not part of these experiments.

Each development set contains only 5 to 17 exact repeats among 427 to 641 paragraphs. The context check rejects all of them, so REUSE never fires here. In 2016, 44 paragraphs receive near-duplicate guidance.

**Cost** Table 5 gives the time per step. Translation takes under a second per paragraph, and the repair

| medical en→pl | 53.2 | 52.6 | 63.2 | **87.0** |
| machine-tool es→eu | 25.6 | 25.6 | 28.5 | **67.4** |
| railways es→eu | 51.8 | 55.0 | 58.5 | **70.8** |
| finance zh-Hant→en | 68.6 | 64.9 | 80.4 | **80.6** |

Table 6: Term success ($TS_{26}$) on the Track 2 test cells with no termbase, the mined termbase, and the one the maintainer builds. Within each block only the termbase changes. *The submitted files.

adds half a second because it fires on 30 percent of paragraphs. The two maintainer calls dominate. Ledger extraction costs more than the translation, and note maintenance more than twice as much. The terminology steps together take 2.8 seconds per paragraph and give the whole gain, while the notes add 2.3 seconds for no measurable gain.

**Random glossary condition** The pipeline delivers a randomly selected glossary as faithfully as the proper one. On the 2016 year, term success on the random dictionary rises from 91.6 under prompting to 93.5 under enforcement. Term success on the proper dictionary falls from 41.4 to 36.9 at the same time, and BLEU by 6.3 against the bare translator.

**Seeding from a mined termbase** The WMT26 zh-Hant→en submission seeds the ledger from a mined termbase (§2.4). The lower block of Table 4 scores this configuration against the official dictionaries. Term success falls below the bare translator (40.6 vs. 43.3). Enforcement works, but the mined inventory covers less than 1% of the dictionary terms. The miner extracts word-level pairs, while the dictionaries hold multiword expressions and names, such as 金立群→"liqun" where the dictionary requires "President Jin Liqun". Against its own inventory the same pipeline reaches 95.3 term success, against 86.8 for the bare translator, and same-corpus termbases reach 97.0 against 80.9.

**Building the termbase with the maintainer** The mined termbase can be replaced by a termbase built by the maintainer from the same sample bitext. The maintainer reads each sample sentence pair and identifies the term pairs it contains. A pair is kept only if both sides occur verbatim in that sentence pair, and disagreements across batches are resolved by majority vote. Terms that occur only in the test documents are translated afterwards, using the verified pairs as references. On mechanical engineering, this procedure produces 761 entries, compared with 108 from the aligner.

Table 6 shows the results on the official test sets. With the backbone held fixed, the model built termbase improves term success by 48.4 points on mechanical engineering, 38.9 on machine tools, 23.8 on medical, and 12.3 on railways. The mined termbase we submitted does not improve the same system as it scores at or below the no-termbase setting on four of the five cells.

The difference is important because the ledger commits each entry once and then requires the same rendering at every later occurrence. A misaligned pair therefore does not cause just one local error, since it can propagate the wrong rendering throughout the document. A termbase containing enough such errors can consequently perform worse than having no termbase at all.

**The proper-name check** The proper-name check utilizes the maintainer in deciding whether a matched term is part of a larger product or company name (§2.4). If it is, the term is removed from the prompt and is not verified. This prevents the system from forcing a translation inside a name that should remain unchanged.

Chinese is written without spaces, so a glossary term can match a substring even when it is part of a larger name, and the check is applied to nearly every term. How often it answers yes therefore changes how many terms the system must deliver, which matters for Tables 3 and 4. The glossary row was run with E4B answering the check, while the STRA-MT rows use E2B, and E4B identifies more terms as part of names. Thus, part of the 5.1-point difference between these rows comes from the check rather than from the pipeline. Using the same E2B check for both settings gives 91.6 for prompting and 92.4 for the pipeline. Turning the check off, as we did for the submitted zh-Hant→en

| Track | Direction | chrF++ | $TS_{26}$ | Ceiling | COMET |
|---|---|---|---|---|---|
| 1 | en→pl | 72.9 | 91.7 | 93.6 | 87.0 |
| 1 | es→eu | 65.8 | 86.3 | 99.1 | 81.3 |
| 2 | en→pl | 67.3 | 38.7 | 94.9 | 84.0 |
| 2 | es→eu | 64.8 | 40.3 | 99.1 | 78.6 |
| 2 | zh-Hant→en | 65.5 | 64.9 | 86.3 | 80.2 |

Table 7: Official WMT26 scores of STRA-MT per direction, Track 1 in proper mode and Track 2 in sample mode (Charkiewicz et al., 2026). Ceiling is the reference scored against itself.

system, gives 95.3 for prompting and 96.4 for the pipeline, with BLEU at 36.6 and 35.6 and COMET equal at 0.866. The pipeline therefore adds about one term-success point under either setting.

We keep the check for en→pl and es→eu, where spaces make the matches unambiguous and the check fires mainly when a term occurs inside a larger name.

**Official results** Table 7 gives the official scores from the organisers. In Track 1, STRA-MT achieves 91.7 $TS_{26}$ on en→pl, compared with a reference ceiling of 93.6. On es→eu, it achieves 86.3 against a ceiling of 99.1. Thus, term success is high on both directions, although the gap to the ceiling is larger for es→eu. Across the two Track 1 directions, the average $TS_{26}$ is 89.0. Track 2 was not the main focus of this system. We submitted a termbase mined from the sample bitext. On the three Track 2 directions, STRA-MT achieves $TS_{26}$ of 38.7 on en→pl, 40.3 on es→eu, and 64.9 on zh-Hant→en. The corresponding chrF++ scores are 67.3, 64.8, and 65.5, and the COMET scores are 84.0, 78.6, and 80.2.

**Ablation on the test set** After the gold data were released, we reran the three main configurations on all four Track 1 test cells and evaluated them using the organisers' scoring code.

For en→pl, the ledger provides a small improvement over prompting alone. It increases term success by 0.2 and 1.7 points, while improving chrF++ by only 0.1 to 0.2 points. Adding the notes removes 0.3 and 1.3 of these term-success points. The submitted files perform better than these reruns, with term-success scores that are 1.1 and 2.0 points higher. These files use an earlier system version followed by output guards.

The results for es→eu show a different pattern. Here, a specialist translator first produces the translation, and the maintainer then post-edits it. The full pipeline improves term success over prompting by 0.9 points on energy and 1.1 points on automotion. The ledger-only configuration gives intermediate results but reduces chrF++ by about one point. The components are therefore most useful when the corrector is responsible for applying the required terminology. When the translator can directly use the glossary, the components provide little benefit and may even reduce performance.

We also evaluated a larger 31B backbone using the ledger alone (Appendix B.3) and the model-built termbase (Table 6). Using the organisers' released scorer and gold annotations,[3] this system reaches 93.1 lemmatised term success and 72.0 chrF++ on Track 1, against 89.0 and 69.3 for the submitted files.

## 4 Conclusion

This paper presents our submission to both tracks of the WMT26 Terminology Translation Task. Our approach uses deterministic control procedures around small language models rather than relying on the model's memory or its ability to maintain terminology consistency on its own. The main idea is that terminology and repeated content can be checked directly. String matching can verify whether a required term appears in the output, while a fixed procedure can reuse previous translations for repeated or related content. We therefore enforce these properties with explicit rules and leave the language model to focus on translation.

Our results show that this approach improves terminology consistency while keeping translation quality close to that of the underlying backbone model. The control procedure provides three main benefits. First, it verifies that required terms are actually delivered. Second, it ensures that the first committed translation of a term is used consistently throughout the document. Third, it enforces an arbitrary or mined inventory as faithfully as a reference one.

For Track 2, building the termbase with the maintainer recovers most of the performance gap caused by using a mined inventory (§3). In contrast, checking terminology at the occurrence level does not improve performance. On the en→pl test cells, it reduces term success by about one point. The main reason is that occurrence-level checking requires regenerating individual sentences, which gives the

[3] github.com/wmt-conference/wmt26-terminology

model less context than regenerating the full paragraph.

Overall, these results suggest that simple deterministic controls can provide reliable terminology enforcement without requiring a larger or more capable translation model.

## Limitations

Translation quality still depends on the backbone model. Errors that are not detected by the guards remain in the output. The heading guard is also enabled separately for each domain by inspecting the released source texts. This manual step does not transfer automatically to new domains.

The system can only enforce the inventory it receives. Therefore, an incorrect first commitment can be repeated throughout the document. For example, if 金管局 is first translated as "Monetary Authority of Taiwan", this translation is reused in later occurrences. Term recognition is based only on surface matching and assumes that each source string is the term and has a single meaning. Both assumptions fail for a form such as English *control*. It is a verb as well as a noun, so the system enforces the glossary rendering on occurrences that are not the term at all. As a noun it names different concepts, so one committed rendering is applied to all of them. The proper-name check removes only the first kind of false match, and only when the term sits inside a larger name. The system performs no part-of-speech filtering and no word-sense disambiguation, so a glossary that lists sense-specific entries for one string cannot be honoured.

The same surface matching procedure is used to restore notes, but we did not measure its recall. A note is not restored when the relevant content appears only as an inflected form, a pronoun, or a paraphrase.

Reference-based development evaluation is available only for zh-Hant→en because WMT26 does not provide development references for es→eu or en→pl. We therefore validated these two directions only with the official test-set scores, which became available after the system was frozen.

All submitted models have at most 4B effective parameters. These smaller models may have weaker capabilities than models with 20B or more parameters and may perform worse on lower-resource languages. Our screening of es→eu backbones shows this effect (§2.2). Appendix B.3 further examines the behaviour of the pipeline with larger models from the same Gemma-4 family.

All reported results are single greedy-decoded runs. The variation across development years is the only variability estimate provided.

# A Prompts

The base translation prompt, without its optional notes and fuzzy-match blocks, and the repair prompt are given in full. The other prompts are summarised.

## A.1 Base translation prompt (instruct translator)

```
Translate the following {src} paragraph
into {tgt}. This is a professional
document; keep terminology precise and
style consistent.

Use EXACTLY these {tgt} terms for the
following {src} terms (mandatory
terminology):
- "{source term}" -> "{committed term}"

{src} paragraph:
{paragraph}

Output ONLY the {tgt} translation,
nothing else.
```

## A.2 Repair prompt

```
Your previous translation:
{draft}

It is missing these mandatory terms:
"{term}", ...
Rewrite the {tgt} translation using ALL
mandatory terms exactly as given.
Output only the translation.
```

## A.3 Other prompts (summarized)

The *fuzzy-match block* for GUIDED paragraphs shows the earlier source and its translation and asks the model to reuse that phrasing, changing only what differs. The *es→eu corrector* prompt, answered by the maintainer, receives the source, NLLB's draft, the mandatory terms, and the active notes, and rewrites the draft so that every mandatory term appears. It runs only when the draft misses a term or notes are active. The rewrite is accepted only if it misses no more terms than the draft, does not raise the overlap with the source, and copies no source span. The *note maintainer* receives the current notes, the term renderings, and the new source–target pair, and returns add, update, and delete operations. The *glossary classifier* labels each term fixed-form or inflecting. The *proper-name check* asks whether a matched span is part of a company, brand, or organisation name. The *ledger extraction* prompt asks which proper nouns and fixed technical terms the translation used. The *heading revision* and *target-language repair* prompts perform the guard repairs and return only the corrected span.

## B Additional development results

### B.1 Qualitative examples

Table 8 shows one delivery example, one consistency example, and one wrong commitment that the ledger repeats identically.

### B.2 Blind-test run statistics

Table 9 shows how the deterministic components behaved on the blind test. The REUSE bypass was rarely used. The context check rejected almost all repeats proposed by the plan. As a result, only five paragraphs in the entire submission were copied without a model call. The en→pl documents contained no such repeats.

GUIDED prompting was used for 19 zh-Hant→en units and was not used for the other language pairs. Near-duplicate content cannot be handled with guided NLLB prompting. The ledger and repair loop were used for all language pairs. After the single repair step, between 4 and 33 percent of the required term slots were still unmet, with the highest rates in the Polish cells.

The output guards also made several corrections. For es→eu, they rewrote 75 of 1,544 automotion paragraphs and 31 of 881 energy paragraphs that still contained source-language text. They accepted 6 of 25 repetition repairs and stopped 17 looping paragraphs. For en→pl, they recased 67 of 78 flagged medical headings. For zh-Hant→en, they rewrote two paragraphs that still contained Chinese.

### B.3 Backbone scale

Table 10 compares the three main configurations with a larger 31B backbone on all four Track 1 test cells. On en→pl the larger model replaces the translator. On es→eu it replaces only the corrector, because NLLB cannot read a prompt.

Without a glossary the larger backbone is better on both metrics, gaining 1.9 to 5.9 chrF++ and 3.9 to 12.5 term-success points. Adding the glossary lifts term success sharply at either size, and at 31B it reaches 96.7, 94.7, 90.9 and 92.5 on the four cells. The full pipeline then scores 95.2, 92.9, 90.2 and 92.4, slightly below the glossary alone everywhere, at equal translation quality.

The pattern differs from the submitted backbone, where the full pipeline is ahead on three of the four cells. Deterministic enforcement therefore helps most when the backbone is small, and a model large enough to follow a glossary by itself has little left for it to add. A 31B corrector also cannot share a 24 GB GPU with NLLB, which limits its use in our setup.

### B.4 Implementation details

The translator loads in bfloat16 and the separate maintainer, where used, in 4-bit NF4, which together fit one 24 GB RTX 4090. The zh-Hant→en Track 2 documents arrive without line breaks, so each is split into sentences for translation and rejoined afterwards. Generation length is $\min(2048, \max(512, |\text{source}|/2))$ new tokens. Stem verification accepts a lowercased token whose prefix matches the term word minus up to three trailing characters, with a minimum stem of four characters, and every word of a multi-word term must match. Both constants were fixed once and not tuned. The inflection classifier is cached per glossary and the proper-name check per term–paragraph pair. BLEU and chrF++ use sacrebleu 2.6.0 (Post, 2018), with the `zh` tokenizer for Chinese targets and `13a` otherwise, and chrF++ with character order 6 and word order 2. The official term-success function is ported verbatim and validated to produce identical scores. Documents are scored as single segments for BLEU and chrF++, and COMET is averaged over aligned paragraphs.

## Abstract

The accurate translation of domain-specific terminology remains a critical bottleneck for ensuring the fidelity and professionalism of machine translation systems. This paper presents our submission to the WMT26 Terminology Translation Shared Task: the TaT (Terminology-aware Translation) system. Built upon a structured, pipelined architecture, TaT integrates five specialized components designed to seamlessly ingest, process, and translate ambiguous textual inputs while strictly adhering to the targeted terminology dictionary. Specifically, the framework comprises a sentence splitter, a terminology retriever, a lexical disambiguator, a baseline translator, and a dedicated terminology extractor tailored for Track 2 constraints. Both internal benchmarking and ablation studies demonstrate that our decoupled pipeline delivers robust performance, successfully meeting design expectations and substantially mitigating terminology omission and misalignment errors in domain-specific translations.

## 1 Introduction

Domain-specific machine translation requires strict adherence to specialized lexicons to ensure technical accuracy and cross-lingual consistency. While contemporary Large Language Models (LLMs) and advanced neural machine translation (NMT) architectures have dramatically elevated general translation fluency, they frequently falter when dealing with rare, highly technical, or polysemous technical terms. In production scenarios, a single mistranslated concept can compromise the entire document's integrity, potentially leading to critical misunderstandings in specialized fields. Consequently, effectively constraining translation outputs to honor predefined terminology lists, while avoiding target-side omissions or misalignments, remains a vital area of empirical study (Semenov et al., 2025).

To rigorously address these limitations, we developed the TaT (Terminology-aware Translation) system, which served as our official submission to the WMT26 Terminology Translation Shared Task. Departing from purely monolithic end-to-end translation frameworks, which often struggle to balance fluid phrasing with rigid lexical constraints, TaT leverages a decoupled, pipelined architecture. The system orchestrates five foundational components in a sequential manner: a sentence splitter to normalize sequence lengths and define localized windows, a terminology retriever to surface domain-specific matches from the target dictionary, a lexical disambiguator to resolve terminology polysemy by evaluating contextual target candidates, a core translator executing the final synthesis, and a specialized terminology extractor explicitly engineered to fulfill the requirements of the Track 2 benchmark by constructing a missing terminology dictionary directly from sample bitexts.

Our internal evaluation and empirical analysis validate the efficacy of this modular design. By isolating the retrieval and disambiguation phases prior to decoding, the TaT framework minimizes the processing load on the translation engine, ensuring highly reliable constraint adherence. These comparative self-evaluations primarily serve to identify the optimal strategy configuration for our pipeline. Across multiple tested tracks and evaluation subsets, the resulting core configuration achieves marked improvements in terminology alignment accuracy without degrading baseline linguistic fluency.

## 2 System Description

Unlike previous editions of the Terminology Translation task (Semenov et al., 2023, 2025), this iteration introduces a strict document-level setup for

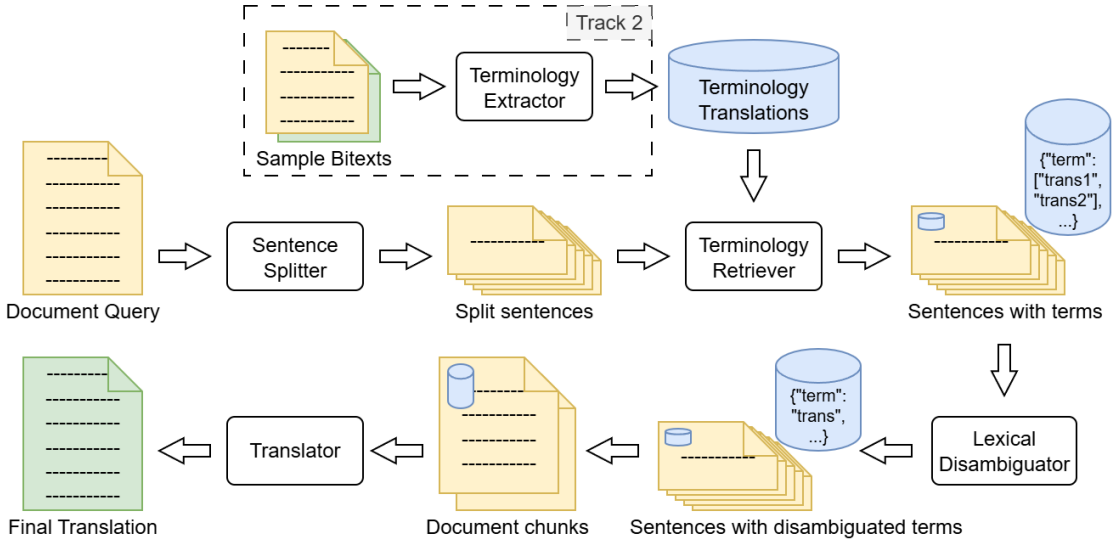

Figure 1: Overall pipeline of the proposed TaT system, consisting of five core components: the sentence splitter, terminology retriever, lexical disambiguator, translator, and terminology extractor (for Track 2).

both evaluation tracks. Furthermore, Track 2 does not provide a predefined terminology database, requiring participants to either utilize the provided sample bitexts directly or extract a structured terminology dictionary from them. The architecture coordinates five functional components: a sentence splitter, a terminology retriever, a lexical disambiguator, a core translator, and a specialized terminology extractor for Track 2.

### 2.1 Sentence splitter

The sentence splitter processes raw documents into segments through four cascading phases: (1) Paragraph boundary detection, which identifies layout structures to maintain document integrity; (2) Multilingual sentence tokenization, offering native support for parsing syntax variations in Chinese, English, and Spanish; (3) Dynamic chunk merging, which groups consecutive brief sentences to fulfill configurable minimum length thresholds; (4) Hierarchical splitting, which applies fallback syntactic rules to decompose exceptionally long sentences at linguistically viable boundaries.

Additionally, the module implements a non-destructive token tracking mechanism. By logging exact separator indices and structural metadata during splitting, the system guarantees the lossless reconstruction of the original document formatting once translation is complete.

### 2.2 Terminology retriever

The terminology retriever extracts relevant terms from a dictionary using a hybrid approach that combines fuzzy matching with LLM verification. First, the module applies fuzzy matching to identify all potential candidate terms within the segment. While this step ensures broad coverage, fuzzy matching inevitably introduces noise and false positives due to word overlapping or morphological variations. Second, to filter out these invalid candidates, the module passes the text and the matched terms to an LLM for validation.

As shown in Appendix A (Table 3), we use a dedicated verification prompt that forces the LLM to confirm if the concepts are genuinely present in the context. The LLM filters out mismatched pairs and outputs a clean JSON array of valid terms. The final output consists of verified term-translation pairs, which are then passed to the downstream tasks to ensure consistent and accurate rendering.

### 2.3 Lexical disambiguator

The terminology lexical disambiguator resolves translation ambiguities when a source term maps to multiple candidate translations in the dictionary. To ensure document-level consistency, the module evaluates these polysemous terms within their global contexts through a two-step process.

First, the module identifies ambiguous terms that appear across different sentences and aggregates their corresponding target candidates. Second, the system leverages an LLM to perform contextual selection. The LLM is provided with the complete sentence-level contexts alongside all translation candidates for each ambiguous term. Its task is to determine and select the single most appropriate

Table 1: Prompt template for document-level translation with terminology constraints.

```
# System Prompt
You are a professional translator from {src_lang} to {tgt_lang}.
Your task is to translate documents with the highest quality standards.

Translation Quality Standards:
1. Accuracy: Faithfully convey the original meaning without adding, omitting, or distorting content;
2. Fluency: Produce natural, readable text that follows target language grammar and style conventions
;
3. Consistency: Use consistent terminology and style throughout the document;
4. Cultural Appropriateness: Adapt expressions appropriately for the target culture while preserving
the original intent;
5. Professional Standards: Maintain the tone, register, and formatting appropriate for the document
type;

Output ONLY the translation. Do not include explanations, notes, or commentary.

# User Prompt
### Translation Instructions
1. Translate the source document from {src_lang} to {tgt_lang}

### Required Terminology
- {src_term_1}: {tgt_translation_1}
- {src_term_2}: {tgt_translation_2}

### Critical Format Requirement
The source text below contains <SEP> markers that represent line breaks (\n).
You MUST preserve the EXACT number and position of all <SEP> markers in your translation.

### Source Document
{document_with_sep_markers}
```

target translation that fits the specific local context while maintaining global consistency.

The output provides a refined dictionary where each source term maps to exactly one contextually correct translation. This elimination of multi-choice ambiguity guarantees that the downstream translator receives deterministic constraints.

The complete prompt template used for terminology disambiguation is provided in Appendix A (Table 4).

### 2.4 Translator

The translator implements a document-level translation strategy to preserve context while avoiding performance degradation caused by long sequences.

To maintain document coherence, the module processes the entire document in a single request whenever possible. However, excessively long contexts can dilute the model's attention, leading to omissions or hallucinations. To mitigate this, the module applies a paragraph-based chunking strategy for documents that exceed a configured length threshold. The text is split at paragraph boundaries into smaller chunks, balancing contextual completeness with manageable sequence lengths.

To maintain paragraph structures during this process, all newline characters in the input chunk are replaced with <SEP> markers before being sent to the LLM. The system instructs the LLM to preserve these markers in the target output.

In practice, when handling long outputs, LLMs frequently introduce unexpected text-internal line breaks, which can cause paragraph misalignment between the input and output. To resolve this formatting error, the module applies a post-processing step: it removes all accidental line breaks generated by the LLM, and then uniformly replaces the verified <SEP> markers back into standard newlines. This design ensures that the translated paragraphs align perfectly with the original layout without losing contextual quality.

The complete prompt template used for the document-level translation with terminology constraints is provided in Table 1.

### 2.5 Terminology extractor

Unlike Track 1, Track 2 only provides sample bitexts without a predefined terminology dictionary. To bridge this gap, our terminology extractor automatically constructs a structured dictionary from the sample bitexts, allowing the subsequent processing pipeline to align entirely with the Track 1

Table 2: Self-evaluation results of different translation strategies.

| Translation Granularity | Base Model | track1 | | | track2 | |
|---|---|---|---|---|---|---|
| | | proper | random | noterm | sample | noterm |
| Sentence-level | Deepseek-V4-Flash | -14.21 | -94.83 | -56.89 | -33.50 | -44.42 |
| Document-level (Chunked) | Deepseek-V4-Flash | -13.44 | -69.54 | -46.95 | -16.26 | -45.07 |
| | Gemini-3.6-Flash | -9.07 | **-67.71** | **-41.29** | -9.64 | -41.24 |
| | Gemini-3-Pro-Preview | **-6.67** | -79.79 | -42.48 | **-4.02** | **-22.45** |

framework.

During preprocessing, the module dynamically adapts to the text granularity of different language tracks: it utilizes BertAlign (Liu and Zhu, 2023) to perform fine-grained sentence alignment for the paragraph-level zh-en data, while directly utilizing the native short segments for tracks like en-es and en-pl to avoid redundant parsing. Next, an LLM is used to extract domain-specific terminology from these segments. The extraction prompt targets technical nouns, multi-word phrases, specialized verbs, and domain adjectives, while explicitly filtering out generic vocabulary (see Table 5 in Appendix A).

To prevent semantic drift, a strict cross-lingual matching criterion is enforced: a source term candidate is retained only if its target equivalent carries the exact same domain-specific meaning within that parallel pair. Finally, all extracted raw terms are lemmatized to their dictionary base forms, such as singular nouns and infinitive verbs, before being deduplicated and merged into a unified terminology dictionary where each source term maps to its verified target translations.

## 3 Self-Evaluation

To optimize system performance, we conducted internal evaluations on key strategy choices, employing DeepSeek-V4-Flash (Xu et al., 2026) as the base LLM for all modular pipeline components except the core translator. Guided by the findings of the WMT25 general machine translation task, where Gemini-2.5 demonstrated superior performance across almost all language tracks (Kocmi et al., 2025), we chose to benchmark leading frontier architectures for our core translator. Specifically, our translation experiments evaluate three candidate models: DeepSeek-V4-Flash (Xu et al., 2026), Gemini-3.6-Flash, and Gemini-3-Pro-Preview (Gemini Team et al., 2023).

### 3.1 Evaluation Metrics

We employ an LLM-based Multidimensional Quality Metrics (MQM) framework (Kocmi and Federmann, 2023) to evaluate translation quality. Source texts and translations are concatenated in their original sequence and processed by an evaluator LLM with document-level context. The LLM identifies translation errors across six standard categories (Accuracy, Fluency, Terminology, Style, Locale, and Other) and assigns severity levels: Critical, Major, and Minor (weighted as -25, -5, and -1, respectively). The final MQM score is programmatically calculated as a cumulative penalty, where scores closer to 0 indicate higher quality.

Since a reference terminology dictionary is unavailable during testing, the evaluator LLM relies entirely on its internal knowledge to judge terminology correctness. While this approach may introduce some deviations from human judgment and cannot reliably distinguish marginal score differences, it provides a sufficient and reproducible signal for guiding internal strategy selection when score gaps are substantial.

### 3.2 Results

As shown in Table 2, the self-evaluation scores reveal clear trends regarding the impact of translation granularity and base models. A direct comparison between the sentence-level and document-level strategies using the same DeepSeek model demonstrates that providing richer contextual information yields substantial translation gains across nearly all tracks. This suggests that a broader document-level context is critical for improving overall translation accuracy and helping models resolve complex lexical ambiguities. Furthermore, we observe noticeable performance variations among different base models under the chunked-document setup, where Gemini-3-Pro-Preview delivers the most robust overall performance and secures the highest MQM scores in three out of five test categories.

The final competition results can be found in the official report (Charkiewicz et al., 2026).

## 4 Conclusion

This paper presented the TaT (Terminology-aware Translation) system for the WMT26 Terminology Translation Shared Task. By decoupling the workflow into five sequential stages—sentence splitting, terminology retrieval, lexical disambiguation, core translation, and Track 2 terminology extraction—our framework effectively integrates terminology dictionary constraints into the translation loop. Internal evaluations confirm that utilizing document-level context via paragraph-based chunking significantly reduces omission and alignment errors compared to sentence-level baselines, with Gemini-3-Pro-Preview yielding the highest overall translation quality.

## Limitations

While the TaT system delivers robust translation performance, its multi-stage framework introduces certain practical limitations. The architecture relies heavily on Large Language Models (LLMs) across almost all core components. Although we intentionally mitigate computational overhead by deploying smaller, lightweight LLMs for upstream tasks like retrieval and disambiguation, the pipeline inevitably accumulates inference latency compared to traditional single-pass end-to-end NMT models. This latency overhead could present challenges in production environments with strict real-time response constraints.

Meanwhile, due to the tight development schedule of the shared task, several hyperparameter choices and prompt configurations were determined empirically. While these configurations fully met our immediate design expectations, a more exhaustive hyperparameter sweep might yield better-optimized settings. We plan to address pipeline acceleration and systematic optimization in future iterations of the framework.

## A Prompt Templates

This appendix contains all the prompt templates used throughout our TaT system. For clarity and reproducibility, we consolidate here every prompt employed in our pipeline components, including the terminology retriever (Table 3), the lexical disambiguator (Table 4), and the terminology extractor (Table 5).

Table 3: The verification prompt template used in the Terminology Retriever.

```
# System Prompt
You are a terminology verification expert. Your task is to verify whether the candidate terms are
genuinely present in the query text. A term is valid only if the query text actually contains or
clearly implies that concept.

# User Prompt
[Query Text]
{query_text}

[Candidate Terms to Verify]
- {term_1}
- {term_2}
- ...
- {term_n}

Verify which terms are genuinely present in the query text. Output ONLY a JSON array of valid term
names.
```

Table 4: Prompt template for terminology disambiguation.

```
# System Prompt
You are an expert translator specializing in {src_lang} to {tgt_lang} translation. Your task is to
select the most appropriate translation for an ambiguous term that appears in multiple sentences.

# User Prompt
[Ambiguous Term]
"{src_term}"

[Candidate Translations]
["{candidate_1}", "{candidate_2}", ..., "{candidate_n}"]

[Contexts - {N} Sentences containing the term]
1. {context_sentence_1}
2. {context_sentence_2}
...
{N}. {context_sentence_N}

Select ONE translation that is most appropriate for ALL contexts. The same translation will be used
consistently in all sentences.
Output ONLY the selected translation (a single word or phrase).
```

Table 5: Prompt template for terminology extraction from sample bitexts.

```
# System Prompt
You are a professional terminology extraction expert [specializing in {domain} domain] for {src_lang}
 to {tgt_lang} translation.
Your expertise lies in precisely identifying technical terms, domain-specific concepts, and
culturally unique expressions from parallel corpora.

# User Prompt
### Rules (Read First)

**What to Extract:**
1. Technical Nouns & Noun Phrases: Core domain concepts, multi-word terms;
2. Domain-Specific Verbs: Action words SPECIFIC to the domain (e.g., 'chamfer', 'broach');
3. Technical Adjectives: Only when part of a fixed technical term;

**What to SKIP:**
1. Common Verbs: use, make, do, have, be, allow, enable, provide, perform, etc.;
2. Generic Nouns: system, machine, part, component, process, method, way, etc.;
3. No clear translation: If target paraphrases or omits, SKIP it;
4. Length: Skip words <3 or >50 characters;

**Semantic Alignment Check:**
1. Does target have a DIRECT lexical equivalent? (not paraphrase)
2. Is meaning preserved exactly? (no semantic drift)
3. Can you point to EXACT word(s) in target?
-> If ANY fails, SKIP the term

**Lemmatization:**
- Nouns: singular, nominative
- Verbs: infinitive form
- Adjectives: remove gender/number markers

### Output Format
{"terms": {"[src_term]": "[tgt_term]"}}

### Input Sentences
SOURCE: {source_sentence}
TARGET: {target_sentence}

Output ONLY valid JSON.

## Abstract

In this paper, we describe our submission to the WMT26 Multilingual Instruction Shared Task (MIST), Sub-task 1 (context-based question answering). We fine-tune Qwen2.5-3B-Instruct with a LoRA adapter on 3,112 extractive-QA examples drawn from the answerable subset of TyDi QA. We submit outputs for the monolingual Arabic (question and context both in Arabic) instances of the official `qa-context` test set. Our system reaches a mean token accuracy of 0.9643 and produces accurate extractive spans. On the held-out split, fine-tuning roughly doubles both exact match (23.81 → 53.97) and token-level F1 (37.00 → 68.52) relative to the base model. The adapter corrects over-refusal tendency in addition to improving span precision. The base model emitted a no-answer string in 60% of passages with answers, versus 0% for the fine-tuned model. We report error analysis and discuss the model's weaker behaviour on cross-lingual context instances.

## 1 Introduction

Extractive question answering is a core component of many Natural Language Understanding systems, and has been driven largely by English resources such as SQuAD (Rajpurkar et al., 2016). Multilingual benchmarks including TyDi QA (Clark et al., 2020), XQuAD (Artetxe et al., 2020) and MLQA (Lewis et al., 2020) have since extended coverage, but performance still degrades for languages with fewer resources and for models small enough to run on a consumer GPU. Arabic is a case in point. Recent surveys identify the scarcity of benchmark datasets, limited text-processing tools, and a persistent reliance on translations of English datasets as central obstacles for Arabic question answering (Essam et al., 2024). Despite dedicated efforts such as ARCD (Mozannar et al., 2019), DAQAS (Alami et al., 2023), AraBERT (Antoun et al., 2020) and EAD-Bi-LSTM-BERT (Saoudi and Mohsen Gammoudi, 2025), extractive QA resources for Arabic remain limited compared with English.

The 2026 Multilingual Instruction Shared Task (MIST) (Schmidtová et al., 2026)[1] evaluates instruction-following capability across languages and tasks under a strict constraint that the final system's total parameter count must be under 10B. The organizers propose three sub-tasks:

- *Sub-task 1* — context-based question answering: given a passage and a question, produce a short answer extracted from the passage;
- *Sub-task 2* — summarization from and to any language;
- *Sub-task 3* — open-ended generation.

Note that Sub-task 1 is cross-lingual in practice. In the official test data the passage and the question are frequently in different languages, and the system must still produce a short answer in the language of the question.

Parameter-efficient fine-tuning has made adaptation of large pretrained models feasible under such constraints. LoRA (Hu et al., 2022) trains a small

[1] https://www2.statmt.org/wmt26/multilingual-instruction.html

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1899–1905
October 28-29, 2026 ©2026 Association for Computational Linguistics

number of low-rank update matrices while leaving the base model frozen, and has been shown to match full fine-tuning on many downstream tasks at a fraction of the memory cost.

In this paper, we present the *alkhder* submission to MIST, which focuses on Sub-task 1, in which a system is given a passage and a question and must produce a short verbatim answer span extracted from the passage. We mainly target the Arabic language. Our submission is therefore best understood as a monolingual case study within the shared task as we deliberately scope it to the 25 test instances where question and passage are both Arabic.

Our system fine-tunes Qwen2.5-3B-Instruct (Qwen et al., 2025) with a LoRA adapter on 3,112 extractive-QA examples drawn from the `answerable_tydiqa` subset of the official sample data. The subset spans multiple languages, but every instance is monolingual and no example pairs a passage in one language with a question in another.

We show that a LoRA adapter with 1.90% of the base model's parameters, trained in under half an hour on RTX 4090, improves Arabic extractive QA. We find that the base model over-refuses on this task, emitting a no-answer string on 60% of the submitted test instances where an answer was present whilst this is not observed with fine-tuning. In addition, we introduce a character-offset-based completion-only loss masking scheme and conduct error analysis to document common failures. A post-submission analysis, machine-translating the context into Arabic before extraction, eliminates this failure mode on a sample of cross-lingual instances. We submit outputs for the monolingual Arabic context-based QA instances in the official test set, and release our code and adapter.[2]

The rest of the paper is organized as follows: Section 2 presents the training data, Section 3 describes our methods, Section 4 details the experimental setup and describes the test set composition and our submission. Section 5 presents results on the held-out split and error analysis, Section 6 discusses limitations and future work and Section 7 presents our concluding remarks.

## 2 Data

### 2.1 Datasets

Table 1 summarises the data used in this work.

[2]Adapter: `https://huggingface.co/hasankh/qwen2.5-3b-arabic-context-qa-lora`.

| Dataset | Use | Instances |
|---|---|---|
| `answerable_tydiqa` | train | 3,049 |
| `answerable_tydiqa` | held-out | 63 |
| MIST test (arb, qa-context) | submission | 25 |

Table 1: Data used

**wmt26-mist-sample.** Training data is drawn from the official `wmt26-mist-sample` release of Schmidtová et al. (2026), which provides input-output pairs in 27 languages. We filter to examples whose `source` field equals `answerable_tydiqa` which constitutes the answerable subset of TyDi QA, via the `copenlu/answerable_tydiqa` derivation. This yields 3,112 context-question-answer triples. Because TyDi QA itself is multilingual and our filter does not further restrict by language, the resulting training corpus spans multiple languages (we observe English, Arabic, and Russian examples upon inspection). Each instance is nonetheless monolingual combining a passage, a question, and a gold answer that appears as a verbatim span of the passage, all three in the same language. No instance pairs a passage and a question in two different languages.

**MIST test set.** The test set is released as JSONL with fields `id`, `prompt`, `task` and `question_lang`. The official `qa-context` test set contains 8,640 instances across 24 languages, of which 96.1% are *cross-lingual* i.e., the passage and the question are in different languages, and the system is expected to return the answer span rendered in the question's language. Of the 360 instances whose question is in Arabic, only 25 have Arabic in both positions. Because our training data contains no cross-lingual example, we scope our submission to these 25 monolingual Arabic instances, where we have direct evidence of reliable model behaviour. Gold answers are not released, so we report test-set behavior via comparison against a base model.

### 2.2 Data Processing

Each training example was converted into a single ChatML-formatted string of the form:

```
<|im_start|>system
You are an extractive multilingual
question answering system...
<|im_start|>user
Context: {context}
Question: {question}
Answer:
```

```
<|im_end|>
<|im_start|>assistant
{answer}
<|im_end|>
```

The same template is used at inference time for both our fine-tuned model and the base model. We reserved 2% of the training data (63 examples) as a held-out evaluation split, sampled uniformly at random with a fixed seed (42).

We apply a filter to `source==answerable_tydiqa`, which selects the answerable subset of TyDi QA. Unanswerable questions were already excluded by the derivation and the model is not shown an example in which the correct response is to abstain.

The absence of cross-lingual examples is inherent to the released `answerable_tydiqa` derivation. Using an automated language check over all training instances, 96 are flagged as potential mismatches (3.1%), all of which manual inspection confirmed as false positives (very short questions, embedded foreign proper nouns, or closely related Cyrillic-script languages). No training example pairs a context and a question in different languages. We chose not to synthesize such pairs (e.g., by pairing passages and questions across languages), since a verbatim gold answer can only be validated within its own passage, and we scope our submission accordingly.

## 3 Method

### 3.1 Base Model and Adapter

We fine-tune `Qwen/Qwen2.5-3B-Instruct` (Qwen et al., 2025) with a LoRA adapter (Hu et al., 2022) (rank $r = 32$, $\alpha = 64$, dropout $= 0.05$) targeting all attention and MLP projection matrices (`q_proj`, `k_proj`, `v_proj`, `o_proj`, `gate_proj`, `up_proj`, `down_proj`). This yields 59.9M trainable parameters, i.e. 1.90% of the base model's 3.15B total parameters. The shared task's 10B budget applies to the total parameter count of the final system including the adapter. At deployment our system consists of the 3.09B frozen base parameters plus the 59.9M adapter (≈3.15B in total), well within the shared task's limit. Training uses BF16 precision throughout. We do not use quantization (`bitsandbytes` was incompatible with our CUDA 13.0 environment at the time of training) and do not use Unsloth or QLoRA (Dettmers et al., 2023).

Qwen2.5-3B-Instruct was selected as it is multilingual and reports competitive Arabic performance for its size. With 3B parameters, it fits in 24GB of VRAM and leaves substantial margin under the 10B budget. We also opted for LoRA over full fine-tuning because the adapter is only 1.90% of the model's parameters and trains rapidly on a single GPU. It has previously been applied to Arabic adaptation under comparable shared-task constraints (Alkhder and Abboush, 2026).

### 3.2 Completion-Only Loss Masking

Extractive QA requires the loss to be computed only on the gold answer span and not on the context or question tokens. The `trl` (Von Werra et al., 2020) library no longer provides completion-only masking for raw-text formats, and template-based token matching is unreliable because subword tokenization is context-dependent (Sennrich et al., 2016). An identical string would yield different token IDs depending on the characters preceding it and the search might not align. We therefore implement a character-offset-based masking scheme, illustrated in Figure 1. Each example is tokenized once with character-to-token offset mapping enabled. The literal response template is located as a plain substring of the raw text, giving a character index $b$ for the answer boundary. Every token whose character span starts before $b$ is assigned the ignore index ($-100$) in the label sequence, and all remaining tokens keep their true label.

Formally, for a sequence of tokens $t_1 \dots t_n$ with character spans $(s_i, e_i)$:

$$\ell_i = \begin{cases} -100, & \text{if } s_i < b \\ t_i, & \text{otherwise} \end{cases}$$

Unlike token-level template matching, our approach locates the answer boundary in the raw character string and is therefore robust to tokenizer merge behavior, and requires no dependence on collator internals.

### 3.3 Training Configuration

We train for 3 epochs with per-device batch size 4 and gradient accumulation 8 (effective batch size 32), a cosine learning-rate schedule peaking at $2 \times 10^{-4}$ with a 3% warmup ratio, gradient clipping at 0.3, a maximum sequence length of 1024 tokens, and gradient checkpointing. Checkpoints are saved every 100 steps (limit 3), with the best

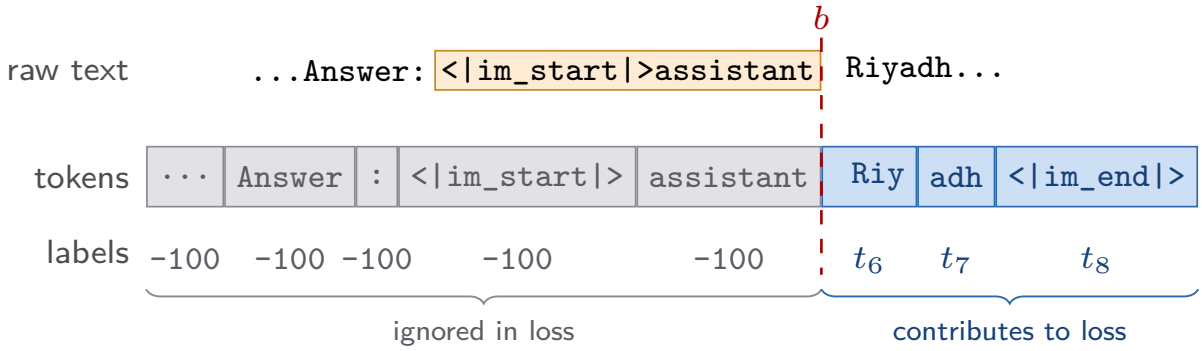

Figure 1: Character-offset loss masking. The response template is located as a substring of the raw text, giving boundary $b$. Tokens whose spans start before $b$ (grey) receive the ignore index, tokens at or after $b$ (blue) contribute to the loss.

selected by evaluation loss. Training ran on a single NVIDIA RTX 4090 (24GB) and took 20 minutes 58 seconds. Our configuration follows common practice for LoRA fine-tuning models of few-billion-parameter models and was fixed across all experiments. No hyperparameter search over ranks, target modules, or learning rates was performed. Full hyperparameters are given in Appendix A, Table 6.

## 4 Experiments

### 4.1 Experimental Setup

**Inference.** Inference uses greedy decoding with no sampling for deterministic reproducible extractive outputs, with generation stopped at the end-of-sequence or `<|im_end|>` token. We initially set `max_new_tokens=64`, which we found truncated enumeration-style answers mid-word. We thus raised this to 128 for all reported results and for the final submission.

**Baseline.** We compare against the `Qwen2.5-3B-Instruct` without our LoRA adapter, executed with the same inference script prompt template and decoding settings above. Only the presence of the adapter differs between the systems.

**Metrics.** We report exact match (EM) and token-level F1, computed after normalization by stripping Arabic and Latin punctuation and collapsing whitespace. We additionally report mean token accuracy on the held-out split.

### 4.2 Test Set Composition and Scope

The official test set includes a total of 8,640 `qa-context` instances across 24 confirmed test languages. Of these, only 340 (3.9%) are monolingual (question language equals context language) and the remaining 96.1% are cross-lingual making the task mostly cross-lingual. Of the 360 instances whose question is in Arabic, 25 (6.9%) have Arabic in both positions, a share above the median across non-English languages in the test set. The remaining 335 pair an Arabic question with a different answer language.

Given that our training data, while multilingual in aggregate, never contained a cross-lingual example, we scope our primary submission to these 25 monolingual Arabic instances and the remaining test instances receive no output from our system.

## 5 Results

### 5.1 Training behaviour

Table 2 summarizes training and evaluation metrics on the held-out split.

| Metric | Split | Value |
|---|---|---|
| Loss | Train (final) | 0.0822 |
| Loss | Eval | 0.1658 |
| Mean token accuracy | Eval | 0.9643 |
| Entropy | Eval | 0.0383 |
| Training runtime | — | 20 min 58 s |
| Trainable parameters (LoRA) | — | 59,867,136 |

Table 2: Training and evaluation metrics on the held-out split.

We observe that fine-tuning converges quickly and cheaply. The adapter reaches a final training loss of 0.0822 and a held-out loss of 0.1658 in 20 minutes 58 seconds. The gap between the two losses is the mild overfitting expected from three epochs over 3,112 examples, and the low output entropy (0.0383) indicates a high confidence about where answer spans begin and end.

Mean token accuracy reaches 0.9643, which might appear to indicate near-perfect extraction. However, this does not necessarily account for the error compounding that occurs during autoregressive decoding. We report EM and F1 below.

### 5.2 Baseline Comparison

We evaluate the unmodified base model on the identical held-out split using identical prompt construction, decoding parameters and tokenizer. Attaching the adapter doubles EM and F1 metrics on the held-out split (Table 3), improving EM by 30.2 points and F1 by 31.5 points. The fine-tuned model returns a correct span on 34 of the 63 items against 15 for the base model. Since the settings are identical for both runs, the improvement is attributable to fine-tuning.

| Model | EM | F1 |
|---|---|---|
| Baseline (no adapter) | 23.81 | 37.00 |
| LoRA fine-tuned (ours) | **53.97** | **68.52** |

Table 3: Exact Match and F1 score on the held-out split.

A second effect appears on the test instances. To characterize behavior on the exact instances we submitted, we ran the unmodified baseline on all 25 Arabic `qa-context` instances under identical decoding settings to the LoRA run, using the training-time system prompt for both. The baseline outputs a no-answer string (لا توجد إجابة) on 15 of 25 instances (60%) where an answer was in fact present in the passage. The fine-tuned model emitted it on none. Fine-tuning thus improves span-extraction precision and corrects refusal tendency in the base model. Table 4 shows example cases.

### 5.3 Error Analysis

We manually reviewed all 25 submission outputs, together with a sample of cross-lingual `qa-context` outputs for the Arabic question language. Table 5 summarizes errors we observed.

The truncation mode is resolved by the generation-length fix and does not affect the final submission. For the answer-type mismatch, the model produces an in-passage short span that is nonetheless the wrong one. We suspect this reflects the extractive objective rewarding short high-overlap spans without an explicit answer-type constraint.

### 5.4 A Translation-Based Approach to the Cross-Lingual Setting

Following the observation that errors we encountered are focused on cross-lingual inputs (Table 5), we evaluated a lightweight translate-then-extract approach post-submission. We sampled 50 cross-lingual `qa-context` instances with Arabic questions, machine-translated the context into Arabic with NLLB-200, and ran our fine-tuned system unchanged on the translated context, comparing against the same instances without translation.

Without translation, 52% of outputs (26/50) contained foreign-language leftovers or script mixing. With translated context, this dropped to 0% (0/50), with 96% of outputs in clean Arabic, one output (2%) showed a repetition artifact, and no refusals occurred in either condition.

## 6 Discussion

Overall, the system improves substantially with the adapter, but several limitations remain. The proposed system has no concept of an unanswerable question. The answerable subset we train on contains no example in which the correct response is to abstain, while the system prompt continues to demand abstention when no answer is present. The model has no learned behaviour for abstaining. Fine-tuning did not so much calibrate this behaviour as invert it. Our EM and F1 figures are therefore not comparable to results on the full test set, which includes unanswerable instances.

Moreover, no training example paired a context and a question in different languages. The model performs unreliably on such inputs, which constitute 96.1% of the released `qa-context` test data. Machine-translating the context into Arabic eliminates the dominant failure mode on a 50-instance sample indicating that the cross-lingual failures stem from context-language mismatch rather than question understanding, and that a translation pass extends our system to the cross-lingual majority of the test set without retraining or additional data collection. All other results are reported on a held-out split of the training distribution, and we do not evaluate on an external benchmark.

Post-submission inspection revealed that the system prompt used during training differs from the submission-generation script. The results reported here use the training-time prompt for both systems and come from a post-hoc re-run, and are therefore not identical to the submitted outputs.

| Instance ID | Question | Baseline | LoRA (ours) |
|---|---|---|---|
| qa-context_4_arb_arb | ما هي الفوائد النفسية والاجتماعية...<br>*What are the psychological and social benefits …?* | لا توجد إجابة<br>*No answer* | تعزز احترام التنوع الثقافي والإبداع البشري<br>*Promotes respect for cultural diversity and human creativity* |
| qa-context_7_arb_arb | ما هي الأنشطة الأخرى المدرجة تحت القسم ج...<br>*What other activities are listed under Section (C) …?* | لا توجد إجابة<br>*No answer* | فنون وتقاليد أداء العروض<br>*Performing arts and performance traditions* |
| qa-context_9_arb_arb | إذا كان تراث مجتمع ما يشتمل على ملاحظات فلكية، فما المجال الذي يغطي هذه الأنشطة؟<br>*If a society's heritage includes astronomical observations, which domain covers these activities?* | لا توجد إجابة<br>*No answer* | الممارسات الاجتماعية والطقوس والاحتفالات<br>*Social practices, rituals and festive events* |

Table 4: Baseline refusal on submitted test instances. English glosses appear in italics below the Arabic text.

| Failure mode | Description | Example ID |
|---|---|---|
| Truncation | Enumeration-style gold answers were cut off mid-word at `max_new_tokens=64`. Resolved by raising the generation budget to 128 tokens. | qa-context_8_arb_arb |
| Unanswerable questions | The model was never trained on unanswerable examples. On unanswerable test questions it fabricates a plausible span instead of a no-answer لا توجد إجابة. | qa-context_15_arb_arb |
| Answer-type mismatch | The model returns an adjacent span that does not satisfy the question's expected answer type. Asked ما هي الدول التي صاغت قرار مجلس الأمن هذا؟, it returns مجلس الأمن — present in the passage, but does not answer the question requesting a list of states. | qa-context_25_arb_arb |
| Cross-lingual: verbatim copy | When the passage language differs from the question language, the model sometimes copies a source-language span verbatim instead of rendering it in the question language. | qa-context_2_arb_ces |
| Cross-lingual: hallucination / script-mixing | On cross-lingual inputs the model occasionally produces text mixing scripts (e.g. Arabic, Bengali and Chinese characters in one span) or topically unrelated to the passage. | qa-context_2_arb_ben |

Table 5: Recurring errors observed during manual review.

For future work, the system could benefit from incorporating unanswerable examples into training, restoring calibrated abstention behaviour.

## 7 Conclusion

In this paper we describe our submission to the WMT26 Multilingual Instruction Shared Task. We present a resource-efficient LoRA fine-tune of Qwen2.5-3B-Instruct for Arabic context-based extractive question answering trained on a consumer GPU in under 21 minutes. Fine-tuning doubles exact match and F1 over the unmodified base model on a held-out split, and eliminates a refusal behavior in which the base model declined to answer despite the answer being available.

# Laniqo at WMT26 Multilingual Instruction Shared Task (MIST): Full-Parameter Knowledge Distillation with Task-Conditional Pivot Decoding Under a 10B-Parameter Constraint

**Adrian Charkiewicz, Artur Nowakowski**
Laniqo, Poznań, Poland
{name}.{surname}@laniqo.com

## Abstract

We describe our submission to the WMT26 Multilingual Instruction Shared Task (MIST). Our system is `google/gemma-4-E4B-it` (8B total / 4.5B effective parameters), fully fine-tuned via knowledge distillation from a larger teacher model (`Gemma-4-31B-it`) on teacher-generated responses spanning three sub-tasks and 24 languages. We find that (i) a two-judge quality-agreement filter on the distillation data provides no measurable benefit over using the teacher's outputs unfiltered, at both LoRA and full-parameter training scale, and (ii) a task-conditional decoding strategy (using two-turn English drafting for open-ended generation and summarization, versus single-turn direct decoding for context-grounded question answering) significantly improves quality where applied and is harmless where it is not. Our final submission combines full-parameter distillation with this task-conditional decoding scheme.

## 1 Introduction

The WMT26 Multilingual Instruction Shared Task (MIST) evaluates a model's ability to follow instructions across languages and task types under a constraint of at most 10B parameters, encouraging research on small, broadly-capable multilingual models (Kocmi et al., 2025).[1] The task covers three sub-tasks, specifically open-ended generation (OEG), context-grounded question answering (QA_CTX), and cross-lingual summarization (SUM), across 24 languages, including two low-resource languages (Yoruba, Central Kurdish) with limited native training data. Last year's edition of this shared task received no valid participating systems (Kocmi et al., 2025), so there is little established submitted-system practice to compare against.

Our system fine-tunes google/gemma-4-E4B-it (Gemma Team, 2026) on teacher-distilled data from a larger model in the same family, and decodes with a strategy chosen per sub-task (pivot vs. direct) rather than one mode applied uniformly. We report two findings we believe are useful beyond our own submission: a data-filtering ablation that is a clean negative result at two different training scales (§4.1), and a pivot-decoding result whose effect on quality is task-dependent and even sign-flips depending on whether the underlying model has been fine-tuned (§4.2). We also directly compare full fine-tuning against LoRA and SFT against CPO/KTO training objectives (§4.3, §4.4); a further ablation (per-task vs. combined-data models) is reported in Appendix B.

## 2 Related Work

Our study builds on four lines of work: knowledge distillation, preference-based fine-tuning objectives, task-conditional decoding, and LLM-as-judge evaluation.

**Knowledge distillation** from a larger teacher model into a smaller student (Hinton et al., 2015) lets us train a submission-eligible ($\leq$10B parameter) student on data quality closer to a much larger model's capability. Unlike recent multi-teacher, cross-family distillation approaches for multilingual translation (Zheng et al., 2026), we use a single same-family teacher, matching the shared task's single-model submission constraint.

**Preference-based fine-tuning** objectives, such as DPO (Rafailov et al., 2023), KTO (Ethayarajh et al., 2024), and CPO (Xu et al., 2024), offer natural alternatives to supervised fine-tuning (SFT) when contrastive (chosen/rejected) training signals are available. For our ablation experiments, preference pairs use the same AND-verified teacher candidate as SFT's target for "chosen," paired with the student's own pre-fine-tuning response as "rejected" (restricted to prompts where that response was itself a judge-scored failure). We compare

[1] WMT26 task page: https://www2.statmt.org/wmt26/multilingual-instruction.html.

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1906–1916
October 28-29, 2026 ©2026 Association for Computational Linguistics

these objectives directly (§4.4); while CPO showed a small, consistent edge over KTO specifically on QA_CTX, standard SFT matched or outperformed every preference-tuning variant overall. Consequently, contrastive objectives were omitted from our final submission, which relies exclusively on SFT.

**Pivot / translate-then-generate prompting**, where a model processes intermediate output in a high-resource language (typically English) before producing its final-language answer, has been explored as both a training-time technique (e.g., instruction tuning to internally pivot (Zhang et al., 2023)) and an inference-time strategy. Closer to our setting, we implement it purely at inference time as a two-turn chat strategy that reuses the first turn's English draft as context, since model weights are fixed by the time decoding strategy is chosen. A recent study of pivot-augmented prompting for low-resource machine translation similarly finds modest, configuration-sensitive gains rather than uniform improvements (Ramasethu et al., 2026). This echoes our observation that pivot decoding's effect is task-dependent and can even invert following fine-tuning, although their work focuses on translation quality via few-shot exemplar selection rather than our two-turn decoding framework for open-ended generation, QA, and summarization.

**LLM-as-judge evaluation** is necessary for scalable quality assessment across diverse multilingual tasks, where human evaluation is prohibitively expensive. Although automated judging carries known biases such as verbosity and self-preference (Gu et al., 2024), we mitigate same-family bias by employing both the teacher (`Gemma-4-31B-it`) and an independent cross-family evaluator (Qwen) as judges. Using both models allows us to cross-validate quality and test empirically for evaluator artifacts (for instance, Gemma wins base-model selection even under Qwen's judge; §3.1). Finally, our two-judge agreement filter (§4.1) offers a lightweight alternative to iterative refine-then-judge data curation schemes (Cayir et al., 2025).

# 3 System Description

## 3.1 Base Model Selection

We evaluated two candidate base models, both satisfying the shared task's $\leq$10B-parameter constraint: `google/gemma-4-E4B-it` (8B total / 4.5B effective parameters) and `Qwen3.5-9B` (Qwen Team, 2026a) (a dense, hybrid-attention model, ∼9.65B parameters). On a stratified 1,200-row sample spanning all three sub-tasks (400 rows per task, which for open-ended generation covered virtually its entire dataset of just over 400 lines), judged by three independently-instantiated judge models under two decoding modes (extended-thinking and non-thinking), with a paired $t$-test pooling all judges,[2] we selected `google/gemma-4-E4B-it` over `Qwen3.5-9B`: it won in 5 of 6 judge×mode cells, including under Qwen's own-family judge, with a pooled difference of $+0.269$ ($p = 1.1 \times 10^{-12}$) in non-thinking mode and $+0.786$ ($p = 1.7 \times 10^{-50}$) in thinking mode. Qwen3.5-9B's thinking mode additionally showed a 23.7% empty-response/repetition-loop failure rate, posing a critical reliability concern independent of output quality. Consequently, we selected `google/gemma-4-E4B-it` as our foundational base model for all subsequent distillation and fine-tuning stages.

## 3.2 Training Data Construction

Training data is built by having a larger teacher model in the same family, `Gemma-4-31B-it` (Gemma Team, 2026), generate one response per prompt across all three sub-tasks and all task languages, for a pool of 20,625 (prompt, response) pairs. For Yoruba and Central Kurdish, which have no native task-formatted data, we backfill with general-purpose multilingual examples from the Aya Dataset (Singh et al., 2024); the volume and task-format match of this backfill varies by language.

We considered requiring two independently-instantiated judge models to agree that a candidate response is high quality before including it in training (an "AND-both" filter). §4.1 reports this ablation; we did not find measurable benefit and submit the unfiltered pool.

## 3.3 Training

The submitted model is fully fine-tuned on the full 20,625-pair unfiltered pool with the hyperparameters in Table 1. We compared this against per-task LoRA adapters and against CPO/KTO preference-optimization objectives trained on the same data (§4.3, §4.4); full-parameter SFT matched or out-

[2] "Qwen judge" throughout this paper refers to `Qwen3.6-27B` (Qwen Team, 2026b); "Gemma judge" refers to `Gemma-4-31B-it` (Gemma Team, 2026), the same checkpoint used as the distillation teacher; "Magistral judge" refers to `Magistral-Small-24B` (Mistral AI, 2025).

performed every alternative and was selected for submission.

Table 1: Submitted model's training hyperparameters.

### 3.4 Inference: Task-Conditional Decoding

At inference time we use task-conditional decoding: for OEG and SUM, the model first drafts a response in English before producing the final answer in the target language (pivot decoding); QA_CTX, the largest sub-task by volume (67.6% of the official test set), uses direct single-pass decoding. Appendix H details prompts; §4.2 reports ablations.

## 4 Experiments

### 4.1 Data-Filtering Ablation

Every candidate response is scored by each judge on a 1–7 Likert scale per rubric criterion (e.g. faithfulness, coherence; criteria vary by sub-task) and averaged; we call a response "high quality" if this average is $\geq 5/7$. "AND-both" keeps a training pair only if *both* Qwen and Gemma independently score it $\geq 5/7$; the alternative "unfiltered" condition keeps every teacher response regardless of score. We tested whether AND-both measurably improves training data quality over a single judge or no filter, on held-out per-task test data, Qwen-judge scored. We ran this comparison at *two* training scales. As Table 2 shows, the two-judge filter is not measurably load-bearing at either scale. We submit the unfiltered pool, which is simpler at equal measured quality.

### 4.2 Pivot vs. Direct Decoding

As shown in Table 3, the impact of pivot decoding depends heavily on both the target task and whether the model has been fine-tuned. While open-ended generation (OEG) and summarization (SUM) consistently benefit from pivot decoding across both base and fine-tuned checkpoints, context-grounded QA (QA_CTX) shows no performance gain after fine-tuning and degrades on the base model. Based on these empirical results, we adopt a task-conditional decoding strategy: applying pivot decoding to OEG and SUM while retaining direct decoding for QA_CTX.

| **Task** ($n$) | **Base** | **AND-both** | **Unfiltered** |
|---|---|---|---|
| *LoRA Scale* | | | |
| OEG (42) | 4.429 | 4.556 | 4.651 |
| QA_CTX (1,484) | 5.279 | 5.491 | 5.426 |
| SUM (866) | 5.991 | 6.161 | 6.152 |
| *Full-FT Scale* | | | |
| OEG (42) | 4.429 | 5.048 | 5.032 |
| QA_CTX (1,484) | 5.279 | 5.469 | 5.482 |
| SUM (866) | 5.991 | 6.237 | 6.209 |

Table 2: Data-filtering ablation at two training scales. Baseline scores correspond to the untrained base model.

| Model | OEG | QA_CTX | SUM |
|---|---|---|---|
| Base | $+0.857^*$ | $-0.408^*$ | $+0.132^*$ |
| Fine-tuned | $+1.238^*$ | $-0.053$ | $+0.111^*$ |

Table 3: Pivot-decoding effect (pivot − direct), held-out data, Qwen-judge. $^*p < 0.05$. On the untrained base model, pivot decoding is significantly *harmful* on QA_CTX ($p$=$1.3 \times 10^{-11}$) – terse English drafts get echoed back instead of translated, but this harm disappears entirely once the model is fine-tuned ($p$=0.26, n.s.), plausibly because SFT improves answer formatting enough to stop tripping the second-phase rewrite instruction. Pivot decoding helps OEG and SUM in both cases.

### 4.3 Full-Parameter Fine-Tuning (Full-FT) vs. LoRA

We compare full-parameter fine-tuning with LoRA to evaluate the practical performance gain relative to training cost for final system submission, rather than as a parameter-matched efficiency study. Both configurations are trained on the exact same dataset using the same SFT objective.

| Task ($n$) | base | LoRA | full-FT |
|---|---|---|---|
| OEG (42) | 4.429 | 4.556 (n.s.) | $5.111^*$ |
| QA_CTX (1,484) | 5.279 | $5.491^*$ | $5.531^*$ |
| SUM (866) | 5.991 | $6.161^*$ | $6.274^*$ |

Table 4: Full fine-tuning vs. LoRA, both trained with the SFT objective. $^*p < 0.05$ vs. base. Full-FT vs. LoRA directly: OEG $+0.556$ ($p = 0.062$, trend), QA_CTX $+0.040$ ($p = 0.22$, n.s.), SUM $+0.114$ ($p = 0.0028$, the only task where full-FT significantly beats LoRA). Full-FT is the only condition reaching significance over base on OEG, so we chose full-FT for submission.

### 4.4 Training Objective: SFT vs. CPO vs. KTO

We further evaluate full-parameter CPO and KTO preference-optimization objectives against SFT on the same per-task data split. To examine sensitivity to training stability, we compare two hyper-

Table 5: Hyperparameter setups for preference tuning.

| Setup | Learning Rate | $\beta$ (KL) | Init |
|---|---|---|---|
| SFT | $2 \times 10^{-5}$ | — | Base |
| Default | $1 \times 10^{-5}$ | 0.1 | Base / SFT |
| Tuned | $2 \times 10^{-6}$ | 0.05 | Base / SFT |

parameter setups: a default baseline and a tuned regime with reduced learning rate and lower KL penalty (detailed in Table 5) across two initialization points: directly from the base model and from the fine-tuned SFT checkpoint.

| Variant | OEG (42) | QA_CTX (1,484) | SUM (866) |
|---|---|---|---|
| base | 4.429 | 5.279 | 5.991 |
| CPO (default) | 4.714 | 5.543* | 6.278* |
| CPO (tuned, base) | 4.333† | 5.495* | 6.229* |
| CPO (tuned, SFT) | 4.873 | 5.539* | 6.303* |
| KTO (default) | 4.476† | 5.465* | 6.259* |
| KTO (tuned, base) | 4.508 | 5.395* | 6.303* |
| KTO (tuned, SFT) | 5.111* | 5.523* | 6.261* |
| **full-FT-SFT (chosen)** | **5.111*** | **5.531*** | **6.274*** |

Table 6: Comparison of training objectives (all full-parameter). "default/tuned" = default vs. tuned hyperparameters; "base/SFT" = initialization checkpoint. $^*p < 0.05$ vs. base; $^\dagger p < 0.05$ vs. SFT (worse). While CPO and KTO improve over base on most tasks, no variant significantly outperforms full-FT-SFT.

# 5 Results

## 5.1 Submitted Model vs. Untrained Base

On the official 12,775-row test set, pairwise comparison (submitted model vs. the untrained base model, task-conditional decoding on both sides) under two independent judges shows the submitted model winning decisively (Table 7).

| Judge | Submitted wins | Base wins | Ties |
|---|---|---|---|
| Qwen | 3,940 | 2,408 | 6,427 |
| Gemma | 3,038 | 2,296 | 7,441 |

Table 7: Official test-set pairwise comparison, submitted model vs. untrained base, task-conditional decoding on both sides.

Because `Gemma-4-31B-it` also served as the distillation teacher, performance gains observed exclusively under the Gemma judge could partly reflect self-preference bias—favoring outputs derived from its own generations—rather than genuine quality improvements. Since Qwen generated no training data, we treat it as an independent evaluator. To ensure our results hold regardless of judge selection, we evaluate the submitted and base model outputs on the held-out test set under both judges using a paired $t$-test.

| | Qwen Judge | | Gemma Judge | |
|---|---|---|---|---|
| **Task** ($n$) | $\Delta$ | $d$ | $\Delta$ | $d$ |
| OEG (42) | $+0.603^*$ | 0.33 | $+0.270$ | n.s. |
| QA_CTX (1,484) | $+0.204^*$ | 0.12 | $+0.181^*$ | 0.12 |
| SUM (866) | $+0.218^*$ | 0.16 | $+0.086^*$ | 0.10 |

Table 8: Per-task score difference ($\Delta$ = submitted − base) and effect size ($d$) across Qwen and Gemma judges using paired $t$-tests ($^*p < 0.05$). Fine-tuning gains remain statistically significant across both judges on QA_CTX and SUM.

The effect holds under both judges on QA_CTX and SUM, so it is not an artifact of Gemma's self-preference risk; OEG's smaller, non-significant effect is consistent in direction and attributable to its small held-out size ($n = 42$), matching the pattern already seen for OEG elsewhere in this paper.

## 5.2 Distillation vs. Unadapted Gold Data

To evaluate whether teacher distillation is necessary, we compare our submitted model against an otherwise identical full-parameter checkpoint trained on the shared task's reference (gold) text. Because raw reference targets often differ in formatting style (e.g., terse spans versus verbose task-formatted responses), we evaluate both verbatim reference text and a reformatted variant where the teacher rewrites each reference into the target format while preserving underlying content.

On the official test set, the distilled submitted model wins decisively over the verbatim reference baseline across both judges (Table 9). When evaluating the reformatted reference model on held-out data under the Qwen judge, open-ended generation (OEG) shows a significant advantage for reference training over the distilled model ($+1.333$, $d = 0.69$, $p = 6.7 \times 10^{-5}$), a moderate-to-large effect comparable in size (though opposite in direction) to the SUM finding. Context-grounded QA (`QA_CTX`) yields comparable performance. However, summarization (`SUM`) consistently favors the distilled model ($d$=$-0.65$).

We attribute this residual gap on `SUM` to the inherent noise in retrieved cross-lingual reference corpora such as CrossSum (Hasan et al., 2021), where targets are aligned via semantic similarity rather than direct translation. In contrast, teacher distillation ensures that target summaries are generated directly from the input context, resulting in tighter

source grounding and fewer factual hallucinations. Complete comparisons, including reformatted reference results and per-source breakdowns, are detailed in Appendix A.

| Judge | Reference wins | Submitted wins | Ties |
|---|---|---|---|
| Qwen | 1,488 | 5,980 | 5,307 |
| Gemma | 1,418 | 5,489 | 5,868 |

Table 9: Pairwise comparison on the official test set between the verbatim reference-trained model and the submitted distilled model (task-conditional decoding applied to both). The submitted model outperforms the reference baseline under both judges.

### 5.3 Low-Resource Languages: Yoruba and Central Kurdish

Yoruba and Central Kurdish lack native task-formatted training data (§3.2). Fine-tuning yields minimal gains for both on `QA_CTX`, with Yoruba remaining at a floor score of $1.0/7$. However, pivot decoding reveals stark differences between them: while direct decoding was chosen globally for `QA_CTX` due to a null aggregate effect ($-0.053$), applying pivot decoding to Yoruba recovers $+1.500$ points ($p < 0.05$, Table 10). Central Kurdish shows no such gain ($-0.222$, n.s.). This divergence demonstrates that low-resource languages do not behave uniformly, indicating that per-language decoding strategies may be beneficial.

| | $n$ | FT$-$base | Pivot$-$direct |
|---|---|---|---|
| Yoruba (QA_CTX) | 32 | 0.000 | $+1.500^*$ |
| Yoruba (SUM) | 18 | $+0.222$ | $+1.250^*$ |
| Central Kurdish (QA_CTX) | 27 | $+0.222$ | $-0.222$ |
| All languages (QA_CTX) | 1,484 | $+0.204^*$ | $-0.053$ |
| All languages (SUM) | 866 | $+0.218^*$ | $+0.111^*$ |

Table 10: Held-out low-resource performance (Qwen judge). "FT$-$base" is fine-tuning gain; "Pivot$-$direct" is pivot-decoding effect. $^*p < 0.05$. Central Kurdish lacks held-out SUM data.

## 6 Limitations

Our submission operates under the WMT26 MIST $\leq$10B-parameter constraint, which rules out larger architectures. Additionally, Yoruba and Central Kurdish lack native task-formatted data and rely on general-purpose Aya Dataset examples (Singh et al., 2024), whose format does not fully match the target distribution (§5.3). While our reference-data diagnosis isolated a major defect in summarization (§5.2), fine-grained error analyses were not extended to `QA_CTX`.

Furthermore, using `Gemma-4-31B-it` as both the distillation teacher and an evaluation judge introduces potential self-preference bias; future work should validate these findings with human evaluation, particularly as the reliability of LLM judges on low-resource languages remains an open question. Methodologically, our 5/7 filtering threshold was a heuristic driven by compute constraints, and filtering was not compared against a size-matched random baseline. Finally, while pivot decoding improves aggregate quality, generating an English draft adds an inference step that increases latency, and risks stripping away localized idioms and cultural nuances in the target languages, particularly in open-ended generation (OEG).

## 7 Conclusion

Our WMT26 MIST submission fine-tunes `google/gemma-4-E4B-it` on unfiltered teacher-distilled targets from `Gemma-4-31B-it`, paired with a task-conditional decoding strategy (pivot decoding for OEG and SUM; direct decoding for `QA_CTX`). Beyond overall system performance, our analysis highlights two key empirical insights: (1) quality-based data filtering yields a consistent negative result across training scales; and (2) the effectiveness of pivot decoding depends heavily on task type and fine-tuning setup.

## A Distillation vs. Reference Training: Full Comparison

Section 5.2 provides a high-level summary of the comparison between teacher distillation and direct reference training. Here we detail the complete methodology, experimental setup, and diagnostic evaluations.

To evaluate whether teacher distillation is strictly necessary, we trained an otherwise identical full-parameter checkpoint on the dataset's gold reference outputs using the same training recipe and prompt pool (20,625 examples). Only 0.2% of the teacher-distilled training target strings are identical to their corresponding reference text, ensuring this comparison measures the effect of the target distribution rather than near-duplicate memorization.

In our initial baseline experiment, reference targets were passed verbatim without reformatting to match our per-language instruction prompt. Open-ended generation (OEG) reference targets were generated by GPT-4.1 for the WMT25 benchmark (Kocmi et al., 2025), representing a high-quality model output. Conversely, summarization (`SUM`) and context-grounded QA (`QA_CTX`) targets were drawn from pre-existing datasets (e.g., CrossSum, WikiLingua, Belebele, TyDiQA) that were never formatted for instruction-following prompts, often consisting of terse text spans (e.g., "3: London"). To address this format mismatch, we later introduced a reformatted reference setup.

To test whether combining reference and teacher targets yields further improvements, we constructed a "best-of" composite dataset. For OEG and `SUM`, reference outputs were scored as model responses using the evaluator judge, and the higher-scoring target (teacher vs. reference) was selected for each prompt. Because the `QA_CTX` evaluation

rubric checks whether an answer matches the reference, comparing the reference to itself produces a circular signal; thus, for QA_CTX, we retained the teacher response if its evaluation score was $\geq 5/7$, falling back to the reference target otherwise. Table 11 reports the selection rates across tasks.

| Task | Reference Chosen | Selection Rule |
|---|---|---|
| OEG | 69.4% (263/379) | Head-to-head evaluation |
| SUM | 4.7% (356/7,526) | Head-to-head evaluation |
| QA_CTX | 20.7% (2,583/12,457) | Floor score rule ($< 5/7$) |
| Overall | 16.8% (3,461/20,625) | — |

Table 11: Proportion of reference targets selected over teacher responses in the composite "best-of" dataset. SUM's low reference selection rate stems from reference targets scoring below 5/7 on 44% of head-to-head comparisons due to formatting discrepancies.

As shown in Table 12, the composite best-of model performs on par with the submitted teacher-distilled model rather than exceeding it. Because the teacher response was retained whenever it matched or exceeded the reference score, 83.2% of the best-of training pool remains identical to the teacher-only dataset. For the remaining 16.8%, SUM swapped only 4.7% of its rows, while OEG underwent a major shift toward reference targets (69.4%) but showed no statistically significant difference on held-out evaluation (Table 13). Consequently, instance-level target selection largely recovers the pure teacher-distilled policy.

**Fixing the Format Confound.** To isolate dataset quality from presentation artifacts, we created a reformatted reference dataset. For SUM and QA_CTX, the teacher model rewrote each reference into a full, instruction-compliant response while preserving all factual content and introducing no new information (e.g., converting a terse span like "3: London" into a complete descriptive sentence). Manual inspection confirmed that rewrites maintained strict factual fidelity across languages. We then fine-tuned a model on this reformatted reference set and re-evaluated performance on the held-out set (Table 14).

Reformatting reference targets significantly improves performance over raw reference training across OEG and SUM. On QA_CTX, performance reaches a tie with the submitted model. However, on SUM, a substantial gap remains ($d = -0.65$), indicating that format mismatch alone does not account for the entirety of the performance difference.

| Task ($n$) | vs. Submitted | vs. Reference-only |
|---|---|---|
| OEG (42) | $+0.429$ | $+0.016$ |
| QA_CTX (1,484) | $+0.027$ | $+0.004$ |
| SUM (866) | $-0.014$ | $+1.750^{*}$ |

Table 12: Held-out per-task effect of the best-of-{teacher, reference} model (mean difference under the primary Qwen judge; $^{*}p < 0.05$). The best-of model does not differ significantly from the teacher-only submitted model on any task, with its primary gain appearing over raw reference training on SUM ($d = 0.87$).

| Task ($n$) | Score Difference (Submitted − Reference) |
|---|---|
| OEG (42) | $+0.413$ (n.s.) |
| QA_CTX (1,484) | $+0.023$ (n.s.) |
| SUM (866) | $+1.764^{*}$ ($d$=0.88) |

Table 13: Held-out per-task performance difference between teacher-distilled submitted and raw reference-trained models under the Qwen judge ($^{*}p < 0.05$). SUM demonstrates a large advantage for the teacher-distilled model ($p = 2.65 \times 10^{-110}$).

**Residual Length Gap and CrossSum Misalignment.** Even after reformatting, reference targets for SUM remain substantially shorter than teacher-distilled outputs (66.9 vs. 165.3 average words; QA_CTX shows 27.2 vs. 74.8 words), as the reformatting prompt instructed the teacher to add no extraneous information beyond the gold reference. Examining per-criterion scores for SUM reveals that the gap is concentrated primarily in coverage (6.41 vs. 3.46), whereas faithfulness (6.22 vs. 5.38) and naturalness (6.06 vs. 5.84) exhibit smaller differences.

Further source breakdown (Table 15) reveals that the performance degradation in SUM is concentrated within CrossSum (Hasan et al., 2021), which comprises 77.9% of the reference pool. CrossSum aligns articles across languages using embedding similarity rather than verified translations, causing 23.9% of its rows to contain reference summaries with factual assertions unsupported by the source text (e.g., a source text detailing a 2–1 football match paired with a reference summary claiming a 3–0 outcome). On clean reference subsets (WikiLingua and MCIF, $n = 177$), the overall performance gap shrinks to non-significance ($+0.167$, $p = 0.13$). Because our submitted model is fine-tuned on synthetic teacher targets generated directly from each input source, it avoids these alignment defects.

| Task ($n$) | vs. Submitted | vs. Raw Reference |
|---|---|---|
| OEG (42) | $+1.333^{*}$ ($d$=0.69) | $+0.921^{*}$ ($d$=0.44) |
| QA_CTX (1,484) | +0.069 (n.s.) | +0.046 (n.s.) |
| SUM (866) | $-1.293^{*}$ ($d$=−0.65) | $+0.472^{*}$ ($d$=0.28) |

Table 14: Held-out per-task effect of reformatted reference training under the Qwen judge ($^{*}p < 0.05$). Reformatting significantly improves over raw reference training on OEG and SUM, narrowing the gap with the submitted model on SUM from $d = -0.88$ to $d = -0.65$.

| Source Dataset ($n$) | Ref. Floor Rate | Δ Faithfulness | Δ Coverage |
|---|---|---|---|
| CrossSum (689) | 23.9% | $+0.95^{*}$ | $+3.57^{*}$ |
| WikiLingua (148) | 4.7% | $+0.43^{*}$ | $+0.53^{*}$ |
| MCIF (29) | 0.0% | +0.34 (n.s.) | +0.14 (n.s.) |

Table 15: Detailed breakdown of the SUM reference-training gap by source dataset under the Qwen judge. "Ref. Floor Rate" denotes the proportion of outputs scoring 1/7 on both faithfulness and coverage. Δ columns represent submitted minus reference scores ($^{*}p < 0.05$).

## B Per-Task Adapters vs. Combined-Data Model

To evaluate task-specific capacity allocation, we compared training separate LoRA adapters for each sub-task against training a single full-parameter model on all combined tasks. Evaluation on held-out data using full-parameter fine-tuning reveals no statistically significant differences between single-task and multi-task setups (Table 16).

| Task ($n$) | Per-Task Model | Combined Model | $p$-value |
|---|---|---|---|
| OEG (42) | 5.111 | 5.000 | 0.68 (n.s.) |
| QA_CTX (1,484) | 5.531 | 5.495 | 0.22 (n.s.) |
| SUM (866) | 6.274 | 6.235 | 0.28 (n.s.) |

Table 16: Performance comparison between per-task adapters and a single combined-data model under full-parameter fine-tuning. All differences are non-significant.

Given the equivalent empirical performance, we deploy a single combined-data model to streamline model serving and inference deployment.

## C Base Model Selection Breakdown

Table 17 and Table 18 present the complete breakdown of the base model comparison across evaluation judges and decoding modes summarized in Section 3.1.

Enabling extended thinking improves Gemma across all tasks (+0.251 to +1.307). In contrast, Qwen exhibits mixed behavior: extended thinking improves QA_CTX (+0.390, $p$=$7.1\times10^{-8}$) but severely degrades SUM (−0.612, $p$=$1.4\times10^{-10}$). Diagnostic inspection revealed that Qwen's thinking mode encountered runaway enumeration failures on 23.67% (284/1,200) of rows, producing empty final responses. Increasing the generation token budget from 3,072 to 6,144 tokens resolved only a minor fraction of these errors. Gemma produced zero empty responses across all 1,200 evaluation runs.

## D Full Data-Filtering Ablation Across Judge Conditions

Table 19 details the full data-filtering ablation comparing single-judge filtering setups (`gemma-only`, `qwen-only`), dual-judge intersection filtering (`AND-both`), and unfiltered training across LoRA and full-parameter scales.

At full-parameter scale, filtering targets via judge scores yields no statistically significant performance gains over unfiltered teacher distillation, establishing a clear negative result for quality-based data filtering when using strong teacher models.

## E Pivot-Decoding Robustness Across Checkpoints

To verify whether the interaction between fine-tuning and pivot decoding is robust across training stages, we evaluated an intermediate full-parameter checkpoint trained prior to final dataset refinement (§3.2).

As shown in Table 20, the sign-flip/attenuation behavior on QA_CTX appears in both fine-tuned checkpoints, confirming that the change in pivot decoding efficacy is a systematic property of task-specific fine-tuning.

## F Engineering and Infrastructure Diagnostics

During system development, two major engineering issues were identified and resolved:

**Cross-Layer KV Sharing Checkpoint Loading in vLLM.** The final 18 layers of `gemma-4-E4B-it` omit dedicated key/value projections to utilize cross-layer KV sharing. While Hugging Face's `Trainer.save_model()` exports these parameter structures natively, vLLM's checkpoint loader expects explicit key/value weight matrices for every layer, leading to loading failures. We resolved this by applying a post-processing script that constructs duplicate weight references

| Variant | Qwen Judge | Gemma Judge | Magistral Judge | Cross-Judge Median |
|---|---|---|---|---|
| gemma_thinking | 6.537 | 6.613 | 6.727 | **6.613** |
| gemma_no_thinking | 5.521 | 6.202 | 6.619 | 6.202 |
| qwen_no_thinking | 5.184 | 5.764 | 6.586 | 5.764 |
| qwen_thinking | 5.610 | 5.416 | 6.492 | 5.610 |

Table 17: Overall average score per evaluator judge across candidate base models. `Gemma-4-E4B-it` achieves superior performance across all judge families.

| Mode | Task | Gemma − Qwen | Cohen's $d$ | 95% CI | $p$-value |

in an auxiliary safetensors shard, enabling standard deployment within vLLM.

**Low-Resource Abstention Behavior on Misformatted Data.** On an initial dataset iteration using raw Aya backfill targets, the `QA_CTX` abstention rate for Yoruba reached 73.0%, significantly exceeding the 20.0–26.0% rate observed across other languages. Re-tuning after standardizing system prompts and target delimiters across the Yoruba backfill reduced its abstention rate to 18.6%, aligning it with the overall cross-lingual average (9.7–27.2%).

| Model Checkpoint | OEG | QA_CTX | SUM |
|---|---|---|---|
| Base Model | $+0.857^{*}$ | $-0.408^{*}$ | $+0.132^{*}$ |
| Fine-tuned (Intermediate Checkpoint) | $+0.778^{*}$ | $+0.020$ (n.s.) | $+0.070$ (n.s.) |
| Fine-tuned (Submitted Checkpoint) | $+1.238^{*}$ | $-0.053$ (n.s.) | $+0.111^{*}$ |

Table 20: Pivot-decoding effect (Pivot − Direct) across three checkpoints ($^{*}p < 0.05$). The shift on `QA_CTX` from negative on the base model to neutral on fine-tuned checkpoints is consistent across both fine-tuned models.

## G Optimization Dynamics and Shortcut Learning in Preference Tuning

In early development, we experimented with training DPO and KTO on a failure-biased subset (∼1.5k prompts where the base model produced incorrect answers). Candidates generated by teacher models or reference outputs were designated as "chosen," while the base model's failed outputs served as "rejected."

Models trained under this setup consistently degraded relative to the untrained base model (dev-set win rate 16.9–18.5%; Wilcoxon $p = 4.3 \times 10^{-5}$). A control experiment with randomly shuffled chosen/rejected pairs resulted in severe policy collapse ($p = 5.5 \times 10^{-11}$). Evaluating an on-policy setup using self-sampled outputs (best-of-8 under the judge) similarly yielded negative results on OEG ($-0.183$, $p = 0.010$) and neutral performance on `QA_CTX` and `SUM`.

Training logs (Table 21) revealed that chosen responses were consistently concise, whereas rejected responses were verbose and hedged (Ta-

| Training Epoch | Train Reward Accuracy | Reward Margin |
|---|---|---|
| 0.08 | 39.0% (Chance) | −0.005 |
| 0.32 | 99.0% | +0.370 |
| 0.73 | **100.0%** | +4.530 |
| 2.00 (Final) | 100.0% | +6.830 |

Table 21: DPO reward metrics over training on failure-biased data (989 pairs). The reward margin saturates by 0.73 epochs without further task-learning gains.

ble 22).

| Recipe | Chosen Median Words | Rejected Median Words | Length Ratio |
|---|---|---|---|
| Teacher-Verified | 63 | 106 | 1.55–4.0× |
| Best-of-Both (QA_CTX) | — | — | Up to 33× |

Table 22: Median word count asymmetry between chosen and rejected sets. Base model failure outputs exhibit consistent verbosity relative to external targets.

Rather than learning semantic correctness, the preference objectives fit a simple length shortcut ("favor shorter, assertive responses"), saturating reward metrics rapidly while degrading model capability on broader distributions.

| Checkpoint | OEG | QA_CTX | SUM |
|---|---|---|---|
| DPO (Epoch 0.48) | +0.022 (n.s.) | +0.017 (n.s.) | −0.060* |
| DPO (Epoch 0.85) | +0.067* | +0.033 (n.s.) | −0.056 (n.s.) |
| Plain SFT | +0.011 (n.s.) | +0.067 (n.s.) | −0.125* |

Table 23: Evaluation of early stopping and non-contrastive SFT on a 300-row held-out sample ($^*p < 0.05$).

As shown in Table 23, fine-tuning on the narrow failure slice using SFT instead of DPO still failed to recover performance on SUM. To address this, we transitioned to SimPO/CPO and expanded the training set to a 90/10 task-wide data blend. This combination resolved the performance loss on SUM, yielding the setup detailed in Section 4.4.

## H Prompts and Generation Settings

For OEG and SUM, we apply a two-turn pivot decoding strategy. In the first turn, the model receives the row's original task prompt with the following instruction override appended, which forces an English draft regardless of the language requested: *"No matter what language is requested above, write your ENTIRE answer in English for this step. Everything else about the task (content, format, completeness) stays exactly the same."*

The resulting English draft is appended to the conversation as an assistant turn, and the model is given a second, standalone user turn: *"Now give your final answer. Rewrite the English draft above in {language}, preserving its content, meaning, and format exactly. Respond only in {language} – do not include any English."* where *{language}* is substituted with the full English name of the target language. No system prompt is used.

For QA_CTX, we use a single-turn direct prompt: the model receives only the original task prompt, with neither the override nor a second turn. To isolate the learned policy, all generations across both training and inference stages use greedy decoding (temperature=0.0) with a maximum generation limit of max_new_tokens=512 per turn (capping pivot rows at 1,024 tokens total).

## I Inference Cost of Pivot Decoding

Pivot decoding requires two sequential generation calls per row instead of one. We measured the realized token overhead on held-out data from the submitted model (Table 24). We did not measure wall-clock latency directly, but the token-volume and call-count overhead make the practical cost of pivot decoding explicit.

| Task | Direct | Pivot (Draft + Final) | Overhead |
|---|---|---|---|
| OEG | 205.8 | 285.0 + 195.6 = 480.6 | 2.3× |
| SUM | 160.9 | 173.7 + 147.7 = 321.4 | 2.0× |

Table 24: Token-volume overhead of pivot decoding vs. direct decoding (average words per response).

## J Extended LLM-as-Judge Diagnostics

**Judge Disagreement on OEG.** Gemma and Qwen judges disagree substantially more often on OEG pass/fail rates than on QA_CTX or SUM (86–99% agreement on the latter). This is consistent with self-preference risk being sharpest on the least-constrained task.

**Low-Resource Judge Reliability.** On the base-model evaluation sample ($n = 16$ rows per language), Gemma and Qwen judges show strong rank agreement on both Yoruba and Central Kurdish (Pearson $r = 0.95$–$0.99$ in non-thinking mode), at least as strong as the cross-language average ($r = 0.73$–$0.84$). Absolute score gaps are occasionally larger for Yoruba specifically (mean absolute difference = 1.34 in thinking mode, vs. 0.21 overall), though both judges agree the outputs are low-quality (mean scores 2.3–3.8/7) rather than disagreeing on direction. Because this sample is small

and drawn from an earlier untrained stage, we treat this as suggestive rather than conclusive.

# SentinelQA: Task-Level Routing and Output Verification for Multilingual Instruction Following

**Asher Egerton-Idehen**
Independent Researcher
asheregerton1@gmail.com

## Abstract

We describe team Sentinel's submission to the WMT26 MIST shared task on multilingual instruction following. We allocate the budget across a pipeline built on `gemma-3-4b-it`: a fixed task-level router that selects between fine-tuned and base behaviour, and a deterministic verification layer checking language, length, repetition and chat-template artefacts. Our submitted system uses **9.46B** parameters. A proposed shared-base LoRA configuration would use 5.16B, but was not evaluated end-to-end. Fine-tuning raises context-based QA token-$F_1$ from 0.267 to 0.74. The verification layer alters roughly 9% of outputs and raises our reference-free compliance measure by 2.2 points; because a replacement is accepted only when it passes more of the same checks, we report this as the yield of the intervention rather than an identified effect. Yoruba compliance falls from 0.816 under base to 0.675 under the augmented full fine-tune, recovering partially to 0.754 with LoRA; these single-seed observations do not isolate augmentation or tuning method as the cause.

## 1 Introduction

The WMT26 MIST shared task evaluates multilingual instruction following across three subtasks: context-based question answering (`qa-context`), open-ended generation QA (`qa-oeg`), and mono- and cross-lingual summarization (`sum-sum`), in 24 languages and subject to a limit of 10B parameters across all deployed components.

The test set contains 12,775 items: 8,640 `qa-context` (67.6%), 2,359 `qa-oeg` (18.5%) and 1,776 `sum-sum` (13.9%). Most items are cross-lingual. Computed from the item identifiers, 95.8% of `sum-sum` items and 96.1% of `qa-context` items ask for output in a language other than that of the source document, almost always English; `qa-oeg` is entirely monolingual.

Our submission is built on `gemma-3-4b-it` (Gemma Team, Google DeepMind, 2025), a 4.37B-parameter instruction-tuned model. We submit three systems. The primary system routes each item by subtask: fine-tuned behaviour for `qa-context`, base behaviour for `qa-oeg` and `sum-sum`. The two contrastive systems are the fine-tuned model alone and the base model alone, the latter doubling as our untuned baseline. All three pass every generation through the same verification layer (§4); Figure 1 shows the proposed shared-base serving configuration.

## 2 Related Work

The verification layer is a minimal instance of the pattern studied in the self-correction literature, e.g. Self-Refine (Madaan et al., 2023) and constraint decomposition approaches such as DECRIM (Ferraz et al., 2024), but its checks are external and non-neural rather than model-judged. Huang et al. (2024) report that LLMs struggle most with autonomous error *detection*, which is the step we delegate to fastText classifiers (Joulin et al., 2017, 2016) trained for language identification (Kargaran et al., 2023; Burchell et al., 2023) and to deterministic parsers. In machine translation, reranking an $n$-best list with a quality-estimation model (Rei et al., 2020; Fernandes et al., 2022; Freitag et al., 2022) is the established way to recover from a bad sample; our single-candidate retry is a cheaper point on that trade-off. Following the WMT25 MIST findings (Kocmi et al., 2025) we treat chrF++ (Popović, 2017) as reportable but not decisive, given its weak correlation with human judgment on low-resource languages.

## 3 Data

We train on the sample release provided by the shared-task organizers (Chen and WMT26 MIST Organizers, 2026), whose per-language table sums

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1917–1924

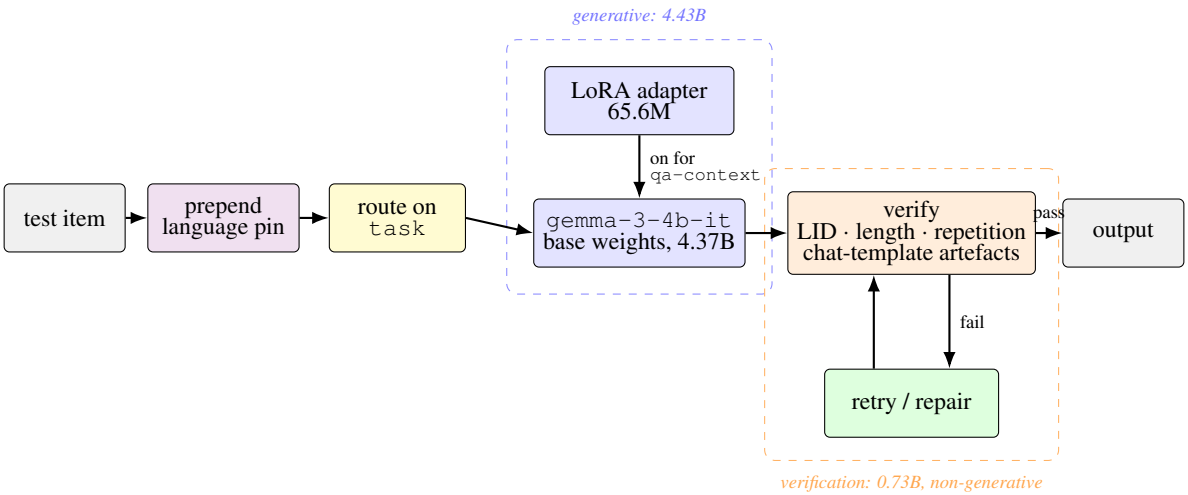

Figure 1: Proposed shared-base configuration of SentinelQA (5.16B parameters; not evaluated end-to-end). The fixed task lookup enables the adapter for `qa-context` and disables it for the other subtasks. The submitted system instead used a separate full fine-tune alongside base (9.46B). Both designs use a target-language pin and four verification checks, with conditional retry or repair (§4).

to the 23,919 rows we audited.

Its sources are TyDi QA (Clark et al., 2020), BELEBELE (Bandarkar et al., 2024), MCIF (Papi et al., 2025), the Aya dataset (Singh et al., 2024), CrossSum (Bhattacharjee et al., 2023), WikiLingua (Ladhak et al., 2020) and the WMT25 MIST OEG submissions.

We first froze an evaluation split, sampling $\min(100, \lceil 0.15n \rceil)$ items from each (language, subtask) cell into a held-out set of 3,599 rows, then made it read-only and hash-pinned. For cells with no data at all — Yoruba `qa-context`, for instance — we filled with teacher distillation from `Qwen3-235B-A22B-Instruct-2507` for `qa-oeg` (2,043 rows), NLLB-200-3.3B (NLLB Team et al., 2022) translation into six languages (747 rows) and native BELEBELE `qa-context` for Bengali, Czech and Yoruba (264 rows). Augmented rows passed the same language and degeneracy checks used at inference. The final corpus is 23,117 rows.

Two properties of the data bear on the numbers below. BELEBELE is parallel, so one passage appears in every language under a shared identifier; we recovered identifiers for all 847 held-out BELEBELE rows and excluded from training every row carrying one of the resulting 400 identifiers, which removes 84% of otherwise-usable BELEBELE but keeps held-out passages out of training. Separately, 48 held-out rows carry an English reference despite a non-English target, all from the three languages outside WikiLingua's 18-language coverage; we score them as a separate slice, so held-out results below use the remaining $n$=3,551.

## 4 System

**Routing.** The router is a fixed lookup on the `task` field with no learned component: `qa-context` takes fine-tuned behaviour, `qa-oeg` and `sum-sum` take base behaviour. Items are copied verbatim from the corresponding stream, so the routed submission is a deterministic recombination of two systems we also submit separately.

The three subtasks rest on evidence of different strength. `qa-context` (67.6% of the test set) is decided by a large margin: token-$F_1$ rises from 0.267 to 0.74 (§6.1). `sum-sum` (13.9%) is decided by length: the fine-tuned models produce a median of 92–134 words on prompts requesting roughly 200, where base produces 210. For `qa-oeg` (18.5%), post-verification compliance differs by only 0.0025 (0.9806 base against 0.9781 fine-tuned), and we have no reference-based accuracy measure. Recorded test-generation diagnostics also favor base (425 flagged outputs versus 562 for Run B), but do not establish better answer quality. We routed it to base partly by analogy with `sum-sum`; this remains the weakest decision. The evidence included a 288-item test-prompt probe and test-output diagnostics, not solely held-out results, and does not establish routing generalization to a new test distribution.

**Verification.** Every generation is prefixed with a target-language system pin (*"Respond only in ⟨endonym⟩"*) and checked on four axes.

**Language** uses dual fastText identification with GlotLID v3 and OpenLID v3, returning PASS/FAIL/UNSCORABLE and rejecting text only when *both* models place it outside the accept set, with short strings marked unscorable rather than failed. **Length** uses a deterministic multilingual parser for explicit word- and sentence-count constraints with script-aware counting; it fires on 85.6% of test prompts, covering 100% of `qa-context` and `sum-sum` prompts and 22.1% of `qa-oeg` prompts. **Degeneracy** uses $n$-gram repetition detection. **Artefacts** checks for chat-template markers and leaked language-pin text. Parser and detector details are in Appendix A.

We summarise these outcomes as **compliance**. The retained held-out tables pool check rates, whereas the test analysis and bootstrap average per-item scores; Appendix A defines these distinct aggregations. Compliance is reference-free, so it can be computed on the test set, and it measures whether an output is well-formed rather than whether it is correct.

A failed check triggers a temperature-0 retry with a fixed correction appended; outputs still degenerate afterwards are regenerated with a repetition penalty, and under-length `sum-sum` drafts get one edit-based expansion pass. In every case the candidate replaces the original only if it passes strictly more checks, or fixes the language without breaking another axis.

**Parameter budget.** The submitted system holds base and a separate full fine-tune, totaling 9.46B with language identification (Table 1, left). A proposed alternative enables Run C's 65.6M adapter against shared base weights for `qa-context` and disables it otherwise, totaling **5.16B** (right). This is a calculated 45% parameter reduction, not a measured memory or speed gain. Run C was evaluated with merged checkpoints; neither the unmerged serving configuration nor a routed Run C submission was evaluated end-to-end. The available comparisons motivate LoRA as a candidate for future deployment, but do not establish equivalence to the submitted Run B system or identical generated outputs. A deployment recommendation requires serving validation and an end-to-end evaluation.

We count the fastText models throughout, since they run at inference and are not negligible at 0.73B; under the adapter accounting they are the second-largest component after the base model itself.

| component | as submitted | proposed |
|---|---|---|
| `gemma-3-4b-it` (base) | 4,365,656,432 | 4,365,656,432 |
| second copy, merged FT | 4,365,656,432 | — |
| LoRA adapter | — | 65,576,960 |
| GlotLID v3 | 418,934,528 | 418,934,528 |
| OpenLID v3 | 307,181,056 | 307,181,056 |
| total parameters | **9,457,428,448** | **5,157,348,976** |

Table 1: Parameter accounting against the task's 10B limit. The left column describes the submitted configuration; the right is a proposed shared-base LoRA configuration, not an evaluated submission.

## 5 Experimental Setup

All training used a single NVIDIA A100-SXM4-80GB with `bfloat16`, sequence length 4096 with packing, loss on assistant tokens only, effective batch size 64, three epochs, a cosine schedule with 3% warmup and seed 20260801. We trained three models (Table 2): Run A on the organizer sample only, Run B on the full augmented corpus, and Run C on the full corpus with LoRA (Hu et al., 2022) ($r$=32, $\alpha$=64, all attention and MLP projections, 65.6M trainable parameters, 1.50% of the model). Run C's adapters are merged into the base weights at each checkpoint save for evaluation convenience, so all three runs are interchangeable under the same inference code; §4 discusses the proposed unmerged serving configuration. Inference used vLLM (Kwon et al., 2023), with first-pass temperatures 0.0 for `qa-context`, 0.3 for `sum-sum` and 0.7 for `qa-oeg`. Runs B and C both start from base, but differ in learning rate as well as tuning method: full fine-tuning uses `paged_adamw_8bit`, while LoRA uses `adamw_torch_fused` and adapter dropout 0.05. Their comparison therefore does not isolate the number of trainable parameters.

Checkpoints were selected by a rule fixed before any results existed: compliance plus `qa-context` $F_1$ on the native held-out slice, subject to an English/German retention gate, with chrF++ reported but not decisive (computed with sacreBLEU, Post, 2018). Both full fine-tunes peaked at epoch 2.

Comparisons use paired bootstrap resampling (Koehn, 2004) with $B$=1000; the finest $p$-value this resolves is $1/B$.

| | Run A | Run B | Run C |
|---|---|---|---|
| data | sample | full | full |
| rows | 20,063 | 23,117 | 23,117 |
| method | full FT | full FT | LoRA |
| learning rate | 1e-5 | 1e-5 | 1e-4 |
| steps | 141 | 159 | 159 |
| final train loss | — | 1.759 | 1.784 |

Table 2: The three training recipes, differing in data selection and optimization settings (§5). Run A's final loss was not recorded.

| system | compl. | $F_1$ | chrF++ | agg. |
|---|---|---|---|---|
| base | 0.8073 | 0.2671 | 25.09 | 1.0744 |
| Run A (e2) | **0.8266** | 0.7462 | 45.17 | **1.5728** |
| Run B (e2) | 0.8238 | 0.7405 | 44.98 | 1.5643 |
| Run C (e3) | 0.8154 | **0.7499** | **45.39** | 1.5653 |

Table 3: Held-out results for the selected checkpoint of each run; compliance pools check rates (Appendix A). "agg." is the unweighted sum of compliance and `qa-context` $F_1$; it has no independent interpretation and is reported only because it was the pre-registered selection rule.

## 6 Results

Held-out numbers use the native slice ($n$=3,551; $F_1$ over the $n$=1,454 `qa-context` items).

### 6.1 Held-out results

Table 3 gives the selected checkpoint of each run against the base model. Fine-tuning raises `qa-context` token-$F_1$ from 0.267 to roughly 0.74 across all three runs. Since the gold spans have a median of four words while the base model emits a median of 30 on the same items, much of this margin reflects acquisition of the expected output format rather than improved comprehension. Compliance varies much less; Run B is slightly ahead of base under the pooled-check aggregation. Appendix B gives a per-language breakdown.

Against the base model, Run B gains $+0.4743$ $F_1$ (95% CI $[+0.4521, +0.4976]$, $p < 1/B$).[1] The available paired comparisons among fine-tuned checkpoints do not resolve differences in compliance or $F_1$ on this single-seed evaluation; this is not an equivalence test. Their compliance intervals use per-item scores, not Table 3's pooled-check score, and therefore do not quantify uncertainty for that table's compliance gaps.

[1] Computed on Run B's epoch-3 checkpoint; the submitted epoch-2 checkpoint differs from base by $+0.4734$ on the same measure.

**Yoruba regression and partial recovery.** Yoruba compliance falls from 0.816 under base to 0.675 under Run B and recovers to 0.754 under Run C (Appendix B). Repetition flags rise from 23/78 to 55/78, then fall to 44/78. B-to-C recovery is concentrated in summaries (25 to 12 repetition flags), while open-ended QA flags increase from 30 to 32; recovery is not uniform across tasks. This slice contains 45 `qa-oeg` and 33 `sum-sum` items, with no `qa-context` items, whereas all 88 added Yoruba examples are `qa-context`. It therefore tests transfer to other tasks, not performance on the augmented task. Repeated article targets in the training corpus plausibly encourage repetitive generation, but the available evidence does not identify a causal mechanism. Base-to-B also introduces fine-tuning, and B-to-C changes the optimization recipe; neither contrast isolates augmentation or LoRA. A row audit additionally found two Yoruba train/held-out input duplicates after normalization and three held-out prompts with falsely parsed length constraints. We retain the historical scores and treat the regression as descriptive, pending clean evaluation and per-language uncertainty estimates.

### 6.2 Verification layer

The retained aggregate analysis compares the first cleaned generation, before retry or repair, with the shipped text on the full test set (Table 4). The three single-model systems alter 8.6–9.9% of outputs and add 2.4–2.8 compliance points; the routed system, whose items are copied from those streams, adds 2.2. Because the acceptance rule of §4 keeps a replacement only when it passes more of the same checks that compliance measures, these figures are the yield of the intervention rather than an independently identified effect. We have no systematic paired human evaluation of the changed outputs, so these gains do not demonstrate improved answer quality.

Figure 2 shows where the yield arises in the routed system: little on `qa-context`, which is already near ceiling, and more on the two generation subtasks, where first-pass output is weakest.

### 6.3 Ablations

**LoRA.** Run C uses 1.50% of the trainable parameters with no resolved aggregate advantage over full fine-tuning in the available paired comparisons. Its `sum-sum` outputs are also short (24 words held-

| system | altered | first | shipped | yield |
|---|---|---|---|---|
| Run B alone | 9.9% | 0.9436 | 0.9715 | +0.0279 |
| Run A alone | 9.2% | 0.9374 | 0.9626 | +0.0252 |
| base alone | 8.6% | 0.9512 | 0.9749 | +0.0237 |
| routed | — | 0.9554 | 0.9773 | +0.0219 |

Table 4: Verification layer over all 12,775 test items. "altered" is the share of outputs that did not ship as first generated. "first" is after deterministic formatting cleanup but before retries and repairs; scores average per-item compliance. The routed row combines Run B's `qa-context` stream with base's other two subtasks.

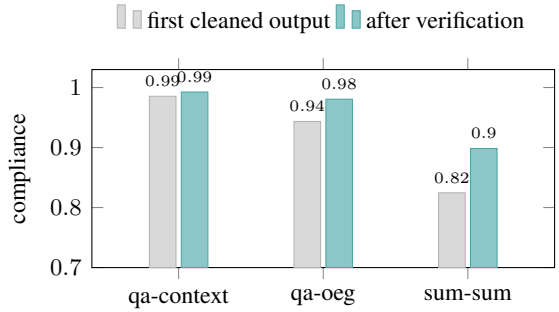

Figure 2: Compliance before and after verification for the routed system, following each subtask to the model that serves it: +0.007 on `qa-context` (from Run B), +0.037 on `qa-oeg` and +0.074 on `sum-sum` (both from base).

out against 25 for Runs A and B, versus 185 for base). This is consistent with adaptation to training targets whose median is about 25 words, but does not rule out other effects of either tuning recipe.

**Language pin.** A 288-item probe over both models shows the English pin helps despite being written in a different language from the prompt: compliance is 89.2% with it versus 86.9% without for Run B, and 90.0% versus 85.0% for base, concentrated in `sum-sum` where base compliance falls to 45.8% without it. This is a small-scale replication of the language-confusion effect documented by Marchisio et al. (2024), who find that models frequently generate in the wrong language and that explicit instruction mitigates it.

**Augmentation.** The sample-only Run A and augmented Run B show no resolved aggregate gain in the available paired comparisons, despite Run B's additional teacher-distilled, translated and native-BELEBELE data. This single-seed result does not establish that augmentation is generally ineffective. Yoruba's regression above is a separate, language-specific observation whose task mismatch prevents a direct augmentation claim.

## 7 Limitations

Compliance measures whether outputs are well-formed, not whether they are correct. Verification yield is measured using the same checks that select repairs, without paired human validation. The weak `qa-oeg` routing evidence and untested shared-base configuration further limit our deployment conclusions. All runs used one training seed: bootstrap intervals describe item-sampling uncertainty conditional on those runs, not variation across retraining. Both full fine-tunes peaked at epoch 2 and declined at epoch 3, showing checkpoint sensitivity rather than establishing seed instability. The recipe ordering and Yoruba pattern have unknown sensitivity to training randomness.

The base held-out score 0.8073 and first-pass test score 0.9512 differ by 14.39 points, but are not the same estimand. Held-out scoring gives the length pass rate (47/169, or 0.2781) one quarter of the pooled score, even though only 4.7% of items have a scored constraint; test scoring averages per-item checks (Appendix A). Task proportions also shift: `qa-context` rises from 41.0% to 67.6% and `sum-sum` falls from 37.1% to 13.9%, while parsed constraint coverage rises to 85.6%. Thus more constraints need not lower the reported score. Aggregation and distribution changes preclude attributing the gap to model improvement; the retained aggregates cannot isolate their individual contributions or predict performance on a new test set.

## 8 Conclusion

We submitted a routed system to WMT26 MIST: fine-tuned and base behaviour under a fixed task lookup with four verification checks. Our submitted outputs used 9.46B parameters; the proposed 5.16B shared-base LoRA configuration remains untested end-to-end.

Fine-tuning improves context-based QA substantially through output-format acquisition. Verification alters roughly 9% of outputs and adds 2.2 compliance points as a yield of its acceptance rule, without demonstrated answer-quality gains. The available single-seed comparisons show no resolved aggregate benefit from augmentation or full fine-tuning over LoRA. Yoruba's regression and partial recovery highlight the need for task-specific data audits and uncertainty estimates before generalizing these observations.

## Acknowledgements

We thank the WMT26 MIST organizers for the shared task data and for the prompt fixes issued during the test release period.

## A Metric definitions

**Checks and aggregation.** For a nonempty output on item $i$, let $L_i$, $D_i$ and $A_i$ indicate language non-failure, non-degeneracy and absence of chat-template artefacts. Unscorable language identification counts as non-failure, not as a confirmed language match or an omitted check. Let $I_i$ indicate a parsed, scorable length constraint and $H_i$ its binary outcome. The test analysis and held-out bootstrap use

$$s_i = \frac{L_i + D_i + A_i + I_i H_i}{3 + I_i}, \qquad C_{\text{item}} = \frac{1}{n} \sum_i s_i,$$

with empty outputs assigned zero. An unavailable length verdict omits that check. Constraint coverage therefore affects the effective weights.

The historical held-out ladder instead pools counters before averaging check rates. With at least one scored length constraint,

$$C_{\text{pool}} = \tfrac{1}{4} \left( \bar{L} + \bar{D} + \bar{A} + \frac{\sum_i I_i H_i}{\sum_i I_i} \right).$$

Without one, it averages the first three rates. Its implementation counts empty outputs in $n$ but skips their checks, so they do not register as failures in the first three rates, unlike the per-item score. The native selected-checkpoint slices reported here contain no empty outputs. Table 3 pools over the entire native slice; Table 5 instead averages language–task cell pooled scores weighted by cell size. Its "all" entry is the global ladder score, not a weighted mean of the displayed language scores. These aggregations are not interchangeable: base's global score is $(0.9932 + 0.9580 + 1 + 0.2781)/4 \simeq 0.8073$. We preserve the historical values and identify their definitions rather than applying the per-item bootstrap intervals to pooled scores. The selection aggregate remains $\text{agg} = C_{\text{pool}} + \text{F}_1^{\texttt{qa-context}}$, the pre-specified selection rule, not an independent quality measure.

**Parser and repetition detector.** The length parser matches localized number and unit forms, including Unicode digits and Yoruba postposed numbers and a spelled-out hundred. It scopes matching to an inferred instruction region; document numbers can still be mistaken for constraints. Ranges use their midpoint, approximate counts allow $\pm 30\%$, and maximum constraints use an upper bound. Missing or unscorable constraints are omitted. Sentence counting counts terminal punctuation characters, not syntactically parsed sentences; abbreviations and repeated punctuation can distort it. Repetition detection flags an exact whitespace-delimited 4-gram occurring at least four times; unspaced Chinese, Japanese and Thai text uses character 6-grams with the same threshold. Legitimate recurring phrases can trigger this heuristic, and it does not assess Yoruba tone-mark or orthographic

correctness. These checks are proxies, not a substitute for human evaluation in low-resource languages.

## B Per-language compliance

Table 5 gives compliance per language on the native held-out slice, aggregated over subtasks and weighted by item count. We report held-out rather than test figures because the per-item test artefacts were not retained; the held-out set covers 27 languages, all but Bhojpuri of the 24 test languages. Per-language confidence intervals were not computed, and the per-item generations required to reconstruct them were not retained. The aggregates do not support recovering paired intervals; these language-level comparisons are descriptive.

## Abstract

This paper describes the TUM-Heilbronn system submission to the WMT26 Multilingual Instruction Shared Task (MIST). The MIST covers three tasks: context-based question answering, open-ended generation, and cross-lingual summarization to evaluate the multilingual instruction-following ability of large language models. We fine-tune Qwen3.5-9B-Instruct on 27 diverse languages, across 10 different writing scripts. Our model outperformed 6 of the 15 models submitted to this shared task. Moreover, we ranked first in truthfulness (i.e., decline to answer when the context lacks sufficient information) on the context-based question-answering task. Cross-lingual summarization remains a challenging task for all submitted models, with the lowest performance observed among the three tasks.

## 1 Introduction

Large Language Models (LLMs) have demonstrated a remarkable capability in following instructions and performing a wide range of tasks effectively. However, this capability is closely associated with the language in which the instructions are provided. Models generally exhibit stronger instruction-following performance in high-resource languages, particularly English (Dey et al., 2024), whereas their performance tends to decline for mid- and low-resource languages (Zeng et al., 2025). This disparity is even more pronounced for low-resource languages that use non-Latin writing systems.

Recent studies show that instruction-following abilities do not transfer equally across languages. Zeng et al. (2025) find a performance gap between high- and low-resource languages, with model size and script also influencing language adherence. Similarly, Le et al. (2025) show that multilingual instruction following becomes particularly challenging for complex information extraction tasks, while Liu et al. (2025), Dussolle et al. (2025), and Dong et al. (2026) report further disparities across languages. Closing these performance gaps is essential for developing LLMs that can reliably follow instructions across languages without degrading performance on NLP downstream tasks, ultimately enabling users to interact with models in their own language.

Table 1: Examples of multilingual instruction following across *three* tasks: `QA-Context` (context-based question answering), `OEG` (open-ended generation), and `SUM` (summarization). English translations of the text are provided in parentheses.

The WMT26 Multilingual Instruction Shared Task (MIST) (Schmidtová et al., 2026) aims to address this challenge by evaluating multilingual instruction-following capabilities of LLMs across diverse languages, scripts, and tasks. MIST proposes three tasks: **Context-based Question Answering** (`QA-Context`), **Open-Ended Generation** (`OEG`), and **Cross-lingual Summarization** (`SUM`). The first two tasks evaluate the model's ability to provide accurate and faithful responses in the input language, while the third evaluates cross-

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1925–1932
October 28-29, 2026 ©2026 Association for Computational Linguistics

lingual generation, where the model is expected to give a summary in a language different from the input document, as illustrated in Table 1.

The shared task covers 27 high- and low-resource languages. High-resource languages include Czech, German, English, Finnish, French, Hindi, Indonesian, Italian, Japanese, Korean, Persian, Portuguese, Russian, Slovak, Spanish, Vietnamese, and Chinese (Simplified). Low-resource languages Arabic, Bengali, Central Kurdish, Haitian Creole, Marathi, Swahili, Telugu, Thai, Turkish, and Yoruba are covered. A surprise language, Bhojpuri, was introduced to assess models' ability to generalize to unseen linguistic contexts. In addition, submissions are restricted to models up to 10B parameters.

Our submission investigates the multilingual instruction-following capabilities of **Qwen3.5-9B**[1] model, across three tasks. The model is jointly fine-tuned on all tasks using the parameter-efficient Low-Rank Adaptation (LoRA) (Hu et al., 2021) technique. Our results show stronger performance on `QA-Context` and `OEG` compared to `SUM`. On `QA-Context`, our model achieves the highest BLEU and ROUGE-L scores among all submitted models[2]. It also performs best on truthfulness, which measures models' ability to decline to answer when the context lacks sufficient information. On `OEG`, our model performs relatively well at providing answers in the target language (i.e., language adherence), although its overall task performance is low. `SUM` remains the most challenging task, with all submitted models performing worse compared to the other two tasks. In addition, the low performance on the surprise language, Bhojpuri, indicates that the model still struggles to generalize to unseen languages.

## 2 Tasks and Languages

MIST comprises three tasks covering 27 diverse languages to evaluate instruction-following abilities of LLMs. For training, the organizers provide a dataset[3], which we extend with additional data discussed in the following sections.

[1] https://huggingface.co/Qwen/Qwen3.5-9B

[2] We compare our results against the best-performing models submitted to this shared task, as gold labels for the test set are not available to us.

| **Total** | | **20,589** | **3,940** | **12,775** |

Table 2: Dataset source and statistics used across tasks.

### 2.1 Context-based Question Answering (QA-Context)

In this task, the model is prompted to answer a question by inferring from a given context, as shown in the example in Table 1. If the context is insufficient to answer reliably, the model should refrain from responding (i.e., truthfulness).

**Dataset:** The training dataset provided by the shared task organizers is a subset of the original data sourced from Belebele (Bandarkar et al., 2024), TyDi QA (Clark et al., 2020), and MCIF (Papi et al., 2026), a multimodal cross-lingual instruction-following dataset covering recognition, translation, question answering, and summarization subtasks, from which only the question-answering subtask was selected.

To extend this dataset, we include additional samples from each source. We further augment the dataset to capture *truthfulness* by introducing a small subset of unanswerable instances, created by replacing the original passages with passages drawn from different articles. Across all three sources, we select an equal number of instances per language and prepare a training and validation set by splitting the data in an 80:20 ratio.

### 2.2 Open-ended Generation (OEG)

Given an open-ended question, the model is expected to provide a natural, helpful response in the same language as the question, as illustrated by the example in Table 1.

**Dataset:** The datasets are collected from Aya dataset (Singh et al., 2024) and the WMT25 Multilingual Instruction Shared Task, hereafter WMT25-OEG (Kocmi et al., 2025).

We extend this data from the same source by retaining instances where the instruction and answer are in the same language, as OEG is designed to

be a monolingual task where the instruction and response are expected to be in the same language. Finally, we use an 80:20 ratio to split the collected data into training and validation sets.

### 2.3 Cross-lingual Summarization (SUM)

This is a cross-lingual task in which the model is instructed, in one language (e.g., German), to summarize a document written in another language (e.g., English), as shown in the example in Table 1. The training data also includes examples in which the output language differs from both the instruction and context languages. For example, an English instruction, *"Summarize the text in Spanish"*, is paired with a Chinese context.

**Dataset:** We used the dataset provided by the organizers, which was collected from CrossSum (Hasan et al., 2021), WikiLingua (Ladhak et al., 2020), and the summarization part of the MCIF dataset (Papi et al., 2026), and we split it into training and validation using a 90:10 ratio.

Overall, we collected $24K$ examples: $20K$ for training and $3.9K$ for validation. (Cf. Table 2). The test set, provided by the organizers, contains $\approx 13K$ instances, with instructions given in 24 languages, including a surprise language, Bhojpuri.

### 2.4 Languages

In total, the training dataset covers 27 languages. Of these, 17 languages, namely Arabic, Bengali, Chinese, English, German, Hindi, Indonesian, Italian, Japanese, Korean, Marathi, Portuguese, Russian, Spanish, Turkish, Vietnamese, and Yoruba, are covered across all three tasks. Four languages, Finnish, Swahili, Telugu, and Thai are each covered by only one task, while the remaining six, Central Kurdish, Czech, French, Haitian Creole, Persian, and Slovak, are covered by exactly two tasks. (Cf. Table 12 for list of languages per task)

Overall, 23 languages are covered in `QA-Context` and `SUM`, while 17 languages are included in the `OEG` task for training. The test set covers 24 languages, excluding French, Swahili, Telugu, and Thai, and introduces Bhojpuri as a surprise language to evaluate the model's ability to generalize to unseen languages during training.

## 3 System Description

**Experimental setup:** We fine-tune the Qwen3.5-9B[4] model on three tasks. We use a 4-bit-quantized Qwen3.5-9B model and apply Low-Rank Adaptation (LoRA) with a rank of $r = 16$ on a single NVIDIA A100 GPU. Training data were reformatted as chat-style instruction pairs. We first fine-tuned for 2 epochs on `QA-Context` and `OEG`, then fine-tuned for an additional 3 epochs on the `SUM` dataset. Loss was computed only on the assistant responses. (Cf. Table 7 for hyperparameters).

**Evaluation metrics:** According to the shared-task scoring scheme, the Ensemble and Gated ROUGE-L scores are used as primary evaluation metrics. In addition, BLEU, ROUGE-L, and chRF++ scores are reported for comparison.

- **Ensemble:** For `QA-Context`, verification accuracy is determined by a majority vote among three LLM judges: *GLM-1*, *Command-A+*, and *Gemma-4-31B*. `OEG` task uses these three judges together with *Qwen3.5-397B*. A prediction is considered correct if at least two judges classify it as correct. (For detail refer Schmidtová et al. (2026))

- **Gated ROUGE-L:** This metric first applies language identification GlotLID (Kargaran et al., 2023) to evaluate whether the model response is in the expected language, then computes ROUGE-L. If the response is not in the expected target language, the instance is assigned a score of 0.0, regardless of its ROUGE-L scores. This metric is used to evaluate the `SUM` task.

- **Lexical overlap**: BLEU (Papineni et al., 2002), chrF++ (Popović, 2015) and ROUGE-L (Lin, 2004) is computed for the `QA-Context` and `SUM` task.

## 4 Preliminary Experiment

We report results on the validation set using BERTScore (Zhang et al., 2020). Our fine-tuned model improves BERTScore by 12% and 6.3% on the `QA-context` and `SUM` tasks, respectively. On `OEG`, it achieves 72.87%, a 7.34% gain over the baseline (Table 9). These improvements provide empirical support to adopt the above experimental

Table 3: **Leaderboard.** Ranking of all 15 systems across the 3 tasks. **Overall Rank** denotes the mean rank across all tasks, while each task block reports the model's performance and corresponding rank for that task. For QA-Context and OEG, performance is reported using the ensemble (LLM-judge majority vote). For SUM, Gated ROUGE-L is reported. Our system is highlighted in gray and the best scores are in **bold**.

setup for the test-set evaluation. Section 5 discusses results on the test set.

## 5 Experimental Results

We compare our model with the best-performing models submitted to this shared task on the *test set* across all three tasks[5]. Overall, *CUNI-variant_B* achieves the best performance on average and ranked first on the OEG task. *CUNI-primary* performs best on the QA-Context task, while *Laniqo-variant_A* achieves the strongest performance on the SUM task. (Cf. Leaderboard in Table 3).

Our model achieves the lowest performance on the SUM task, with a Gated ROUGE-L score of 12%. In contrast, it achieves substantially higher scores on the QA-Context and OEG tasks, with scores of 59.16% and 60.48%, respectively.

**QA-Context:** Although our system ranks eighth in the ensemble score, it obtains the highest BLEU and ROUGE-L scores as shown in Table 4. Moreover, our model ranks first on truthfulness-F1, suggesting that it is less likely to generate unsupported answers or hallucinations, as shown in Table 5.

**OEG:** The system achieves an ensemble score of 60.48%, while providing answers in the expected target language in 87% of cases, shown in Table 8. Despite prior findings that models tend to fall back to English when instructed in non-English languages (Marchisio et al., 2024), our results demonstrate a strong ability in instruction following and language understanding.

**SUM:** Our model achieves a Gated ROUGE-L score of 12.5%, and performs considerably worse on lexical-overlap metrics (See Table 6). In addition, our model achieves 75.3% accuracy in providing answers in the target language. (See Table 8). Overall, the results indicate significant challenges in the SUM task in generating suitable summaries

[5]We omit baseline results on the test set as gold labels are not available to us. Instead, we compare our results with other participants of this shared task. In addition, we report BERTScore on our validation data .

| | BLEU | chrF++ | ROUGE-L (LCS F1) |
|---|---|---|---|
| CUNI-primary | 8.7 | 35.1 | 24.14 |
| CUNI-variant_B | 10.6 | **38.2** | 26.96 |
| Laniqo-primary | 9.5 | 36.1 | 24.88 |

| Sentinel-RunB | 9 | 64.72 |
| PSK-primary | 10 | 63.40 |

Table 5: **Truthfulness:** F1 score on unanswerable questions.

and, to a lesser extent, in consistently responding in the target language.

For the surprise language, Bhojpuri, our model achieves scores of 52.2% on QA-Context, 29.6% on OEG, and 9.5% on SUM. These results are substantially below the best-performing models, indicating a limited ability to generalize to unseen languages. (Cf. Table 11, for per-language performance and Table10 for each LLM judge scores)

| | BLEU | chrF++ | ROUGE-L |
|---|---|---|---|
| Laniqo-variant_A | **6.5** | 34.5 | **19.23** |
| CUNI-variant_B | **6.5** | **38.3** | 18.93 |

| TUM-Heilbronn-primary | 4.4 | 25.8 | 14.58 |

Table 6: **SUM:** Performance of the TEST SET measured using BLEU, chrF++, and ROUGE-L scores. and ROUGE-L scores. Best scores are in **bold**.

## 6 Conclusion

We presented our submission to the WMT26 Multilingual Instruction Shared Task, in which we participated in three tasks: Context-based Question Answering (QA-Context), Open-Ended Generation (OEG), and Summarization (SUM)covering diverse languages and scripts. We fine-tuned the Qwen3.5-9B model on the three tasks and evaluated its instruction-following ability across 23 languages and one surprise language. The results show that our model performs differently across tasks, with stronger performance on QA-Context and OEG than on SUM. In the QA context, the model achieves competitive results and performs best on the truthfulness F1 score. In OEG, it demonstrates relatively good language adherence despite lower overall task performance. In contrast, SUM remains challenging, with a substantially lower overall ensemble (Majority vote) score. Performance also drops considerably for the surprise language, Bhojpuri, across all three tasks. Overall, these results highlight the challenges of multilingual instruction following, particularly for less-resourced languages and cross-lingual generation tasks.

## 7 Limitations

**Model:** We evaluate only a single model, i.e., Qwen3.5-9B, across the three tasks. It is important to evaluate smaller and different architecture models, as performance and cross-lingual generalization may vary substantially. We note that comparing multiple model families is relevant to assessing whether our findings generalize beyond this specific model.

**Training strategy:** We do not experiment with hyperparameter tuning. All hyperparameters. A more systematic hyperparameter search could improve performance.

**Analysis of relation between tasks:** We do not examine the interactions between tasks, such as whether one task complements or comes at the cost of another. However, we observe one such interaction. Further training on summarization data leads to shorter open-ended answers that are less likely to meet the requested sentence length, likely due to the summarization objective biasing the model toward concise outputs.

Understanding these interactions could shed light on shared structure across tasks, but we leave this investigation for future work.

**Analysis on the relation between languages:** We did not analyze how languages influence one another in instruction-following tasks. Since the model is fine-tuned jointly on all languages, the presence of certain languages may affect performance on others through shared representations, and this interaction could be shaped by factors such as script, language family, or resource availability. Understanding these effects could help explain performance disparities across languages.

## 8 Acknowledgments

## A Hyperparameters

Table 7 summarizes the hyperparameters that were used to fine-tune the Qwen3.5-9B model.

| Hyperparameter | Value |
|---|---|
| Learning rate | $2 \times 10^{-4}$ |
| LoRA $r$ | 16 |
| Alpha $\alpha$ | 32 |
| Batch size | 16 |
| Epochs | $^{\dagger}5$ |
| Optimizer | AdamW |
| Seed | 42 |

Table 7: Hyperparameters used for fine-tuning. $^{\dagger}$ The model was initially fine-tuned for 2 epochs on QA-Context + OEG and continued fine-tuning for 3 epochs SUM, i.e., a total of 5 epochs.

## B Truthfulness

In Context-based Question Answering, truthfulness measures the model's ability to refrain from answering when the given context does not contain enough information to answer the question. We report the results in Table 5.

## C Language Identification

Previous studies have shown that multilingual models tend to fall back to English when prompted in less well-supported languages (Marchisio et al., 2024; Holtermann et al., 2024). To assess whether the generated responses are in the expected target language, GlotID (Kargaran et al., 2023) is used. Results are reported in Table 8.

| Task | Accuracy |
|---|---|
| QA-Context | 92.2 |
| OEG | 87.7 |
| SUM | 75.3 |

Table 8: Language identification (GlotID) accuracy

## D LLM Judge Accuracy

Table 10 shows the scores by each judge across tasks.

## E Preliminary result on Validation set

| | Baseline | | Finetuned | |
|---|---|---|---|---|
| | BERTScore | ROUGE-L | BERTScore | ROUGE-L |
| QA-Context | 69.97 | 15.17 | 82.57 | 28.21 |
| SUM | 66.55 | 9.54 | 72.87 | 15.78 |
| OEG | 65.53 | - | 71.08 | - |

Table 9: Results on the dev set across tasks. ROUGE-L is reported for comparison for QA-Context and OEG tasks.

| | Ensemble [Majority Vote] | Command-A+ [Judge] | GLM-1 [Judge] | Gemma-4-31B [Judge] | Qwen 3.5 397B [Judge] |
|---|---|---|---|---|---|
| QA | 59.16 | 61.59 | 54.48 | 64.05 | – |
| OEG | 60.48 | 58.26 | 61.28 | 60.32 | 63.57 |
| SUM | – | 52.36 | 47.41 | – | – |

Table 10: LLM judge verification accuracy (%) across tasks. For SUM, GLM-1, and Command-A+, judges evaluate target-language fluency and grammar

## F Performance of each language

The performance of our model vs. the top 3 models submitted to this shared task. The results reported in Table 11 covering three tasks across 25 languages.

Table 12: Languages covered by the WMT26 Multilingual Instruction Shared Task, with ISO 639-3 + script codes and number of instances per language. † indicates languages not included in the test set, and ‡**Bhojpuri** is a surprise language only covered in the test set. Light green indicates languages covered by only one task and light pink indicate languages covered by two task. The uncolored languages are covered by all three tasks. Overall, 23 languages are covered by QA-Context and SUM. 17 languages are in OEG.

# Probe Before you Answer! Answerability Probing for Abstention in Cross-Lingual Context-Based Question Answering

**Lea Krause[1], Stefan Schouten[1], Michiel van der Meer[2], Piek Vossen[1]**

[1]Vrije Universiteit Amsterdam, [2]Leiden University

## Abstract

We separate answering from abstention in a context-based question answering task, where a language model answers a question about a document in a possibly different language or abstains when the document contains no answer. A LoRA adapter on Qwen3.5-9B, trained only on answerable questions, generates the answer, while a linear probe on the frozen base model's activations decides answerability independently and returns the required refusal string when it predicts none exists. This isolates the model's answerability signal from its instruction-following. The probe's ranking of answerable against unanswerable questions transfers across languages, corpora, and negative constructions it was not trained on, but its decision threshold does not; training on in-domain multilingual data, rather than recalibrating the threshold, closes most of that gap. For the adapter, how the answer target is constructed trades off automatic correctness metrics against well-formedness and answer length.

## 1 Introduction

Language models produce different answers depending on the language they are prompted in (Manev, 2026), which raises the question of what else varies with language, including whether a model can tell that a question has no answer at all. We report our submission to the Multilingual Instruction Shared Task (Schmidtová et al., 2026), Sub-task 1: context-based question answering. Given a document in language $X$, the task asks a question about that document, in $X$ or in a different language $Y$, and requires either an answer grounded in the document or a fixed refusal string when the document does not contain one. This setup couples two abilities: that of refusing to answer (abstaining) and of generating an answer. Most work on abstention teaches the decision through explicit prompting, calibrated rejection scores, or fine-tuning the answering model itself (Jiang et al., 2021; Yang et al., 2024; Madhusudhan et al., 2025), which ties the decision to the model's instruction-following. The studies that leverage model's internal representations for answerability directly have so far stayed monolingual (Wen et al., 2025). However, in cross-lingual settings, where the question, the passage, or both can be in a language the model handles poorly, it is unclear whether refusing and answering draw on the same underlying capability, or whether a model can know a question is unanswerable without being able to say so.

We separate the two into (1) a LoRA adapter, trained only on answerable questions, that generates answers and (2) a linear probe on the frozen base model's whose activations decides answerability. If the probe decides to abstain, the adapter is not consulted, and the system returns a fixed refusal string. Neither component's accuracy depends on the model following an instruction to refuse, so combining the two estimates an upper bound for a model this size, separate from whether an instruction-tuned model would make the same decisions unprompted. We show that the probe's ranking of answerable against unanswerable questions transfers to unseen languages, corpora, and negative constructions, but the threshold it applies to that ranking does not, and that training on in-domain multilingual data, rather than recalibrating a fixed threshold, closes most of that gap. We find that how the answer target is written trades off automatic correctness metrics against well-formedness and target length. We submit two adapters built on these results, both paired with the same probe.

## 2 Related Work

### 2.1 Answerability & Abstention

Teaching models to withhold answers under uncertain predictions or for unanswerable questions

*Proceedings of the Eleventh Conference on Machine Translation*, pages 1933–1948
October 28-29, 2026 ©2026 Association for Computational Linguistics

has its roots in uncertainty prediction (Ulmer et al., 2022; Shorinwa et al., 2025). Recent approaches teach explicit abstention via calibrated uncertainty scores (Jiang et al., 2021; Madras et al., 2018), model collaboration (Feng et al., 2024b), or fine-tuning on rejections (Yang et al., 2024). On Abstain-QA, explicit prompting and CoT boost abstention performance in larger models (Madhusudhan et al., 2025), a finding corroborated by AbstentionBench scores across frontier LLMs (Kirichenko et al., 2025). However, smaller models which benefit less from explicit prompting remain understudied (Wen et al., 2025). We build on recent work combining cross-lingual abstention with model collaboration (Sun et al., 2025; Feng et al., 2024a), noting that prior multilingual uncertainty and abstention studies report considerable cross-lingual variation (Krause et al., 2023; Wen et al., 2026).

### 2.2 Probing

Probing trains a simple classifier on frozen activations to measure the task-relevant information they encode (Alain and Bengio, 2018; Belinkov, 2022; Tenney et al., 2019), and has been applied extensively to multilingual models (e.g. Şahin et al., 2020; Yin et al., 2022). Probing multilingual models' internal activations reveals a largely shared, English-centred representation space: non-English inputs are processed through an English-like "concept space" in middle layers before mapping back to the target language in final layers (Wendler et al., 2024; Schut et al., 2025; Zhao et al., 2024), with even independently trained monolingual models converging on the same circuit for certain tasks (Zhang et al., 2025). Other studies paint a more nuanced picture: models do not rely on a fully-aligned semantic space (Lu et al., 2025), and models retain language-specific features (Deng et al., 2025) and language-specific decoding mechanisms in later layers (Harrasse et al., 2026).

Similarly, probing has been applied to answerability, where models have been shown to encode the answerability of an input strongly at the very first decoded token (Kadavath et al., 2022; Slobodkin et al., 2023). Sparse autoencoders (SAEs) can recover good answerability features across domains, though struggle to generalise (Heindrich et al., 2025). Models also tend to internally represent unanswerability even when they fail to verbalise this in their output (Liu et al., 2026). For parametric answerability, where no passage is given, probes trained on low-resource languages achieve better performance on high-resource-projected representations of those languages than on the low-resource representations themselves (Xiao et al., 2025). Crucially, probing studies of answerability have largely remained monolingual (Wen et al., 2025). These two strands of research combined warrants the investigation of multilingual model representations for answerability.

## 3 Data

Two of our sources are corpora provided in the task, used as train and development set: TyDiQA (Clark et al., 2020) and BELEBELE (Bandarkar et al., 2024). We identified the Universal Declaration of Human Rights (UDHR) dataset as part of the test set, and built training data from the sections the shared task does not use. Our two trained components use the data differently. The answerability probe is trained on TyDiQA and UDHR. Of the two answer-generation adapters we submit (§4.1), one is trained on TyDiQA alone and one on a mix of all three datasets. The sections below describe how we extended each source for training and evaluation. Table 1 gives an overview of the resulting sets.

**TyDiQA/cross** TyDiQA provides question-passage-answer triples in a single language. We extend it to the cross-lingual setting by translating the questions and answers, leaving the passages original. We used Tencent's `Hy-MT2-7B`[1] (Zheng et al., 2026) for 18 languages (TyDiQA/cross18) and `MADLAD-400-10B`[2] (Kudugunta et al., 2023) to supplement five it does not cover: Bhojpuri, Central Kurdish, Finnish, Haitian Creole and Slovak (TyDiQA/cross23). Previous qualitative analysis had shown that MADLAD translations were frequently not of sufficient quality. We therefore used back-translation to filter the translations as well as checks for repetition loops, copy-through, length-ratio outliers, and over-frequent answer strings. Retention is 33.6% for Bhojpuri, 55.9% for Central Kurdish, 57.2% for Finnish, 62.7% for Haitian Creole, and 62.7% for Slovak. Yoruba was dropped due to very low back-translation scores and high occurrence of repetition loops. These five languages contribute 4,081 samples, or 4.1% of the set, at 504 to 941 samples each against roughly 5,355 for each Hy-MT2 language. The result is 100,466 examples, with questions in

| **Evaluation** | | | | | | |
| Test/silver | legal + cultural | designed | $25 \times 24$ | 360 | 8,640 | eval only |

Table 1: QA datasets. We list datasets twice, once for fine-tuning and once for probing, since they use different renderings: the probe sets carry unanswerable samples and the generation sets deliberately do not. "items" is the pool of distinct passage–question pairs a dataset is drawn from, before language expansion. The mixed adapter samples 24,000 / 30,000 / 6,000 from TyDiQA/cross, BELEBELE and UDHR respectively, while the TyDiQA-only adapter uses all 100,466 TyDiQA/cross samples.

23 languages and passages in the 11 languages TyDiQA itself covers, over 245 distinct language pairs. Appendix B shows how this extends TyDiQA's language coverage.

**BELEBELE/unanswerable** BELEBELE is already fully cross-lingual, but contains only answerable questions. We additionally construct unanswerable questions by removing the sentences that contain the gold label span, which removes the information the question asks for.

**UDHR** The test data for the contextual question answering subtask consists mostly of legal documents, and we established that one source of the test data was the Universal Declaration of Human Rights, which is available in all languages the task targets. The test set only uses specific sections of it, leaving the rest available for training. We sectioned the 24 unused articles into 18 passages of 224–714 characters, matching the length of the test set's own passages, and had Claude Opus 5 generate five questions per passage, reviewed by an independent pass. Eighteen of the 90 items are authored unanswerable, a 20.0% share taken from the test set's own rate. The adapter is never shown a question it should refuse, so its training set uses the 72 answerable items alone. The probe set uses all 90, plus 74 transplants (a question moved onto a passage that does not answer it) for 164 items.

**Test/silver** We used Claude Opus 5 to generate silver labels for the provided test set. This data was used purely for evaluation (Section 5), not for training or the selection of parameters of our system.

## 4 System

Our QA system has two components[3]:

1. A pre-trained language model (Qwen3.5-9B; Qwen Team, 2026), using the `unsloth/Qwen3.5-9B`[4] checkpoint, complemented with LoRA adapters optimised for question answering, and

2. a probe operating on the same base model, deciding on the answerability of the question.

If the probe detects that a question is unanswerable, the LoRA weights remain unused, and instead of generating an answer from the model, we simply return the fixed 'not answerable' phrase mandated in the instructions.

With this approach, we mean to estimate the empirical upper limit, using the probe to directly assess how well the model can decide on answerability in principle, regardless of its ability to follow instructions. This then allows us to train the adapters purely for answering the question correctly, independent of whether the model should attempt to answer it. By providing such a system, we aim to give insight into the best performance that may be expected from a model this size. [5]

### 4.1 Adapter Training

We submit two answer-generation adapters: one trained on TyDiQA/cross23 only, and one on a mix of all three sources.

[3] Code at https://github.com/lkra/answerability_probing

[4] https://huggingface.co/unsloth/Qwen3.5-9B

[5] Another system trained for Subtask 2 Summarization is described in Appendix C.

**Adapter 1: TyDiQA/cross** Our first adapter is trained on the 100,466 TyDiQA/cross23 examples of §3, with questions in 23 languages, passages in 11, and every example cross-lingual by construction. Based on the task instructions, targets should be short one-sentence answers rather than passage quotations. We therefore used TyDiQA's answer sentence, in cases it is brief enough, or the answer span otherwise, at a median of 41 characters. Answer spans are normalised to be capitalised and terminated. The terminator for each language is the majority sentence-final character over existing target sentences. The result is *danda* for Bengali and Hindi, the ideographic full stop for Japanese and Chinese, and the period elsewhere. It assigns the period to Bhojpuri, where our generated silver references use *danda*. We follow the training data, so Bhojpuri surface form remains open. The set contains answerable questions only, so the model is never shown a question it should refuse, and the loss is computed on completions alone. Training is a single epoch of LoRA ($r = 16$, $\alpha = 16$, dropout $= 0$, all linear layers, learning rate $= 1\mathrm{e}-4$, batch size $= 8$, sequence length $= 4096$). We keep the checkpoint with the lowest held-out loss of 62 evaluations, at step 12,400 of 12,534 and an eval loss of 0.3905.

**Adapter 2: Mixed data** We submit a second adapter trained on a mix of TyDi, BELEBELE, and UDHR, using identical hyperparameters and selection rules as Adapter 1. The mix is 40% TyDi, 50% BELEBELE, and 10% UDHR over 60,000 samples. We cap each distinct completion at four occurrences per language, so a language with fewer acceptable translations contributes fewer samples rather than being topped up with repeated ones.

The two adapters differ in data composition and in target construction, so the comparison in §5.1 is not a strict ablation of either. The mixed set is more repetitive, at 62.6% distinct completions against 90.9%. It covers one additional language, Yoruba, through the two additional data sources. It contains 1,495 monolingual samples, or 2.5%, which the TyDi-only set does not and the test set does.

### 4.2 Probe training

The probe decides, for a given input, whether the question can be answered from the information in the provided passage. Throughout, the probe is a linear classifier on frozen layer 19 of 33 of Qwen3.5-9B (Qwen Team, 2026), trained once and applied unchanged. The probe incorporated into the system was trained on the original, monolingual TyDiQA and our UDHR development data set. The layer was chosen by a sweep over all 33 layers (see Appendix E). During both train- and test-time the probe is presented with samples wrapped in the model's chat template, but without any kind of instruction. The probe is applied to the final input token, which is the newline after the start of the assistant response, i.e. the token immediately prior to the model's generated response.

## 5 Evaluation

We evaluate our system through various ablations for both the adapter fine-tuning data and the probes.

### 5.1 Answer Generation Adapter

The adapter modifies the base model so that it performs well at answering questions as accurately as possible, regardless of whether they are answerable. We currently evaluate against the silver references of Section 3, on the 6,325 answerable test samples and report scores against gold references for the two submitted adapters (Table 3). Central Kurdish is excluded throughout, since its silver references are in the wrong Kurdish variety. Each approach uses identical inference settings to compare the effect of training data alone.

Based on the shared task, we evaluate four aspects: (1) following the format instructions, (2) giving the correct answer, (3) writing a well-formed sentence, and (4) answering in the correct language. We measure answer correctness with chrF (Popović, 2015) and a rescaled BERTScore (Zhang et al., 2020) over XLM-R large (Conneau et al., 2020). Instruction following is measured through the median answer length in characters, currently against 48 for the silver reference. Well-formed sentences are computed as the share of answers that are both capitalised and sentence-terminated. Finally, we observe the share of responses detected in a language other than the one the question was asked in using the fastText `lid.176` classifier (Joulin et al., 2017). The official evaluation uses GlotLID over all 24 question languages and reports 95.9% and 95.4% of answers in the requested language for the two submitted adapters.

BERTScore is reported with the baseline rescaling of Zhang et al. (2020), $(F_1 - b)/(1 - b)$, but with the baseline $b$ estimated per variant. We esti-

| Target construction | chrF | BERT | med. len | well-f. | off-t. |
|---|---|---|---|---|---|
| Full sentence, 23 lang. | 36.2 | 23.8 | 159 | 79.8 | **0.7** |
| Adaptive | **39.4** | 30.0 | 59 | 42.8 | 2.1 |
| Adaptive+normalised | 38.9 | 33.3 | 56 | **97.7** | 2.3 |
| Mixed sources | 37.1 | **37.5** | 34 | 97.2 | 1.7 |
| *silver reference* | — | — | *48* | *100* | *0.7* |

Table 2: Adapter variants, on 6,325 answerable samples with Central Kurdish excluded. BERT is BERTScore rescaled against a per-variant baseline, as a percentage of the distance from that baseline to a perfect score. Off-target is restricted to the 13 languages where the detector is reliable. The last two are the submitted adapters.

| | judge | chrF++ | R-L | COMET | C-QE | NLI | lang. |
|---|---|---|---|---|---|---|---|
| Adapter 1 | **67.5** | **36.3** | **28.3** | 71.2 | 62.7 | 24.4 | **95.9** |
| Adapter 2 | 62.0 | 34.8 | 27.7 | **72.6** | **63.3** | **26.1** | 95.4 |

Table 3: Official scores of the submitted adapters against gold references (Schmidtová et al., 2026). *judge*: majority vote of three LLM judges, the primary criterion; R-L: ROUGE-L; C-QE: reference-free COMET; NLI: mutual entailment with the reference; *lang.*: share of answers in the requested language. Adapters 1 and 2 rank 5th and 6th of 14.

mate it by re-pairing each of a variant's predictions with another sample's reference from the same language, which holds language and register fixed and changes only the answer content. Measured this way, the baseline lies between .855 and .875 and raw $F_1$ between .889 and .922, so we report the margin above the baseline.

The results can be seen in Table 2. The adapters differ in the target format and which sources were used in training. *Full sentence* takes the whole sentence containing the answer as the target, over the 23 languages (see Section 3). *Adaptive* takes the answer sentence where it is already brief and the answer span otherwise, and + *normalised* additionally capitalises and terminates it. *Mixed sources* uses a subset of all three corpora rather than TyDiQA alone (see Section 4.1). The last two rows are the two adapters we submit.

**Correctness** The two automatic metrics rank the two submitted adapters in opposite orders, and the ranking seems to be based on answer length: character overlap favours the longer variant, embedding similarity the shorter one. Scores against gold references (Table 3) show the same split. On the primary criterion the difference is 67.5% against 62.0%, and Adapter 1 is ahead in 22 of 24 question languages. The gap is largest in Korean (+16.9) and Chinese (+16.3) and within a point in English, German and Spanish.

**Target length** Shortening the target from the full answer sentence to a short answer raises chrF by 3.2 and rescaled BERTScore by 6.2 and moves the median answer from 159 characters to 59. No hyperparameter we varied produced a comparable effect. It is also the only change that brings answer length near the length of the silver references.

**Well-formedness** The span fallback costs well-formedness, which falls from 79.8% to 42.8%. A span extracted from a passage is a bare noun phrase with no sentence punctuation, so only 54.8% of the adaptive targets are terminated, and the model reproduces that rate in its own answers. The outputs are lowercase fragments such as *"the language"* and *"must be brought to justice"*, with correct content and length not exceeding one sentence. ChrF places this variant as strongest. Normalization of the targets restores the well-formedness to 97.7% at a cost of 0.5 chrF.

### 5.2 Answerability Probe

We construct two probes for answerability detection, differing only in what they are trained on: **TyDi**, which uses only the natural, multilingual answerability data (not the cross-lingual derivative we create), and **TyDi+UDHR**, which adds the cross-lingual UDHR data in the legal domain. The second probe is used in combination with both adapters in our submission.

We evaluate probes on four datasets, each of which removes a different assumption: TyDi (validation), monolingual with natural negatives; UDHR, cross-lingual and in the test set's own legal domain; BELEBELE/cross, cross-lingual with constructed negatives and passages from a corpus no probe here was trained on; and the shared task's own test set (with silver labels).

The rest of this section asks four questions of that probe, in order: (1) Does it transfer to *languages* it has never been trained on? (2) Does it transfer to the *cross-lingual* setting, where the question is not in the passage's language? (3) Does it transfer between *distributions* such as another register, another way of constructing negatives, another class balance? And (4) where transfer fails, how much of the failure is due to the threshold and how much to the probe direction? The first three of those are measured with AUROC, which is a ranking metric: it measures only whether answerable samples

| evaluation set | samples | lexical | TyDi | **TyDi+UDHR** |
|---|---|---|---|---|
| TyDi (validation) | 9,813 | .755 | .981 | **.981** |
| UDHR (validation) | 17,280 | .795 | .888 | **.959** |
| BELEBELE | 780 | .700 | .883 | **.917** |
| BELEBELE/cross | 20,280 | .701 | .823 | **.869** |
| passage lg. above the baseline | | | 22/26 | **25/26** |

Table 4: Probe AUROC, a threshold-free ranking measure, against the lexical baseline. The two BELEBELE samples rest on 15 items and differ only in whether the question is in the passage's language, so the third row is a 780-sample diagonal rather than an independent evaluation; UDHR is 164 items and TyDi validation is sampled.

outscore unanswerable ones and is unchanged by any monotonic rescaling of the score. It says nothing about whether the probe would decide correctly at any particular threshold. This is what allows us to distinguish between the language-independence of a direction, which ranks, and a threshold, which decides.

**Chance is not 0.5** Because every corpus here builds its negatives from text closely related to the passage (Section 3), word overlap between question and passage is by itself a strong predictor. Hence, on TyDi, a lexical baseline reaches .755 for its validation set, rather than 0.5. On the cross-lingual datasets, where we have human translations into the passage's language, a similar baseline is appropriate. Specifically, we look at the overlap computed for human-translated questions, i.e., what a lexical system with a perfect translator would achieve, which gives .795 on UDHR and .701 on BELEBELE.[6]

### Overall probe generalisation

Table 4 shows generalisation across languages, domains, and negative constructions for both probes.[7] The TyDi+UDHR probe beats the lexical baseline in 25 of 26 passage languages. The exception is Bengali, where the probe ties the baseline, .830 against .831. It has the second-highest lexical baseline of the 26 and the fourth-lowest probe score. The three languages with the highest lexical baselines in the set are Vietnamese, Bengali, and Hindi, and those are three of the four languages the TyDi-only probe also fails to beat (the fourth is Marathi, where the baseline is unremarkable and the probe is weak).

### Transfer to unseen languages

To test whether the probe relies on features specific to a language, we train probes on data without that language. Every sample whose question or passage is in that language is dropped from every training source.[8] and the probe is then scored on that language alone. We hold the number of training samples fixed, so that the removal changes which languages are seen and not how much data. Relative to the probe fitted on all languages, removal costs $-.007$ AUROC for the TyDi probe over its 11 languages and $+.000$ for TyDi+UDHR over its 24. The ranking is almost unchanged: the probe does not need to have seen a language to read answerability in it. For this leave-one-language-out experiment, the held-out language still has the same register, negative construction, and class balance the probe was fitted on. We investigate whether the direction is impacted by a change in those below.

### Transfer to the cross-lingual setting

On BELEBELE/cross we reach an AUROC of .869 against a lexical baseline of .701. The cost of asking the question in a different language from the passage is –.048 AUROC on that data set. The penalty depends on how the negatives were built. Varying only the question language, the penalty is –.014 on TyDi's natural negatives against –.048 where the answer sentence is deleted from the true passage.

We also checked if the question sharing a script with the passage helps, but on TyDi/cross18 it only adds .0047 AUROC, computed within passage language. Having seen the question language during training also helps little, on either cross-lingual set: the TyDi probe scores .9635 on the 11 TyDi/cross18 question languages it never trained on, against .9646 on the 7 it did, and .823 on BELEBELE's 16 unseen against .824 on its 11 seen.[9]

### Transfer across distributions

The third question is about the data-generating process. This includes: (1) how the negatives were built (Appendix F), (2), the class balance, and (3) the register, i.e. the kind of text the passages are

[6] Overlap on the cross-lingual pair actually presented to the probe is near chance at .519.

[7] Every split is item-disjoint rather than sample-disjoint, since each UDHR item appears in many language renderings (also see Appendix D).

[8] TyDi is monolingual, so there the two removals coincide; the distinction bites only on the cross-lingual sources.

[9] Neither split can be run informatively for TyDi+UDHR, which has seen 26 of BELEBELE's 27 question languages and all 18 of translated TyDi's.

drawn from, encyclopaedic in TyDi, news prose in BELEBELE, and legal in UDHR and the test set.

A probe trained on UDHR alone reads its own register very well (AUROC .944 on held-out UDHR items) but falls to .886 on TyDi validation, against .981 for a probe that saw TyDi. So a probe fitted on one register does not generalise outside of it. Training on both allows the probe to handle both registers. TyDi+UDHR loses .0003 AUROC on TyDi validation relative to the TyDi-only. It also improves transfer performance on BELEBELE by .032 AUROC, a corpus with a different register, a different negative construction and a different class balance from either of its training sets.

The negative construction can be varied on its own, holding the register, the items, the languages and even the answerable samples fixed, by substituting a different passage instead of deleting the answer sentence from the true one. Doing so is worth about $+.10$ AUROC, the submitted probe's performance rises from .863 to .960, but nothing in margin, because it raises a lexical baseline by the same amount (.696 to .792). The harder construction is therefore harder for reasons that do not apply uniquely to a probing strategy (see Appendix F for details).

Class balance is equally important, since on the provided test set, according to our silver labels, only 20% of the samples are unanswerable, compared to an even split on TyDi. While this only influences the validity of a threshold, not a ranking, it matters for the final classification.

**How much of the gap is the threshold?**

So far, we have looked at ranking performance as measured by AUROC, but in the system, we need to actually classify samples as answerable or not. This requires a threshold. Since we are hoping for a probe that can classify different combinations of question and passage languages, we want a threshold that transfers as well as the direction did, i.e. one that does not depend on the languages in a sample. To investigate this, we introduce a per-language log-odds offset, which is a constant added to the probe output for every sample in that language. This is equivalent to a per-language threshold. We look at the spread of log-odd offsets across languages, since we ideally want all languages to require similar log-odd adjustments (similar thresholds).

On the test set, the per-language log-odds offset that the TyDi-only probe needs is $+1.1$ larger for languages absent from its training data than for languages present in it. A probe's direction therefore transfers to unseen data and languages more easily than its threshold does.

| offsets fitted on | TyDi | **TyDi+UDHR** |
|---|---|---|
| UDHR (held-out items) | 1.011 | **0.231** |
| BELEBELE | 0.908 | **0.427** |
| Test/silver | 0.959 | **0.451** |
| *noise floor* | *0.215* | |
