**Models** We use GPT-4o-mini as the editor for all methods. Claude-haiku 4.5 is used as the universal judge, while Gemini-2.5-Pro and GPT-5 are included for cross-family robustness checks. Averaging PE across judges from different model families mitigates model-specific preference effects and yields a more stable evaluation signal, consistent with recent findings on self-preference bias and multi-judge evaluation in LLM-as-a-Judge systems (Wataoka et al., 2025; Verga et al., 2024). We further use the PE gap between the same-family judge (`GPT`) and cross-family judges (`Claude` / `Gemini`) as a direct proxy for quantifying self-bias. For the debate gate, we use EXAONE-4.0-32B as the native judge for Korean and Qwen3-32B for Chinese, Japanese, German, and French, while reference-free metrics are computed with Qwen2.5-7B for PPL and XLM-RoBERTa-large for BERTScore and MAUVE. See Appendix F.

**Baseline models.** We compare against three representative editing baselines. *Naive Polish* performs a single polishing pass using a generic instruction without any explicit detection or verification stage. *LiL Polish* reproduces the polishing prompt proposed in Lost in Literalism (Li et al., 2025), consisting of a single polishing call that emphasizes native-like phrasing and stylistic adaptation. *Self-Refine* (Madaan et al., 2023) adopts an iterative refinement framework that alternates between feedback generation and refinement, terminating when no further improvement is suggested or after a maximum of three refinement iterations.

### 3.2 Evaluation Metrics

We evaluate performance from three perspectives: preference, distribution matching, and lossless. See Appendix C for details.

**Preference** We use pairwise LLM judgments to compute the prefer-edit rate (PE) as the primary evaluation metric. PE is defined as the proportion of cases in which the judge considers the method output $y_p$ more natural than the baseline output $y_o$:

$$\text{PE} = \frac{1}{n} \sum_i \mathbf{1}\left[L_p^{(i)} - L_o^{(i)} \geq 0.5\right], \tag{11}$$

where $L^{(i)}$ denotes the average Likert score over the nine rubrics. To mitigate position bias, we conduct two evaluations by swapping the presentation order of $(y_o, y_p)$, and report their average. See Appendix C.2 for details.

**Distribution matching** To measure distributional similarity between method outputs and human references, we use MAUVE (Pillutla et al., 2021) and calibration error, defined as $\Delta_{\mathrm{O}} = \mathrm{PE} - \mathrm{Oracle\ PE}$, where Oracle PE denotes the PE of human references. As auxiliary metrics, we report automatic indicators of translation naturalness, including lexical density (Lex), length variance (Len), and perplexity (PPL) (Li et al., 2025), along with stylometric distance metrics such as BERTScore, cosine similarity, lexical JSD, and comma and em-dash frequency differences.

**Lossless** To evaluate semantic loss during editing, we measure the bidirectional NLI entailment rate (Maynez et al., 2020). The threshold $\tau_{\mathrm{nli}}^{(\ell)}$ is calibrated for each language using the 95th percentile of the entailment score distribution.

### 3.3 Multilingual Main Results

Table 2 presents PE and MAUVE for three prior baselines (Naive Polish, LiL Polish, Self-Refine) and three MELT variants: *MELT-LLM*, which uses a single LLM for detect–edit–verify without rule-based verification or multi-agent debate; *MELT-Hybrid*, which additionally incorporates a rule-based surface detection and verification layer; and *MELT-MAS*, which further adds selective multi-agent debate for self-bias-prone categories. The initial LLM translation (raw MT) serves as the baseline across five target languages on FLORES-200. PE is averaged over three judges (Claude-Haiku 4.5, Gemini-2.5-Pro, and GPT-5), and $\overline{|\Delta_{\mathrm{O}}|}$ quantifies calibration error as the average absolute difference between PE and Oracle PE across the five languages, where lower values indicate closer calibration to the human reference distribution.

The experimental results show that MELT simultaneously achieves calibration and meaning preservation in multilingual translationese mitigation. 1) MELT variants consistently maintain results closest to Oracle preference, exhibiting more stable post-editing characteristics compared to Naive Polish or Self-Refine. In contrast, some baselines show a tendency to substantially exceed Oracle preference despite recording high PE, which we interpret as the effect of self-preference bias, where LLM judges favor LLM-style expressions closer to their pretraining distribution over human-like naturalness. 2) Self-Refine shows lower preference than the baseline across several languages, suggesting that iterative rewriting can induce over-editing that causes outputs to deviate from the original meaning and stylistic distribution. MELT controls edits with potential for meaning distortion through its detect–edit–verify structure, verification gates, and rollback mechanism, enabling stable editing even in a training-free setting. In particular, MELT variants show notably larger improvements in languages with wordy structures and register variation, such as Japanese, indicating that translationese is a language-universal phenomenon while exhibiting different surface realizations across languages. These results demonstrate that the unified training-free framework combining typology-aware category detection and selective verification can operate as a consistent post-editing strategy across language types.

Moreover, MELT-LLM achieves the lowest calibration error among all baselines ($\overline{|\Delta_O|} = 3.9$), while requiring only 3.0 model calls per sample. As shown in Table 10, MELT-LLM and MELT-Hybrid add only one model call compared to the single-pass baselines, resulting in an approximately 2-second increase in latency. In contrast, MELT-MAS incurs substantially higher latency due to native-judge inference. Compared with Self-Refine (6.9 model calls per sample, $\overline{|\Delta_O|} = 15.5$), these results suggest that the performance gains are not simply due to increasing the number of model calls, but primarily stem from the proposed detect–edit–verify formulation itself.

### 3.4 Monolingual Main Results

Table 3 presents the main results in the monolingual author-style recovery scenario. The experimental setup involves translating pre-LLM-era authors' original texts into English and then back-translating them into the source language, a process that tends to weaken the original author's idiolect and register and converge toward a more averaged LLM-style expression. Each method takes the back-translated output as input and attempts to recover the original author's style, and performance is measured using pairwise preference-based PE and BERTScore F1 against the author's original text.

The experimental results reveal different patterns in the monolingual recovery setting compared to the multilingual translation setting. LiL Polish records the highest PE in Korean, Chinese, German, and French, while MELT variants show superior performance in Japanese. Meanwhile, the PE gap between Oracle and each method is relatively small in Japanese, German, and French, which we in-

Table 3: Monolingual author-style recovery main results. Pipeline: pre-LLM-era author original → English forward MT → target language back MT → recovery attempt by each method. PE denotes prefer-edit rate and BS denotes BERTScore F1. Full metric set and per-judge breakdown are provided in Appendix Table 15.

terpret as the LLM judge favoring more generic and standardized MT-style expressions over outputs that preserve pre-LLM-era writing styles. This suggests that LLM judge evaluation alone is insufficient to fully reflect human stylistic authenticity, confirming the necessity of calibration-aware evaluation. BERTScore remains at nearly identical levels across methods and languages, confirming that discriminability appears along the stylistic preference axis rather than semantic similarity. Full metric sets and per-judge breakdowns are provided in Appendix Table 15.

## 4 Results and Analysis

We analyze whether the key design components of MELT perform their intended roles in practice. The analysis examines the effects of the verification gate and selective debate on calibration and meaning preservation, and compares self-bias patterns across languages under different cross-family judge configurations. Finally, through monolingual author-style recovery and reference-free naturalness analysis, we evaluate whether MELT contributes to stylistic authenticity and idiolect restoration beyond fluency polishing.

### 4.1 Cross-family Judge Composition and Self-bias

Table 4 and Figure 3 show that self-preference bias in the LLM-as-a-judge setting varies substantially depending on the judge family. Evaluating the same GPT-4o-mini editor output while varying only the judge, Oracle PE is lowest for the same-family judge GPT-5 and tends to increase sequentially for cross-family judges Claude-haiku 4.5 and Gemini-2.5-Pro. GPT-5 evaluates GPT-4o-mini MT outputs as more natural than human references in Korean, Chinese, and Japanese, which can be interpreted as self-preference bias where same-family judges favor expressions similar to their own generation distribution. Cross-family judges maintain relatively stable preference for human reference, indicating that cross-family calibration is necessary for multilingual post-editing evaluation. Across languages, Korean shows the lowest Oracle preference across all judges, which we attribute to the conciseness

| Judge | Ko | Zh | Ja | De | Fr | Avg | $\overline{\Delta}_{\text{lik}}$ |
|---|---|---|---|---|---|---|---|
| **GPT-5** | 20.8 | 28.5 | 31.2 | 36.4 | 36.6 | 30.7 | −0.09 |
| **Haiku 4.5** | 25.3 | 45.8 | 44.5 | 43.0 | 40.9 | 39.9 | +0.01 |
| **Gemini 2.5 Pro** | **36.8** | **50.3** | **53.2** | **49.0** | **42.8** | **46.4** | **+0.09** |

Table 4: Judge self-bias, per family. Per-language performance is a decomposition of Oracle PE from Table 2 by LLM. Lower values indicate stronger self-bias, where the judge prefers same-family MT output over human references. Per-rubric Likert metrics and scores are in Appendix C.1 and Appendix J.

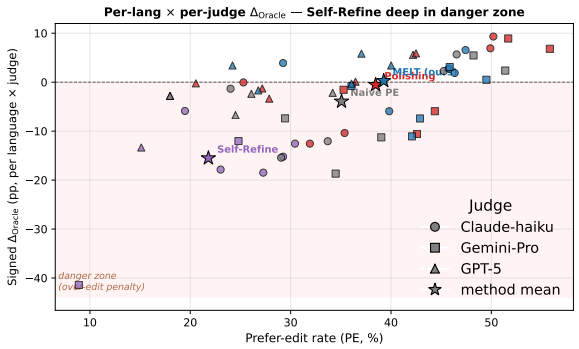

Figure 3: Per-language × per-judge signed $\Delta_{\text{O}}$ scatter. Each method is represented by 15 points (5 languages × judges), where ⋆ denotes the method mean. The negative $\Delta_{\text{O}}$ region indicates a danger zone where the judge rejects edits more than Oracle.

and implicature of professionally translated Korean not fully aligning with the fluency prior of current LLMs. In Figure 3, MELT variants are distributed relatively stably near Oracle, demonstrating that the calibration-aware detect-edit-verify structure is more robust to changes in judge family.

Although LiL Polish achieves the highest raw PE in German and French, these scores exhibit larger deviations from the corresponding Oracle preference, resulting in increased calibration error. Moreover, the PE differences between LiL Polish and MELT are not statistically significant in either language (Appendix H). In contrast, MELT consistently remains closer to the Oracle preference across all languages, indicating better calibration to human-reference preferences.

### 4.2 Reference-free Naturalness

Separate from the LLM judge-based preference and stylometric divergence analysis, we analyze the output of each method using the reference-free naturalness metrics, such as lexical (Lex), length (Len), and PPL, proposed by Li et al. (2025) (Appendix C.4). These metrics measure how well output texts align with the natural language distribution, but can simultaneously be interpreted as LM-aligned fluency metrics that reflect similarity to the training distribution of modern LLMs.

Table 5 shows that the PPL of pre-LLM-era authors' original texts (Original) is consistently higher than that of all post-editing outputs. Human-authored original texts are evaluated as unnatural by PPL, as PPL measures alignment with the modern LM distribution rather than human-likeness itself. In practice, most post-editing methods converge toward fluent and averaged LM-style expressions, with LiL Polish recording the lowest PPL and most stable length variance across several languages. This tendency is observed equally in the FLORES translation experiments, indicating that polishing-based instructions produce outputs most closely aligned with the modern LLM prior.

In contrast, MELT variants show a tendency to shift toward the author original distribution in the Lex (content-word ratio) metric across multiple languages. This indicates that MELT does not perform fluent rewriting, but operates in a way that better preserves content-word distribution and stylistic markers. This difference is pronounced in languages where discourse convention and register variation have a strong influence, such as Korean and Japanese. High performance on LiL metrics does not imply human-like stylistic authenticity or author-style preservation, and we confirm that MELT is closer to stylistic distribution recovery than LM-style fluency optimization.

## 5 Conclusion

In this paper, we propose MELT, a training-free method that mitigates translationese across five languages and brings generated text closer to native naturalness. Our empirical analysis of MELT focuses on three aspects: 1) For *Typology-aware detection*, we classify translationese patterns into five categories for each target language and quantitatively measure their typology-conditioned realizations. 2) For *Training-free pipeline*, we show that MELT can mitigate translationese without weight updates while preserving meaning. The experimental results on FLORES-200 show that MELT-LLM achieves the lowest average calibration error across the three judges among all baselines, with $\overline{|\Delta_{\text{O}}|} = 3.9$ pp. MELT-Hybrid shows the closest results to Oracle PE in four of the five languages. Although LiL Polish attains the highest raw preference scores in German and French, MELT con-

| Method | Ko | | | Zh | | | Ja | | | De | | | Fr | | |

sistently remains better calibrated to the Oracle preference across languages. 3) for *Idiolect restoration*, we confirm that, in a monolingual recovery scenario involving 49 pre-LLM-era authors, MELT better preserves BERTScore and stylometric distributions in the direction of the original authors than the baselines.

In future work, we plan to extend the five category taxonomy proposed in this paper to a broader range of linguistic patterns. We will also expand native-speaker validation to cover more pattern types and examine settings where translationese accumulates across multiple stages to further assess the generalizability of MELT. Building on these extensions, we will explore the integration of MELT as a post-editing component within broader agentic translation workflows.

## Limitations

The five category taxonomy and detect-edit-verify pipeline of MELT are designed to target *LLM-specific unnaturalness*, including translationese, post-training distortion, and English-structure mimicry. General copy-editing errors, such as spelling mistakes, subject-predicate agreement, or clause-comma placement, are not primary target. Surface errors may also be addressed during category-conditioned editing by the LLM editor in the edit gate. Cases that involve semantic distortion are blocked by the bidirectional NLI gate in the verify gate. However, we do not report quantitative metrics such as "spelling accuracy" or "grammar error rate". MELT is not a replacement for a grammar checker. For production use, we recommend applying MELT followed by a separate spell or grammar checker.

MELT modifies stylistic characteristics while constraining changes to semantic content through the NLI gate, but this capability could potentially be misused to evade MT detection or authorship analysis. We do not overstate the effectiveness of existing defenses. Stylometric features alone may not reliably distinguish human-written text from machine-generated text, and MELT explicitly reduces the very signals targeted by such analyses. Therefore, rather than claiming that our analysis provides a countermeasure, we identify the reliable detection of MT outputs edited by MELT as an open challenge for future work. In addition, our taxonomy and native-speaker judges implicitly assume a language-specific notion of *nativeness*, although perceived naturalness can vary across dialects, generations, and registers.

## Ethical Considerations

All datasets and models used in this work are publicly available, and pre-LLM-era literary texts used in the monolingual author-style recovery experiments are sourced from public domain repositories, including Aozora Bunko, Wikisource, and Project Gutenberg. We are not aware of any direct negative societal impacts specific to this work beyond those generally associated with the advancement of large language models.

## A Related Work

**Measuring and Mitigating Translationese** Translationese analysis has examined the unnaturalness of Neural Machine Translation(NMT) from multiple perspectives since Volansky et al. (2015) characterized translationese through automatic classification based on statistical features. Prior studies have measured various aspects of translationese, including reduced lexical diversity (Vanmassenhove et al., 2019), the acceleration of post-editese (Toral, 2019), and the reassessment of human-parity claims (Toral et al., 2018). These studies have shown that translationese is not a mere stylistic deviation, but a systematic phenomenon observable across statistical features and syntactic choices (Daems et al., 2018). Approaches for distinguishing human and machine translation based on information theory (Bizzoni et al., 2020) and translationese aware multilingual NMT (Riley et al., 2020) have also been proposed as methods for measuring and mitigating translationese. Translationese has been shown to affect not only machine translation itself but also evaluation sets, with test sets containing translationese reported to distort system comparisons (Zhang and Toral, 2019). Jalota et al. (2023) propose a translation-based style transfer approach that mitigates translationese without relying on parallel data. As LLMs have become widely adopted, Li et al. (2025) mitigate unnaturalness through SFT data curation based on reference polishing and unnatural-instance filtering, while Guo et al. (2025) address multilingual unnaturalness using corpus-level lexical JSD measurements and DPO alignment. However, these mitigation approaches rely on training-time methods such as SFT or DPO, thereby incurring additional retraining costs.

**Characterizing Post-training Distortion** Post-training distortion analysis addresses non-translationese aspects of translationese. Singhal et al. (2024a) show that reward improvements from RLHF can be reduced to response length inflation, while Hosking et al. (2024) analyze how a single preference score can conflate factuality with assertiveness. Sharma et al. (2024) demonstrate that sycophancy originates from preference data. From the perspective of output diversity, Kirk et al. (2024) and Padmakumar and He (2024) show that RLHF and writing with language models can reduce output diversity. Liang et al. (2024) and McGovern et al. (2025) quantify lexical fingerprints characteristic of LLM outputs, including words such as "delve" and "intricate".

However, these studies mainly focus on diagnosis and characterization, and there has been no multilingual attempt to mitigate both translationese and post-training distortion within a unified inference-time framework. We integrate translationese and post-training distortion under a five category taxonomy and propose a training-free post-editing approach for mitigating translationese.

**LLM-as-a-Judge and Limitations** LLM-as-a-judge has been widely adopted as an efficient means of replacing or assisting human judgment in large-scale generation evaluation. Zheng et al. (2023a) demonstrate that LLM judges can serve as useful comparative evaluation tools on MT-Bench and Chatbot Arena, and the potential of LLM judges for translation quality evaluation has also been reported (Kocmi and Federmann, 2023). However, several studies show that LLM judges are not always neutral or stable. Xu et al. (2024) show a tendency toward self-bias, while Wataoka et al. (2025) and Chen et al. (2025) quantitatively analyze this bias as a potential structural characteristic of judges, and Spiliopoulou et al. (2025) propose a statistical method for measuring self-bias. Hosking et al. (2024) analyze the limitations of single preference scores, and Singhal et al. (2024b) show that length inflation following RLHF can lead to overestimation of fluent-but-long outputs. To mitigate these issues, we propose an approach that combines not only an LLM judge but also surface-based verification and bidirectional NLI.

## B Datasets

Table 6 summarizes the sample size, average length, and sources of the two corpora used in this paper. We then describe the selection rationale and composition of each corpus in detail.

**Multilingual setup: FLORES-200.** We use 1,012 paired sentences from the devtest split of NLLB Team et al. (2022), with English as the source language and five target languages: Ko `kor_Hang`, Ch Simplified `zho_Hans`, Ja `jpn_Jpan`, De `deu_Latn`, Fr `fra_Latn`. For Ko, only 1,010 samples are valid (2 excluded due to NLI tokenizer overflow), and Oracle (human reference) evaluation for Fr is based on 1,008 samples (4 references are empty). All samples are at the sentence level, with average length ranging from 70 (Ko) to 150

*(a) FLORES-200 devtest: main evaluation*

| Lang | $N_{src}$ | $N_{ref}$ | chars | words |
|---|---|---|---|---|
| En (source) | 1012 | — | 130.4 | 21.6 |
| Ko | 1012 | 1010 | 65.1 | 15.2 |
| Zh | 1012 | 1012 | 42.7 | — |
| Ja | 1012 | 1012 | 56.3 | — |
| De | 1012 | 1012 | 152.0 | 21.5 |
| Fr | 1012 | 1008 | 155.7 | 25.3 |

*(b) Pre-LLM-era author corpus: Frame B (idiolect)*

| Lang | Auth. | Para. | chars | Source |
|---|---|---|---|---|
| Ko | 10 | 200 | 351.9 | Wikisource |
| Zh | 8 | 135† | 354.3 | Wikisource |
| Ja | 10 | 200 | 362.1 | Aozora Bunko |
| De | 10 | 200 | 320.3 | Wikisource |
| Fr | 11 | 220 | 330.6 | Gutenberg |
| **Total** | | **955** | | |

Table 6: Dataset statistics. (a) FLORES-200 (NLLB Team et al., 2022) devtest split. $N_{src}$ = paired source sentences, $N_{ref}$ = valid human reference targets (Ko: 2 NLI-tokenizer overflows; Fr: 4 empty references). *chars* = mean character length per sentence; *words* = mean whitespace-split token count (omitted for Zh/Ja which lack inter-word spaces). English source is identical across all 5 target conditions. (b) Pre-LLM-era author corpus used for Frame B (idiolect preservation), restricted to authors active before any LLM training cutoff (pre-2018 publication) so the baseline is "LLM-uncontaminated." Per paragraph filtered to 80–400 characters; multiple works per author are sampled to inject within-author topic diversity. †Zh: 17 paragraphs identified as chapter title lists / table-of-contents (rather than prose) were excluded from author-recovery evaluation (152 collected → 135 used).

(De) characters per language.

**Monolingual setup: Pre-LLM-era authors corpus.** We collected 972 paragraphs from 49 authors across five languages, targeting approximately 20 paragraphs per author. For Zh, some samples corresponded to chapter-list TOC; after removing 17 such samples, 955 paragraphs were used for the author-recovery evaluation.

All authors were active prior to the LLM training cutoff (2018–2023), serving as an "LLM-uncontaminated" baseline. Each paragraph is filtered to the range of 80–400 characters, and samples are drawn from multiple works per author to ensure within-author topic diversity. Sources and author list:

- Ja (10 authors, 200 paragraphs), Aozora Bunko[1]: Soseki Natsume (夏目漱石), Mori Ogai (森外), Ryunosuke Akutagawa (芥川之介), Osamu Dazai (太宰治), Kenji Miyazawa (宮賢治), Izumi Kyoka (泉鏡花), Higuchi Ichiyo (口一葉), Sakaguchi Ango (坂口安吾), Yokomitsu Riichi (光利一), Nagai Kafu (永井荷風).
- Ko (10 authors, 200 paragraphs), Korean Wikisource[2]: Dongin Kim (김동인), Jingeon Hyeon (현진건), Sang Lee (이상), Hyoseok Lee (이효석), Mansik Chae (채만식), Gwangsu Lee (이광수), Hun Sim (심훈), Yujeong Kim (김유정), Seohae Choi (최서해), Dohyang Na (나도향).
- Zh (8 authors, 152→135 paragraphs after TOC filtering), Chinese Wikisource[3] (Republican-era 작가): Yu Dafu (郁達夫), Zhu Ziqing (朱自), Qu Qiubai (瞿秋白), Hu Shi (胡適), Liang Qichao (梁超), Lao She (老舍), Zhou Zuoren (周作人), Lu Xun (魯迅).
- De (10 authors, 200 paragraphs), German Wikisource[4]: Johann Wolfgang von Goethe, Friedrich Schiller, Thomas Mann, Rainer Maria Rilke, Hugo von Hofmannsthal, Arthur Schnitzler, Theodor Storm, Theodor Fontane, Heinrich von Kleist, Adalbert Stifter.
- Fr (11 authors, 220 paragraphs), Project Gutenberg[5]: George Sand, Victor Hugo, Gustave Flaubert, Guy de Maupassant, Émile Zola, Honoré de Balzac, Marcel Proust, Stendhal, Charles Baudelaire, Alphonse Daudet, Paul Verlaine.

## C Evaluation Metrics in Detail

### C.1 Per-rubric Likert mean

We evaluate post-edited outputs using a 9-rubric LLM judge. For each sample, the judge scores each candidate output on a 1–5 Likert scale along nine dimensions: faithfulness, adequacy, fluency, syntax, lexicon, discourse, register, conciseness, and human-likeness. The resulting per-rubric scores are used both as auxiliary diagnostic metrics and as the basis for pairwise preference evaluation.

Claude-haiku-4.5 is used as the default judge, and the default judge is selected from a different model family than the editor to mitigate self-bias.

[1] https://huggingface.co/datasets/globis-university/aozorabunko-clean
[2] https://ko.wikisource.org/
[3] https://zh.wikisource.org/
[4] https://de.wikisource.org/
[5] https://www.gutenberg.org/

To analyze judge-family dependence, evaluation results using Gemini-2.5-Pro and GPT-5 are also reported in the appendix. We report corpus-level means for each of the nine rubrics. Results are shown in Tables 21, 22, and 23.

### C.2 Prefer-edit rate (PE)

LLM judge-based pairwise preference has been studied in the context of human pairwise preference in RLHF (Stiennon et al., 2020), and has been extended to the LLM-as-a-judge framework (Zheng et al., 2023b) and automated win-rate evaluators (Dubois et al., 2023) as a representative evaluation method for open-ended text generation. We adapt this approach to the multilingual post-editing setting, following a setup similar to edit-task pairwise evaluation (Dwivedi-Yu et al., 2022). Specifically, the LLM judge using nine rubrics compares the method output $y_p^{(i)}$ and the baseline output $y_o^{(i)}$ for sample $i$, and produces 1–5 Likert scores $L_p^{(i)}$ and $L_o^{(i)}$ for each candidate. To mitigate ordering bias, we perform position-swapped evaluation by exchanging the presentation order of $(y_o, y_p)$ (Zheng et al., 2023b).

Recent studies show that LLM judges exhibit self-preference bias (Xu et al., 2024; Chen et al., 2025), where they favor LLM-style outputs similar to their pretraining distribution, as well as length bias toward longer responses (Dubois et al., 2024). Raw PE can simultaneously reflect both actual quality improvements and judge bias effects, and high PE does not necessarily imply improved naturalness as perceived by humans.

To address this, we follow the calibration perspective of Chen et al. (2025) and use human references as calibration anchors. In this setup, human references are not directly provided in the judge prompt; pairwise evaluation is performed using only the source sentence and two candidate outputs. Human references are used exclusively in the separate Oracle PE computation, serving as calibration anchors. Oracle PE denotes the prefer-edit rate obtained by the human reference under the same judge and baseline conditions. Method outputs and human references are thus evaluated under the same judge bias, and the difference between the two values represents a relative preference that partially cancels out the common bias of the judge.

$$\Delta_O^{(m,\ell)} = \mathrm{PE}^{(m,\ell)} - \mathrm{PE}^{(\mathrm{Oracle},\ell)},$$
$$\overline{|\Delta_O|}^{(m)} = \frac{1}{|\mathcal{L}|} \sum_{\ell} \left| \Delta_O^{(m,\ell)} \right|. \tag{12}$$

A smaller $|\Delta_O|$ value indicates that the method output is closer to the Oracle (human reference). When $\Delta_O > 0$ (over-shoot), the judge prefers the method output over the human reference, and this over-shoot phenomenon suggests that LLM-style characteristics targeted for removal may have instead been reinforced (Xu et al., 2024). We therefore use $\overline{|\Delta_O|}$ as the primary calibration metric in place of raw PE. $\overline{|\Delta_O|}$ in the last column of Table 2 is averaged over five languages. Per-language $\Delta_O$ values are provided in Appendix Table 13.

### C.3 Auxiliary Metrics

**Length-controlled PE (LC-PE).** We apply the length-controlled evaluation of Dubois et al. (2024) to PE. For each language $\ell$, the linear relationship between PE scores and output length is estimated as follows.

$$\mathrm{PE} = a + \beta \log(|y_e|/|y_{\mathrm{MT}}|) + \epsilon \tag{13}$$

$|y_e|/|y_{\mathrm{MT}}|$ denotes the length ratio of the post-edited output relative to the initial MT output, which is subtracted from the PE score to define length-controlled PE.

$$\text{LC-PE}^{(m,\ell)} = \mathrm{PE}^{(m,\ell)} - \hat{\beta}^{(\ell)} \log \left( \frac{|y_e^{(m,\ell)}|}{|y_{\mathrm{MT}}^{(\ell)}|} \right). \tag{14}$$

LC-PE is a PE score that mitigates length bias favoring verbose outputs. Results are provided in Appendix 13.

**MAUVE.** Following the distribution-matching metric of Pillutla et al. (2021), we measure the distributional difference between human reference $P$ and method output $Q$. Both text sets are transformed into a contextual embedding space, discrete distributions are estimated through $k$-means quantization, and the KL-divergence frontier is computed with respect to the mixture distribution $M_\lambda = \lambda P + (1-\lambda)Q$.

$$C(P,Q) = (\mathrm{KL}(Q\|M_\lambda), \mathrm{KL}(P\|M_\lambda)) \tag{15}$$

The final score is a normalized value of the area under the frontier, ranging in $[0, 1]$, where values closer to 1 indicate better alignment of the output

distribution with the human reference distribution. Since MAUVE evaluates the distributional alignment of the entire output set rather than similarity at the individual sentence level, both under-generation with insufficient diversity relative to the reference distribution and over-generation that deviates from the reference distribution are reflected as lower scores. Used in Tables 2 and 15.

### C.4 LiL-style metrics (Lex / Len / PPL)

Following the automatic evaluation protocol of Li et al. (2025), we report three LiL-style naturalness metrics: lexical density (Lex), length variety (Len), and perplexity (PPL). These metrics are designed to capture surface-level signals of translationese and target-language naturalness.

**Lex.** Lex measures lexical density, defined as the ratio of content words to total tokens:

$$\text{Lex} = \frac{\#\{\text{ADJ, ADV, NOUN, PROPN, VERB}\}}{\#\{\text{all tokens}\}}.$$

We obtain POS tags using Stanza.

**Len.** Len measures whether the method preserves native-like length variation:

$$\text{Len} = \frac{\sigma(\text{method lengths})}{\sigma(\text{reference lengths})}.$$

Values closer to 1.0 indicate that the method better matches the length variance of human references.

**PPL.** PPL denotes the mean per-text perplexity of method outputs. While Li et al. (2025) use Llama-3.1-8B, we use Qwen2.5-7B as a multilingual open-weight alternative. Lower PPL is interpreted as more natural generation from the perspective of the language model. (Used in Table 5.)

**Stylometric distance to reference.** We analyze how much each method output differs from the human reference using BERTScore F1, sentence embedding cosine similarity, LexJSD, and differences in length and punctuation usage. BERTScore F1 measures semantic similarity with the reference using XLM-RoBERTa-Large. Sentence embedding cosine similarity is the cosine similarity between the corpus-level mean embeddings of method outputs and references, obtained using `paraphrase-multilingual-mpnet-base-v2`. LexJSD is the Jensen-Shannon divergence between the token distributions of method outputs and references, where lower values indicate greater similarity to the lexical distribution of the reference. $\Delta$len denotes the relative difference in output length compared to the reference, while $\Delta$comma and $\Delta$em-dash represent how much more or less frequently commas and em-dashes are used relative to the reference, measured per 100 characters. Detailed results are provided in Appendix Table 11.

**Faithfulness and language-specific calibration.** Faithfulness is determined by bidirectional NLI to assess whether meaning is preserved before and after editing. We compute forward and backward entailment probabilities using a multilingual NLI classifier (based on XNLI / KorNLI / OCNLI), and an edit is judged as *faithful* when both values meet or exceed the language-specific threshold $\tau_{\text{nli}}^{(\ell)}$ is selected for each language to satisfy 95%-tile precision using paired human references from the FLORES-200 dev split. Used in Equation 5 and Table 9.

## D Translationese Taxonomy in Details

The translationese taxonomy used in this work consists of five top-level categories, namely faithfulness, voice, register, naturalness, and surface form, along with their sub-components. Each category specifies (i) the type of detectable signal, (ii) the measurement method (surface / NLI / LLM judge), and (iii) the evaluation comparison baseline.

**Faithfulness.** Alignment with the meaning of the source text. Sub-components include semantic entailment (bidirectional NLI), numeric and named-entity accuracy, and LLM judge factual preservation. The primary measurement methods are bidirectional NLI entailment (Maynez et al., 2020) and LLM judge. This serves as a hard constraint for all methods, with mandatory rollback upon failure.

**Voice.** Preservation of the speaker's idiolect. Sub-components include voice anchor (author anchor consistency, stylometric distance), voice drift (change in idiolect distance before and after editing), and register-anchor consistency. Activated only in Monolingual test set, and measured using stylometric centroid distance combined with native judge voice evaluation.

**Register.** Consistency of honorifics, keigo, and formal/informal register. Sub-components include intra-document register consistency, formality alignment with source intent, and conformity to the

native register distribution of the target language. The primary measurement methods are phrase-level lexicon (Ko ending classification, Zh 把/被 frequency, etc.) and LLM judge.

**Naturalness.** Multi-faceted naturalness. Sub-components include lexical naturalness (JSD with native distribution), word order naturalness, discourse marker appropriateness, hedge/emphasis balance (post-training distortion detection), and discourse structure naturalness. In terms of measurement, lexical naturalness is evaluated using LexJSD, hedge/emphasis balance using epistemic-marker frequency, and the remaining sub-components using an LLM judge.

**Surface form.** Surface-level artifacts such as punctuation, formatting, whitespace, and character normalization are corrected. Sub-components include comma over-use (z-score), dash overuse, English-style colons, forced bullets, and NFC, full-width, half-width, and whitespace normalization, all of which are handled through deterministic surface metrics and a rule-based fixer without affecting meaning.

## E Hyperparameters

We summarize the default hyperparameters of MELT in Table 7.

## F Model Cards

Table 8 summarizes all models used in this paper according to their roles.

## G Per-language Metric Breakdown

In addition to the prefer-edit rate reported in Table 2 of §3.3, the method-level breakdown of NLI entailment rate is provided in Table 9, while the computational cost and efficiency are summarized in Table 10.

From a cost–latency perspective, MELT-LLM and MELT-Hybrid add only one additional model call compared to the single-pass baseline, resulting in an increase in latency of approximately 2 seconds. MELT-MAS is designed for high-accuracy operation and exhibits higher latency due to local inference with a 32B native-judge model, while its API cost remains only USD 1.80 for 1,012 samples. The debate gate is activated only for a subset of samples rather than the entire dataset, and overall, MELT-Hybrid provides a practical cost–performance trade-off.

**Stylometric divergence from human reference.** To quantify translationese, we measure how much each method's output differs from the FLORES human reference along three dimensions, namely semantic similarity, lexical distribution, and surface markers (Table 11). BERTScore F1 remains within a narrow range of $0.948-0.968$ across all methods, indicating that differences between methods arise primarily from surface distributional differences rather than meaning preservation. In terms of length, comma frequency, and lexical distribution, polishing-based methods produce longer outputs and higher comma frequency than the reference across several languages, suggesting that the "Polishing PE $>$ Oracle PE" phenomenon observed in §3.3 may be interpreted as LLM-typical stylistic preference rather than genuine semantic quality improvement. MELT variants show a general tendency to suppress verbosity and comma overuse. LexJSD does not decrease consistently across all languages, and is therefore interpreted as an effect of correcting surface markers directly related to translationese, such as length and punctuation, rather than alignment of the overall lexical distribution.

## H Statistical Significance Analysis

Table 12 shows statistical significance analyses for the main results in Table 2. Statistical significance is assessed on the per-sample mean Likert difference, which is the continuous quantity underlying the binary Prefer-Edit Rate (PE). We compute 95% paired bootstrap confidence intervals using 2,000 paired bootstrap resamples and perform paired sign-flip permutation tests. Each entry reports the mean Likert difference ($\Delta$, multiplied by 100) together with its 95% confidence interval.

all MELT variants significantly outperform Self-Refine across the five target languages. Compared with LiL Polish, statistically significant improvements are consistently observed for Ko and Ja, whereas differences in De and Fr are not statistically significant. Zh exhibits mixed behavior across MELT variants, with MELT-LLM significantly outperforming LiL Polish, while MELT-Hybrid and MELT-MAS significantly favor LiL Polish. These results suggest that the apparent preference differences between MELT and LiL Polish in De and Fr fall within the range of sampling variability rather than reflecting consistent performance differences.

| Symbol | Stage | Value | Description |
|---|---|---|---|
| $\tau_z$ | Detect (surface) | 2.0 | comma over-use $z$-threshold |
| $\tau_{\text{IoU}}$ | Detect (merge) | 0.5 | hybrid merge IoU cutoff |
| $\tau_{\text{deg}}$ | Verify (surface) | 0.5 | surface gate degradation tolerance |
| $\tau_{\text{nli}}^{(\ell)}$ | Verify (NLI) | [0.65, 0.75] | bidirectional NLI threshold (per language) |
| $w_n^{(d)}$ | Debate | 0.6 | native priority weight ($d \in \mathcal{D}_{\text{sel}}$) |
| $\tau_{\text{debate}}$ | Debate | 0.5 | debate gate confidence threshold |
| $\delta_c$ | Debate | 0.3 | round-1 consensus tolerance |

Table 7: Default hyperparameter values for MELT. All values are determined on a 200-sentence pilot subset of FLORES-Ko/Zh and applied directly to the remaining three languages. Only the per-language $\tau_{\text{nli}}^{(\ell)}$ is calibrated per language.

# I Calibration Metrics

We report a per-language decomposition of the $\overline{|\Delta_O|}$ (average across the five languages) from Table 2 in §3.3.

The $\Delta_O$ of MELT-MAS is most accurately calibrated to Oracle PE across four languages (Ko, Ja, De, Fr) within $|\Delta| \leq 3$, whereas LiL Polish shows inconsistent calibration with over-shoot of $+6.9/+9.3$ in De/Fr and under-shoot in Ja/Zh. In particular, Zh is an outlier with $\Delta_O$ values 1.5–2 times larger than other languages (Ko 25.3 vs. Zh 45.8), and all methods under-shoot in Zh due to a Zh-specific reference distribution gap. In terms of LC-PE, LiL Polish shows the highest performance, suggesting that judge preference may be influenced not only by verbosity but also by more general stylistic bias. Table 13 reports the per-language calibration metrics on FLORES.

Table 14 reports the results of an additional human evaluation conducted on 10% of the evaluation data for each target language (101 samples per language) to examine whether the proposed calibration metric is associated with human-perceived naturalness. Native speakers of each target language directly evaluate the naturalness of translations produced by LiL Polish and MELT, with the human reference serving as the Oracle condition. MELT achieves a mean calibration error of 4.0pp in the human evaluation, which is 1.8pp lower than the 5.8pp of LiL Polish. This provides evidence that MELT's lower calibration error is not solely attributable to LLM judge preferences, but also corresponds to a preference distribution closer to that of the human reference under direct human judgments of naturalness.

# J Per-rubric Mean Likert Score

Tables 21, 22, and 23 report the mean Likert scores for each rubric assigned by the three LLM judges.

# K Judge-Free Stylometric Analysis of Translationese Recovery

To complement LLM-judge-based evaluation, we additionally conduct a judge-free stylometric analysis using classical authorship attribution techniques (Patchala and Bhatnagar, 2018).

## K.1 Human-reference Style Recovery in the Multilingual Translation Setting.

We apply the same stylometric probe to the FLORES translation benchmark to analyze whether MELT shifts raw MT toward the human-reference translation style. Since FLORES does not contain author labels, we reformulate the problem as a 2-class style discrimination task that distinguishes human references (H) from raw MT (M), replacing the conventional authorship attribution setup. We construct character trigram, POS trigram, and function-word-based templates from Oracle references and raw MT, and assign the stylometric signature of each output to the nearest template based on KL divergence. We measure the proportion of outputs classified as Oracle-reference style in Table 16.

The experimental results show that only 36.4% of raw MT outputs are classified as human-reference style based on character trigrams, whereas actual human translations record 60.0%, confirming that distinguishable stylometric differences exist between human translations and MT even in the direct MT setting of FLORES. All editing methods shift raw MT toward the human-reference style, with MELT-LLM showing the largest improvement. This suggests that training-

| MELT-Hybrid | .992 | .894 | .993 | .997 | .999 |
| MELT-MAS | .991 | .892 | .989 | .999 | .999 |
| Oracle (human reference) | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 |

Table 9: Auxiliary NLI metric reported alongside PE in Table 2. NLI = bidirectional NLI entailment rate based on multilingual XNLI / KorNLI / OCNLI; threshold $\tau_{\text{nli}}^{(\ell)}$ is calibrated to the per-language 95%-tile. Higher values indicate better meaning preservation.

free editing can partially recover general human translation style in the multilingual MT setting. In particular, the human-reference ceiling itself was as low as $\sim$50% in De and Ko, suggesting that human translations and raw MT are stylometrically relatively close in these languages.

### K.2 Judge-free Validation: Authorship Attribution and Recovery Ceiling.

As an additional analysis that excludes dependence on LLM judges, we apply classical stylometric authorship attribution (Patchala and Bhatnagar, 2018). Specifically, we construct per-author relative frequency templates based on character trigram, POS trigram, and function-word features, and attribute test texts to the author with the minimum KL divergence. In the experiments, each author's original texts are split into template and test sets, and attribution is performed among approximately 10 candidate authors (Table 17).

The original texts achieve a macro attribution accuracy of 45.9%, reaching 49.8% when character trigrams are used alone. However, after round-trip MT, performance collapses to 20.2%, approaching chance level ($\sim$10.3%). This analysis also reveals a clear recovery ceiling for training-free editing. All editing methods partially shift surface stylometric statistics toward the human-reference direction, but none recover the author-specific idiolect fingerprints lost during the MT process. In practice, no method including MELT achieves authorship recovery that meaningfully exceeds the MT baseline ($\sim$20%). This is interpreted as editing methods normalizing outputs toward a more general fluent translation style rather than reconstructing the style of a specific author. Sentence-level style cosine similarity shows the same tendency (original: 0.284, MT: 0.225, all methods: $\sim$0.221). Taken together, we confirm that training-free editing can recover surface stylometric characteristics such as comma usage, lexical regularity, and phrasing, but cannot

| Method | Calls / sample (↓) | Generated tokens / sample (↓) | Latency / sample (s) (↓) | Cost / 1,012 samples (USD) (↓) |
|---|---|---|---|---|
| Naive Polish | 2.0 | 224 | 5.3 | 0.35 |
| LiL Polish (Li et al., 2025) | 2.0 | 237 | 5.3 | 0.36 |

restore the fine-grained authorial identity removed by MT.

**Dual-track Evaluation Metrics.** This dissociation supports the evaluation methodology recommended in this paper. LLM judge PE remains a valid user-facing quality proxy for production deployment, as end users also tend to be LLM-style friendly, but the effects of stylistic preservation and translationese removal must be measured separately using stylometric distance metrics. Since MELT's verification gate maintains the stylometric distribution in the direction of the reference without inflating LLM judge PE, the trade-off along both axes is clearly separated and measured.

## L Qualitative MELT post-editing examples

Table 18 (phrase-level; Fr, De) and Table 19 (sentence-level; Zh, Ja, Ko) present representative examples showing how translationese patterns in GPT-4o-mini literal translations across five target languages are corrected through MELT's `detect` → `edit` → `verify` pipeline. Red spans indicate translationese traces identified by MELT's typology-aware detector, while blue spans indicate portions rewritten by MELT into target-native expressions. All examples are preferred over the LLM output by all three judges (Claude Haiku 4.5 / Gemini 2.5 Pro / GPT-5) with an avg.avg. score $\geq 0.56$; PPL measured by Qwen2.5-7B also decreases in all cases ($-1.1 \sim -5.1$).

**Per-category Detection Statistics.** Table 20 presents the aggregated results of translationese detected by $\Phi_{\text{llm}}$ and $\Phi_{\text{surf}}$ on FLORES raw MT, broken down by top-level taxonomy category ($n$=1,012/lang). As these figures represent detector-flagged span counts, they are used for relative cross-lingual trend analysis rather than as absolute counts based on human-annotated gold labels. Naturalness is detected at high frequency in Korean, Chinese, and Japanese. Surface form is relatively prominent in Chinese, showing a large gap compared to other languages. Register is strongly concentrated in Korean, and is rarely detected in Chinese and French. This indicates that English-structure mimicry is a language-universal core characteristic of translationese. Faithfulness and Voice show low overall frequency but are relatively distributed across multiple languages. These results demonstrate that translationese exhibits both universal characteristics and typology-conditioned language-specific biases.

**Per-category Post-editing Performance.** Figure 4 presents a comparison of MELT's post-editing performance broken down by taxonomy

Table 15: Author-style recovery experiment (Frame A + B combined): distributional alignment and LLM judge preference comparison between the original texts of five languages × 49 pre-LLM-era authors / 972 paragraphs and each method's output. Pipeline: original → English (forward MT) → target language (back MT, "MT round-trip" baseline; reference with strongly injected LLM-ese) → "editing by each method to attempt recovery of the original author's style" PE H/G/G5 = 3-judge prefer-method rate (%, method output vs. round-trip baseline).

| Condition | Reference-style rate (% H, 5-lang macro-avg) | | | |
|---|---|---|---|---|
| | char3 | POS-tri | func | comb. |
| Human reference (H) | **60.0** | **53.3** | **55.0** | **58.0** |
| raw MT (M) | 36.4 | 43.9 | 49.6 | 40.6 |
| Naive Polish | 39.5 | 43.6 | 50.6 | 42.3 |
| LiL polish (Li et al., 2025) | 39.8 | 45.0 | 50.9 | 43.0 |
| Self-Refine (Madaan et al., 2023) | 41.1 | 44.9 | 48.7 | 42.9 |
| MELT-LLM | **42.8** | 45.3 | **51.2** | **45.0** |
| MELT-Hybrid | 41.9 | 46.2 | 50.5 | 44.4 |
| MELT-MAS | 41.9 | **46.5** | 50.8 | 44.9 |
| Chance (2-class) | 50.0 | | | |

Table 16: Judge-free FLORES style discrimination: 2-class nearest-template classification (human reference H vs raw MT M) over the same features as Table 17 (Patchala and Bhatnagar, 2018). Metric is the reference-style rate (% classified as H), 5-lang macro-average. All editors shift raw MT toward human-reference style and MELT-LLM shifts it most.

| Condition | Attribution acc. (%, 5-lang macro-avg) | | | |
|---|---|---|---|---|
| | char3 | POS-tri | func | comb. |
| Original (author) | **49.8** | **28.7** | **22.6** | **45.9** |
| MT round-trip | 22.2 | 16.2 | 16.9 | 20.2 |
| Naive Polish | 22.3 | 16.3 | 16.9 | 19.4 |
| LiL polish (Li et al., 2025) | 20.9 | 17.4 | 15.6 | 20.6 |
| Self-Refine (Madaan et al., 2023) | 22.9 | 16.5 | 16.6 | 20.6 |
| MELT-LLM | 22.2 | 16.7 | 15.9 | 21.4 |
| MELT-Hybrid | 22.4 | 16.6 | 15.5 | 20.6 |
| MELT-MAS | 22.4 | 18.2 | 14.7 | 20.2 |
| Chance | $\approx 10.3$ | | | |

Table 17: Judge-free authorship attribution accuracy (Patchala and Bhatnagar, 2018; per-author KL template matching over character trigrams / POS trigrams / function words / combined), 5-lang macro-average over $\sim$10 candidate authors. MT Round-trip collapses author identifiability toward chance and no training-free editor restores it above the MT floor.

category for translationese detected by $\Phi_{\text{llm}}$ and $\Phi_{\text{surf}}$ (five languages pooled, 3-judge average PE). All MELT variants show consistent improvements over raw MT across all categories. In particular, MELT-LLM records high PE in most categories, with notably large improvements in naturalness and surface form. This is consistent with the calibration results in Table 2.

## M Cross-family Editor Evaluation

Table 24 shows the results across three editor families. GPT-4o-mini, Claude Haiku 4.5, and Gemini 2.5 Flash are used as editors while keeping the remaining MELT pipeline unchanged. All methods are evaluated using a single Claude Haiku 4.5 judge.

MELT exhibits stable performance across different editor families. MELT-LLM or MELT-Hybrid achieves higher PE than LiL Polish in 11 of the 15 editor-language combinations. The MAUVE metric also remains consistently high across all editor families, indicating stable distributional alignment with human references regardless of the editor model. In contrast, LiL Polish shows substantial degradation under the Claude Haiku 4.5 editor, where MAUVE drops to 0.03 (Zh) and 0.31 (Ja). Inspection of the generated outputs reveals that LiL Polish frequently returns the original MT without editing under this editor (no-edit rates of 92%, 82%, and 57% for Ko, De, and Ja, respectively), suggesting that its behavior is more sensitive to the prompt–editor combination. Calibration results show that MELT achieves the smallest $\overline{|\Delta_O|}$ under GPT-4o-mini and Claude Haiku 4.5, whereas all methods overshoot the Oracle under Gemini 2.5 Flash. This suggests that the calibration behavior is more dependent on the editor family than the judge-free distributional alignment measured by MAUVE.

| Phrase-level LLM-ese: structural calque on a single clause | |
|---|---|
| **Source** | Travellers are strongly advised to be aware of any risk of severe weather affecting their area… |
| **LLM** | Les voyageurs sont fortement conseillés de se renseigner sur tout risque de conditions météorologiques sévères affectant leur région… (PPL: **7.4**) |
| **MELT** | Il est recommandé aux voyageurs de se tenir informés des risques de conditions météorologiques sévères dans leur région… (PPL: **5.6** ↓) |
| DETECTOR: `B1_voice_shift`: French does not license a person-subject *être conseillé*; MELT restores the impersonal *Il est recommandé à*. | *Fr-877* |
| **Source** | No immediate reports of damage have been received by the United States Geological Survey (USGS) and its National Earthquake Information Center. |
| **LLM** | Es liegen keine unmittelbaren Berichte über Schäden vor, die vom United States Geological Survey (USGS) und seinem National Earthquake Information Center erhalten wurden. (PPL: **14.4**) |
| **MELT** | Es wurden keine unmittelbaren Berichte über Schäden vom Geologischen Dienst der Vereinigten Staaten und seinem Nationalen Erdbebeninformationszentrum erhalten. (PPL: **9.3** ↓) |
| DETECTOR: `D1_phrasing_unnatural`: English passive "*reports have been received by*" calqued; English institution names left untranslated. MELT inverts to the German active-passive "*Es wurden… erhalten*" and translates the proper nouns. | *De-182* |

Table 18: Phrase-level MELT post-editing examples. Single-clause anglicisms (red) flagged by MELT's typology-aware detector and rewritten into target-native phrasing. PPL drops with the rewrite. See Table 19 for sentence-level cases.

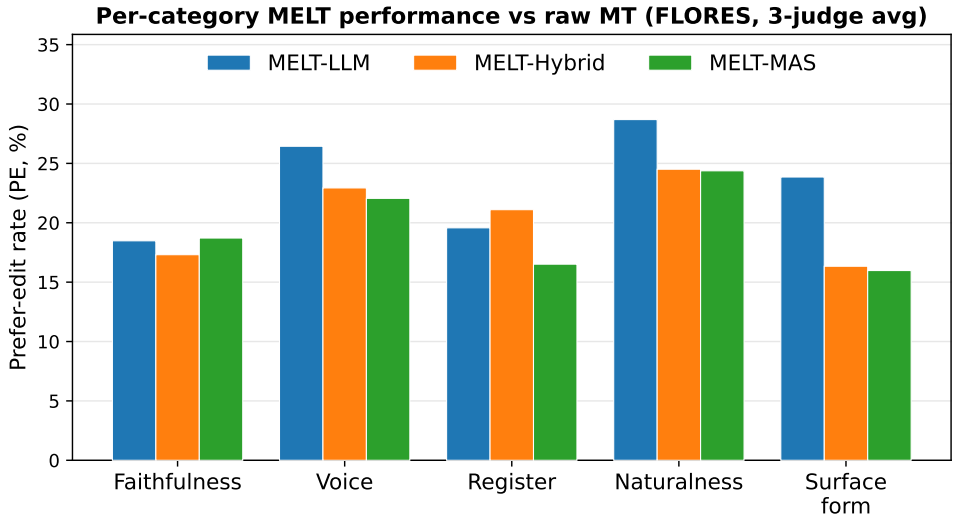

Figure 4: Per-category MELT performance on detector-flagged subsets from FLORES raw MT (pooled across the five languages). Bars denote PE averaged across three judges (Claude Haiku 4.5, Gemini-Pro, GPT-5). All MELT variants consistently improve over raw MT, while MELT-LLM achieves the strongest gains in most categories, particularly naturalness and surface form.

**Sentence-level LLM-ese: clause-coordination and register mismatch**

**Source** As NSA, he assisted Carter in diplomatically handling world affairs, such as the Camp David Accords, 1978; normalizing US-China relations...

**LLM** 作家安全，他助特在外交上理世界事，例如1978年的戴；在1970年代末期正常化美中系；伊朗革命，致1979年的伊朗人危机；... (PPL: **10.1**)

**MELT** 他任家安全期，助特理多事，包括1978年的戴 1970年代末美中系正常化 1979年的伊朗革命及其引的伊朗人危机... (PPL: **5.5** ↓)

DETECTOR: `D1_phrasing_unnatural` + `D2_connective_overuse`: light-verb "作" + semicolon-separated English-style clauses + over-formal "致". MELT replaces with native "任...期" and merges the list with "、" / "及其引的". *Zh-019*

**Source** Mass car ownership also leads to a higher incidence of accidents on the roads, which leads to the invention of new techniques in healthcare...

**LLM** 大量の自動車所有は 道路上での事故の生率を高め それが損傷した身を修復するための新しい療技術の明につながります 。(PPL: **9.5**)

**MELT** 自動車の普及は道路での事故を加させ 損傷した身を修復する新しい療技術の明につながる 。(PPL: **8.4** ↓)

DETECTOR: `D1_phrasing_unnatural` + `D2_connective_overuse`: literal "大量の自動車所有" + redundant pronoun-bridge "それが" calques English "*which leads to*". MELT uses native "自動車の普及" + verb-chain coordination, removing the bridge entirely. *Ja-485*

**Source** Blogs can also help improve student writing. While students often begin their blog experience with sloppy grammar and spelling, the presence of an audience generally changes that.

**LLM** 블로그는 학생들의 글쓰기 향상에도 도움이 될 수 있습니다. 학생들이 종종 엉성한 문법과 철자로 블로그 경험을 시작하지만, 청중이 존재하면 일반적으로 그런 점이 변화합니다. (PPL: **10.1**)

**MELT** 블로그는 학생들의 글쓰기를 향상시키는 데 도움이 됩니다. 학생들은 종종 엉성한 문법과 철자로 블로그를 시작하지만, 청중이 있으면 그런 점이 달라집니다. (PPL: **5.9** ↓)

DETECTOR: `C1_honorific_mixing` + `D1_phrasing_unnatural`: register over-formal for encyclopedic content + literal "블로그 경험을 시작" + verbose "존재하면 일반적으로... 변화합니다". MELT compresses to "있으면... 달라집니다". *Ko-687*

Table 19: Sentence-level MELT post-editing examples. Multi-clause LLM-ese involving coordination calque (Zh/Ja) or register/encyclopedic-tone mismatch (Ko). Every example is preferred over the LLM baseline by all three judges with avg. score $\geq 0.56$; PPL drops accompany every rewrite.

| Category | Ko | Zh | Ja | De | Fr | All |

# MITRA-MT: Continued Pretraining, Parallel Corpus Mining, and Multi-Directional Machine Translation for Sanskrit, Tibetan, and Buddhist Chinese

**Sebastian Nehrdich**[1] **Kurt Keutzer**[2]

[1]Center for Integrated Japanese Studies, Tohoku University,
[2]University of California, Berkeley, Berkeley Artificial Intelligence Research (BAIR)

## Abstract

Buddhist literature is preserved in a network of classical languages, above all Sanskrit, Pāli, Buddhist Chinese, and Tibetan, for which machine translation support remains limited, and largely restricted to translation into English. In order to address this shortcoming, we present three connected contributions. First, we release MITRA-parallel v2, a corpus of 1.69 million automatically aligned parallel records (2.34 million segment pairs) between Sanskrit, Tibetan, and Buddhist Chinese, mined with an embedding-based span-mining pipeline. Second, we present MITRA-MT, a domain-adapted large language model built by continued pretraining of Qwen3.5-9B on a 22.6-billion-token corpus of classical Asian languages and related modern material, followed by a lightweight translation fine-tune and preference optimization. Third, we introduce a multi-directional evaluation suite covering 17 translation directions at sentence level (ten of them also at paragraph level), including cross-classical directions (Sanskrit↔Tibetan, Sanskrit↔Chinese, Tibetan↔Chinese) and from Tibetan into seven modern languages beyond English. On this suite, MITRA-MT outperforms all open baselines, including instruction-tuned LLMs up to 122B parameters and dedicated MT systems, on all directions, and matches commercial references on the large majority of directions when evaluated via chrF, with the largest margins for translation into Tibetan, Sanskrit, and Classical Chinese. We release the parallel corpus, the evaluation data, and the model weights.

## 1 Introduction

The Buddhist tradition has produced one of the largest bodies of premodern literature in existence, preserved primarily in Pāli, Sanskrit, Buddhist Chinese, and Tibetan. Much of this material was translated between these languages historically: from Indic languages into Chinese beginning in the 2nd century CE, and into Tibetan from the 8th century CE onwards. The corpus therefore features a high degree of parallelism across languages, yet these parallels are largely uncataloged. In addition to this, translation into modern languages remains far from complete: for example, only about 10% of the digitally available Buddhist Chinese corpus has an English translation (Nehrdich et al., 2023), and translation coverage into languages other than English is thinner still.

Recent work has shown that domain-adapted LLMs are effective translators for individual classical languages (Nehrdich et al., 2023, 2025), but systematic evaluation has focused almost exclusively on translation into English. For NLP downstream applications and wider use in translation projects, other directions are also very important: Sanskrit→Tibetan and Chinese→Tibetan translation supports the study of the canonical transmission, and translation from Tibetan into languages such as French, Spanish, or Portuguese serves communities that today access this literature primarily through those languages.

We make the following contributions to this set of challenges:

- MITRA-parallel v2, a dataset of 1.69M automatically aligned records (2.34M segment-level pairs) across Sanskrit–Tibetan, Sanskrit–Chinese, and Chinese–Tibetan,[1] mined with an embedding-based pipeline.
- A domain-adapted LLM for classical Asian languages, built by continued pretraining of Qwen3.5-9B on 22.6B tokens.
- A multi-directional MT evaluation suite: 17 sentence-level directions (33,259 pairs), 10 of which are also evaluated at paragraph level

[1]Throughout the paper, "Chinese" without qualification refers to Buddhist Chinese, the classical Chinese of the Buddhist canon. Modern Chinese occurs only as a target language of the Tibetan→modern suite and is marked as such.

October 28-29, 2026 ©2026 Association for Computational Linguistics

(1,908 blocks of up to 10 consecutive sentences), including cross-classical pairs and Tibetan into seven modern languages.

- A detailed evaluation of MITRA-MT against open LLMs (Qwen3.5 at 9B and 122B, Llama-3.1, Gemma-4 up to 31B), dedicated MT systems (NLLB-200, MADLAD-400, TranslateGemma, Tower-Plus), and commercial references (Gemini Flash family), in chrF, BLEURT, and COMET, with zero-/few-shot arms, and a per-collection Tibetan→English breakdown.

The parallel corpus and evaluation data are available at https://github.com/dharmamitra/mitra-parallel; the fine-tuned translation and embedding models are released in the MITRA Qwen3.5 collection at https://huggingface.co/collections/buddhist-nlp/mitra-qwen35-2026. An interactive gateway to the parallel data is provided at https://dharmamitra.org/db.

## 2 Related Work

Computational detection of textual parallels in Buddhist literature has been studied for Sanskrit (Hellwig, 2013), Tibetan (Klein et al., 2014), and Buddhist Chinese (Nehrdich, 2020), with cross-lingual work on Tibetan–Chinese (Felbur et al., 2022) and Sanskrit–Tibetan (Nehrdich, 2022). Standard bitext-mining approaches based on multilingual sentence embeddings (Schwenk, 2018; Artetxe and Schwenk, 2019a,b; Feng et al., 2022) assume that cosine similarity separates parallel from non-parallel sentences sufficiently. However, in our setting this assumption often does not hold: Buddhist texts are highly formulaic, with frequent occurrences of highly similar but not exactly matching passages, and genuinely parallel passages often have diverging sentence segmentation across languages and can be buried in clusters of very similar but not directly related material, which makes sentence-based cosine similarity alone a weak signal for sentence-pair mining. Our mining pipeline (Section 3.1) instead relies on the document-level geometry of parallel passages rather than on per-sentence similarity thresholds.

For machine translation of these languages, dedicated encoder–decoder systems cover parts of the space: NLLB-200 (Team et al., 2022) includes Sanskrit and Tibetan, and MADLAD-400 (Kudugunta et al., 2023) covers over 400 languages. Domain-specific neural MT for Buddhist Chinese was presented by Nehrdich et al. (2023). Following the recipe of TOWER (Alves et al., 2024), recent work adapts strong open LLMs to translation by continued pretraining on mixed monolingual and parallel data; Nehrdich and Keutzer (2026) applied this recipe to Gemma-2 (Gemma Team, 2024) for this language family. This paper is a continuation of that study and applies it at larger scale to Qwen3.5-9B, extending evaluation from into-English to a multi-directional protocol.

## 3 MITRA-parallel

### 3.1 Mining Pipeline

The pipeline described here is a revision of the passage-mining approach introduced with the first MITRA release (Nehrdich and Keutzer, 2026). That version translated all documents into English with a domain-adapted MADLAD-400 model, retrieved candidate regions on the English side with BGE-M3 embeddings, and aligned sentences with BERTALIGN under a moving-average cosine threshold. For MITRA-parallel v2 we drop the English pivot entirely and operate directly on multilingual embeddings, produced by the domain-specific embedding model `gemma-2 mitra-e` released with the previous pipeline;[2] BERTALIGN is replaced by VECALIGN, and the single cosine threshold by an ensemble of lexical and geometric gates and a supervised aligner screen. It covers the three pairs Sanskrit–Tibetan (sa–bo), Sanskrit–Chinese (sa–zh), and Chinese–Tibetan (zh–bo); we use these codes for the three classical languages throughout the paper. Its basic unit is the *segment*, the sentence-level unit of the source editions, delimited by the available punctuation.

The pipeline exploits the observation that true parallels form long *monotone chains* of matching passages across two works, whereas semantically similar but structurally unrelated material does not. In our data, genuinely parallel translated paragraph pairs and merely topically related ones often have nearly indistinguishable cosine similarity, so per-pair thresholds are uninformative and further geometric signal needs to be taken into account. The pipeline proceeds in five stages.

[2] https://huggingface.co/buddhist-nlp/gemma-2-mitra-e

**(1) Embedding.** All works across Sanskrit, Tibetan, and Chinese are embedded at paragraph-window granularity. Windows span about 300 characters for Tibetan and Sanskrit and 100 characters for Chinese, are advanced by 200 and 70 characters respectively, and are extended to whole segment boundaries, so that consecutive windows overlap. These window sizes follow the average length ratio of matching translations across these languages. The search space is the canonical trilingual working set of 3.22M windows over 12,348 texts detailed in Appendix A. Each language is stored as an L2-normalized matrix in an exact (flat inner-product) FAISS index (Douze et al., 2024).

**(2) Anchors.** Margin-scored cross-lingual $k$NN search (Artetxe and Schwenk, 2019a) produces possible anchor pairs. For each source window we retrieve its $k$=20 nearest target windows and score every candidate with a ratio margin, $\cos(x, y) \,/\, \left(\frac{1}{2}\,\mathrm{bg}(x) + \frac{1}{2}\,\mathrm{bg}(y)\right)$, where the background similarity $\mathrm{bg}(\cdot)$ of a window is its mean cosine to a fixed random sample of 8,192 same-language windows, with the top 1% trimmed so that genuine co-witnesses and near-duplicates do not inflate it. Margin scoring helps to reduce the impact of formulaic "hub" passages that are very frequently encountered in Buddhist literature, since such passages have a high background similarity. All candidates with cosine $\geq$ 0.30 and margin $\geq$ 1.25 are kept as anchors, not only the top-1 neighbor. Against 951 gold-standard parallel pairs, anchor recall is 95.3% at $k$=20.

**(3) Chains.** For each candidate work pair with at least eight anchors, we detect the best monotone chain of anchors in the plane of source and target window positions by dynamic programming with a gap penalty (0.04 per window beyond a free gap of six windows) and a slope constraint (0.1–10); up to 40 disjoint chains of at least eight anchors are extracted iteratively, since a work pair may share several separate passages. Each chain is scored with geometric statistics. *Contiguity* is the number of distinct chain positions divided by the span the chain covers, computed on both sides and reduced to the minimum, i.e., a local two-sided coverage of the chain's bounding box (global coverage of the whole work is recorded but not used for acceptance, since it penalizes short passages shared by large collections): a genuine translation is contiguous on both sides, whereas verses quoted inside a commentary are contiguous only on the short side. The *longest-increasing-subsequence $z$-score* compares the chain length with the $\sim 2\sqrt{m}$ expected for the longest increasing subsequence of $m$ randomly placed anchors in the chain's bounding box, so it measures how far the chain exceeds chance. The *slope-inlier fraction* is the share of chain anchors within a tolerance band of a RANSAC-fitted line (Fischler and Bolles, 1981), measuring a consistent translation rate. The discriminative value of these statistics was established on a labeled set from the Abhidharmakośa corpus, which is well suited for this purpose because it contains the same material in several closely related forms: as positives the known translations (the Tibetan and Chinese kārikā, D4089 and T1560, and the Tibetan and Sanskrit bhāṣya, D4090 and the Abhidharmakośabhāṣya), and as hard negatives the kārikā contained in the bhāṣya in both languages, the bhāṣya against the bare kārikā, and the sibling Abhidharma text Nyāyānusāra (T1562), i.e., pairs that are topically near-identical but not translations of each other. T1562 is an especially useful hard negative: it reproduces significant portions of the bhāṣya but rearranges them and introduces new commentarial sections, so it is not structurally a matching translation, yet it exposes exactly the kind of challenge that leads to false positives in translation matching. Two-sided contiguity and slope separate the two groups completely (positives reach a contiguity of at least 0.64, the negatives at most 0.13, and the negatives show extreme slopes), whereas mean cosine (about 0.5 for both groups) and the $z$-score alone do not, since a commentary containing its root text also forms a long continuous chain, and cosine similarity is very sensitive to domain and language effects. The hand-set rule derived from this set (contiguity $\geq$ 0.35, $z \geq 8$, inlier fraction $\geq$ 0.85, at least 10 anchors, mean margin $\geq$ 1.15, slope in $[0.15, 6]$, and no contiguity asymmetry above a factor of 1.8) served as the starting point; the acceptance rule used for the release generalizes it with a per-pair random-forest classifier over 21 bounding-box and trajectory features of a chain, trained on chains that contain at least three sentence pairs attested in our bilingual dictionary alignments as positives and chains from works without any attested alignment as negatives, with the threshold set to 95% recall on the positives under grouped cross-validation, and with chains subsumed by a much larger chain of the same source

work (the root-text-in-commentary case) removed. In the v2 run, 360,347 work pairs yielded 323,591 chains, of which 44,085 were accepted; after removing spans whose bounding boxes overlap another accepted span by at least 80% on both sides, 12,318 spans were passed on to sentence alignment.

**(4) Sentence alignment.** Accepted spans are aligned at sentence level with VECALIGN (Thompson and Koehn, 2019), restricted to the segment range of the span rather than the whole works, using `gemma-2 mitra-e` as the embedding model with alignments of up to four segments on either side. This is followed by cosine- and lexicon-based trimming of span edges, since author or translator colophons, section banners, etc. are usually not part of the actual translation, do not match across languages, and therefore contribute alignment noise. Leading and trailing segments whose best cross-lingual cosine to any segment group on the other side is below 0.30 are removed, as are edge segments for which fewer than 34% of their bilingual-dictionary terms have a translation attested anywhere on the other side. Trimming never removes more than a third of a side or reduces it below three segments. Both thresholds were set by manually inspecting the trimming decisions on development spans.

**(5) Ensemble filter and screening.** A final ensemble filter combines three gates, each manually calibrated on genuine and spurious spans. (i) *Bilingual-dictionary diagonality*: for every dictionary term of the source side, we test whether one of its translations occurs in the paired target segment (on the diagonal) or only elsewhere in the span (off the diagonal); the rarity-weighted on-diagonal share must be at least 0.40. (ii) *Alignment density*: at least 45% of the segments of a span must take part in a non-empty alignment, which removes partial or verse-only overlaps and sibling texts. (iii) A *length-ratio gate*: the fraction of aligned pairs whose character-length ratio deviates by more than 2.5 median absolute deviations from the pair-specific ideal ratio must stay below 0.50 (sa–bo, sa–zh) or 0.25 (zh–bo), which removes structurally parallel but untranslated material. Alignments already covered by a larger overlapping span are removed. We further flag texts with low average cosine scores across the alignment records and manually inspect them to remove spurious text pairs where alignment was not successful. It needs to be noted that while we manually inspected low-scoring instances, no systematic human audit has yet been performed for this corpus.

| Pair | Records | Seg. pairs | Median chars |
|---|---|---|---|
| sa–bo | 555,558 | 1,005,439 | sa 49 / bo 96 |
| zh–bo | 836,559 | 836,559 | zh 22 / bo 47 |
| sa–zh | 301,613 | 496,402 | sa 48 / zh 20 |
| Total | 1,693,730 | 2,338,400 | |

Table 1: MITRA-parallel v2 after decontamination and exact deduplication. Each record aligns one source segment to one or more target segments; segment pairs count individual segment-to-segment links (in the sa→bo, zh→bo, sa→zh directions); for zh–bo every record is a single segment pair. Median segment lengths in characters per language side; segmentation granularity differs between pairs, reflecting the source editions.

### 3.2 Dataset

Table 1 summarizes the released corpus, which covers the three classical pairs Sanskrit–Tibetan, Sanskrit–Chinese, and Chinese–Tibetan. The released files are decontaminated against the evaluation suite of Section 3.3 (normalized substring matching, following the same protocol as the training-data decontamination in Section 4) and exact-deduplicated.

### 3.3 Evaluation Data

As part of this work we release the held-out evaluation suite used in Section 5. Table 2 shows the composition with 33,259 sentence pairs and 1,908 paragraph blocks over the 17 directions reported below. It contains (i) randomly sampled sentence-level test sets of 2,000 pairs per direction for Sanskrit↔Tibetan, Tibetan↔Buddhist Chinese, Sanskrit↔Buddhist Chinese (all sourced from the manually aligned multilingual editions of the Thesaurus Literaturae Buddhicae (Braarvig, 2007–2022), part of the Bibliotheca Polyglotta of the Norwegian Institute of Philology and the University of Oslo), and 2,594 pairs per direction for Sanskrit↔English (drawn from the Mitrasamgraha dataset (Nehrdich et al., 2026), whose test split is divided into disjoint halves so that the two directions share no pair); (ii) the published MITRA-zh-eval benchmark (Nehrdich et al., 2025) for Buddhist Chinese→English (2,662 pairs drawn from 32 canonical texts); (iii) a Tibetan→X suite based on translations of Lotsawa House,[3] covering trans-

Table 2: Composition of the evaluation suite: sentence pairs and paragraph blocks (up to 10 consecutive sentences) actually scored per direction. TLB = Thesaurus Literaturae Buddhicae; MITRA-zh-eval = Nehrdich et al. (2025); Mitrasaṃgraha = Nehrdich et al. (2026), split into disjoint halves for the two directions; the bo→en row pools the four collections of Figure 3 (84000, Khyentse Vision Project, Lotsawa House, Tsadra Foundation).

lation into French, Spanish, German, Portuguese, Italian, Dutch, and Modern Chinese, sized per language by the amount of human-aligned material available, from 2,000 pairs for French down to 100 for Dutch; and (iv) a Tibetan→English suite of 3,979 pairs drawn as 100 blocks of ∼10 consecutive sentences from each of four translation projects (84000,[4] Khyentse Vision Project,[5] Lotsawa House, Tsadra Foundation[6]), enabling a per-collection difficulty breakdown on sentence and paragraph level. Directions with document-contiguous references are additionally evaluated at paragraph level on blocks of up to 10 consecutive sentences (Par. column). A number of further directions whose reference translations cannot be redistributed for licensing reasons were evaluated under the identical protocol but are excluded from the released suite and from the main translation results; six of them are used in the judge study of Section 5.2.

## 4 Domain-Adaptive Pretraining

### 4.1 Data Composition

Table 3 gives the composition of the continued-pretraining corpus with a total of 22.56B tokens counted with the Qwen3.5 tokenizer. The three dominant components are monolingual Tibetan (25.6%; Tibetan Unicode text from high-quality manual input as well as OCR-derived and quality-filtered material, sourced among others via the Asian Classics Input Project and Buddhist Digital Resource Center), monolingual Sanskrit (22.1%; manually typed e-texts and quality-gated OCR sources, the latter drawn from the Sangraha corpus of IndicLLMSuite (Khan et al., 2024), in IAST), and domain-specific English (20.8%; OCR-processed academic literature on Buddhist Studies and published translations). Buddhist Chinese (4.7%) is drawn from the CBETA[7] and Kanripo[8] collections. We include a 13.8% multilingual replay component to counteract catastrophic forgetting of general multilingual ability: web text drawn from FineWeb (Penedo et al., 2024) for English (the 10BT sample) and from FineWeb-2 (Penedo et al., 2025) for 16 further languages,[9] with per-language token budgets between 80M and 650M tokens. Parallel data (6.9%) combines the mined MITRA-parallel v2 corpus of Section 3 with human-translation pair collections from translation projects and publishers, used for training under their respective terms and not redistributed. We additionally include the Digital Corpus of Sanskrit (Hellwig, 2010–2021) in CoNLL-U form (2.7%), providing sandhi-split, lemmatized, and morphologically annotated Sanskrit. All Tibetan is in Tibetan Unicode script; Wylie transliteration was normalized out of the corpus. For Sanskrit and for the small Pāli component (about 0.1B tokens of monolingual and Pāli–Sanskrit parallel text; Pāli is used in pretraining only and is part neither of MITRA-parallel v2 nor of the released evaluation suite), we decided to use IAST transliteration as it gives better tokenizer efficiency at comparable baseline performance on the Qwen3.5 model family. For Chinese, we use traditional characters in Unicode.

| Sanskrit treebank (DCS) | 0.61B | 2.7% |
| *General multilingual* | | |
| Replay mix (17 languages) | 3.11B | 13.8% |
| Total (stage one) | 22.56B | 100% |
| *Stage two (16k context)* | | |
| Bidirectional parallel data | ≈3.0B | 46% |
| Stage-one replay (en upsampled) | ≈2.4B | 37% |
| Instruction data (Tülu 3, Aya) | ≈0.6B | 9% |
| Document-level parallel (added) | 0.5B | 8% |
| Total (stage two) | 6.4B | 100% |

Table 3: Composition of the continued-pretraining corpus, grouped by data type. The upper block is the stage-one corpus; the lower block gives the second, translation-oriented stage (Section 4), whose base mixture was specified as 50/40/10 over 5.9B tokens before 0.5B tokens of document-level parallel text were added; stage-two shares are given over the 6.4B tokens actually trained. Token counts are exact counts under the Qwen3.5 tokenizer (vocabulary 248k); DCS = Digital Corpus of Sanskrit in CoNLL-U form; stage-one proportions are natural, i.e., no component is up- or down-sampled, whereas the stage-two mixture is imposed by resampling (with English in-domain material upsampled). The replay mix counteracts forgetting of general multilingual ability.

### 4.2 Continued Pretraining

We continue pretraining from Qwen3.5-9B-Base (Qwen Team, 2026), an 8.95B-parameter hybrid-attention model. We chose this model after comparing the zero-shot translation quality of the instruction-tuned Qwen3.5 and Gemma-4 releases on our evaluation suite (Appendix B): at comparable scale, Qwen3.5-9B and Gemma-4-12B perform on par (mean chrF 19.9 vs. 19.9 over the official directions), while Qwen3.5 has a lower parameter count and is therefore more efficient to train given the available compute budget. Documents are shuffled at file level (fixed seed), concatenated with EOS separators, and packed into fixed 8,192-token windows. No component is up- or down-sampled. Training uses 8×H100 with ZeRO-2, bf16, micro-batch 4 with 4-step gradient accumulation (1.05M tokens per optimizer step), peak learning rate $2\times10^{-5}$ with cosine decay, 1% warmup, and weight decay 0.1. The checkpoint used in this paper has seen 27,000 steps ≈ 28.3B tokens (≈1.3 epochs).

A second, shorter pretraining stage (lower block of Table 3) extends the context window to 16,384 tokens and shifts the data distribution toward translation and instruction following. The corpus is repacked into a mixture of 50% bidirectional parallel data, 40% replay of the stage-one distribution with upsampled English in-domain material, and 10% general multilingual instruction data consisting of a uniform random subsample of the Tülu 3 SFT mixture (Lambert et al., 2024) (∼0.6B tokens) together with the Aya dataset (Singh et al., 2024) restricted to our 21 deployment languages (∼19M tokens), rendered as chat-template conversations, supplemented with 0.5B tokens of document-level parallel text created by merging adjacent sentence pairs from the main parallel corpus. This stage runs for 6,145 steps (6.4B tokens, one epoch) at peak learning rate $1\times10^{-5}$ with 5% warmup on the same 8×H100 ZeRO-2 setup; since the sequence length doubles, the micro-batch is reduced to 1 and gradient accumulation raised to 8, so that each optimizer step still sees 64 sequences (1.05M tokens).

### 4.3 Translation Fine-tuning

Two lightweight steps turn the pretrained model into the translation model MITRA-MT. First, an *interface calibration* fine-tune: 50 optimizer steps (approximately one epoch) on 6,315 plain-prompt translation instructions distilled from Gemini 3 Flash, spanning 15 target languages and using exactly the instruction format of our evaluation protocol (Section 5). In our experiments this stage functions as calibration rather than knowledge injection: translation capability tracks the amount of continued pretraining, while extending instruction tuning beyond ∼50 steps on this dataset yields no measurable gain. We report this checkpoint as the ablation MITRA-SFT.

Second, 100 steps of GRPO (Shao et al., 2024) in the memory-efficient Dr. GRPO variant (Liu et al., 2025): LoRA (rank 16, $\alpha$=32) at learning rate $5\times10^{-6}$, KL coefficient 0.01, 8 sampled completions per prompt, on a pool of 8,173 held-out translation prompts in the same plain format. The reward is an unnormalized weighted sum of five terms: chrF against the reference (weight 0.2),

BLEURT-20 (0.4), an LLM-judge adequacy score with Gemini 3.1 Flash-Lite as the judge (0.4), a non-repetition term (0.2), and a target-script check (0.2); the weights sum to 1.4 and were not rescaled. The effect of this stage on judged adequacy and on chrF is quantified in Section 5.2. The GRPO checkpoint is the MITRA-MT evaluated below.

**Decontamination.** Since pretraining sources (canonical collections) and evaluation sets draw on overlapping literature, we decontaminate training data against evaluation data by string matching: every evaluation sentence pair is normalized (NFC, whitespace-collapsed, lower-cased) and matched as a substring against all parallel training data using an Aho–Corasick automaton, with per-script minimum-length rules so that ubiquitous formulae do not trigger mass deletion (e.g., CJK $\geq$15 characters, Tibetan $\geq$40, Latin/IAST $\geq$25 characters and 5 words). This removes 112,382 training lines. It needs to be emphasized that deduplication of Buddhist digital text collections is very difficult as the frequent repetition of nearly identical passages is a core feature of parts of this literature. We therefore do not deduplicate against the monolingual training data, as this would remove large parts of the corpus.

## 5 Machine Translation Evaluation

### 5.1 Setup

**Protocol.** All systems translate the same inputs at temperature 0.2 with thinking/reasoning modes disabled (LLMs; Gemini 3.6 Flash runs at its minimum thinking budget of 128 tokens, since the API rejects full disabling for this model) or with beam search (dedicated MT models). Instruction-tuned LLMs—including MITRA-MT, with no system-specific prompt engineering—receive the identical instruction "*Translate the following {source} text into {target}. Output only the translation.*" through their chat template; NLLB-200 receives source/target language codes and MADLAD-400 target-language tags, with Sanskrit transliterated IAST→Devanāgarī on input. Because systems differ in output script (Devanāgarī vs. IAST for Sanskrit, Wylie vs. Tibetan script for Tibetan), all outputs for Sanskrit and Tibetan targets are script-normalized (Devanāgarī→IAST, Wylie→Tibetan Unicode) before scoring, for every system identically. A five-shot arm supplies Gemma-4-31B with five in-context exemplar pairs drawn from decontaminated training-side data. Paragraph-level inputs are blocks of up to 10 consecutive sentences translated as a single input.

**Metrics.** Our primary metric is chrF (Popović, 2015), a deliberate choice driven by the multi-directional setting: it is the only established metric that applies uniformly across all 17 directions, requiring no tokenizer, no language-specific model support, and no assumptions about script or word segmentation. In this we follow Team et al. (2022), who adopt character-level chrF as the primary automatic metric for NLLB-200 in a massively multilingual setting. The learned metrics BLEURT-20 (Sellam et al., 2020) and COMET-22 (Rei et al., 2022) lack domain adaptation for classical Buddhist material and language support for our targets (COMET's encoder does not cover Tibetan and compresses, or even inverts, large chrF differences on Tibetan-target directions; see Appendix C). LLM-as-judge metrics are potentially powerful for this setting as they show strong correlation with human judgment on Sanskrit→English translation (Nehrdich et al., 2026), but their correlation with human judgments on non-English classical language targets is not yet studied and therefore uncertain. Section 5.2 reports a controlled two-judge experiment that motivates this choice and quantifies where judges and chrF disagree.

**Baselines.** We compare against three groups of systems. *Open instruction-tuned LLMs*: Qwen3.5-9B, Llama-3.1-8B (Grattafiori et al., 2024), Gemma-4-12B/31B (Gemma Team, 2026), and Qwen3.5-122B-A10B (AWQ-quantized mixture-of-experts). *Dedicated MT systems*: NLLB-200-3.3B (Team et al., 2022), MADLAD-400-3B-MT (Kudugunta et al., 2023), TranslateGemma-27B (Finkelstein et al., 2026), and the translation-specialized LLM Tower-Plus-9B (Rei et al., 2025). *Commercial references*: Gemini 3.1 Flash-Lite, 3.5 Flash, and 3.6 Flash. Tables abbreviate these systems as Qwen3.5, Llama-8B, G4-12B, G4-31B (G4-31B-5s for the five-shot arm), Q-122B, NLLB, MADLAD, TG-27B, Tower+, Flash-Lite, 3.5-Flash, and 3.6-Flash; MITRA-SFT denotes our model before GRPO. API costs confine our commercial comparison to a single vendor family. Main-text tables report the most recent model in the family, 3.6 Flash, together with 3.1 Flash-Lite; complete results are given in Appendix C. We do not include the Gemma-2-based model of Nehrdich

and Keutzer (2026), as the deduplication of the evaluation data used in this paper with the training data of that model cannot be established.

### 5.2 Metric Choice and LLM Judges

To check how the choice of chrF as the main metric influences the results compared to LLM judges, we ran a small selection study. For each direction we drew a fixed 50-segment sample from the sources common to all systems and scored every system on those identical items with two judges from two different model families, Gemini 3.1 Flash-Lite and Claude Sonnet 5, using a reference-based GEMBA-style prompt (Kocmi and Federmann, 2023): 23,670 judgments per judge over 21 sentence-level and 12 paragraph-level directions.[10] The scale is deliberately limited, and the results should be read as indicative rather than as a full evaluation.

Table 4 reports the outcome. Agreement with chrF is strong at the system level (Spearman $\rho = 0.93$ for the Gemini judge and 0.96 for Sonnet), and the two judges agree even more closely with each other ($\rho = 0.99$). The disagreement that remains is concentrated at the top of the table: both judges place Gemini 3.5 and 3.6 Flash above MITRA-MT on the aggregate, where chrF places MITRA-MT first (chrF 34.4 vs. 32.5; Gemini judge 80.7 vs. 83.7; Sonnet judge 73.5 vs. 75.3). Because an independent judge reproduces the ranking of the Gemini judge almost exactly, this is not attributable to judge–system family affinity. The effect is also direction-dependent: both judges favor MITRA-MT into Tibetan, Chinese, Korean and Japanese (the latter two being supplementary directions), and favor the commercial systems into Sanskrit and into several European targets, with English→Sanskrit the largest single deficit. Restricting the comparison to English targets (Table 7, Appendix D), where reference-based judging is best established and the judges' own language coverage is strongest, reproduces the same picture on a narrower base: our models lead on chrF by roughly 3.5 points while both judges place 3.5 and 3.6 Flash ahead by around 3. While we adopt chrF as the main metric of our study on cost and applicability grounds, in this limited trial chrF appears to undervalue the Gemini family, and MITRA-MT's aggregate chrF lead over the commercial references should be read as metric-specific and not as a uniform quality claim.

The judge study also quantifies the effect of the preference-optimization stage of Section 4.3. On its held-out validation set, judge-rated adequacy improved from 81.1 to 82.9 and chrF from 39.0 to 39.2, and the same asymmetry appears on the evaluation suite proper: against MITRA-SFT, MITRA-MT gains $+1.3$ GEMBA points at sentence level and $+1.1$ at paragraph level under the Gemini judge (95% CI $+0.5$ to $+2.1$ and $+0.3$ to $+1.9$; better on 18 of 22 and 10 of 13 directions respectively), and $+1.5$ at paragraph level under the independent Sonnet judge, while chrF moves by $+0.03$ and $+0.41$. As the five strongest systems in the study are separated by only 4.4 GEMBA points in total, the preference stage recovers roughly a third of the range spanning MITRA-SFT and the best commercial system. The gain is consistent in judged adequacy and almost entirely invisible to string metrics, which we see as a strong hint that chrF, chosen here for cost and coverage, is insensitive to the kind of improvement our preference optimization targets.

### 5.3 Sentence-Level Results

Figure 1 presents sentence-level chrF for all 17 directions, where bo→en is the pooled four-collection Tibetan→English benchmark; exact values for every system are given in Appendix C. Three patterns organize the results. First, into classical target languages the gap is structural: MITRA-MT leads every open baseline by wide margins into Tibetan and Sanskrit (sa→bo 55.0 vs. 33.4 for the strongest open baseline, Qwen3.5-122B; zh→sa 39.1 vs. 27.3)—capabilities that neither scale nor instruction tuning provides. Second, against the commercial references MITRA-MT leads Gemini Flash-Lite on 16 of the 17 directions, including sa→en (38.5 vs. 36.6) and zh→en (38.7 vs. 37.3), and leads the stronger Gemini 3.6 Flash on 13 of the 17 directions with a tie on sa→en (38.5 vs. 38.5); the remaining deficits are at most 3.3

[10] The judged directions are the 17 directions of Section 3.3 without bo→en, plus six *supplementary* directions that were evaluated under the identical protocol but whose reference translations cannot be redistributed (sa→ja, sa→de, sa→hi, zh→fr, zh→ko, pa→en); these supplementary directions appear in this paper only within the judge study. The counts 21 and 12 are the directions covered by every system (NLLB-200 has no pa→en run, and paragraph-level zh→en is available for nine systems); the pairwise MITRA-MT vs. MITRA-SFT comparison in Section 4.3 uses all 22 and 13 directions that the two models share. The 23,670 judgments are the sum over systems and directions of the items actually judged; bo→nl, for instance, has only 10 paragraph blocks.

| | Sentence | | | Paragraph | | |
|---|---|---|---|---|---|---|
| System | chrF | Gem. | Son. | chrF | Gem. | Son. |
| **MITRA-MT** | 34.4 | 80.7 | 73.5 | 46.0 | 89.3 | 82.4 |
| MITRA-SFT | 34.4 | 79.3 | 72.7 | 45.6 | 87.6 | 80.1 |
| 3.5-Flash | 32.5 | 83.7 | 75.3 | 44.9 | 92.5 | 86.0 |
| 3.6-Flash | 31.9 | 83.4 | 75.1 | 43.2 | 91.5 | 83.2 |
| Flash-Lite | 30.5 | 82.0 | 71.7 | 42.6 | 91.9 | 83.4 |
| G4-31B-5s | 26.6 | 65.8 | 56.2 | — | — | — |
| G4-31B | 25.8 | 65.1 | 54.3 | 39.0 | 82.3 | 68.6 |
| Q-122B | 25.5 | 68.3 | 59.0 | 37.4 | 81.9 | 67.6 |
| TG-27B | 21.6 | 48.7 | 35.6 | — | — | — |
| G4-12B | 20.5 | 44.5 | 33.5 | 33.8 | 58.0 | 39.3 |
| Qwen3.5 | 20.2 | 44.8 | 32.6 | 32.9 | 53.7 | 34.5 |
| Llama-8B | 15.9 | 28.4 | 17.0 | 22.0 | 22.5 | 12.5 |
| Tower+ | 15.5 | 26.4 | 16.2 | 24.8 | 27.8 | 15.5 |
| NLLB | 12.7 | 15.4 | 8.6 | — | — | — |
| MADLAD | 9.4 | 13.4 | 7.2 | — | — | — |

Table 4: LLM-judge selection study: chrF against two reference-based GEMBA-style judges (Gem. = Gemini 3.1 Flash-Lite, Son. = Claude Sonnet 5) on a fixed 50-segment sample per direction, identical items for every system (21 sentence-level and 12 paragraph-level directions). Rows are ordered by sentence-level chrF. The judges agree with each other ($\rho = 0.99$) more closely than either agrees with chrF ($\rho = 0.93, 0.96$); the ordering they disagree on is confined to the top of the table. Table 7 reports the same study restricted to English targets.

chrF except for en→sa, where both Gemini systems lead by up to 5.1 chrF (33.3 vs. 38.3). Third, on Tibetan→modern-language directions (Lotsawa House), MITRA-MT leads consistently, with the dedicated MT systems far behind.

### 5.4 Paragraph-Level Results

Figure 2 reports paragraph-level results for the directions with document-contiguous data, created by merging up to 10 consecutive source and target sentences on both sides. For the Tibetan→modern directions and bo→en, the paragraph blocks are exactly the sentence-level test items regrouped, so the two granularities score the same references and differ only in input context; for zh→en the blocks cover 2,440 of the 2,662 sentence-level items. For sa→en, by contrast, the 321 blocks are a separate contiguous sample from the Mitrasamgraha pool and share no item with the sentence-level set, so its sentence–paragraph difference reflects the test material as well as context. Paragraph-level scores exceed sentence-level scores for the three evaluated systems MITRA-MT, Gemini 3.6 Flash and Gemma-4 31B by 8–12 chrF, which shows that context is immensely helpful for translating classical Buddhist texts into modern languages.

### 5.5 Tibetan in Detail

Figure 3 breaks Tibetan→English down by source collection. The ordering is stable across all systems: translations of canonical sūtra material (84000) score highest, material from the Khyentse Vision Project and Lotsawa House sits in between, and the translations sponsored by the Tsadra Foundation are hardest (∼9 chrF below 84000 for MITRA-MT). Pooled over the four collections, MITRA-MT reaches 43.2 chrF, ahead of every baseline including Gemini 3.6 Flash (40.7) and Gemma-4-31B (36.1).

## 6 Conclusion

We presented a pivot-free mining pipeline and the resulting 1.69M-record trilingual MITRA-parallel v2 corpus; MITRA-MT, a domain-adapted translation model built with a fully documented 22.6B-token continued-pretraining recipe on Qwen3.5-9B and a lightweight translation fine-tune step; and a 17-direction evaluation suite that extends assessment of classical Asian language MT beyond translation into English, including cross-classical directions and Tibetan into seven modern languages. For the chrF metric, MITRA-MT sets the strongest open-model results on most evaluated directions, while LLM-judge-based evaluation indicates that MITRA-MT, although it does not outperform commercial models, closes much of the gap and is therefore a viable open alternative. Corpus, evaluation data, and model weights are released openly via the MITRA Qwen3.5 collection on Hugging Face, with an interactive gateway to the parallel data at `https://dharmamitra.org/db`.

## 7 Limitations

**Corpus quality assessment.** The alignment quality of MITRA-parallel v2 is validated by automatic gates, but no manual evaluation of the released alignments was possible within the scope of this work: the corpus has undergone neither a stratified human audit with multiple annotators nor any record-level accuracy assessment, and the manual inspection we did perform was targeted at low-scoring texts rather than drawn as a representative sample. Expert annotators for Sanskrit–Tibetan–Chinese alignment are scarce, and the scale of the corpus makes even a modest stratified sample a substantial annotation effort. Partial and indirect reassurance comes from downstream training. All three cross-classical pairs are learned to

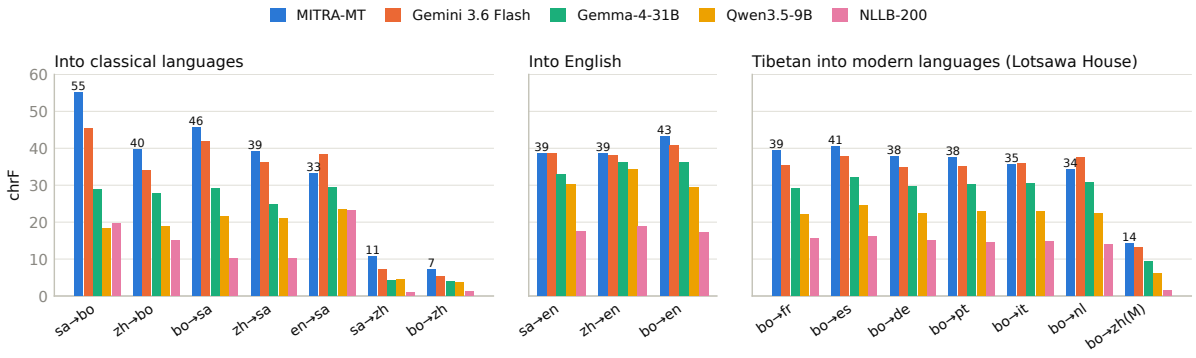

Figure 1: Sentence-level translation quality (chrF) by direction, grouped by target family. MITRA-MT numbers are labeled. bo→en pools the four-collection Tibetan→English benchmark. All systems evaluated under the identical protocol, including output script normalization.

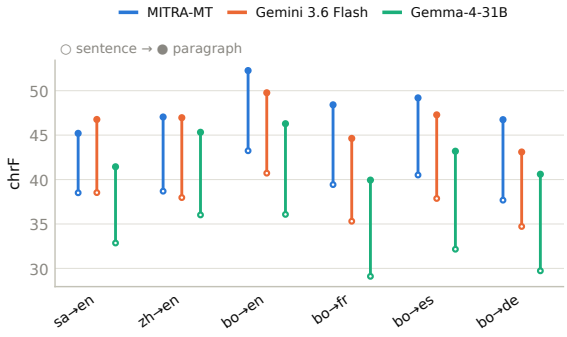

Figure 2: Sentence-level (open marker) vs. paragraph-level (filled marker) chrF. Context helps all LLM systems; the ordering is largely preserved.

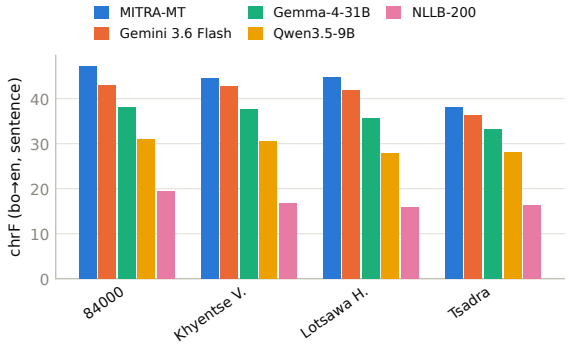

Figure 3: Tibetan→English difficulty by source collection (sentence level). The ordering is stable across systems.

a level that no system trained without this data approaches. Against the strongest open baseline (Qwen3.5-122B, a model an order of magnitude larger), MITRA-MT reaches 55.0 vs. 33.4 chrF on sa→bo, 45.7 vs. 29.5 on bo→sa, 39.6 vs. 29.2 on zh→bo, and 39.1 vs. 27.3 on zh→sa. If the alignment quality had significant flaws, such consistent gains would not be possible. A direct quality estimate nevertheless remains open for future work.

**Metrics.** Our reliance on chrF is another methodological limitation of this study. Character n-gram overlap is the only metric that applies uniformly across all our directions, but it measures surface form rather than adequacy, under-measures quality for Tibetan and Chinese targets whose writing systems are fundamentally different, and is demonstrably insensitive to differences that LLM judges do register. The preference-optimization stage of Section 4.3 moves judged adequacy while leaving chrF essentially unchanged, and in Section 5.2 chrF and both judges disagree on the ordering at the top of the table. LLM-as-judge is the most promising alternative and the one we would prefer, but it fails on two independent counts. First, its cost quickly becomes prohibitive for an evaluation dataset of this size when comparing even a modest number of systems. Second, its validity beyond English targets is unestablished: agreement with expert human judgment has been shown for Sanskrit→English (Nehrdich et al., 2026), but for Tibetan, Buddhist Chinese, and the modern non-English targets no calibration against human annotation exists.

## Acknowledgments

Generative AI coding assistants, including Claude Code using the 4.8 Opus and 5 Fable models, were used during software development for code generation, debugging, refactoring, and development of experimental and visualization scripts. All generated code and experimental results were reviewed and validated by the authors. We thank the Tsadra Foundation for their generous support in making

this study possible.

## A Corpus Composition of the Mining Search Space

The span miner of Section 3.1 operates on the corpus collections curated for the DharmaNexus intertextuality system. All texts are segmented into overlapping paragraph windows of consecutive canonical segments and embedded with `gemma-2-mitra-e`. Pair mining for MITRA-parallel v2 searches the canonical trilingual working set, comprising 3.22M paragraph windows over 12,348 texts:

**Tibetan (1.91M windows; 5,013 texts).** The Derge Kangyur (1,158 texts; 604k windows) and Derge Tengyur (3,431 texts; 1.25M windows) in the Esukhia eKangyur/eTengyur input transcriptions, complemented by 424 further canonical texts catalogued under BDRC scan identifiers (53k windows).

**Chinese (936k windows; 6,623 texts).** The Taishō Tripiṭaka in the CBETA edition: 5,749 texts of the first Taishō division (740k windows) and 874 texts of the second division (196k windows).

**Sanskrit (371k windows; 712 texts).** Buddhist scriptures (251 texts; 159k windows) and Buddhist treatises (461 texts; 212k windows), drawn from GRETIL, the Digital Sanskrit Buddhist Canon, and editions digitized within the Dharmamitra project.

## B Base-Model Choice

Table 5 compares the zero-shot performance of the instruction-tuned Qwen3.5-9B against the Gemma-3 and Gemma-4 releases on the official evaluation directions, under the protocol of Section 5. At comparable parameter count (9B vs. 12B) no model clearly dominates. While Gemma-4-31B leads most directions, it is 3.4× the size of our base, making finetuning and deployment significantly more challenging.

| Direction | Qwen-9B | G3-12B | G4-12B | G4-31B |
|---|---|---|---|---|
| sa→bo | 18.3 | 26.8 | 19.6 | **28.9** |
| bo→sa | 21.5 | 21.4 | 21.3 | **29.1** |
| bo→zh (B) | 3.5 | 3.0 | 2.9 | **4.0** |
| zh→bo | 18.9 | 26.3 | 20.4 | **27.8** |
| sa→en | 30.3 | 28.3 | 28.8 | **32.9** |
| en→sa | 23.5 | 25.1 | 27.6 | **29.4** |
| sa→zh | **4.6** | 4.4 | 3.0 | 4.2 |
| zh→sa | 21.0 | 19.5 | 19.7 | **24.7** |
| zh→en | 34.4 | 32.3 | 32.7 | **36.0** |
| bo→fr | 21.9 | 21.9 | 22.1 | **29.1** |
| bo→es | 24.4 | 24.1 | 25.0 | **32.2** |

| bo→pt | 22.9 | 22.4 | 22.6 | **30.3** |
| bo→it | 22.8 | 22.8 | 22.5 | **30.6** |
| bo→nl | 22.5 | 21.1 | 23.3 | **30.8** |
| bo→zh (M) | 6.1 | 5.1 | 5.6 | **9.2** |
| Mean | 19.9 | 20.4 | 19.9 | **25.6** |

Table 5: Zero-shot chrF of instruction-tuned Qwen3.5-9B (Qwen-9B), Gemma-3-12B (G3-12B), and Gemma-4-12B/31B (G4-12B/31B) on 16 of the 17 evaluation directions (bo→en is not included), identical protocol as all other systems (mean over directions available for all listed systems). At comparable scale no model dominates; Gemma-4-31B leads most directions at 3.4× the size of our base.

## C All-Systems Overview and Neural-Metric Reference

Figure 4 gives the complete sentence-level chrF picture for every evaluated system; Table 6 provides COMET-22 and BLEURT-20 for the strongest systems.

## D LLM-Judge Study on English Targets

Table 7 repeats the judge study of Section 5.2 restricted to the English-target directions, where reference-based judging is best established and the judges' own language coverage is strongest. The ordering disagreement between chrF and the two judges observed on the full direction set reappears on this narrower base.

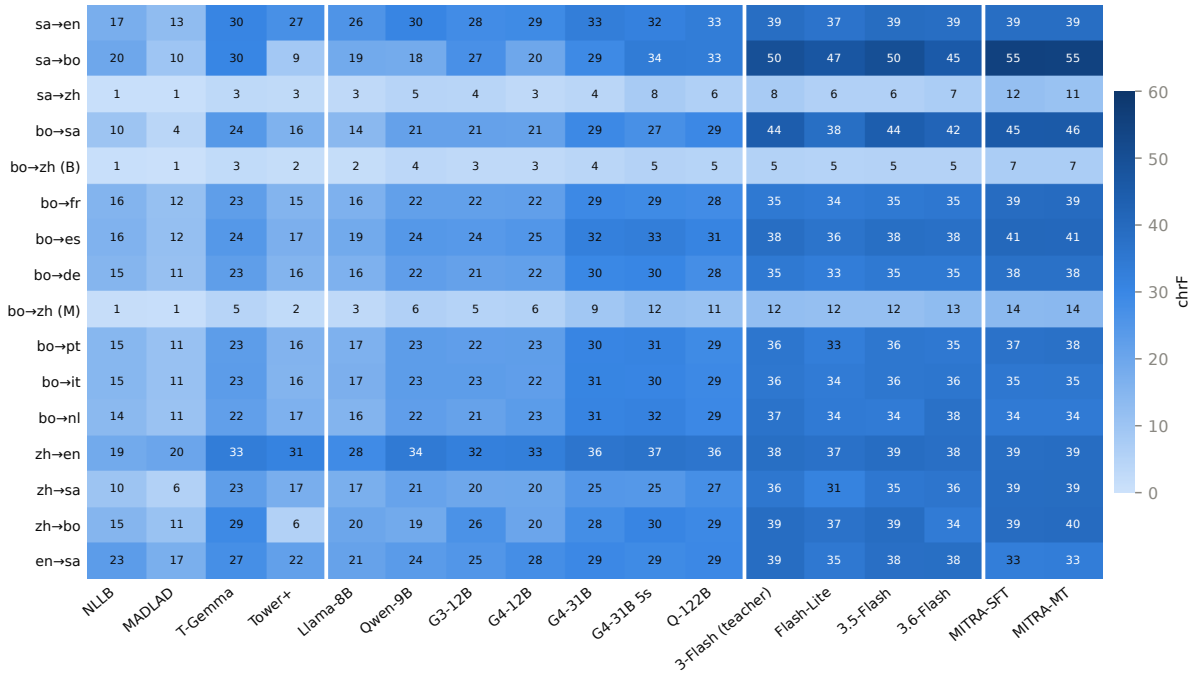

Figure 4: Sentence-level chrF for all systems (columns, grouped left to right: dedicated MT, open LLMs, commercial references, ours) across 16 of the 17 directions (rows; bo→en, scored per collection, is not included). Column abbreviations: NLLB = NLLB-200-3.3B; MADLAD = MADLAD-400-3B-MT; T-Gemma = TranslateGemma-27B; Tower+ = Tower-Plus-9B; Llama-8B = Llama-3.1-8B-Instruct; Qwen-9B = Qwen3.5-9B; G3-12B = Gemma-3-12B; G4-12B/31B = Gemma-4-12B/31B; G4-31B 5s = Gemma-4-31B with five in-context exemplars; Q-122B = Qwen3.5-122B-A10B (AWQ); 3-Flash (teacher) = Gemini 3 Flash Preview, the SFT distillation teacher; Flash-Lite / 3.5-Flash / 3.6-Flash = Gemini 3.1 Flash-Lite / 3.5 Flash / 3.6 Flash; MITRA-SFT = our model without GRPO; MITRA-MT = our full model. Row labels: (B) = Buddhist Chinese, (M) = Modern Chinese; the Tibetan→modern rows use Lotsawa House data.

## Abstract

Although machine translation is often considered solved for high-resource languages, it remains challenging for texts involving poetic language, philosophical concepts, and layered metaphors, characteristics that are central to Sanskrit literature. Additionally, Sanskrit's rich morphology, sandhi, and compounding, combined with its multi-millennial and multi-domain textual tradition, highlight the need for large, diverse parallel resources, which are currently scarce. We introduce Mitrasaṃgraha, a large-scale Sanskrit–English machine translation dataset containing 391,548 aligned sentence pairs, over 4 times larger than the previously available Itihāsa corpus (Aralikatte et al., 2021). The dataset spans more than 3 millennia of Sanskrit literature across multiple domains and includes temporally annotated data for studying domain and period effects on translation performance. We release manually corrected development (5,587) and test (5,552) sets. Benchmarks show that fine-tuning models such as NLLB and Gemma substantially improves translation quality, and retrieval-augmented prompting further enhances performance. In a controlled cross-dataset comparison, training on Mitrasaṃgraha outperforms both Itihāsa and web-mined bitext for two model families. Despite these gains, our results reveal persistent challenges in translating complex compounds, philosophical terminology, and metaphorical language in Sanskrit, highlighting the need for further research in this area.

## 1 Introduction

Sanskrit represents one of the longest continuous literary traditions in human history, spanning more than 3 millennia and encompassing a wide range of textual genres, including ritual hymns, epic narratives, philosophical treatises, poetry, and scientific literature (Kumar and Gaurav, 2025). Despite its historical and cultural importance, Sanskrit remains severely under-resourced in modern natural language processing (NLP) (Sandhan et al., 2023a; Das et al., 2025). In particular, the development of high-quality machine translation (MT) systems for Sanskrit has been limited by the scarcity of large and diverse parallel corpora (Krishna et al., 2020).

Existing Sanskrit–English parallel datasets (Aralikatte et al., 2021; Team et al., 2022; Maheshwari et al., 2024; Nehrdich, 2022) are typically restricted in size, domain coverage, or historical scope. Many available corpora focus primarily on a small number of texts, often epic literature such as the Mahābhārata or Rāmāyaṇa and frequently rely on translations produced by a single translator. As a result, these datasets fail to capture the linguistic diversity, stylistic variation, and domain breadth present in Sanskrit literature. This limitation hinders the development and evaluation of robust machine translation models and restricts broader computational research on Sanskrit texts.

Beyond data scarcity, Sanskrit poses several intrinsic linguistic challenges for machine translation. The language exhibits rich morphology, extensive compounding, and relatively free word order (Nehrdich et al., 2024; Krishna et al., 2019; Sandhan et al., 2023b). In addition, phonological processes such as sandhi merge adjacent words and alter their surface forms, making tokenization and alignment more difficult. Sanskrit texts also frequently contain dense philosophical concepts, metaphorical language, and poetic structures that can lead to multiple valid translations in English. These characteristics complicate both the training and evaluation of machine translation systems.

To address these challenges, we introduce Mitrasamgraha, a large-scale Sanskrit–English parallel corpus designed to support machine translation research across a broad range of historical periods and literary domains. The dataset contains 391,548 aligned sentence pairs, making it the largest publicly available Sanskrit–English machine translation dataset to date. Unlike previous datasets, Mi-

Table 1: Comparison of Mitrasamgraha with existing published Sanskrit-English datasets.

trasamgraha covers texts composed over a span of nearly three millennia and includes diverse genres such as Vedic literature, epic narratives, philosophical treatises, poetry, and religious texts. In addition, we provide manually post-corrected development and test sets to enable reliable evaluation. The domain/time annotations enable controlled evaluation and error analysis across historical strata and genres, and can support more targeted train/dev/test splits or domain-adaptive training.

Beyond assembling the dataset, we conduct a systematic study of several key components required for building reliable machine translation systems for Sanskrit. First, we evaluate sentence alignment approaches for noisy historical texts and identify BERTAlign as the most effective method for Sanskrit–English alignment. Second, we investigate the suitability of different automatic evaluation metrics for Sanskrit translation by comparing them against expert human judgments. Finally, we benchmark a wide range of translation systems, including commercial large language models, open-source multilingual MT models, and retrieval-augmented generation setups, demonstrating how the Mitrasamgraha dataset improves translation performance.

Our key contributions are as follows:

- We introduce *Mitrasamgraha*, the largest publicly available Sanskrit–English MT dataset with 391,548 aligned sentence pairs across diverse domains and historical periods.
- We release manually verified development and test sets with document-level metadata for reliable evaluation and domain analysis.
- We evaluate automatic MT metrics for Sanskrit and show that LLM-based judges align substantially with expert judgments, while string-based and learned neural metrics (BLEURT, COMET) struggle.
- We provide comprehensive MT benchmarks across commercial models, open-source systems, and retrieval-augmented approaches, together with a per-period and per-domain breakdown.
- We report a controlled cross-dataset comparison showing that Mitrasaṃgraha outperforms both Itihāsa and web-mined bitext as training data for two model families.

## 2 Related Work

For Classical Sanskrit, Aralikatte et al. (2021) introduced a dataset consisting of 93,000 pairs of Sanskrit verses with their English translations. This dataset consists of two central epic Sanskrit texts, the Mahābhārata and the Rāmāyaṇa, composed between the 4th century BCE and the 4th century CE. Both texts have been translated by the same person, M.N. Dutt in the late 19th century. Regarding contemporary Sanskrit, Team et al. (2022) provide 244k automatically mined sentence pairs. Gala et al. (2023) expand this dataset by adding 27.7k sentences from the Wiki and 5.4k sentences from the Daily domains (day-to-day spoken language). Another Sanskrit dataset was published in Maheshwari et al. (2024). This dataset consists of about 53k sentence pairs, which are written in contemporary prose and therefore do not cover the classical domain. When it comes to other language directions, Nehrdich (2022) provides a Sanskrit-Classical Tibetan sentence-aligned dataset that covers 317k sentence pairs.

## 3 Mitrasamgraha Dataset

### 3.1 Data Collection Pipeline

We follow a structured multi-step workflow for data collection and preprocessing/postprocessing as il-

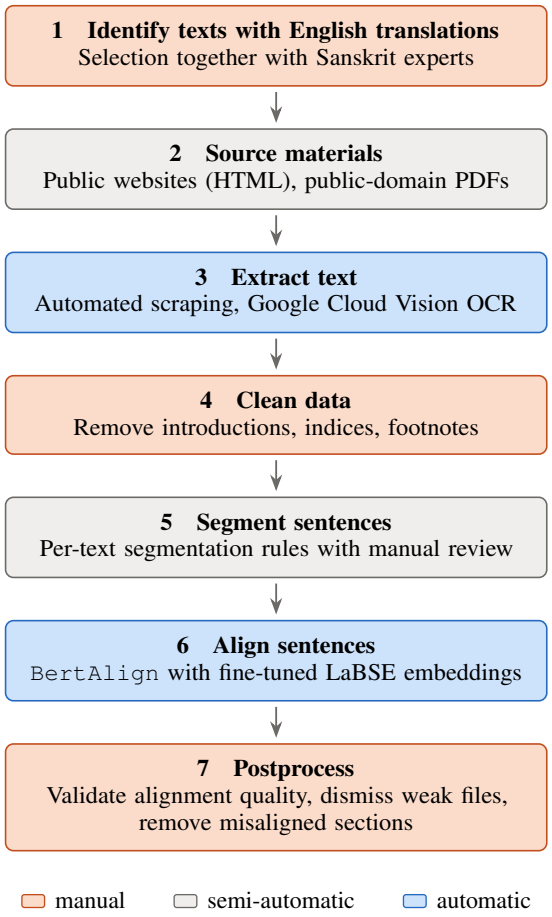

Figure 1: Our Sanskrit–English bitext collection and alignment procedure.

lustrated in Figure 1. First, we collaborate with domain experts of Sanskrit literature to identify Sanskrit texts that have corresponding English translations. We then source these text pairs from publicly available resources. For data extraction, we employ a systematic preprocessing pipeline. For texts available on public websites, we use automated scraping systems to extract high-quality content from HTML sources. For public domain PDFs, we apply an OCR pipeline using Google Cloud Vision, followed by manual cleanup to remove irrelevant sections such as introductions, indices, and notes. Once the text is preprocessed, we segment the Sanskrit source as well as the English translation into individual sentences using a rule-based approach with manual review, since depending on the input format, different rules need to be applied for successful sentence segmentation. These rules need to be selected and adjusted for each text individually. After the sentence segmentation, we utilize `BertAlign` to generate aligned bitext pairs. Once the automatic alignment is completed, we manually review the output and dismiss files with

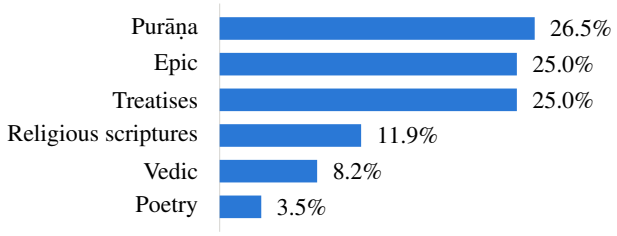

Figure 2: Domain composition of the Mitrasaṃgraha training corpus, as a share of sentence pairs.

insufficient alignment quality. For those that we keep, we do a coarse manual inspection where we remove sections that are obviously misaligned.

### 3.2 Data Sources

We provide an overview of the domain composition of the dataset in Figure 2 and compare Mitrasaṃgraha with previously published datasets in Table 1. A detailed per-document breakdown of the dataset is given in Appendix D. To demonstrate the domain distribution, we assigned high-level categories to each text. These categories are intentionally broad; for instance, "treatises" encompasses Dharmaśāstra literature, medical texts, and commentaries on religious scriptures, among others. The temporal classification of Sanskrit literature presents significant challenges, as philological research typically establishes only approximate ranges, often spanning several centuries. Given these constraints, we divide our dataset into four broad periods: Vedic (before 500 BCE), Epic (500 BCE–200 CE), Classical (200–1000 CE), and Medieval (1000–1800 CE), while acknowledging the inherent imprecision of such categorization. The Sanskrit sources in our dataset span nearly three millennia, from the second millennium BCE to the early eighteenth century CE. This breadth is complemented by the diversity of translators represented in the corpus, with at least forty identified contributors. Some works, such as the *Mahāsubhāṣitasaṃgraha*, are anthologies comprising contributions from numerous additional translators. The combination of temporal range and domain variety means that our dataset captures the linguistic and stylistic evolution of Sanskrit literature across its major historical periods, from the earliest Vedic hymns to late medieval treatises.

### 3.3 Sanskrit-English Sentence Alignment

Aligning Sanskrit-English sentence pairs presents unique challenges compared to high-resource lan-

guage pairs. Sanskrit's sandhi (phonological changes at word boundaries), frequent compounding, and free word order weaken lexical alignment signals. Additionally, divergent punctuation conventions between Sanskrit editions and English translations create frequent one-to-many/many-to-one mappings, while English texts often contain extraneous material (footnotes, headers) with no Sanskrit counterpart. We evaluated two state-of-the-art alignment algorithms on manually aligned gold-standard data with synthetic noise injection to mimic real-world conditions: VECALIGN (Thompson and Koehn, 2019), and BERTALIGN (Liu and Zhu, 2022). In line with findings on Sanskrit–Tibetan alignment by Nehrdich (2022), we focus our benchmark on embedding-based aligners and omit purely length- and lexicon-based methods, which performed substantially worse in our setting. Following Lamraoui and Langlais (2013), we report sentence-level F-measure ($F_S$), which measures whether correct sentences are paired regardless of many-to-many mappings. BERTALIGN demonstrated superior performance across all evaluated domains, achieving $F_S$ scores ranging from 70.15 (Tattvasaṃgraha) to 97.12 (Manusmṛti), significantly outperforming the other algorithms. Based on these results, we adopted BERTALIGN for creating Mitrasaṃgraha. While certain domains still show room for improvement, the alignment quality is sufficient for downstream machine learning applications. Detailed alignment results and methodology are provided in Appendix B.

### 3.4 Compliance of Mitrasaṃgraha with ARR Guidelines for New Dataset Release

We release Mitrasaṃgraha in two versions to accommodate different licensing requirements: (1) a complete dataset under CC BY-NC-ND 4.0 containing all 391,548 sentence pairs, and (2) a research-friendly subset under CC BY-SA 4.0 containing 372,791 sentence pairs (excluding 18,757 pairs with BY-NC-ND restrictions). Detailed licensing information for each text is provided in Appendix D. All data collected or scraped from various sources (e.g., websites, PDF books) has been manually verified to be publicly accessible without copyright restrictions. The resources and pre-existing datasets incorporated into our collection are used in a manner consistent with their originally intended purposes (where specified) and are aligned with our declared intended use. Our dataset does not raise any anonymity concerns, as it contains no personally identifiable information or offensive content.

## 4 Experiments

**Baselines:** In order to quantify the impact of Mitrasaṃgraha and to give an overview of the performance landscape of current MT systems for Sanskrit-to-English, we benchmark three families of translation systems.

- **Commercial, off-the-shelf LLMs (zero-shot)**: Google Translate, GPT-4o-mini / GPT-4o (OpenAI), Claude 3.5 Haiku (1022) / Claude 3.5 Sonnet (1022) / Claude 3.7 Sonnet (0219) (Anthropic), and Gemini 1.5 Pro / Gemini 2.0 Flash (Google).
- **Open-source multilingual MT models:** both in their original "zero-shot" form and after supervised fine-tuning on our training split: NLLB-200 600M & 3.3B (Team et al., 2022), and MADLAD-400-3B-MT (Kudugunta et al., 2023). We also test the general-purpose instruction LLMs Llama-3-Instruct (8B) (Grattafiori et al., 2024) and Gemma-2-Instruct (9B) (Team, 2024) by prompting them as translators and by fine-tuning Gemma 2 9B on our corpus.
- **Retrieval-augmented generation (RAG):** the top-performing commercial LLMs (Claude Sonnet, Gemini 1.5 Pro, Gemini 2.0 Flash) are paired with a sentence-level fine-tuned LaBSE retriever that feeds the most similar Sanskrit–English pairs from the training set into the prompt, following the recipe of Ram et al. (2023).

All non-commercial models are decoded with greedy search and beam-search. Performance is reported on the held-out test split using chrF (Popović, 2015a), BLEURT (Sellam et al., 2020), and GEMBA (Kocmi and Federmann, 2023a); the latter is the metric that showed the strongest correlation with expert judgments in Section 5.2.

**Main Results:** We show the results in Table 2.[1] Among the commercial baselines, Google Trans-

[1]The results in this table were computed using an expanded training corpus that includes an additional augmentation set, increasing the size to a total of 477,236 sentence pairs for training. For licensing reasons, this augmentation material cannot be redistributed, and is therefore excluded from the publicly released version of the dataset.

| Model | chrF | BLEURT | GEMBA |
|---|---|---|---|
| *Commercial baselines* | | | |
| Google Translate | 28.28 | 47.42 | 38.52 |
| GPT4o-mini | 29.44 | 50.16 | 48.58 |
| GPT4o | 32.63 | 53.53 | 69.76 |
| Claude 3.5 Haiku | 31.34 | 52.45 | 64.01 |
| Claude 3.5 Sonnet | 33.42 | **55.28** | 76.97 |
| Claude 3.7 Sonnet | **34.58** | 54.74 | **77.50** |
| Gemini 1.5 Pro | 31.62 | 51.20 | 64.96 |
| Gemini 2.0 Flash | 34.24 | 53.87 | 75.89 |
| *Commercial + RAG* | | | |
| Claude 3.7 Sonnet | **38.83** | **57.54** | **82.13** |
| Gemini 1.5 Pro | 37.07 | 55.46 | 74.20 |
| Gemini 2.0 Flash | 38.80 | 56.69 | 79.92 |
| *Open model baselines* | | | |
| NLLB 600M | 15.04 | 37.17 | 6.11 |
| NLLB 3.3B | 16.90 | 37.33 | 5.10 |
| MADlad400-3b-mt | 12.89 | 33.04 | 4.00 |
| IndicTrans2 1B | 16.76 | 39.35 | 6.87 |
| Llama-3.1-8B-Instruct | 24.35 | 43.53 | 21.79 |
| Gemma2 9b it | **27.58** | 47.97 | 35.79 |
| Gemma3 12b it | 25.78 | 47.92 | **47.67** |
| Gemma3 27b it | 27.5 | **49.13** | 47.48 |
| *Open models fine-tuned* | | | |
| NLLB 600M w/o augment | 35.53 | 52.77 | 54.23 |
| NLLB 600M | 35.59 | 52.88 | 53.84 |
| NLLB 3.3B | 36.06 | 53.89 | 60.24 |
| Gemma2 9b | **38.36** | **55.10** | **72.15** |

Table 2: Translation performance across different models (chrF, BLEURT, GEMBA on the test set). GEMBA is computed with the Gemini 3.1 Flash Lite judge validated against expert judgments in Section 5.2. Best scores per section in **bold**. W/o augment: trained without the additional license-restricted augmentation data.

late underperforms all chat systems from OpenAI, Anthropic, and Google. Claude 3.7 Sonnet performs best in chrF and GEMBA, Claude 3.5 Sonnet in BLEURT. All commercial models that have in-context learning abilities (which excludes Google Translate) benefit significantly from retrieval augmentation; the effect is most strongly pronounced for Gemini 1.5 Pro (+9.2 GEMBA), while the best overall results are achieved by Claude 3.7 Sonnet with retrieval augmentation. Among the open model baselines, the decoder-only LLMs Llama-3.1-8B-Instruct and Gemma-2 9B significantly outperform the encoder-decoder models NLLB, MADLAD-400, and IndicTrans2, which without fine-tuning frequently generate nonsensical output; as NLLB shows, a higher parameter count does not improve baseline performance. The decoder-only LLMs are able to provide much better results, but they fall short compared to even the weakest commercial chat systems GPT-4o-mini and Claude 3.5 Haiku, while being somewhat comparable to Google Translate in chrF and BLEURT scores. All open models benefit significantly from full-parameter fine-tuning (last section of Table 2): NLLB 3.3B outperforms NLLB 600M on all metrics, and fine-tuned Gemma-2 9B outperforms the encoder-decoder models. Notably, NLLB 600M fine-tuned without the license-restricted augmentation data performs on par with the augmented version, indicating that the augmentation does not drive the observed trends.

**Performance by period and domain:** We break down GEMBA performance by source text and historical period in Table 3. A consistent difficulty hierarchy emerges across all system families: epic and narrative literature (*Bhagavadgītā*, *Rāmāyaṇa*) is translated most reliably, while Vedic texts (especially the *Ṛgveda*) and dense philosophical treatises (*Tattvasaṃgraha*) remain the hardest. Notably, retrieval augmentation helps most where zero-shot performance is weakest as is the case for Claude 3.7 Sonnet, which gains +12.4 GEMBA on the *Ṛgveda* and +13.9 on the *Tattvasaṃgraha*.

| Text | GT | G2.0F | C3.7 | +RAG | NLLB | G2-9b |
|---|---|---|---|---|---|---|
| *Vedic* | | | | | | |
| Ṛgveda | 14.3 | 60.9 | 64.8 | **77.2** | 61.7 | 63.4 |
| Śatapatha-Brāhmaṇa | 20.6 | 69.7 | 69.3 | **74.7** | 50.0 | 66.4 |
| *Epic* | | | | | | |
| Bhagavadgītā | 61.8 | **92.1** | 92.0 | 91.8 | 71.9 | 81.5 |
| Rāmāyaṇa (Itihāsa) | 55.4 | 84.2 | 85.2 | **86.4** | 65.4 | 81.0 |
| Manusmṛti | 40.5 | 83.8 | 85.8 | **91.3** | 78.7 | 77.4 |
| Buddhacarita | 43.1 | 81.4 | 84.1 | **85.3** | 58.4 | 77.8 |
| Vimalakīrtinirdeśa | 40.5 | 76.5 | 78.3 | **83.3** | 64.9 | 76.3 |
| *Classical* | | | | | | |
| Bhāgavata-Purāṇa | 37.2 | 74.1 | 74.6 | **76.7** | 46.0 | 60.1 |
| Skanda-Purāṇa | 58.7 | 84.5 | 86.7 | **88.1** | 68.6 | 79.2 |
| Yogavāsiṣṭha | 35.3 | 70.3 | 72.1 | **73.9** | 49.0 | 64.0 |
| Tattvasaṃgraha | 24.9 | 61.5 | 62.8 | **76.7** | 47.6 | 67.4 |
| *Medieval* | | | | | | |
| Kathāsaritsāgara | 44.5 | 82.5 | 84.5 | **86.6** | 66.8 | 78.4 |

Table 3: GEMBA scores on the test set by source text and historical period. GT: Google Translate; G2.0F: Gemini 2.0 Flash; C3.7: Claude 3.7 Sonnet; +RAG: Claude 3.7 Sonnet with retrieval augmentation; NLLB: NLLB 3.3B fine-tuned; G2-9b: Gemma2 9b fine-tuned. Best score per text in **bold**.

**Cross-dataset comparison:** To isolate the contribution of the dataset itself, we fine-tune NLLB-600M and Gemma2-9B with identical, compute-matched recipes on five training corpora: Itihāsa, Mitrasaṃgraha, its publicly released subset, Mitrasaṃgraha combined with Itihāsa, and the 244,367 highest-confidence pairs of the web-mined NLLB bitext (Table 4).

Three findings hold across both model families. First, on the multi-domain test set, training

on Mitrasaṃgraha clearly outperforms training on Itihāsa (NLLB-600M: +3.8 chrF, +7.0 GEMBA; Gemma2-9B: +3.1 chrF, +5.9 GEMBA), whereas on the epic-only Itihāsa test set the single-domain, single-translator Itihāsa corpus retains its expected advantage. Second, the released subset performs comparably to the augmented corpus (within one chrF point for NLLB-600M, slightly ahead for Gemma2-9B), so the gains do not depend on the license-restricted augmentation material. Third, fine-tuning on the web-mined bitext degrades both models below their own zero-shot performance (GEMBA 1.6–2.9): This shows that for classical Sanskrit, curated parallel data is necessary, not merely preferable. Combining both corpora gives the best overall balance, recovering most of the epic-domain gap at essentially no cost on the multi-domain test set. The weaker performance of the combined dataset on the epic-only test set is likely due to the fact that the diverse and to a large extent non-epic material in Mitrasaṃgraha drags the target domain away from the the specific style and preference of the single-translator Itihāsa corpus.

| Training corpus | n | Mitrasaṃgraha test | | Itihāsa test | |
|---|---|---|---|---|---|
| | | chrF | GEMBA | chrF | GEMBA |
| *NLLB-600M* | | | | | |
| Itihāsa | 69k | 25.01 | 24.98 | **28.68** | **55.40** |
| Mitrasaṃgraha (augm.) | 477k | **28.85** | 31.93 | 22.61 | 40.97 |
| Mitrasaṃgraha (rel.) | 391k | 27.94 | 28.17 | 22.91 | 37.40 |
| Mitrasaṃgraha + Itih. | 546k | 28.75 | **32.33** | 26.36 | 48.51 |
| NLLB web-mined | 244k | 10.84 | 2.85 | 9.57 | 2.49 |
| *Gemma2-9B* | | | | | |
| Itihāsa | 69k | 29.95 | 53.78 | **29.57** | **72.58** |
| Mitrasaṃgraha (augm.) | 477k | 31.33 | 57.08 | 22.65 | 60.85 |
| Mitrasaṃgraha (rel.) | 391k | **33.09** | 59.66 | 24.13 | 67.05 |
| Mitrasaṃgraha + Itih. | 546k | 33.05 | **59.89** | 26.71 | 70.17 |
| NLLB web-mined | 244k | 12.49 | 1.63 | 11.21 | 1.44 |

Table 4: Cross-dataset comparison. Both models are fine-tuned with identical, compute-matched recipes (NLLB: 2,000 steps × 512 effective batch; Gemma2: 500 × 256), differing only in the training corpus. *Augm.* is the corpus behind the fine-tuned models in Table 2; *rel.* is the publicly released subset without license-restricted material; *NLLB web-mined* is the 244,367 highest-confidence pairs of the mined bitext (Team et al., 2022). BLEURT is omitted for space and shows no consistent preference between the curated corpora. Best per column within each family in **bold**.

**Impact of decoding strategies:** We compare greedy decoding and beam search for two unfine-tuned baselines, NLLB-600M and Gemma2-9B-IT (Table 5). For NLLB-600M, beam search yields small but consistent gains across all three metrics; for Gemma2-9B-IT it produces a metric trade-off (higher GEMBA but slightly lower chrF/BLEURT), indicating that decoding shifts the balance between judge-based adequacy and reference similarity.

| Model | chrF | BLEURT | GEMBA |
|---|---|---|---|
| NLLB 600M (Greedy) | 15.04 | 37.17 | 6.11 |
| NLLB 600M (Beam Search) | **15.28** | **37.56** | **6.17** |
| Gemma2 9b it (Greedy) | **26.69** | **45.89** | 31.48 |
| Gemma2 9b it (Beam Search) | 26.15 | 45.32 | **32.12** |

Table 5: Ablation results for NLLB 600M and Gemma2 9b it with greedy decoding vs. beam search.

## 5 Analysis

### 5.1 Ablations with data cleaning methods

To study the influence of noisy samples on model performance, we conduct an ablation study with different data cleaning methods. Given the alignment results shown in Table 8, we can expect noise to be present in our dataset. We therefore evaluate two approaches for removing noisy datapoints: (1) a deterministic rule-based method combining fixed criteria such as string length ratios with MT evaluation scores using multiple translation models as references; and (2) an LLM-based cleaning method utilizing a specialized prompt pattern.

For the deterministic cleaning approach, we begin with 391,548 datapoints and first filter out samples whose input-output string length ratio falls outside a predetermined range. We then train a Gemma-2-based MT model on the remainder as an initial reference, and score each sample against its output with BLEU, chrF, and BERTScore, flagging roughly 20% of datapoints as potentially faulty. For these flagged sentences, we generate additional reference translations using both Google Translate and Claude 3.5 Sonnet. We then compute evaluation scores (BLEU, chrF, and BERTScore) between the flagged datapoints and these MT/LLM-generated references. Samples with scores below a certain threshold for all three metrics across all three models (our fine-tuned Gemma-2, Google Translate, and Claude 3.5 Sonnet) are removed. This process yields a cleaned dataset of 368,415 datapoints. While using a model trained on the same data to detect faulty samples introduces potential bias, we mitigate this by incorporating external models as additional voters in the pruning process. For the LLM-based approach, we process the complete set of 391,548 datapoints using Gemini 1.5 Pro, employing a specialized prompt pattern to clean and post-correct the alignments.

| Model | chrF | BLEURT | GEMBA |
|---|---|---|---|
| NLLB 600M ft (unclean) | 35.59 | **52.88** | 53.84 |
| NLLB 600M ft (clean) | **36.11** | 52.85 | **59.91** |
| G1.5 Pro Base | 31.62 | 51.20 | 64.96 |
| G1.5-Pro + Grammar | 32.42 | 51.52 | 67.05 |
| G1.5-Pro + RAG | **37.07** | 55.46 | **74.20** |
| G1.5-Pro + RAG + Gram | 34.57 | 54.01 | 73.50 |
| G1.5-Pro + RAG (clean) | 36.94 | **55.52** | 73.74 |
| G1.5-Pro + RAG (G-clean) | 35.81 | 54.83 | 72.65 |

Table 6: Results of the ablation study on different data cleaning strategies and augmentation via grammatical annotation.

We present the results in Table 6. The results show that our deterministic filtering leads to performance increases of +6.07 GEMBA and +0.52 chrF on the fine-tuned NLLB model, while BLEURT shows no improvement. For the RAG setup, the cleaned dataset does not perform significantly better on any metric. Adding grammatical analysis to the Gemini 1.5 Pro as a prompt augmentation technique yields slight performance increases. However, when combining grammatical analysis with the RAG setup, this significantly decreases performance compared to using the RAG setup alone. The dataset cleaned with Gemini 1.5 prompting visibly underperforms compared to both the uncleaned base dataset and the deterministically cleaned dataset across all metrics.

The overall patterns across these ablations are as follows. For encoder–decoder finetuning (NLLB), deterministic cleaning consistently improves chrF and GEMBA relative to the unfiltered baseline. For Gemini 1.5 Pro prompting, adding grammatical information helps in the no-retrieval setting, but when combined with retrieved sentence pairs it yields lower scores, suggesting that the additional grammatical scaffold becomes redundant or distracting once parallel evidence is provided. Finally, for the RAG setup, neither deterministic filtering nor LLM-based cleaning shows a consistent improvement across metrics; given the added cost/-complexity and mixed outcomes, we therefore treat data cleaning as optional rather than a default recommendation in this setting.

### 5.2 Human-Evaluation of Results

In order to assess the effectiveness of different automatic metrics for Sanskrit-to-English machine translation evaluation, we asked two expert annotators to independently assess machine-generated translations for 100 sentences. For each of the 100 sentences, we generated three translations with GPT-4o-mini, Claude 3.5 Haiku, and Claude 3.5 Sonnet. We then randomized the order of the translations, without disclosing the identity of the models to the annotators. We asked the annotators to determine for each sentence which of the three translations is the best, and which is the worst. All annotators either hold PhDs or are doctoral candidates specializing in Sanskrit literature. We conducted a one-hour annotation training session where the annotators together evaluated the machine translations of ten sentences, in order to ensure common evaluation standards. We present the results for the inter-annotator agreement on determining the best and worst translations in Table 7.

| **Measure** | **Best** | **Worst** | **Avg** |
|---|---|---|---|
| Pearson's $\rho$ | 0.549 | 0.554 | 0.552 |
| Spearman's $\rho$ | 0.544 | 0.551 | 0.548 |

Table 7: Inter-annotator correlation between Annotator A and Annotator B on "best" vs. "worst" translation rankings, with the average of both.

### 5.3 What does make Sanskrit-English translation task difficult?

Evaluating Sanskrit-English machine translation presents unique challenges that impact the suitability of automatic metrics. Standard n-gram-based metrics such as BLEU and chrF are limited by specific features of Sanskrit. There is the phenomenon of sandhi, where phonemes at word boundaries change and merge, creating ambiguity in word segmentation. Second, Sanskrit has a relatively free word order compared to English, leading to variations in sentence structure that metrics struggle to capture. Additionally, Sanskrit literature often employs complex compounding, figurative language, and compressed verses, making direct surface-level comparison difficult. Finally, many core semantic concepts in philosophical or religious texts lack direct English equivalents, leading humans to adopt different valid approaches. All these factors lead to significant stylistic and structural variation even among high-quality human reference translations.

To quantify the extent of this diversity in translation and its potential impact on evaluation, we conducted a focused analysis. We manually collected seven different high-quality human translations of 100 verses of the *Bhagavad-gītā*. We then measured corpus-level BLEU, chrF, and reference-

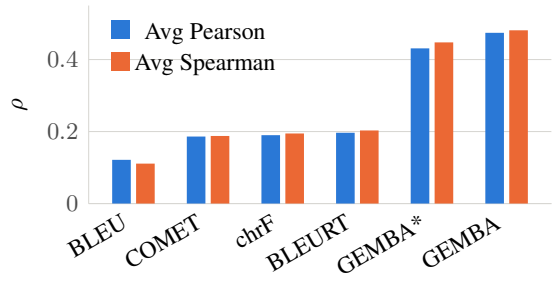

Figure 3: Average Pearson (blue) and Spearman (orange) correlations of automatic metrics vs. human judgments. GEMBA* is the reference-free implementation of GEMBA (Kocmi and Federmann, 2023b), while GEMBA is reference-based.

based BLEURT scores for all 42 possible directed pairwise comparisons among these seven human translations. The average pairwise BLEU score was 25.2, and the average pairwise chrF score was 44.0. This highlights the considerable surface-level divergence even among expert human renditions, showing that multiple perfectly fine English translations can substantially disagree when it comes to surface characteristics such as wording and structure. We investigate how different metrics correlate with expert human judgment in light of these challenges.

In Figure 3 we show how the automatic metrics BLEU, chrF, COMET, BLEURT, and GEMBA perform against the human annotations. BLEU (Papineni et al., 2002) and chrF (Popović, 2015b) capture word n-gram precision/recall and character-level overlap and are calculated on document level. BLEURT (Sellam et al., 2020) ("BLEURT-20" checkpoint) and COMET (Rei et al., 2022) (`wmt22-comet-da`) are learned metrics built on BERT and XLM-R respectively, both widely used in the WMT campaigns; we average their scores across samples. GEMBA (Kocmi and Federmann, 2023b) uses LLMs to rate translation quality; we implement it with the Gemini 3.1 Flash Lite API (August 2026). GEMBA denotes the reference-based variant (source, reference, and candidate) and GEMBA* the reference-free variant (source and candidate only).

Our results show weak correlations for the string-based metrics BLEU and chrF, which is in line with previous research for high-resource languages (Kocmi et al., 2024), which established that these metrics are not very suitable to compare machine translation quality across different model types. Strikingly, the learned reference-based metrics BLEURT and COMET perform no better than chrF in our setting, all clustering around correlations of 0.19–0.20. We attribute this to the limited domain-specific coverage of the underlying multilingual encoders and the large legitimate surface variation between English renderings discussed above. Only the LLM-based judges depart from this cluster: Gemini-3.1-flash-lite based GEMBA and the reference-free GEMBA* reach correlations of 0.47–0.48 and 0.43–0.45, respectively. The strong performance of the reference-free GEMBA* is encouraging for domains where reference translations are scarce. In summary, the conventional metric suite, string-based and learned reference-based alike, struggle to track expert judgment for Sanskrit; we therefore report GEMBA results along chrF and BLEURT in our experiments.

Two caveats bound these conclusions. First, LLM judges are known to favour outputs from their own model family, and our judge is Gemini-based. The three systems in the annotation study (GPT-4o-mini, Claude 3.5 Haiku, Claude 3.5 Sonnet) include no Gemini system, so the correlations reported here are not themselves affected; the concern applies to the Gemini rows of Table 2, which should be read with that in mind. A systematic cross-judge study of self-preference bias is left to future work. Second, the annotation study covers 100 sentences and three systems judged by two annotators; its correlations are best read against the agreement between the annotators themselves ($\rho \approx 0.55$, Table 7), which gives a rough sense of the noise floor of the task. The study is exploratory and is intended as a starting point for further research on metric evaluation for Sanskrit–English translation.

## 6 Conclusion

We introduced Mitrasaṃgraha, the largest publicly available Sanskrit-English parallel corpus with 391,548 bitext pairs — over four times larger than Itihāsa — spanning the Vedic, Epic, Classical, and Medieval periods, with manually verified validation and test sets of roughly 5,500 pairs each, aligned using BertAlign with a fine-tuned LaBSE embedding model. Our metric evaluation showed that LLM-based judges correlate substantially with expert assessments, while string-based and learned neural metrics alike struggle with the domain of Sanskrit to English machine translation. Our benchmarks showed that fine-tuning open mod-

els on Mitrasaṃgraha yields consistent gains, that retrieval from it enhances commercial models, and that in a controlled comparison it outperforms both Itihāsa and web-mined bitext. Mitrasaṃgraha thus provides a foundational resource for Sanskrit NLP and digital humanities.

## Limitations

Several limitations should be acknowledged. First, the creation of Mitrasaṃgraha faced challenges due to frequent mismatches in sentence segmentation between Sanskrit sources and their English translations, leading to complex one-to-many or many-to-one alignments. While our chosen aligner, BertAlign, is designed for such scenarios, these alignments inherently carry a higher risk of error, potentially introducing noise. Additionally, as large portions of the dataset were sourced from OCR-processed texts, persistent OCR mistakes are likely present despite preprocessing. Second, while Mitrasaṃgraha provides extensive parallel data, it does not by itself solve deep semantic challenges in Sanskrit MT, such as multi-layered metaphors or complex philosophical concepts; models trained on it may still fail to capture these phenomena. Third, our cross-dataset comparison (Table 4) uses a compute-matched but deliberately moderate training budget; the absolute scores of these controlled arms are therefore lower than those of the fully trained models in Table 2, and the comparison should be read as a relative assessment of the training corpora rather than as best-achievable performance. Finally, although Mitrasaṃgraha significantly expands domain and temporal coverage, certain specialized domains within Sanskrit literature, such as technical treatises on astronomy or mathematics, remain entirely missing or are severely underrepresented. Addressing these gaps will require dedicated future data collection and curation efforts.

## Acknowledgements

We thank all contributors who supported our data collection efforts, particularly in data scraping and cleaning, including Harsh Gupta (AI Engineer, PredIQt), Abdul Nasir (B.Tech, IIT Kanpur), Yashwant Narsupalli (B.Tech, IIT Kharagpur), Chinmaya H S (Cambridge Institute of Technology, Bengaluru), and Shrey Kamoji and Bibhudutta Pati (IIT Kharagpur); and as interns at the Berkeley AI Research Lab, UC Berkeley: Kush Bhardwaj, Kayshav Bhardwaj, Pragun Seth, Om Chandran, Aarnav Srivastava, Rohan Sarakinti, Varun Rao, Devika Gopakumar, Miranda Zhu, Siya Mehta, Sanjana Srinivasan, Sai Srinivasan, Rhea Mehta, Raj Mehta, Daksh Parikh, and Laksh Patel.

# A The Sanskrit Language

Sanskrit is a classical language of the Indo-Aryan branch of the Indo-European languages. It was widely used as a lingua franca by religious, scientific and literary communities of ancient India. Since the second half of the first millennium BCE, Sanskrit was used for the production of Buddhist literature. Early Buddhist works in Sanskrit show a strong influence of Middle Indian dialects, which has decreased over time (Edgerton, 1985). Sanskrit relies heavily on morphology to indicate grammatical relations and has a relatively free word order. It follows the nominative-accusative alignment, has a complex verbal system and a rich nominal declension. Nominal compounds are frequently found. Another special characteristic and challenge in the computational processing of Sanskrit is the phenomenon of sandhi, by which the contact phonemes of neighboring word tokens are changed and merged, and which creates unseparated strings spanning multiple tokens (Hellwig and Nehrdich, 2018).

# B Detailed Sentence Alignment Evaluation

## B.1 Evaluation Methodology

Sentence alignment is considered largely solved for high-resource language pairs with matching punctuation and clean input, where even simple length-based algorithms perform reliably (Gale and Church, 1993; Brown et al., 1991). Sanskrit<>English, however, poses far greater challenges. Sanskrit editions and their English translations frequently diverge in sentence boundaries, omit or reorder passages, and the English side is often cluttered with footnotes, headers, and page numbers that survive OCR but have no Sanskrit counterpart. Divergent punctuation conventions produce many one-to-many or many-to-one mappings, and Sanskrit's pervasive sandhi and prolific compounding weaken the surface lexical cues that many alignment approaches implicitly benefit from.

Following Lamraoui and Langlais (2013), we report two complementary scores: the alignment-level F-measure ($F_A$), which counts a link as correct only when the entire bisegment exactly matches the gold reference, and the sentence-level F-measure ($F_S$), which checks whether the correct sentences are paired irrespective of how they are grouped into bisegments. Using both metrics captures performance under a strict criterion that penalizes many-to-many links ($F_A$) and a more permissive view that tolerates them ($F_S$). Because many-to-many alignments can harm $F_A$ while leaving $F_S$ relatively unaffected, both measures are necessary to characterize alignment quality.

We begin with manually aligned gold pairs and synthetically corrupt them to mimic realistic noise. Specifically, we (i) randomly split some source or target segments on punctuation, creating one-to-many / many-to-one cases, and (ii) inject random extraneous English sentences (footnotes, headers, etc.). This stresses the aligners' ability to match uneven sentence counts while discarding irrelevant material.

We present the results of the alignment benchmark in Table 8. Across datasets, the embedding-based aligners VECALIGN and BERTALIGN perform strongly under the sentence-level metric $F_S$, indicating that they typically identify the correct sentence pairings even when boundaries are noisy. BERTALIGN generally outperforms VECALIGN in both $F_A$ and $F_S$, suggesting it is the more reli-

| | VecAlign | | BertAlign | |
|---|---|---|---|---|
| Dataset | $F_A$ | $F_S$ | $F_A$ | $F_S$ |
| Manusmṛti | 60.64 | 82.67 | **82.88** | **97.12** |
| Tattvasaṃgraha | 15.11 | 63.55 | **30.00** | **70.15** |
| Buddhacarita | 63.07 | 79.55 | **85.50** | 74.62 |

Table 8: Comparison of VecAlign and BertAlign scores across datasets.

able choice for Sanskrit–English alignment in this setting.

Even BERTALIGN attains relatively modest $F_A$ scores, which is expected given frequent many-to-many correspondences and boundary divergence between editions and translations. For downstream use, the $F_S$ scores are more indicative; they range from 70.15 to 97.12, suggesting accuracy sufficient for many machine learning applications. At the same time, the lower-performing domains (e.g., *Tattvasaṃgraha* and *Buddhacarita*) highlight that alignment quality remains uneven and warrants further attention in future work.

# LAND: Learning an Adaptive Number of Draws for Bayesian Best-of-N Selection

**Koen Oostermeijer**[*†] **and Teryn Jones**[*]
Aleph Alpha Research

[*]Equal contribution
[†]Corresponding author: koen.oostermeijer@aleph-alpha-research.com

## Abstract

Best-of-N decoding improves generation quality by sampling multiple candidates and selecting the best, but it allocates equal compute to sources regardless of how much they benefit from additional sampling: the expected benefit is small for sources with low-variance score distributions and potentially much larger for those with high-variance distributions. To address this shortcoming, we propose LAND (Learning an Adaptive Number of Draws), which dynamically allocates samples according to their posterior-predictive marginal value. LAND learns a discrete empirical mixture of source-conditioned score distributions from calibration data, updates its belief about a source as completion scores are observed, and stops sampling when the expected improvement of another draw falls below a shared compute price. Across machine-translation experiments with multiple models and language pairs, LAND achieves better MetricX scores than fixed best-of-N at matched average compute. Conversely, at matched translation quality, LAND requires approximately 20-40% fewer candidate generations. Adaptive allocation therefore provides a simple way to retain the benefits of best-of-N while substantially improving its compute efficiency.

## 1 Introduction

Model-generated data have become an increasingly important component of the training and fine-tuning of large language models (LLMs) (Long et al., 2024; Wang et al., 2023). A larger teacher model can generate training data for a smaller model, thereby transferring some of its capabilities through knowledge distillation. This approach has a long history in machine translation (MT), where sequence-level knowledge distillation uses translations generated by a teacher model as targets for a student model (Kim and Rush, 2016).

Historically, machine translation systems were trained primarily on naturally occurring parallel data collected from multilingual sources and subsequently filtered and aligned (Tiedemann, 2012). Synthetic data initially served mainly as a supplement to these corpora, most notably through back-translation of monolingual source texts (Sennrich et al., 2016; Edunov et al., 2018). Over time, however, the balance has shifted: as the quality of machine-translated data outpaced that of web-crawled corpora (Finkelstein et al., 2024), their share of the training data used by modern MT systems now constitutes an increasingly large fraction, in some cases completely replacing natural data (Finkelstein et al., 2026). As reliance on generated translations grows, selecting high-quality candidates becomes an increasingly important part of the data-generation pipeline.

One simple way to improve the quality of generated translations is to sample multiple candidates and retain the candidate with the highest score according to some quality metric, a technique referred to as *best-of-$N$* sampling. Previous work has shown that filtering data for quality-estimation metrics can result in improved downstream performance (Peter et al., 2023).

However, conventional best-of-N generates the same number of candidates for every source sentence. This allocation implicitly assumes that an additional sample is equally valuable for all source sentences. In practice, the distributions of candidate scores can differ substantially between source sentences. As illustrated in Figure 1, some intrinsically simple sentences consistently produce high-scoring translations, such that additional sampling offers little added improvement, while others produce more variable candidates and may benefit considerably from further sampling. Given a collection of source sentences and a fixed generation budget, the relevant question is therefore not only how many candidates to

*Proceedings of the Eleventh Conference on Machine Translation*, pages 520–529
October 28-29, 2026 ©2026 Association for Computational Linguistics

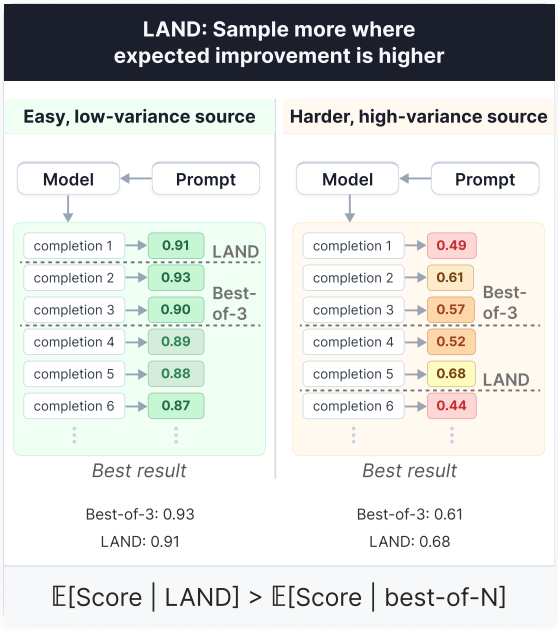

Figure 1: Fixed best-of-N always generates the same number of candidates for every source. However, higher overall scores can be achieved by allocating less compute to sources whose candidate scores are tightly concentrated and more compute to sources with higher-variance score distributions, where additional draws offer greater potential for improvement.

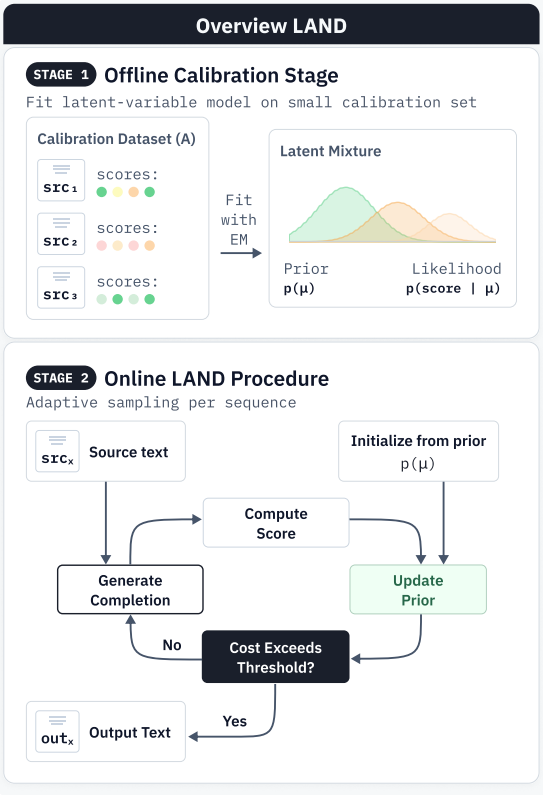

Figure 2: During calibration, LAND fits a discrete empirical mixture and calibrates a global compute price. At deployment, candidates are generated and scored sequentially, the posterior over source types is updated, and sampling continues while the expected improvement of another draw exceeds the compute price.

generate, but also where additional candidates are most valuable. This motivates our central research question: how should a fixed generation budget be allocated across source sentences so that additional candidates are generated where they offer the greatest expected marginal improvement?

We introduce **LAND** (**L**earning an **A**daptive **N**umber of **D**raws), an adaptive procedure that allocates generation compute according to the expected marginal improvement of additional candidates for each source sentence. A high-level overview of LAND is shown in Figure 2. LAND is related in spirit to Weitzman's Pandora's-box rule (Weitzman, 1978), which uses reservation values to balance the potential benefit of further search against its cost. Unlike the classical setting, however, the source-specific score distributions in our problem are unknown and each source sentence may be sampled repeatedly. LAND therefore updates a posterior over the score distribution after every observed candidate and adjusts its stopping threshold on the fly. To avoid imposing a restrictive parametric form, we estimate these distributions using a discrete empirical model constructed from observed scores.

In summary, our contributions are as follows:

- We formulate best-of-N selection as a compute-allocation problem in which the number of candidates may vary across source sentences under a shared average budget.
- We derive an oracle allocation rule that relates the decision to generate another candidate to its expected marginal improvement.
- We introduce LAND, a posterior-adaptive procedure that estimates this improvement online using a discrete empirical model of source-conditioned score distributions.
- We evaluate LAND against fixed-allocation and adaptive baselines for machine translation under matched average generation budgets.

## 2 Related Work

### 2.1 Quality Filtering and Selection in Machine Translation

Quality-estimation metrics have been used both to select translation hypotheses and to filter training data. Fernandes et al. (2022) apply reference-free metrics to N-best reranking and minimum Bayes risk decoding, while Peter et al. (2023) use them to retain higher-quality parallel sentence pairs. For synthetic data, Xu et al. (2022) show that the usefulness of back-translated examples depends on both translation quality and example importance. Complementing quality-based filtering, Kocmi et al. (2025) prioritize difficult training examples. Related work also uses quality estimates to allocate computation: Cheng et al. (2025) selectively evaluate candidates from a fixed list, and Farinhas et al. (2025) defer low-quality translations to a larger model.

### 2.2 Bayesian Stopping and Adaptive Allocation

LAND shares similarities with Weitzman's Pandora's-box problem, in which costly alternatives with known reward distributions are inspected until further search is no longer worthwhile (Weitzman, 1978). This framework has subsequently been applied to settings such as cost-aware Bayesian optimization and adaptive LLM sampling (Xie et al., 2024). Related optimal-stopping approaches have also been proposed for LLM inference. Wan et al. (2025) introduce BEACON, which models each prompt's reward distribution as Gaussian and applies a Bayesian finite-horizon stopping rule, whereas Kalayci et al. (2025) learn an unknown Weitzman threshold using upper confidence bounds.

More broadly, LAND is related to Bayesian adaptive-allocation methods such as Thompson sampling (William, 1933), which use posterior uncertainty to allocate observations sequentially rather than committing the same sampling budget to every alternative.

AdaBoN (Raman et al., 2025) also studies adaptive Best-of-$N$ allocation, but is designed for batched allocation with relatively large exploration budgets. Since LAND targets sequential stopping in a substantially lower-budget regime, we consider the methods complementary rather than directly comparable.

LAND differs from these approaches in both how it models uncertainty and how it allocates compute. It learns a discrete empirical mixture of source-conditioned score distributions and updates a posterior over source types as candidates are observed. Rather than treating each source independently with a fixed sampling cost, LAND uses a shared compute price to allocate a fixed average generation budget toward sources with the greatest posterior-predictive marginal value of additional draws.

## 3 Problem Formulation

We consider a set of source texts and a fixed compute budget for generating completions. For each source text, an LLM generates one or more candidates, from which the highest-scoring completion is selected. Metrics that assign lower scores to better candidates are transformed so that higher values consistently correspond to better completions. The budget is specified by a target expected number of completions per source text, $N$, although in practice we allow the realized average to differ slightly due to finite-sample effects.

Our goal is to determine how to allocate the available compute across source texts so as to maximize the average score of the selected completions.

Applying the scoring function to the distribution of generated candidates induces a corresponding distribution over quality scores. Each source text has a latent mean score $\mu$, defined as the expected score of a completion generated for that source text. Across source texts, these means follow the distribution

$$\mu \sim \mathcal{D}_{\mathrm{d}}, \tag{1}$$

whose expectation value $\mathbb{E}[\mu]$ is the score associated with the best-of-1 baseline, i.e. the average score obtained when exactly one completion is generated per source text.

Conditional on $\mu$, the score $X$ of an individual completion follows a distribution

$$X \sim \mathcal{D}_{\mathrm{c}}\left(\cdot \,|\, \mu, \sigma^2(\mu)\right), \tag{2}$$

where $\sigma^2(\mu)$ captures variation among completions generated for the same source text, which may depend on the latent mean $\mu$.

## 4 Budget Allocation

Rather than generating a fixed number of candidates for every source text, i.e. best-of-N,

our strategy is to sample until the score exceeds a source-specific threshold. These thresholds are optimized to maximize the average selected score subject to an expected sampling budget of $N$ completions per source text.

In the following we will derive an allocation rule assuming that $\mu$ is known, which is not the case in practice, as this is a latent variable; we relax this assumption in the following section.

For a source text with mean score $\mu$, let $\{X_1, X_2, \ldots\}$ be independent draws from the conditional score distribution $\mathcal{D}_{\mathrm{c}}(\cdot \mid \mu)$, with probability density function $f_\mu$ and cumulative distribution function $F_\mu$. We define the stopping time $K$ as the number of samples it takes to exceed the threshold $\lambda(\mu)$. Since each draw has a probability of $1 - F_\mu(\lambda(\mu))$ to exceed the threshold, $K$ follows a geometric distribution with expectation value

$$\mathbb{E}[K \mid \mu] = \frac{1}{1 - F_\mu(\lambda(\mu))}. \tag{3}$$

Because the sampling process is halted when the stopping condition is met, the final score $X_K$ is also the one corresponding to the selected completion. Its expected value is the threshold plus the expected overshoot:

$$\begin{aligned} \mathbb{E}[X_K \mid \mu] &= \lambda + \mathbb{E}\left[X - \lambda | X > \lambda, \mu\right] && (4) \\ &= \mathbb{E}\left[X | X > \lambda, \mu\right]. && (5) \end{aligned}$$

The optimal threshold function maximizes the expected selected score across source texts, subject to an average sampling budget of $N$:

$$\begin{aligned} &\max_{\lambda(\cdot)} \mathbb{E}_\mu \left[\mathbb{E}\left[X | X > \lambda(\mu), \mu\right]\right] \\ &\text{subject to } \mathbb{E}_\mu \left[\frac{1}{1 - F_\mu(\lambda(\mu))}\right] = N. \end{aligned} \tag{6}$$

As derived in Appendix A, the optimal threshold satisfies

$$H_\mu(\lambda) \equiv \mathbb{E}\left[\left(X - \lambda(\mu)\right)_+ \middle| \mu\right] = \Lambda, \tag{7}$$

where $(z)_+ \equiv \max(z, 0)$ denotes the positive part of $z$. Thus, the left-hand side is the expected improvement of one additional draw over the current threshold. The global constant $\Lambda$ is chosen so that the average-budget constraint holds. The optimal policy therefore equalizes the expected marginal improvement across source texts.

## 5 Posterior-Adaptive Allocation

The optimal allocation derived above assumes access to the latent source-specific mean $\mu$. In practice, $\mu$ is unknown and must be inferred from the completion scores observed during sampling. We therefore maintain a posterior distribution over $\mu$ and update the stopping rule after each generated completion.

Let $\mathcal{X}_t \equiv \{X_1, \ldots, X_t\}$ denote the scores observed after $t$ draws for a given source text, and let

$$q_t(\mu) \equiv p(\mu \mid \mathcal{X}_t) \tag{8}$$

be the corresponding posterior over its latent mean. Before observing any completions, this posterior is initialized as the population-level prior from Equation 1,

$$q_0(\mu) = P_{\mathrm{d}}(\mu). \tag{9}$$

Then, after observing a new score $X_{t+1}$, Bayes' rule gives

$$q_{t+1}(\mu) = \frac{f_\mu(X_{t+1}) q_t(\mu)}{\int \mathrm{d}\mu' \, f_{\mu'}(X_{t+1}) q_t(\mu')} \tag{10}$$

where $f_\mu$ is the conditional score density for a source text with mean $\mu$.

The expected-improvement function is averaged over this posterior:

$$\begin{aligned} \widehat{H}_t(\lambda) &\equiv \int \mathrm{d}\mu \, q_t(\mu) H_\mu(\lambda) && (11) \\ &= \mathbb{E}\left[(X_{t+1} - \lambda)_+ | \, \mathcal{X}_t\right]. && (12) \end{aligned}$$

Thus, $\widehat{H}_t(\lambda)$ is the expected improvement of one additional draw over a current score $\lambda$.

Let $B_t \equiv \max_{1 \le i \le t} X_i$ be the best score observed so far. The optimal policy is to continue sampling whenever it exceeds the global compute cost $\Lambda$:

$$\widehat{H}_t(B_t) > \Lambda. \tag{13}$$

Equivalently, we may define an adaptive threshold $\lambda_t$ by

$$\widehat{H}_t(\lambda_t) = \Lambda. \tag{14}$$

The procedure continues while $B_t < \lambda_t$. Unlike the previous threshold $\lambda(\mu)$, the adaptive threshold $\lambda_t$ changes as new scores are observed. Each completion updates both the best score $B_t$ and the posterior belief about the source-specific score distribution, allowing the stopping decision to adapt online.

## 6 Practical Implementation

The practical implementation of LAND starts by estimating the score distributions using a small calibration set. We first rescale all scores to the interval $[0, 1]$, with larger values denoting better completions. These scores are then partitioned into $J$ cells, with each cell $j$ assigned a representative value $v_j$. The boundaries of these cells are initialized using the quantiles of these calibration scores, which provides greater resolution in densely populated regions of the score distribution.

We model variation across source texts using a mixture of $I$ latent source distributions. We do not assume that source variation is fundamentally discrete. Rather, this is a finite approximation to continuous population heterogeneity while reducing posterior updates and expected-improvement calculations to finite sums. Each type $i$ has prior probability

$$\pi_i = \Pr(z = i), \tag{15}$$

and a categorical distribution over score cells,

$$p_{ij} = \Pr(X \text{ falls in cell } j | z = i). \tag{16}$$

Here, $z$ denotes the latent source type and $X$ denotes the score of a generated completion. This discretized distribution greatly simplifies calculations and avoids imposing a restrictive parametric form on the source-conditioned score distributions. In particular, we found that parametric families such as (truncated) Gaussian or Beta distributions often impose inaccurate assumptions about tail behavior, which can substantially distort LAND's cost allocation policy.

Since the latent source types are not observed, we fit the mixture using expectation-maximization (EM). Suppose the calibration set contains $L$ source texts. For source $\ell$, let $n_{\ell j}$ denote the number of observed completion scores that fall in cell $j$, and let

$$n_\ell = \sum_{j=1}^{J} n_{\ell j}. \tag{17}$$

EM estimates the model parameters by maximizing the marginal log-likelihood of the observed data:

$$\mathcal{L} = \sum_{\ell=1}^{L} \log \left[ \sum_{i=1}^{I} \pi_i \prod_{j=1}^{J} p_{ij}^{n_{\ell j}} \right]. \tag{18}$$

After fitting the mixture, we use it to initialize the stopping thresholds: For a source of latent type $i$, the expected improvement from one additional draw over a current best score $b$ is computed as

$$H_i(b) = \sum_{j=1}^{J} p_{ij}(v_j - b)_+. \tag{19}$$

During sampling, each component-specific expected improvement is weighted by the posterior probability that the source belongs to the corresponding latent type. These weights are initialized as the population mixture weights, $q_{0,i} = \pi_i$. After observing a completion score $x_{t+1}$ in cell $c(x_{t+1})$, the posterior is updated as

$$q_{t+1,i} = \frac{q_{t,i} p_{i,c(x_{t+1})}^{\tau}}{\sum_{k=1}^{I} q_{t,k} p_{k,c(x_{t+1})}^{\tau}}, \tag{20}$$

where $\tau \in (0, 1]$ is a likelihood-tempering parameter. The standard Bayesian update is recovered when $\tau = 1$. We use tempering to prevent the posterior from becoming overly concentrated after only a small number of observations.

Let $B_t$ denote the best score observed after $t$ draws. The posterior-predictive expected improvement of one additional draw is

$$\widehat{H}_t(B_t) = \sum_{i=1}^{I} q_{t,i} H_i(B_t). \tag{21}$$

LAND continues sampling whenever this expected improvement exceeds the global compute price $\Lambda$. In addition, we impose a maximum number of draws per source text of $K_{\max}$ to bound the worst-case allocation.

### 6.1 Calibrating $\Lambda$

The global cost limit $\Lambda$ is calibrated by replaying the complete posterior-adaptive policy on a held-out set of calibration trajectories. For a candidate value of $\Lambda$, each trajectory is processed using the same posterior updates, running maximum draw rule, and sampling cap used at deployment. If $K_\ell(\Lambda)$ denotes the resulting number of draws for replay source $\ell$, the estimated average compute is set to equal $N$:

$$\frac{1}{L_{\text{replay}}} \sum_{\ell=1}^{L_{\text{replay}}} K_\ell(\Lambda) \approx N. \tag{22}$$

This is to ensure the policy captures posterior transitions and stopping behavior as closely as possible.

Finally, to correct for any residual calibration error or potential distribution shift, we update $\Lambda$ after each batch of completed source texts. Let $\overline{K}_m$ be the average number of draws in batch $m$. We apply the log-space update

$$\log \Lambda_{m+1} = \log \Lambda_m + \eta \frac{\overline{K}_m - N}{N}. \quad (23)$$

When the realized number of completions exceeds the target budget, the update increases $\Lambda$ and makes further sampling less likely, and vice versa when the realized number falls below the target.

### 6.2 Complete LAND Procedure

The preceding subsections describe the individual components of LAND: fitting the discrete empirical mixture, updating the posterior over latent source types, estimating the posterior-predictive value of another draw, and calibrating the global compute price. The procedure is sequential: once LAND stops sampling a source and moves to the next source, that source is not revisited. Algorithm 1 summarizes how these components are combined into the complete procedure. The mixture model and initial value of $\Lambda$ are estimated during calibration. At deployment, each newly observed completion updates both the current best score and the posterior over source types, and sampling continues only while the posterior-predictive expected improvement justifies its compute cost, subject to the maximum-draw constraint.

**Algorithm 1** LAND with a discrete empirical mixture

**Require:** Mixture-fit trajectories $\mathcal{C}_{\text{fit}}$, replay trajectories $\mathcal{C}_{\text{replay}}$, target budget $N$, tempering $\tau$, cap $K_{\max}$

Construct score cells and representatives $\{v_j\}_{j=1}^{J}$
Fit $\{\pi_i, p_{ij}\}$ on $\mathcal{C}_{\text{fit}}$ using EM
Compute $H_i(b) = \sum_j p_{ij}(v_j - b)_+$
Calibrate $\Lambda$ on $\mathcal{C}_{\text{replay}}$
**for** each deployment source $s$ **do**
    $q_i \leftarrow \pi_i$, $B \leftarrow -\infty$, $K \leftarrow 0$
    **repeat**
        Generate and score one completion $x$
        $K \leftarrow K + 1$, $B \leftarrow \max(B, x)$
        $q_i \leftarrow q_i p_{i,c(x)}^{\tau} / \sum_k q_k p_{k,c(x)}^{\tau}$
    **until** $K \geq K_{\max}$ or $\sum_i q_i H_i(B) \leq \Lambda$
    Return the highest-scoring observed completion
    Add $K$ to the current update batch
    **if** the update batch is full **then**
        Update $\Lambda$ using the batched log-space rule
    **end if**
**end for**

## 7 Results

We evaluate LAND on source sentences drawn from the OPUS parallel corpus. (Tiedemann, 2012) We use only the source side of each selected sentence pair and generate new translations with the evaluated model; the original target sentences are not used as generation targets. Using Gemma4 31B, (Gemma Team, 2026) we consider four translation directions: Ukrainian→German, Spanish→English, Dutch→Hungarian, and Turkish→Russian. Translation quality is evaluated with reference-free MetricX[1] (Juraska et al., 2024). For each translation direction and target budget $N$, we separately tune the sampling cap $K_{\max}$ and tempering parameter $\tau$ using the corresponding mixture-fit and replay trajectories. We evaluate average sampling budgets up to $N = 32$ and compare LAND against fixed best-of-$N$ selection at each budget. Using MetricX for both selection and evaluation is intentional: LAND addresses how efficiently a given filtering objective can be optimized, rather than whether that objective improves downstream model training. The utility of QE-based filtering for MT data has been established independently by prior work (Peter et al., 2023).

Figure 3 shows the normalized MetricX score as a function of the sampling budget, averaged across the four Gemma4 language pairs. LAND consistently achieves higher translation quality than fixed best-of-N at the same number of draws. Equivalently, LAND reaches the same MetricX score with substantially fewer candidate generations. At the operating points highlighted in the figure, LAND matches the performance of fixed best-of-N while using approximately 20-30% fewer draws. Although the relative savings are largest at lower budgets, they remain substantial throughout the evaluated range.

[1] https://huggingface.co/google/metricx-24-hybrid-xxl-v2p6-bfloat16

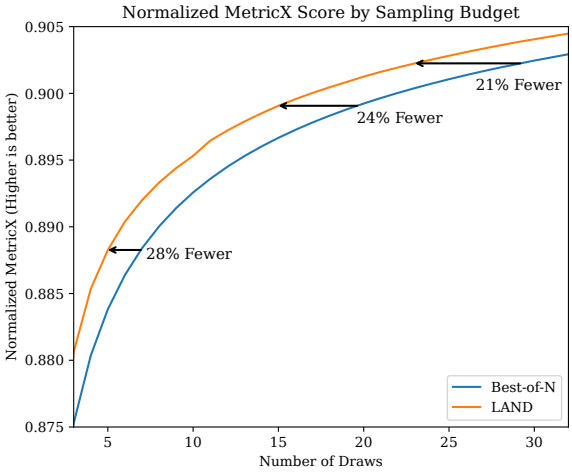

Figure 3: Normalized MetricX score as a function of the number of draws, averaged over the four Gemma4 31B translation directions. LAND reaches the same translation quality as fixed best-of-N using approximately 20-30% fewer draws at the highlighted operating points.

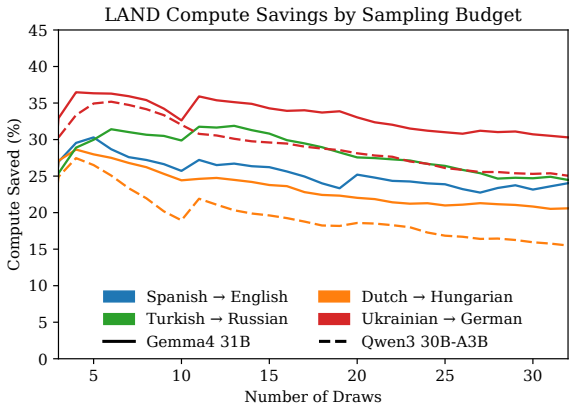

Figure 4: Candidate-generation savings of LAND relative to fixed best-of-N at matched MetricX performance. LAND reduces the number of required draws across all evaluated language pairs and sampling budgets.

Figure 4 reports the candidate-generation savings separately for each translation direction. In addition to the four Gemma4 31B experiments, we evaluate Ukrainian→German and Dutch→Hungarian using Qwen3 30B-A3B (Qwen Team, 2025). The savings are computed relative to fixed best-of-N at matched MetricX performance. Across models, language pairs, and sampling budgets, LAND reduces the required number of completions by approximately 20-40%.

The magnitude of the savings varies across translation directions. Ukrainian→German exhibits the largest and most consistent reductions in compute, while Dutch→Hungarian generally shows smaller gains, especially for Qwen3 30B-A3B at larger budgets. Nevertheless, LAND provides positive candidate-generation savings across all evaluated settings.

LAND targets an average budget of $N$ rather than enforcing this exactly. The adaptive compute-price update nevertheless keeps the realized budget very close to its target: across the six evaluated model-language settings, the mean absolute deviation from $N$ ranges from 0.01 to 0.04 draws. Across repeated runs on the same data with different random orderings, the standard deviation of the resulting draw savings is approximately 0.8-1.5 percentage points across the evaluated settings.

Overall, these results show that allocating the same number of candidates to every source sentence is inefficient. By directing additional samples toward source sentences for which they have greater posterior-predictive value, LAND preserves the quality gains of best-of-N while substantially reducing generation cost.

### 7.1 Comparison to BEACON

Finally, we compare LAND against BEACON (Wan et al., 2025), a Bayesian adaptive-sampling method that models the reward distribution for each source as Gaussian and updates its parameters online. In our experiments, BEACON underperforms fixed best-of-N, requiring more compute to reach the same average MetricX score for all sampling budgets, language pairs, and generation models considered. This seems to indicate that its stopping rule is not well suited to the score distributions encountered in this setting. One possible explanation is the Gaussian modeling assumption: the source-conditioned MetricX distributions can exhibit shapes that are poorly captured by a single parametric distribution. LAND's performance similarly suffered under this modeling assumption. A second possible factor is that BEACON must infer the reward distribution of a new source from the small number of samples observed for that source, while LAND can exploit population-level structure learned across calibration sources. However, we have not isolated the contribution of these differences, and a more detailed investigation would be required to determine the cause of BEACON's underperformance in this setting.

## 8 Conclusion and Limitations

We introduced LAND, an adaptive alternative to fixed best-of-N sampling that allocates generation compute according to the posterior-predictive value of additional candidates. Rather than committing to the same number of draws for every source, LAND uses observed completion scores to update its belief about the source-specific score distribution and continues sampling only when the expected improvement of another draw exceeds a global compute price. A discrete empirical mixture provides a flexible approximation to the population of source-conditioned score distributions, while replay-based calibration allows the resulting policy to satisfy a prescribed average generation budget.

Across the machine-translation settings considered in this work, LAND consistently improves the compute-quality trade-off relative to fixed best-of-$N$. At matched average compute, adaptive allocation yields better translation quality; conversely, at matched MetricX performance, LAND reduces the required number of candidate generations by approximately 20-40% across the evaluated models, language pairs, and sampling budgets. These results indicate that a substantial fraction of best-of-N compute can be saved simply by reallocating samples toward more promising sources.

Although our experiments focus on machine translation, the formulation of LAND is not specific to translation. The method applies whenever multiple candidate outputs can be sampled for the same input, evaluated with a continuous scalar reward, and compared to select the best candidate. It therefore extends directly to other best-of-N settings, although performance will depend on the informativeness of the chosen score. Our current experiments validate LAND only with MetricX, on a limited set of model families, and in machine translation. Future work will test alternative metrics, additional model families and scales, and other generation tasks equipped with continuous reward or quality scores.

Some limitations remain. First, LAND requires calibration data containing multiple completion scores per source in order to estimate the empirical mixture and calibrate the compute price. This introduces an upfront cost that fixed best-of-N does not require and may be undesirable when only a small dataset is to be generated. Second, the fitted score-distribution model remains fixed during deployment. Although LAND updates its posterior for each individual source and adjusts the compute price $\Lambda$ to control the realized average budget, it does not use the completion scores collected across previously processed deployment sources to refine the empirical mixture itself. Consequently, additional information acquired during deployment is unused. Extending LAND to periodically update its mixture parameters from newly observed scores could reduce its dependence on an initial calibration set and allow it to adapt to distribution shift over time. And finally, we use the number of candidate generations as a proxy for compute. Since generations can differ in length and execution cost, the reported reduction in draws need not translate one-to-one into wall-clock or hardware savings. We leave this to future work.

# Appendix

## A Derivation of the Allocation Rule

To solve the optimization problem from Equation 10, define

$$C_\mu(\lambda) \equiv \mathbb{E}[K|\mu], \tag{24}$$

$$G_\mu(\lambda) \equiv \mathbb{E}[X_K \mid \mu] = \frac{\int_\lambda^\infty \mathrm{d}x\, x f_\mu(x),}{1 - F_\mu(\lambda)}. \tag{25}$$

Setting the constraint via a Lagrange multiplier $\Lambda$ results in the functional

$$\mathcal{L}[\lambda] = \mathbb{E}_\mu\left[G_\mu(\lambda(\mu))\right] - \Lambda\big(\mathbb{E}_\mu\left[C_\mu(\lambda(\mu))\right] - N\big). \tag{26}$$

The corresponding first-order condition is

$$\frac{\delta \mathcal{L}}{\delta \lambda(\mu)} = G'_\mu(\lambda(\mu)) - \Lambda C'_\mu(\lambda(\mu)) = 0, \quad (27)$$

where

$$G'_\mu(\lambda) = \frac{f_\mu(\lambda)}{1 - F_\mu(\lambda)}(G_\mu(\lambda) - \lambda), \quad (28)$$

$$C'_\mu(\lambda) = \frac{f_\mu(\lambda)}{(1 - F_\mu(\lambda))^2}. \quad (29)$$

This yields the equation

$$\Lambda = (1 - F_\mu(\lambda))(G_\mu(\lambda) - \lambda) \quad (30)$$

$$= \int_\lambda^\infty \mathrm{d}x (x - \lambda) f_\mu(x) \quad (31)$$

$$= \mathbb{E}[(X - \lambda(\mu))_+ | \mu] \quad (32)$$

# How Many Raters Do We Need to Recognize a Bad Translation via Perplexity?

## Abstract

The perplexity assigned by a large language model (LLM) to a translation is a cheap, reference-free signal of translation quality, but the judgements of any particular model are likely to include noise based on its specific weights. We treat each LLM as one *rater* of English to Czech machine-translation output and ask if we can use their pooled judgements to reliably separate good translations from faulty ones. We measure the AUROC, which reflects the separation of good and bad translations, of all possible ensembles of 13 open-weight raters on two error types: morphologically *broken* sentences and semantically *corrupted* ones — both types both from human references and LLM generated translations, giving a total of 4 classes. With the raters' own machine translations as positives, the approach is reasonably successful — a well-chosen pair reaches a held-out AUROC of 0.887 and the optimum of 0.890 needs only *three* raters, after which further raters only erode the best score. In the second experiment we replace the machine-translated positives with human reference translations and the signal collapses for every damaged class written by LLMs: the best ensemble reaches only 0.727 and we see that when comparing human references against semantically damaged machine translations, most ensembles assign higher perplexities to the human references. Perplexity of two to three LLM raters is thus good for distinguishing good and bad machine translations but falls short for human translations.

## 1 Introduction

Reference-free estimation of machine-translation (MT) quality is attractive wherever references are unavailable or costly to obtain. A particularly cheap signal is *perplexity*: a fluent and well formed translation should be more probable under a language model of the target language than a damaged one. Furthermore, for a multilingual language model with the context of source-translation pair (en: source sentence, cs: translated sentence), an adequate translation should be more probable than an inadequate one. Perplexity can be obtained from any open-weight LLM that has been trained on both languages of the language pair we're interested in.

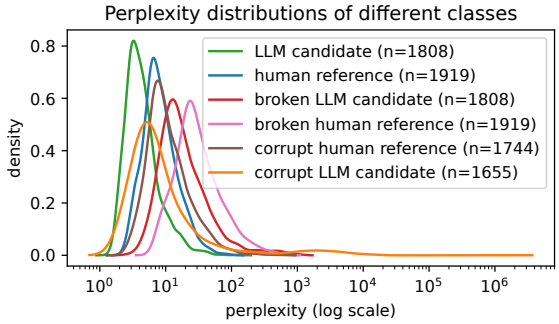

Figure 1: Perplexity densities (`dolphin` model, log scale) for good machine and human translations and their degraded versions: morphologically *broken* and semantically *corrupt*. The classes overlap heavily, motivating model ensembling. Human references score worse than semantically corrupt machine translations.

The weakness of the signal is equally obvious: it is the opinion of a single model, shaped by that model's training data, tokenizer, and coverage of the target language. A straightforward approach to remedy is to use an ensemble of models (Dietterich, 2000). We therefore treat every LLM as one *rater* and pool the raters' judgements to obtain the ultimate score. We ask how many raters to pick and how does our choice when picking them matter.

We answer this question exhaustively in an English–Czech setting. Starting from a collection of translations and a collection of systematically degraded variants, we score every candidate translation with 13 open-weight LLMs and evaluate every one of the $2^{13} - 1 = 8\,191$ possible rater ensembles.

To examine the tendency of LLMs to prefer LLM

*Proceedings of the Eleventh Conference on Machine Translation*, pages 530–540
October 28-29, 2026 ©2026 Association for Computational Linguistics

output to human one, we conduct two experiments, one with LLM-generated candidate translations and one with manual references.

Our contributions are:

- An exhaustive evaluation of all 8,191 perplexity-rater ensembles over 13 open-weight LLMs on Czech MT output, for two error types (morphological and semantic) and their union, using a 10-fold rotating holdout.
- The same enumeration with about 38 human references per source sentence as the positive class. Importantly, these diverse human references obtain *higher* perplexity than semantically corrupt machine translations and the best of all the 8k ensenbles reaches a held-out AUROC of only 0.727.
- A quantitative answer to the title question: the optimum for the examined language pair is a triple (`llama`, `dolphin`, `gptoss`) at 0.890, the best pair is within 0.003 of it, and the full 13-rater pool (0.848) is worse than the most successful singleton (0.876).
- Evidence that rater *composition* dominates rater *count*: the marginal value of a rater is not always predicted by its singleton score, nearly half the raters subtract value from the ensembles they join, and indiscriminate pooling converges to a mid pack performance rather than becoming better than any of its parts in isolation.

## 2 Related Work

**MT quality estimation.** Reference-based metrics such as BLEU (Papineni et al., 2002) and chrF (Popović, 2015) require references and correlate imperfectly with human judgement (Mathur et al., 2020). Learned metrics — BERTScore (Zhang et al., 2020), COMET (Rei et al., 2020), BLEURT (Sellam et al., 2020) — improve correlation at the cost of task-specific training, and reference-free quality estimation removes the reference requirement (Fomicheva et al., 2020; Ranasinghe et al., 2020). LLMs themselves have been used as direct quality judges (Kocmi and Federmann, 2023).

**Perplexity as a quality signal.** Language-model perplexity is an established filter for noisy corpora (Wenzek et al., 2020), and cross-entropy difference has long been used for data selection (Moore and Lewis, 2010; Junczys-Dowmunt, 2018).

**Multiple raters.** In human MT evaluation, aggregating several annotators is standard practice and the required number of raters is an explicit design decision (Freitag et al., 2021). Ensembles of learned models reduce variance when members err independently (Dietterich, 2000); our setting tests how much does this logic hold when the "raters" are frozen LLMs whose judgements are correlated by shared training data.

**Scoring in isolation vs. choosing from a list.** Picking the good translation out of several candidates is a multiple-choice question, and how it is put to an LLM matters. Robinson et al. (2023) contrast *cloze prompting*, where each option is scored on its own by the model's likelihood, with *multiple choice prompting*, where all options share the context and the model names its pick — the multiple choice prompting being substantially stronger; closed and open answer formats differ for evaluation more generally (Myrzakhan et al., 2024). Our raters are squarely on the cloze side: a candidate is scored without seeing its competitors, which is what makes enumerating 8,191 ensembles affordable, but no rater here ever compares two translations directly.

## 3 Task and Data

### 3.1 Source corpus

In order to reasonably represent the *variance* of possible translations and avoid excessive cost, we needed an existing test set with a diverse collection of human references. A good option for this was the DepRefSet dataset of very many Czech references from 50 English source sentences from WMT11 data (Bojar et al., 2013). In DepRefSet, each of the source sentences is equipped with thousands to hundreds of thousands of manually revised possible translations. This makes our second experiment possible at all: it gives us a human positive class of the same order of magnitude as the machine-generated one, over exactly the same source content.

Czech as the target language is also a good choice because it is a morphologically rich language with good language processing tools that are allowed to reliably damage the good translations, see below.

**LLM candidate translation** To obtain a corpus of candidate LLM translations, the English source sentences from DepRefSet are translated

into Czech by open-weight LLMs — the same that we will use as raters, see Table 1 — with a few-shot prompt (see Appendix A) asking the LLM to provide the translations and demonstrating good translation pairs, giving the *LLM candidate* class.

**Broken translation (morphological damage).** Czech translations from the *LLM candidate* class are first analyzed using the Czech morphological analyzer MorphoDiTa (Straková et al., 2014), then for randomly chosen content words, one morphological feature of the positional tag — gender, number, case, or person — is replaced and the surface form is regenerated. Every word remains a valid Czech form with a meaning that fits the context, but agreement with its context is violated.

We obtain these syntactically damaged sentences from both the reference translations in DepRefSet which are already in Czech and the *LLM candidate* class described above to get two separate classes *broken LLM candidate* and *broken human reference*.

**Corrupt translation (semantic damage).** To create semantically damaged sentences, an LLM is given a reference translation and prompted, with few-shot examples showing several rewritten sentences (for example: "The morning was cold, but sunny" → "The morning was neither cold nor rainy"), to produce rewrites that are grammatically well-formed but inadequate translations of the source sentence. This corruption is carried out monolingually, in Czech only, see the full prompt in Appendix B.

Applying this process we get the two classes *corrupt LLM candidate* and *corrupt human reference*.

After using the LLM-based methods to obtain the *LLM candidate* and *corrupt* candidate sets, we removed faulty sentences from them by filtering out empty lines and sentences in which the Czech morphological analyzer didn't find any Czech words (typically LLM explanations of their answers) and then manually removing sentences where the model obviously misunderstood the task. After this step we generated the *broken* set from the *LLM candidate* set. We got about 3 sentences per class,model and source sentence.

This way we obtained 1,808 LLM candidates, 1,919 human references, 1,919 broken human references, 1,808 broken LLM candidates, 1,744 corrupt human references and 1,655 corrupt LLM generated candidates.

### 3.2 Raters

Table 1 lists the 13 open-weight LLMs used as raters. They span 3.35B–36B parameters, multilingual and English-centric training, and several model families.

## 4 Method

### 4.1 Ensembles of perplexity raters

Given a sentence $s$ and a rater $m$ with parameters $\theta_m$, the rater's raw score is the perplexity

$$\mathrm{PPL}_m(s) = \exp\Big(-\tfrac{1}{|s|}\textstyle\sum_{t=1}^{|s|} \log p_{\theta_m}(w_t \mid w_{<t})\Big). \tag{1}$$

While the perplexity is only summed over the tokens of the target sentence, the rater model is given each sentence in the context of a good few shot translation prompt including the appropriate source sentence. Tokens of the prompt do not themselves contribute to the perplexity sum but they have impact on the perplexity assigned to the tokens of the target sentence.

Different raters produce log-perplexities on very different scales, so before pooling we standardize each rater: the rater's judgement of a sentence is its z-scored log-perplexity

$$z_m(s) = \frac{\log \mathrm{PPL}_m(s) - \mu_m}{\sigma_m}, \tag{2}$$

where $\mu_m$ and $\sigma_m$ are the mean and standard deviation of $\log \mathrm{PPL}_m$ over the training sentences of all classes (Section 4.2), so that every rater's judgements have zero mean and unit variance on the training data. An ensemble $E \subseteq \mathcal{M}$ of raters scores the sentence with the sum of its members' z-scores,

$$\mathrm{score}_E(s) = \sum_{m \in E} z_m(s), \tag{3}$$

i.e. an unweighted pooling of the raters' standardized log-judgements.

### 4.2 10-fold cross-validation

Evaluating 8,191 candidate ensembles and reporting the maximum invites the winner's curse: with thousands of comparisons, the top score is biased upward and the identity of the winner may be an artifact of noise. We therefore split the corpus, estimate the best ensembles and the marginal values of each rater using only a training partition and then evaluate the results on the held-out data.

Importantly, we make this split at the level of the source sentences and project it onto the candidate sentences generated from them to avoid contaminating the held-out partition with close variation of sentences in the training partition.

We utilize a 10-fold cross-validation approach. The seeded permutation of the 50 sentences is cut into $N = 10$ blocks of five, each block is the development side of exactly one fold and the training side of nine, and the whole experiment is re-run ten times from scratch. A reported figure is the mean over all ten folds; because the folds partition the corpus, every unit contributes to exactly one development estimate, and the pooled development number is an average over the whole corpus.

### 4.3 Separation measure

We measure how well an ensemble's score separates reference sentences from degraded sentences with the AUROC: the probability that a randomly drawn degraded sentence receives a higher (worse) score than a randomly drawn reference one (Hanley and McNeil, 1982). We compute it from the Mann–Whitney $U$ statistic (Mann and Whitney, 1947), with ties counted as $\frac{1}{2}$; 0.5 means no discriminative power and 1.0 perfect separation.

To quantify uncertainty, we estimate AUROC using subsampling: within each split we repeatedly ($500\times$) draw 400 reference and 400 degraded scores (with replacement) and compute the AUROC of the draw. Alongside it we report the *fold spread*: the standard deviation of the ten per-fold means. The two answer different questions and differ by a factor of 1.6–1.9. (Table 2). The subsample interval says how precisely this quantity is measured on the units we have; the fold spread says how much the answer moves if the source sentences change to different ones.

| | Ensemble | Subsample | Fold sd |
|---|---|---|---|
| E1 | `dolphin` | $\pm.062$ | .038 |
| E1 | `dolphin,gptoss` | $\pm.039$ | .022 |
| E1 | `llama,dolphin,gptoss` | $\pm.041$ | .024 |
| E1 | all 13 | $\pm.057$ | .034 |
| E2 | `gptoss` | $\pm.111$ | .058 |
| E2 | `dolphin,gptoss` | $\pm.077$ | .043 |
| E2 | all 13 | $\pm.086$ | .047 |

Table 2: Two measures of uncertainty on combined development AUROC: the half-width of the 90% interval over all $10 \times 500$ subsamples, and the standard deviation of the ten per-fold means. Across the folds, the Experiment 1 (E1) *optimum* ranges from 0.853 to 0.921 and the Experiment 2 (E2) optimum from 0.649 to 0.788. Differences smaller than the fold spread should not be read as differences between ensembles.

### 4.4 Exhaustive enumeration

We evaluate every non-empty subset of the 13 raters, i.e. 8,191 ensembles, for each of the damaged classes individually and their union (*combined*) using either the *LLM candidate* or the *human reference* class as the reference class. Since every ensemble is evaluated on the same sentence pool (Section 3.1), all scores below are directly comparable across ensemble sizes and compositions. Unless stated otherwise, the numbers we quote are holdout AUROCs of ensembles chosen on the training split.

## 5 Results

### 5.1 Experiment 1: Machine translation as the positive class

#### 5.1.1 Singleton raters

Table 3 shows each rater's singleton AUROC on the held-out split. Individual raters span 0.764–0.876 on the combined task: the spread between the best rater (`dolphin`, 0.876) and the weakest (`ibm`, 0.764) is more than twice the fold spread of either, so rater choice clearly has a significant impact. The four negative classes separate cleanly and in the same order for every rater without exception: broken human references are easiest (0.879–0.982), followed by broken machine candidates (0.803–0.942), then corrupted human references (0.762–0.883), and corrupted machine candidate are the hardest (0.517–0.698). They tell a clear story that perplexity is better as a *fluency* detector than as an *adequacy* detector and that it is a detector of authorship assigning higher probabilities to sentences written by machines.

| Rater | BM | BH | CM | CH | Comb. | Marg. |
|---|---|---|---|---|---|---|
| dolphin | 0.941 | 0.974 | **0.698** | 0.867 | **0.876** | +.011 |
| llama | **0.942** | **0.982** | 0.666 | 0.835 | 0.862 | +.008 |
| commandr | 0.928 | 0.978 | 0.645 | 0.842 | 0.855 | +.007 |
| mistral7b | 0.926 | 0.980 | 0.598 | 0.863 | 0.849 | +.005 |
| gptoss | 0.928 | 0.977 | 0.692 | 0.769 | 0.848 | **+.019** |
| qwen | 0.906 | 0.969 | 0.593 | **0.883** | 0.845 | +.005 |
| darwin | 0.921 | 0.964 | 0.608 | 0.805 | 0.832 | −.001 |
| eu | 0.919 | 0.968 | 0.566 | 0.800 | 0.821 | −.004 |
| aya | 0.894 | 0.961 | 0.589 | 0.806 | 0.819 | −.004 |
| tower | 0.881 | 0.936 | 0.619 | 0.762 | 0.806 | −.007 |
| ayaexp | 0.874 | 0.963 | 0.536 | 0.819 | 0.806 | −.008 |
| gemmabig | 0.856 | 0.926 | 0.517 | 0.765 | 0.774 | −.015 |
| ibm | 0.803 | 0.879 | 0.580 | 0.770 | 0.764 | −.017 |

Table 3: Experiment 1: cross-validated singleton AUROC per rater and class, sorted by the combined score. *BM* is morphological damage to a machine candidate, *BH* is morphological damage to a human reference, *CM* the LLM's corruption of a machine candidate, *CH* its corruption of a human reference. Fold spreads are ∼0.04 (BM), ∼0.03 (BH), ∼0.04 (CM), ∼0.08 (CH) and ∼0.04 (combined). *Marg.* is the rater's size-matched marginal contribution to combined dev AUROC when added to an ensemble (Section 5.1.1).

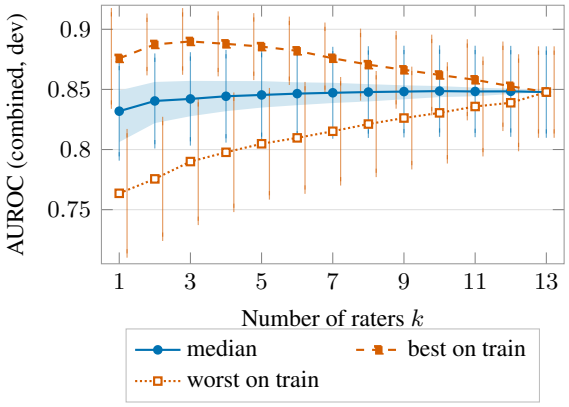

Figure 2: Experiment 1: cross-validated combined dev AUROC versus ensemble size $k$: the size-$k$ ensembles that are best (dashed) and worst (dotted) on the *training* split, evaluated on held-out sentences, and the median over all size-$k$ ensembles with the interquartile band (solid; shaded). Whiskers are the fold spread — one standard deviation of the plotted quantity over the ten folds (0.022–0.050 here) — while the shaded band is the spread across ensembles at that size: the band narrows with $k$, the whiskers do not.

The last column of Table 3 reports each rater's size-matched marginal value: the mean combined AUROC of all ensembles containing the rater minus that of all equally sized ensembles without it. Only six raters have positive marginal value (a seventh, `darwin`, is essentially neutral), and one rater notably differs in its marginal rating from its singleton ranking: `gptoss` (+0.019) consistently contributes the most despite ranking only fifth of thirteen as a singleton — its judgements complement the others (Section 5.1.5).

### 5.1.2 AUROC as a function of ensemble size

Figure 2 summarises the central result. For each size $k$ we plot the distribution of combined dev AUROC over all size-$k$ ensembles (median and interquartile band) together with the dev scores of the best and worst ensembles of that size *as selected on the training split*.

Three interesting observations are as follows: First, the *best* ensembles peak almost immediately (Table 4): from 0.876 ($k$=1) to 0.887 ($k$=2), with the optimum of 0.890 already at $k$=3 using the raters (`llama, dolphin, gptoss`). From there the best achievable score starts to *decline* all the way down to 0.848 for the full 13-rater sum, which would place it fifth or sixth of fourteen if it was a singleton rater. The best pair already delivers about 80% of the total gain between the best singleton rater and the optimum.

Second, the *median* ensemble improves only from 0.832 at $k$=1 to 0.848 at $k$=13 and never reaches the performance of the best singleton rater. We see a tendency towards mediocre results — the whole distribution narrows toward the full-pool score of 0.848 — pooling avoids the very weak results but it avoids the very strong ones as well.

Third, the selections done on training partition *generalize* to held-out sentences: the ranking of all 8,191 ensembles on the training split carries over to the development split almost unchanged (Spearman $\rho = 0.998$), and the triple selected on the training split is *exactly* the best ensemble found anywhere on held-out content (`llama, dolphin, gptoss`, 0.890). All of these differences are however very small in the context of the $\sim\pm 0.024$ fold spread: the bests of sizes 1–6 are mutually indistinguishable. The consistent shape of the curves across sizes is what supports the trend, not any single pairwise comparison.

### 5.1.3 Four error classes

Figure 3 splits the analysis into four classes:

**Broken human references: the easiest class, and the one control that holds.** Morphological damage to a *human* reference is the easiest of the four classes for every rater without exception: singletons span 0.879–0.982, the weakest rater on this class (`ibm`, 0.879) beats the best rater on *cor-*

| $k$ | Best ensemble (train) | Train | Dev | sd |
|---|---|---|---|---|
| 1 | dolphin | 0.870 | 0.876 | .038 |
| 2 | + gptoss | 0.887 | 0.887 | .022 |
| 3 | + llama | **0.888** | **0.890** | .024 |
| 4 | + qwen | 0.886 | 0.888 | .024 |
| 5 | + commandr | 0.884 | 0.886 | .024 |
| 6 | + mistral7b | 0.881 | 0.882 | .025 |
| 13 | all thirteen raters | 0.845 | 0.848 | .034 |

Table 4: Experiment 1: best ensemble per size, selected by combined AUROC on the training splits, with its cross-validated score on both sides and the standard deviation of its ten per-fold dev means. Every row extends the row above by one rater — the chain is nested here, which it need not be — and coincides with what greedy forward selection picks.

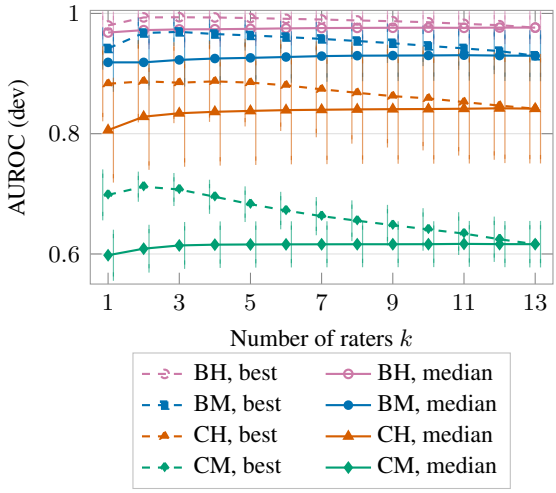

Figure 3: Experiment 1: best (dashed) and median (solid) dev AUROC per ensemble size for the four error types; best is selected on the training splits. *BH* is the morphologically broken human reference, *BM* a broken machine translation. *CH* is the LLM's corrupted rewrite of a human reference, *CM* its corrupted write of the machine's own translation. The four sit at clearly separated levels that no amount of pooling closes, and all four peak at $k \leq 4$; what adding raters buys is the convergence of best and median, not a higher ceiling.

*rupt LLM candidate* by 0.18, and the best pair (`llama+gptoss`) reaches 0.993. In this class the singleton picked on the training split is not the one that turns out best on held-out data, so the $k$=1 point of Figure 3 sits at 0.980 rather than at the 0.982 of Table 3. The optimum is a triple (`commandr`, `qwen`, `gptoss`) at 0.994, after which the usual decline sets in, to 0.976 for the full pool. The comparison with *broken candidate* is the informative one. The two classes are the same operation applied to differently authored text, and the human-authored arm is *easier* at every size, because morphological corruption of an already-improbable human sentence pushes it further from the model's expectations than the same corruption of a fluent machine translation does.

**Broken machine candidates: one complementary pair suffices.** Every rater detects morphological damage well (singletons 0.80–0.94), so the signal is broadly shared, and one complementary pair — `dolphin+gptoss` scoring 0.967— is effectively the best ensemble of *any* size, an improvement of +0.025 over the best singleton `llama` (0.942) Adding this best singleton to the ensemble yields further 0.002 (0.969) and after that the best size-$k$ score declines monotonically to 0.930 at $k$=13.

**Corrupt human references: the signal lives in one rater.** Semantic corruption is a different story: `qwen` (0.883) beats the second best (`dolphin`, 0.867) by a margin of 0.16, and the best size-$k$ corrupt ensemble contains `qwen` at *every* size. The best ensemble selected on the training split is `qwen, mistral7b, dolphin, gptoss` at $k$=4 (dev 0.887) — a mere +0.004 over `qwen` alone, and indistinguishable on held-out data from the best pair `qwen,dolphin`, which the training split ranks lower but which reaches the same 0.887 in Figure 3. From $k$=5 the best ensemble declines steadily to 0.842. It seems our ceiling on adequacy detection is limited by the rater capabilities, not by rater noise: pooling cannot manufacture a signal that most raters simply lack.

**Corrupt LLM candidates: hardest, one signal masks other.** The model's corruption of its own translation is by a wide margin the hardest class, with singletons at 0.517–0.698 and a ceiling of 0.712 (`dolphin+gptoss` at $k$=2). The damage is the same rewriting operation that produces *corrupt*, which every rater except `gptoss` detects 0.14–0.29 AUROC better. What differs is the input's authorship. A corrupted human reference is a non-model-typical sentence with a semantic mistake on top, while a corrupted machine translation is more model-typical, which is a signal that masks the semantic inadequacy by working in the opposite direction.

### 5.1.4 Reliability of larger ensembles

Although the best-performing ensembles are small, larger ensembles are *safer*: the worst-on-train size-$k$ ensemble (the dotted curve in Figure 2) improves

from 0.764 ($k$=1) to 0.839 ($k$=12) on the dev split. Size buys insurance but not performance — the floor rises, but the ceiling falls.

A simple approach of greedy forward selection on the training split (add the rater that most improves combined train AUROC) finds the train-optimal triple in three steps: it picks `dolphin`, then `gptoss`, then `llama` (train 0.888, dev 0.890) and peaks there, which is the same triple and the same score the exhaustive search finds.

#### 5.1.5 Rater correlation

Table 5 reports the Spearman rank correlation between the per-sentence perplexities of every rater pair. Correlations are computed within each class separately and then averaged with sentence-count weights: pooling the classes first would let the shared reference-versus-degraded signal, which every competent rater carries, inflate all pairwise correlations, whereas the within-class correlation asks the question that actually matters for ensembling — do two raters find the *same* sentences suspicious?

The matrix splits the pool into twelve like-minded raters and one outlier. Every pair among the twelve non-`gptoss` raters correlates between .69 and .90 (median .82): whatever their family, size, or training mix, these raters largely rank the same sentences the same way. `gptoss`, by contrast, correlates at most .39 with any other rater (median .305). This substantiates our reading of Table 3: `gptoss` is only a mid-table singleton, yet the most valuable rater to add, because it contributes genuinely new information rather than another copy of the consensus.

### 5.2 Experiment 2: Human references as the Positive class

Experiment 1 asked the raters to tell good *machine* translations from damaged ones. Experiment 2 changes exactly one thing: the positive class consists of human reference translations per source sentence instead of the LLMs' own output. The rest of the experiment setup — the negative classes, the raters, the prompts, the pooling rule and the AUROC protocol are all unchanged.

#### 5.2.1 The performance worsens considerably

Table 6 gives the singleton scores. Every number is dramatically worse than its Experiment 1 counterpart. The best single rater on the combined task, `gptoss`, reaches 0.707 against 0.876 for the best rater in Experiment 1, and the weakest (`gemmabig`, 0.556) is barely above chance.

When we look at the breakdown by error type, the reason becomes clear. On *broken human references* — morphologically damaged human references, judged against undamaged human references — the performance stays reasonable: the raters span 0.74–0.93, the best ensemble of any size reaches 0.954, and even the full 13-rater pool scores 0.911. On morphologically *broken LLM candidate* sentences a real if weakened signal survives: the raters span 0.59–0.83 and the pool still detects that agreement violations make Czech improbable. On *corrupt human reference* sentences — the LLM's rewrites of human references — the signal is nearly gone: the raters span 0.48–0.63, the best ensemble of any size reaches 0.631, and that best ensemble is a singleton (`qwen`), the same rater that leads this class in Experiment 1. On *corrupt LLM candidate* the signal does not just weaken but reverse. LLMs prefer inadequate machine translations to adequate human ones and twelve of the thirteen raters score below 0.5, and so do 8,190 of the 8,191 ensembles; the median ensemble sits at 0.339 and the best reaches 0.501 — `gptoss` alone, at essentially chance.

#### 5.2.2 Ensembling does not significantly help

Figure 4 and Table 7 repeat the size analysis. The shape of the curves is recognizably the same as in Experiment 1 — a fast rise to a small optimum, a decline afterwards, a rising floor, a distribution narrowing on the full-pool score — but the whole family of curves has dropped by roughly 0.18 AUROC.

#### 5.2.3 Why: the perplexity of the classes

The cause is visible directly in the raw perplexities. Table 8 gives, per rater, the geometric-mean perplexity of each of the six classes over the same 50 source sentences.

We can see that the order of the pooled mean perplexities is not the one we hoped to obtain. Sorted by probability, the classes come out: machine translations (geometric mean 6.6), the semantically corrupted machine translations (11.5), human references (13.8), semantically corrupted human references (16.7), morphologically broken machine translations (25.3) and morphologically broken human references (43.7). Authorship is more important for perplexity than semantic damage. The mechanism is exactly the one exploited by machine-generated-text detectors (Gehrmann et al.,

| | gemmabig | ayaexp | commandr | eu | qwen | mistral7b | llama | dolphin | darwin | ibm | gptoss | aya |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| ayaexp | .83 | | | | | | | | | | | |

| gemmabig | 0.644 | 0.809 | 0.243 | 0.483 | 0.556 | −.025 |

Table 6: Experiment 2: cross-validated singleton AUROC per rater and class with human references as the positive class, sorted by the combined score. Fold spreads are ∼0.06 (BM and BH), ∼0.10 (CH), ∼0.05 (CM) and ∼0.06 (combined). Values below 0.5 mean the rater ranks human references as *worse* than damaged sentences more often than not; the *CM* column is below 0.5 for twelve of the thirteen raters and the thirteenth is at chance.

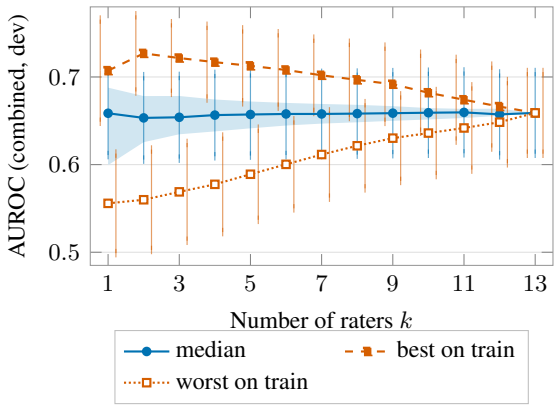

Figure 4: Experiment 2: cross-validated combined dev AUROC versus ensemble size $k$ with human references as the positive class, plotted exactly as Figure 2. Note the $y$ range: the best ensemble of any size (0.727) does not reach the *worst* singleton rater of Experiment 1 (0.764).

2019): the corruption of a LLM translation leaves fluent, high-probability, model-typical Czech. The damage the rewrite does is semantic — it is invisible to a fluency signal — while the fluency gain from being model-generated is large and directly visible. The two effects work in opposite directions and they very nearly cancel.

## 6 Discussion

**So, how many raters?** In our experiments, the best results were achieved with well chosen ensembles of two or three: dolphin+gptoss already reach 0.887 and a third (llama) the optimum 0.890, past which the best achievable score only declines, with the full pool (0.848) ending up *worse* than the best singleton rater (0.876). If the raters cannot be chosen intentionally — i.e. we don't know how good they are — then more raters raise the floor and protect against a bad pick, but they are unlikely to beat a smaller ensemble of better raters.

**Composition beats count.** The size-matched marginal values in Table 3 suggest an explanation why: rater quality for ensembling is not equivalent to the rater's singleton quality. gptoss is a mid-table singleton on machine translations (0.848, fifth of thirteen) but the most valuable team member, because its perplexity errs differently from the other models' — its rank correlation with every other rater is at most .39, against .69–.90 for any

| $k$ | Best ensemble (train) | Train | Dev | sd |
|---|---|---|---|---|
| 1 | gptoss | 0.704 | 0.707 | .058 |
| 2 | + dolphin | **0.725** | **0.727** | .043 |
| 3 | + llama | 0.720 | 0.722 | .040 |
| 4 | + tower | 0.714 | 0.717 | .041 |
| 5 | + eu | 0.708 | 0.713 | .042 |
| 6 | + commandr | 0.704 | 0.708 | .042 |
| 13 | all thirteen raters | 0.650 | 0.659 | .047 |

Table 7: Experiment 2: best ensemble per size on the combined task, selected on the training splits, with the standard deviation of its ten per-fold dev means. Every row extends the row above by one rater, and the chain is exactly what greedy forward selection picks — including the optimum at $k$=2.

Table 8: Geometric-mean perplexity of each class per rater, over the same 50 source sentences, columns sorted by the pooled value. The two undamaged classes are grouped apart from the four damaged ones. *MT* is the machine-translated *good* class and *Human* the ∼38 human references per sentence; *CM* is the LLM's corruption of the former, *CH* its corruption of the latter, *BM* morphological damage to the former and *BH* the same damage to the latter. Nine of the thirteen raters rank a *corrupted machine translation* as more probable than an untouched human reference.

other pair (Table 5). This is the classical ensemble-diversity argument (Dietterich, 2000) played out over frozen LLMs: what matters is decorrelation of errors, which singleton AUROC does not reveal but the correlation matrix of Table 5 makes directly visible.

**Fluency vs. adequacy, revisited.** The class-level results refine the standard observation that perplexity measures fluency: for fluency violations (morphology) LLM raters broadly agree, and a single complementary pair captures nearly all the signal (0.967); for adequacy violations (semantics) the signal is for all raters harder to pick up than fluency.

**Correctness vs authorship** Taken together, the two experiments suggest that a perplexity ensemble is in addition to *fluency* and *adequacy* a detector of *model-typicality* to a degree that can outweigh the *adequacy* signal. Experiment 1's positives and negatives are both LLM output, differing only in the damage applied afterwards, and there the perplexity judging does well. Experiment 2 breaks that symmetry by using human references and we see that when comparing human text against deliberately wrong machine text, the ensembles prefer the wrong machine text.

## 7 Conclusion

We exhaustively evaluated all 8k ensembles of 13 open-weight LLMs used as perplexity raters of English to Czech translation, twice, under 10-fold cross-validation over the 50 source sentences. With LLM-based translations as the positive class, a single good rater separates good from degraded ones with held-out AUROC 0.876, a well-chosen pair reaches 0.887, and the optimum of 0.890 needs only three raters (`llama`, `dolphin`, `gptoss`). The full 13-rater pool (0.848) scores below the best singleton rater and the median ensemble of any size never beats it. The cross-validation confirms the selection isn't merely lucky: the ensemble ranking transfers from training to test items at $\rho = 0.998$, and the train-selected optimum is exactly the best ensemble found anywhere on the test set.

With human reference translations as the positive class, the approach massively worsens whenever the comparison is against machine generated sentences: the best of all ensembles reaches AUROC of 0.727, and against the LLM's corruptions of its own translations the ordering *inverts* — all but one of the ensembles score below 0.5, with a median of 0.339. Furthermore, the examined LLMs thus do not discriminate well between diverse correct human translations and semantically corrupted LLM translations. Semantic modeling in available open-weight models is thus still unreliable.

## Limitations

Our study needed a dataset with a high number of reference translations. Such a dataset was available for English→Czech translation but it also brought the main limiting factor for our study: We exper-

iment with only one language pair with a single, morphologically rich target language. Furthermore, the underlying corpus contains only 50 source sentences. This reflects in a lower stability of our estimates, e.g. during the cross-validation, the same ensemble scores 0.853 and 0.921 on two different folds in Experiment 1, 0.649 and 0.788 in Experiment 2. The fold spreads of Table 2 are $\pm 0.02$ and $\pm 0.04$ on the two optima — any differences smaller than those shouldn't be seen as representative. In particular, the optimum at three raters is more accurately read as an optimum around one to six raters.

The degradations are synthetic and controlled; real MT errors mix fluency and adequacy problems in ways our classes separate artificially. While the study uses 13 different models, they are (apart from one) strongly correlated with each other, a more diverse set of raters may yield different outcomes. This rater sameness issue carries over to the LLM good and LLM corrupt classes which may therefore provide less diversity than their size suggests.

Finally, the set of human references was publicly available since 2011 and could have leaked to the LLM training data. The high perplexity these translations obtain however does not support this worry.

## A Few-shot Translation Prompt

We used this prompt to obtain LLM-based translations:

> Create a Czech translations for the given English sentence, format the answer exactly as in the examples, don't add anything else
> en: "The morning was cold but sunny."
> cs: "Ráno bylo chladné, ale slunečné."
> en: "We waited for the train for full two hours."
> cs: "Než vlak přijel, strávili jsme dvě hodiny čekáním."
> en: "I have never seen such a beautiful sunset."
> cs: "Tak krásný západ slunce jsem ještě neviděl"

## B Semantic Corruption Prompt

> Introduce semantic mistakes to the given Czech sentence, format the answer exactly as in the examples, add nothing more.
> correct: "Ráno bylo chladné, ale slunečné."
> wrong: "Ráno nebylo chladné, ani nepršelo."
> correct: "Než vlak přijel, strávili jsme dvě hodiny čekáním."
> wrong: "Než autobus přijel, strávili jsme pět minut čekáním."
> correct: "Tak krásný západ slunce jsem ještě neviděl."
> wrong: "Tak krásný východ slunce jsem už viděl."

# Comparing Machine and Human Simultaneous Interpreting

**Dongpeng Pan and Kilian G. Seeber**
Faculty of Translation and Interpreting (FTI), University of Geneva
dongpeng.pan@unige.ch; kilian.seeber@unige.ch

## Abstract

We evaluate four machine simultaneous interpreting (SI) systems, an open-weight and a commercial instance of both the cascaded and the end-to-end speech-native architecture, on simulated conference discourse interpreted into five languages. All outputs are compared with professional interpretations. Reference-free quality metrics are first calibrated against blind expert ratings of the human renditions: their association with expert ratings is strongest for content, weaker for presentation, and weakest for style. Machine systems attain content-similarity scores within or above the professional range and higher median segment coverage at the reported alignment threshold. Coverage can count professional compression as omission and is sensitive to transcription and alignment error, so the surplus does not establish better interpreting. For latency, only the commercial speech-native system approaches professional timing. Estimated content lag thus ranges from under twice to more than ten times the professional median, and each system's delay is associated with an observable operating property: commit granularity, synthesis queuing, or compute limits. Together, the rating-calibrated metrics and professional distribution provide a reference-free procedure for evaluating machine interpreting on unsegmented, full-length conference discourse.

## 1 Introduction

Simultaneous speech translation is deployed on long-form, unsegmented, spontaneous speech, whereas its established evaluation methods presuppose sentence-segmented input with reference translations (Ma et al., 2020; Papi et al., 2025). In simultaneous interpreting (SI), professional renditions can involve compression and syntactic restructuring (Liontou, 2011; Hodzik et al., 2024). A corpus-based analysis of English–Japanese SI also describes reformulation through information packaging at conceptual and translation-unit levels (Ishizuka, 2024). A single sentence-aligned reference may therefore fail to capture this variation, and expert evaluation panels cannot be convened as frequently as systems are updated. An evaluation matched to this setting must therefore (i) operate reference-free on unsegmented audio, (ii) apply identically to systems whose internals are inaccessible, and (iii) demonstrate, rather than assume, that its automatic metrics measure what expert judges of interpreting evaluate.

This paper contributes such an evaluation and applies it to the two architectures currently in use. Cascaded systems decompose the task into recognition, text translation, and synthesis; end-to-end speech-native systems translate speech directly without a committed text stage. We instantiate each family twice, as an open-weight system, whose internal states remain available for subsequent model analysis, and as a commercial service, which the protocol must handle as a black box. The systems are an open cascade (Whisper-large-v3, NLLB-200, MMS-TTS) and the commercial cascade Azure Speech Translation; the open end-to-end SeamlessStreaming and the commercial speech-native `gpt-realtime-translate`.

A completed experiment on distance interpreting (Seeber and Pan, 2026) provides renditions of the same four enacted conference scenarios (on average 10.5 minutes each) by 78 professional conference interpreters into six languages (74 enter the analyses; Section 3), with 3,016 discrete blind expert ratings on content, style, and presentation. The ratings validate the reference-free metrics before any machine output is scored (Section 6.1): the metrics are more strongly associated with the experts' content judgments than with presentation or style, so machine claims are confined to content. The renditions define the *human performance envelope*, the empirical distribution of professional latency, coverage (the share of source segments receiving a rendition), and content-similarity scores

*Proceedings of the Eleventh Conference on Machine Translation*, pages 541–553
October 28-29, 2026 ©2026 Association for Computational Linguistics

under the same instruments, in which every machine result is placed; the five machine languages and four speeches are fixed by this corpus.

Three research questions structure the study:

**RQ1** Which reference-free quality metrics align with professional judgment of interpreting, on which rating criteria, and finely enough to resolve known quality differences?

**RQ2** Where does each system score within the professional envelope on content similarity and content coverage?

**RQ3** Does any system reproduce professional temporal behavior: the listener-experienced content lag and its regulation over a full speech?

Sections 3 and 4 describe the data and systems, Section 5 the measurement protocol, Section 6 the metric validation and the comparison.

## 2 Related Work

**Evaluating simultaneous speech translation.** Latency evaluation for SimulST standardized around SimulEval (Ma et al., 2020) and the average-lagging family: AL (Ma et al., 2019), its length-adaptive correction LAAL (Papi et al., 2022), and DAL (Cherry and Foster, 2019). These measures presuppose sentence-segmented input, which deployment speech does not provide. StreamLAAL (Papi et al., 2024) extends latency measurement to unbounded streams, and Papi et al. (2025) show that reported SimulST performance degrades substantially under realistic long-form conditions. We provide measurement on unsegmented ecological speech with instruments that require no access to system internals, so that open models, closed services, and human interpreters are scored by the same procedure.

**Reference-free quality estimation.** Where suitable references are unavailable, quality estimation substitutes learned judgment: COMET-QE and CometKiwi on text (Rei et al., 2020, 2022), and, for speech, BLASER and BLASER-2.0 (Chen et al., 2023; Seamless Communication et al., 2023b), regressors over SONAR sentence embeddings (Duquenne et al., 2023) that score target speech directly against source speech. All are trained on translation-adequacy judgments; interpreting strategies such as compression and syntactic restructuring (Liontou, 2011; Hodzik et al., 2024) may complicate the interpretation of their scores. RQ1 tests whether, and for which criteria, these metrics align with expert interpreting judgment.

**Human evaluation of machine interpreting.** Fantinuoli and Prandi (2021) framed machine-interpreting evaluation communicatively, arguing that MT metrics miss what users of interpretation need. Deployed systems have since been assessed by expert panels (Matsushita, 2026; World Health Organization, 2025), with reported lags up to 32 seconds and low acceptability rates. Such panels judge each machine anew, which cannot be repeated at the pace systems change. Our design places human judgment at the beginning instead: expert ratings that already exist, of human renditions, are used once to test which automatic metrics align with expert judgment (RQ1, Section 6.1), and the selected metrics can then score additional systems. Their validity on machine output still requires testing (Section 6.1). The two uses of human judgment are complementary.

An earlier report for ITCILO compared Wordly and Stenomatic with human interpreting on three event excerpts, using manually aligned transcripts and reference-free XCOMET-XL (*ITCILO Advisory Services*, 2025, pp. 14–19). The report cautioned that automated scores may penalize interpreters' context-sensitive adaptations, including compression (pp. 37–38). This provides a methodological precedent for examining how automatic evaluation handles human interpreting.

**Cascade and end-to-end systems.** Both architecture families are currently in use, cascaded systems dominating the market and speech-native systems commercially available since 2026 (Adelani et al., 2026; OpenAI, 2026). A current comparison must therefore cover both in open-weight and commercial form. Our comparison anchors both architecture families in a distribution of professional performance on identical ecological input, with automatic metrics calibrated against expert ratings of human renditions.

## 3 The Human Benchmark

The human reference data originate from a completed experiment on distance interpreting (Seeber and Pan, 2026), conducted before any system described in this paper existed, and are reused here unchanged as measurement infrastructure. In that experiment, 78 professional conference interpreters each rendered the same four re-enacted conference scenes in English (roughly 10.5 minutes each; 2,559 s of source speech) in a counterbalanced $2 \times 2$ within-participant design crossing modal-

ity (audio-only, ARI, versus video remote, VRI) with sound quality (full-band HQ, 125 Hz–15 kHz, versus telephone-band LQ, 300 Hz–3.4 kHz). Target languages were French (45 interpreters), Spanish (11), German (6), Russian (6), Italian (5), and Dutch (5; no machine counterpart, retained only in envelope descriptives). The machine systems consume clean full-band audio, so the machine-matched human stratum is the audio-only, full-band condition (ARI-HQ). Machine placements are also checked against the remaining strata as a sensitivity analysis. Four of the 78 recorded participants are excluded on the original study's pre-existing grounds (one produced no usable audio, one was dropped from the original quality evaluation, one completed only two of the four trials, one withdrew), leaving 74 in the envelope (App. A).

The same experiment produced a blind expert quality evaluation of the human renditions: professional raters (6 for French, 4 for Spanish, 5 each for German, Italian, and Russian) scored 8 fixed excerpt windows per interpreter on 7-point scales for content, style, and presentation, yielding 3,016 ratings of 69 interpreters with no missing cells (ICC = .642). These ratings provide the criterion for validating the reference-free metrics (RQ1, Section 6.1). No machine output is rated by humans, no new ratings are collected, and no individual interpreter is scored, ranked, or identified.

**Ethics.** The original experiment was conducted in line with the Declaration of Helsinki and approved by the Board of Ethics of the Faculty of Translation and Interpreting (FTI), University of Geneva; all participants gave informed consent. The present study is a secondary analysis of those recordings and ratings within the scope of that consent: no new human data were collected, rendition audio was processed exclusively as research data, and no individual interpreter's results appear in this paper or its released artifacts.

## 4 Four Machine Systems

Table 1 summarizes four systems: one open-weight and one commercial system for each of two architectures, cascaded and end-to-end speech-native. Because the systems also differ in their models, training data, and implementation, the comparison cannot establish whether architecture or openness accounts for their performance differences.

**Open cascade (Open-Cascade).** A pipeline of open components: Whisper-large-v3 for recognition (Radford et al., 2023), NLLB-200-1.3B for translation (NLLB Team et al., 2022), and MMS-TTS for synthesis (Pratap et al., 2024), with a Piper voice for Italian because the MMS Italian checkpoint was withdrawn from distribution during the study (App. A). Whisper-large-v3 provides an openly available recogniser that can be run locally with fixed weights and decoding settings. The same checkpoint was used for English recognition in CUNI's IWSLT 2025 simultaneous translation system (Macháček and Polák, 2025). Whisper's translation mode produces English text; the present English-to-other-language directions therefore require a separate translation model (OpenAI, 2022). A streaming voice-activity detector commits speech to the pipeline: an utterance closes after 500 ms of silence, and an open buffer is force-committed at 8 s. Each chunk contains up to 8 s of source speech. Recognition, translation, speech synthesis, and waiting for playback can add further delay. The saved run records do not contain separate ASR start and finish times, so the ASR share of that delay was not measured.

**Commercial cascade (Azure Speech Translation).** Azure's speech-translation service; the cascaded architecture is documented by the vendor (Microsoft, 2026). Synthesis is emitted per finalized recognition segment, a commit-policy property shared by deployed cascade products.

**Open end-to-end (SeamlessStreaming).** SeamlessStreaming (Seamless Communication et al., 2023b,a) translates speech to speech directly, with no committed text stage. The evaluated system is the streaming RunPod run on a rented A100. The model determines when to emit speech under its streaming policy. Machine content lag is reconstructed from client-side timing records under the playback model described in Section 5.

**Commercial speech-native API (`gpt-realtime-translate`).** A commercially available realtime speech-translation API, generally available since May 2026 at $0.034 per audio minute (OpenAI, 2026). We classify it as end-to-end from vendor documentation; nothing in the comparison depends on the label.

**Operating-point selection.** The documented development sweeps used the first speech into French to select the lowest-latency setting that did not audibly damage output integrity. Azure Speech Translation kept its default semantic segmentation (the silence-timeout alternative halved com-

| System | Class (as labeled) | Components / access | Cost |
|---|---|---|---|
| Open-Cascade | open cascade | Whisper-large-v3 → NLLB-200-1.3B → MMS-TTS (Piper for Italian); VAD commits: 500 ms close, 8 s cap; local GPU | ≈9 GPU-h |
| Azure Speech Translation | closed cascade (vendor-documented ASR → TrueText → MT → TTS) | Speech SDK `TranslationRecognizer`; neural-voice synthesis; accessed 2026-08-03–04 | $0 billed; list ≈$18–36 |
| SeamlessStreaming | open end-to-end | SeamlessStreaming; client-side timing records; rented A100 (RunPod) | ≈30 GPU-h |
| `gpt-realtime-translate` | closed; end-to-end per vendor documentation alone | realtime WebSocket API; accessed 2026-08-03 | $0.034/min |

Table 1: The four machine systems: both architecture families in current use, each in open-weight and commercial form. Closed-system class labels are vendor-attributed and hedged (see text).

mit lag but truncated mid-clause); `gpt-realtime-translate` exposes no latency-relevant settings; Open-Cascade selected 500 ms/8 s. Settings and development sweeps are reported in Appendix A.

**Unified input and timing protocol.** The same source audio is pushed to each system as real-time-paced raw audio samples (PCM); client-side monotonic timestamps are recorded for every received audio chunk and text event; latencies are reported as distributions; each system's quantization floor (buffer size, segment-finalization granularity, delta cadence) is disclosed alongside. All commercial runs occurred on August 3–4, 2026, to bound version drift.

## 5 Measurement Protocol

The protocol measures at two layers: a *comparison layer* (Layer A), for all human renditions and machine runs, and a *diagnostic layer* (Layer B), computed from machine client-side event streams. Figure 1 summarizes how recordings, transcription, alignment, expert-rating validation and system comparison connect.

**Layer A (comparison)**: each full passage is transcribed (faster-whisper large-v3), its sentences aligned to the canonical source segments by multilingual-embedding similarity under a monotonic one-to-one dynamic program, and scored for content lag (onset-to-onset on the source clock) and content coverage. Matched source and target excerpts are scored using BLASER-2.0-QE on audio and SONAR text similarity on transcripts.

Coverage is the share of the speech's canonical source segments (460 across the four speeches, 108–121 each) that receive a retained alignment to a target sentence; source segments without a retained match at or above the similarity floor of 0.25 are counted as uncovered. Because each target sentence can match only one source segment, a sentence combining content from several source segments cannot give coverage credit to all of them (App. A). The contributions of compression, restructuring and transcription error to the human–machine coverage difference have not been quantified.

Transcription is needed despite the reference-free metrics: it supplies sentence units for alignment and text for SONAR; audio-based BLASER needs no transcript. Machine transcript times are mapped from concatenated output audio to estimated playback positions using client-side timestamps and a sequential playback model. Without this remapping, machine content could appear to precede its source. The reconstructed machine lag has not been independently validated against recorded live playback. Client-side records also support the selection of machine excerpts.

**Layer B (diagnostics)**: the machine event streams provide time to first audio, output delay relative to each system's source timestamps, output tail, and real-time factor, where the required records are available. Expert ratings are available only for human excerpts and are used to assess the association of BLASER and SONAR scores with expert judgment (Section 6.1). Every human–machine comparison uses Layer A.

Alignment quality was hand-validated on complete side-by-side walkthroughs of three renditions per language before any downstream number was computed. Throughout, the professional envelope denotes the empirical distribution of per-rendition values in the machine-matched human stratum of Section 3; figures that display intervals show the 5th to 95th percentile of that distribution.

Every machine system completed all four pas-

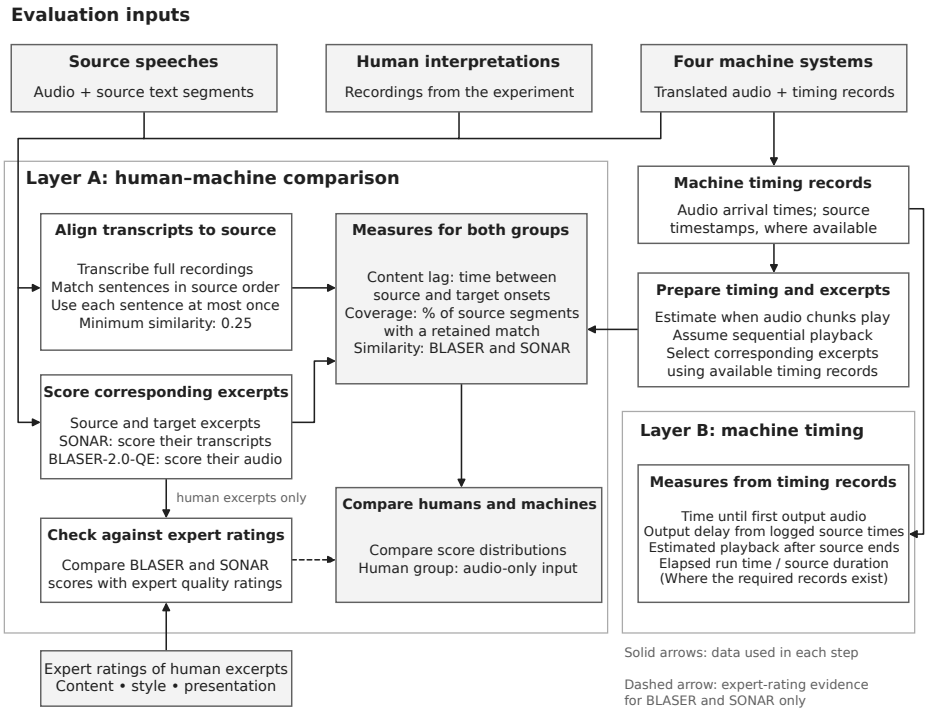

Figure 1: Evaluation workflow. Layer A compares human and machine interpretations using content lag, coverage and excerpt similarity. Expert ratings of human excerpts provide validation evidence for BLASER and SONAR (dashed arrow). Layer B reports timing measures derived from machine records.

sages in all five machine languages (20 runs per system). The archived alignment files contain 286 human renditions, densest in French (176) with 20 to 44 per other language. The 20 runs per system are not independent samples; every cross-system comparison is therefore paired within speech×language cells, and inference is conditional on these materials.

## 6 Results

### 6.1 Validity of the Similarity Metrics (RQ1)

Before BLASER and SONAR are applied to machine output, their relation to expert judgment is estimated on the excerpts the experts rated. The 3,016 blind ratings were matched to their excerpts, and each criterion was regressed on each metric in a cumulative-logit mixed model (`ordinal::clmm`, Laplace approximation, flexible thresholds) with random intercepts for rater, interpreter, and excerpt and language fixed effects. The excerpt intercept accounts for ratings of the same excerpt: each metric value attaches to one of 552 excerpts. Content was designated the primary criterion in advance; the remaining slopes are reported descriptively.

Both metrics showed their strongest estimated association with content ratings, followed by presentation and then style (Fig. 2): one SD of SONAR text similarity multiplies the odds of a higher *content* rating by 1.66 (95% CI 1.48–1.87, likelihood-ratio $p < 10^{-16}$), a higher *presentation* rating by 1.26, and a higher *style* rating by 1.11 ($p = .017$); the audio-based BLASER-2.0-QE shows the same shape (1.26, 1.15, and a style odds ratio of 1.04, $p = .37$). The content slope is stable under leave-one-language-out refits (OR 1.53–2.05, significant in every refit); excerpt-level correlations are consistent (content .40 vs. style .15).

Machine similarity claims below are interpreted in relation to the content criterion; the study does not provide validated machine measures of style or presentation. The metric also resolves a known quality contrast: human raters registered a decrement of 0.13–0.22 points under degraded telephone-band sound, and the primary metric separates the same conditions ($\Delta$=.031, 95% CI [.005, .057]); the contrast serves only to test metric resolution, as the machine comparison uses full-band audio. Finally, the two reference-free metrics agree well across the 552 rated excerpts ($\rho$=.70): the two encoders give correlated rankings of the human renditions. We use SONAR as the primary similarity measure because its estimated association with expert content ratings is stronger.

This validity is established on human renditions; its transfer to machine output is an explicit as-

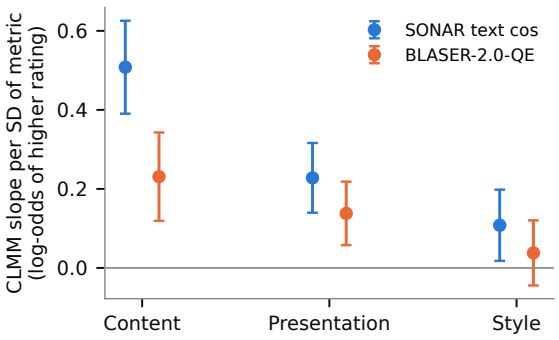

Figure 2: Criterion validation against 3,016 blind expert ratings: cumulative-logit mixed-model slope of each rating criterion on each metric (rating $\sim$ metric + Language + (1|Rater) + (1|interpreter) + (1|excerpt); error bars 95% CI). Associations are strongest for content, weaker for presentation, and weakest for style (BLASER: $p = .37$). This comparison supports the use of similarity as a content-related measure.

sumption, not a demonstrated fact. Fluent hallucinated content can escape a similarity metric (Section 6.5), and machine scores above the human range are extrapolations on the validated axis. Machine placements are therefore reported as *similarity* percentiles within the human distribution, never as expert-rated quality.

### 6.2 Placement in the Human Envelope (RQ2)

Figure 3 shows content lag on the horizontal axis, against coverage (Section 5) on the vertical. In the machine-matched ARI-HQ stratum, interpreters have a median content lag of 3.2 s and median measured coverage of 75%, with unmatched segments potentially reflecting compression, restructuring, actual omissions, or transcription and alignment error (Section 6.5). On these materials every machine system has measured coverage at or above the professional median (medians 83%–94% vs. human 75%); coverage, however, rewards literal retention (Section 6.4) and is therefore not a claim of better interpreting. Only `gpt-realtime-translate` delivers its coverage in human time.

On the calibrated similarity axis (Section 6.1), `gpt-realtime-translate`'s window similarity sits at the 90th–100th percentile of the human similarity distribution and Azure Speech Translation's at the 100th; placements above the human maximum are extrapolations. Percentiles are capped at the 100th percentile and therefore cannot separate values above the human maximum. Equal percentile placements do not imply equal raw similarity; Table 2 reports raw similarity separately by language.

### 6.3 Temporal Behavior (RQ3)

The four systems have median content lags (`gpt-realtime-translate` 5.3 s, Azure Speech Translation 25.7 s, SeamlessStreaming 39.9 s, Open-Cascade 40.5 s) against the human 3.2 s (Fig. 5). SeamlessStreaming was evaluated in its streaming RunPod configuration on a rented A100; its content-lag values are playback-model estimates (App. A). Distributional distances from the ARI-HQ human lag distribution ($n = 71$ per-rendition medians) are large for every system except `gpt-realtime-translate`: the 1-Wasserstein distance, the average shift in seconds needed to match a system's lag distribution to the human one, is 2.5 s for `gpt-realtime-translate`, 25.6 s for Azure Speech Translation, 48.1 s for SeamlessStreaming, and 33.5 s for Open-Cascade; the Kolmogorov-Smirnov distance, the largest gap between the two cumulative distributions, is $\geq 0.94$ for every system. Only `gpt-realtime-translate` overlaps the human band and sits systematically on the slow shoulder of the human distribution.

The event streams provide system-specific timing diagnostics: Azure Speech Translation commits quickly once its recognizer closes a segment (median 1.3 s commit-to-audio) but waits for semantic segment boundaries ($\sim$7 s units) and then queues synthesized audio behind earlier playback; Open-Cascade's median per-commit processing delay is 2.6 s (the 8 s cap limits source buffering, not processing or playback delay) but its synthesis speaks at nearly the source's pace, so playback debt compounds across the passage; SeamlessStreaming's timing depends on the model's emission decisions and computation time (App. A). These processes may contribute to the wide per-run spread of the three slower systems (IQRs spanning tens of seconds): lag accumulates with each speech's density and pause structure. `gpt-realtime-translate`, which streams continuous $\sim$200 ms audio deltas instead of queuing synthesized segments, is the only system whose per-run lags concentrate near a stable value. Human per-rendition median lags have a narrow interquartile range (2.6–3.5 s) across these 10.5-minute passages. This between-rendition pattern does not directly establish how lag is regulated within a passage.

On these materials, the fastest system combines relatively low content lag with high measured segment coverage and source similarity. This comparison does not establish a causal quality–

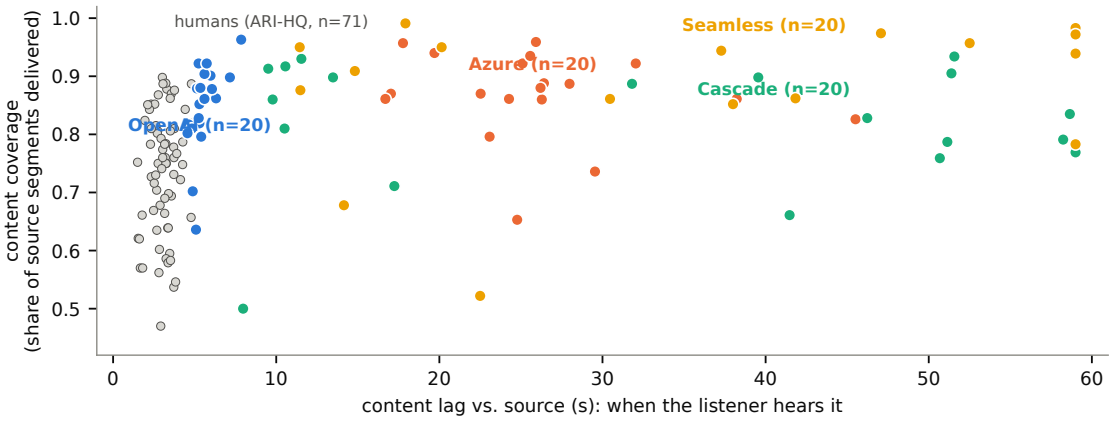

Figure 3: Content lag versus content coverage, per rendition/run. Each gray point is one professional interpreter's full-passage rendition (ARI-HQ stratum); colored points are machine runs (one per speech×language). Content lag is onset-to-onset on the source clock: for humans, directly from the alignment; for machines, transcript times are first mapped from concatenated output audio to their queue-model playback position. Lags >59 s drawn at the frame edge.

| | fr | de | es | it | ru |
|---|---|---|---|---|---|
| Humans (ARI-HQ) | 0.67 | 0.57 | 0.67 | 0.58 | 0.62 |
| `gpt-realtime-translate` | 0.75 | 0.74 | 0.73 | 0.72 | 0.65 |
| Azure Speech Translation | 0.82 | 0.82 | 0.85 | 0.86 | 0.83 |
| SeamlessStreaming | 0.65 | 0.65 | 0.76 | 0.71 | 0.63 |
| Open-Cascade | 0.76 | 0.73 | 0.80 | –[a] | 0.74 |

Table 2: Per-language content similarity to source windows (SONAR text cosine, median over rated windows); the human row is the machine-matched stratum (audio-only, full-band sound; ARI-HQ). Most machine-language medians meet or exceed the corresponding human median; source similarity can penalize professional compression and does not establish interpreting quality. [a]Italian Open-Cascade windows were not scored (runs completed post-freeze, Section 4); their run-level lag and coverage are included in all analyses.

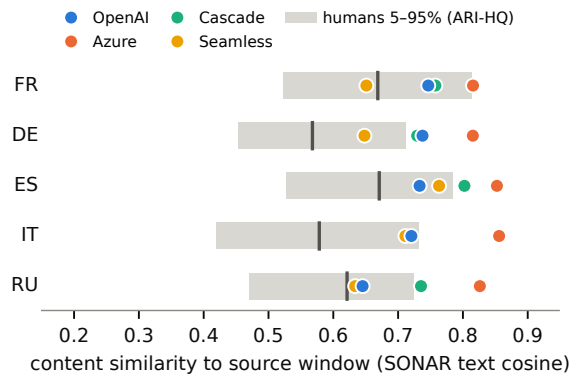

Figure 4: Human SONAR-similarity distributions per language (5–95%, ARI-HQ) with machine medians.

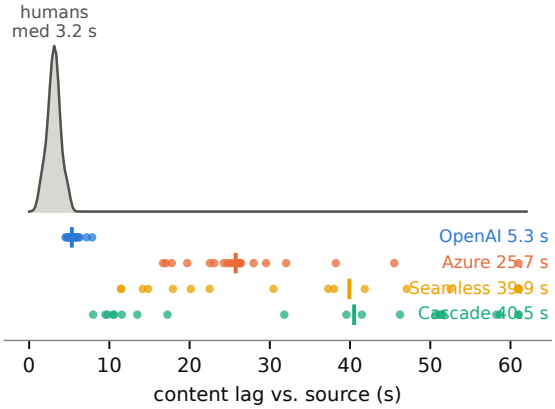

Figure 5: Content lag on the source clock: human density (per-rendition medians, machine-matched ARI-HQ stratum, $n = 71$) with per-run machine values. Machine transcript times remapped to the source clock (App. A).

latency trade-off. Paired coverage differences between systems span 1 to 6 points across the 20 speech×language cells (cell-level paired differences resampled with replacement, 2,000 replicates, percentile intervals), with intervals crossing zero for every pair, so the data establish neither an ordering nor equivalence, and both commercial systems place at the envelope top despite a five-fold lag difference.

### 6.4 Stability, Cost, and the Human Scale

Figure 4 illustrates that higher source similarity can reflect greater literal retention. The measure does not distinguish professional compression from content loss or measurement error, so its values do not constitute an overall quality ranking. Costs: `gpt-`

| | n runs | content lag | coverage | first audio | tail | similarity pctile |
|---|---|---|---|---|---|---|
| Humans (ARI-HQ) | 71[a] | 3.2 s [2.6–3.5 s] | 75% | – | – | (envelope) |
| `gpt-realtime-translate` | 20 | 5.3 s | 86% | 0.8 s | 6.5 s | 90th–100th |
| SeamlessStreaming | 20 | 39.9 s[c] | 94% | 5.1 s | 56.5 s | 96th (IQR 33–100) |
| Azure Speech Translation | 20 | 25.7 s | 88% | 13.8 s | 30.2 s | 100th |
| Open-Cascade | 20[b] | 40.5 s | 83% | 12.4 s | 54.2 s | 100th (IQR 45–100) |

Table 3: Main comparison. Lag, coverage and timing entries summarize runs or renditions; similarity percentiles summarize excerpt scores. Content lag = source-to-target onset delay on the source clock, reconstructed for machines; coverage = share of source segments with a retained alignment; similarity pctile = placement of window SONAR similarity in the ARI-HQ human distribution (the content-anchored proxy of Section 6.1; values above the human range are extrapolations). [a]renditions in the machine-matched stratum (audio-only, full-band sound; ARI-HQ), of 286 aligned across all strata. [b]Italian runs completed post-freeze via the repaired Piper voice and are included (App. A). [c]streaming run on a rented A100 (RunPod).

**Source (opening):** "Without further ado, let's get started. Firstly, I'd like to welcome you all to what promises to be a really interesting discussion . . . "

**SeamlessStreaming:** "*Sans plus de douille*, on commence. Premièrement, j'aimerais vous accueillir dans ce que promet d'être *des sites intéressants* . . . "

**Source (final words):** " . . . Well, firstly, thank you for having me, of course." *[interview continues to cutoff]*

**`gpt-realtime-translate`:** " . . . Je vous remercie d'avoir écouté *cette vidéo* . . . j'espère que vous aurez apprécié cette vidéo. Merci à tous. À bientôt."

Figure 6: Orthogonal failure modes (both ARI-4, French). Top: SeamlessStreaming commits before disambiguating context arrives; "without further ado" becomes the nonsensical *sans plus de douille* ("douille" = cartridge casing). Bottom: `gpt-realtime-translate` invents a complete video-outro that has no counterpart in the source when the input trails off. The output is fluent, polite, and entirely hallucinated.

`realtime-translate` cost $7.25 at $0.034/min; Azure Speech Translation $0 billed (free-tier credits; list-price equivalent ≈$18–36 for both sweeps); the open systems cost GPU time (≈9 GPU-h, ≈30 GPU-h), SeamlessStreaming requiring datacenter-class compute to approach real time (Section 6.3).

### 6.5 Qualitative Failure Modes

SeamlessStreaming commits *too early* on partial context, which surfaces as broken lexical choices an expert would score under *content*. `gpt-realtime-translate` *hallucinates*: it completes *too fluently* at the end of input, producing confident invented content that a similarity metric barely penalizes (its full-passage SONAR cosine is *higher* than SeamlessStreaming's, 0.85 vs. 0.78). Neither similarity placement nor criterion calibration reliably detects the hallucinated outro; only manual source-output inspection revealed it. Both failures were found by listening to runs and inspecting transcripts against the source during alignment validation; no exhaustive hallucination census across all eighty runs was performed, so the frequency of such events is unknown (Limitations).

## 7 Discussion

**Timing differences at the tested operating points.** The SimulST literature treats latency as a controllable policy parameter: wait-$k$ policies trade quality against a chosen delay (Ma et al., 2019), learned read-write policies make that trade adaptive (Seamless Communication et al., 2023b), and the average-lagging metric family scores exactly this trade (Ma et al., 2019; Papi et al., 2022). All paired bootstrap intervals for coverage cross zero, establishing neither an ordering nor equivalence (Section 6.3). The commercial systems differ approximately five-fold in median lag while both occupy the upper end of the human similarity distribution; the capped percentiles cannot quantify their similarity difference. The timing records identify candidate contributors to these differences: semantic-segment closure and synthesis queuing for the cascades, computational demands for the open speech-native model, and continuous ∼200 ms emission for the commercial speech-native system. Cherry and Foster (2019) argued that average-lagging values are not comparable across systems with different commitment behavior; at passage scale, the comparable quantity is the listener-experienced lag distribution on a shared source clock.

**Computation and passage-scale latency.** Papi et al. (2025) showed that reported SimulST performance degrades substantially once computation and realistic long-form input enter the clock. For speech-to-speech systems, content-lag estimates depend on both output-emission decisions and the computation required on the reported hardware (Section 6.3). Latency claims must there-

fore report hardware and compute budgets. Our content-lag measure extends the resegmentation move of StreamLAAL (Papi et al., 2024) to speech-to-speech with no committed text on either side, allowing one instrument to score humans, open models, and closed services.

**Hallucination and over-generation at passage scale.** LAAL exists because over-generation gamed average lagging at sentence scale (Papi et al., 2022). Two passage-scale analogues appear here. First, machine coverage near 90% against the professional 75% does not establish superior interpreting. Greater literal retention is one possible explanation, but coverage alone cannot distinguish useful compression, substantive omissions, and transcription or alignment error. Second, the invented outro (Fig. 6) is over-generation at the input boundary, and it exposes the metric consequence: embedding similarity (Duquenne et al., 2023; Chen et al., 2023) rewards fluent topical continuation, so the hallucinated ending outscores a faithful but fragmented alternative. Quality-estimation metrics inherit the norms of the judgments they are trained on (Rei et al., 2020, 2022), and those norms are translation adequacy, not interpreting: they read strategy as loss and invention as adequacy. This supports delivery-aware, multimodal evaluation with access to prosody, seams, and timing. For presentation, candidate indicators include pause distributions, articulation rate, pitch variation, and audible repetitions or synthesis boundaries, measured from delivered audio. For style, transcript-based assessments could examine register and idiomatic expression. These indicators would require validation against the corresponding expert ratings, followed by testing on rated machine excerpts; none is treated here as an established substitute for those judgments. The human reference has a median lag of 3.2 s (IQR 2.6–3.5 s across rendition medians). Audible boundaries in segment-committed synthesis warrant direct assessment under presentation.

**What would move each architecture into the envelope.** The timing diagnostics (Section 6.3) suggest engineering changes to test. The cascades' latency floor is set by segment closure plus synthesis at speech pace; newer cascades with an LLM translation stage (Grigoryan et al., 2026) warrant comparison, but this study does not measure their similarity or latency. Time-aware synthesis (TTS that accepts a duration target) and sub-segment commitment are the levers. For open speech-native systems, emission policy and computational capacity should be evaluated together. That the only system inside the human band streams continuous audio deltas suggests commit granularity, not architecture family, is the operative variable, a hypothesis the next system generation can test. Expert panels judging deployed systems (World Health Organization, 2025; Matsushita, 2026) reported the same tens-of-seconds lag scale our instruments measured; the one in-band system shows such verdicts are policy-specific, not generic.

**A recipe for human-anchored evaluation of machine interpreting.** Applying the protocol elsewhere involves five steps: (1) reuse or obtain a rated human corpus for the register; (2) validate candidate reference-free metrics per rating criterion against its ratings, keeping only the criteria they align with; (3) run every system on the same passages as real-time-paced audio, logging client-side events; (4) apply the scoring protocol to humans and machines and quantify transcription and timing-estimator differences; (5) report placements in the human distribution with paired contrasts. Human calibration can be reused within a corpus, but transfer to new machine outputs requires checks for system-specific failure modes.

**Future work.** The corpus supports three extensions: blind expert ratings of stratified machine excerpts to test transfer of criterion validity; listener studies of audience comprehension and listening effort under matched conditions; and mechanistic analysis of the open systems, whose attention states are observable during inference.

## 8 Conclusion

We compared four machine simultaneous-interpreting systems with the professional reference distribution: human renditions of the same discourse, with automatic metrics assessed against 3,016 blind expert ratings of 552 excerpts from 69 interpreters. The metrics were most strongly associated with content judgments. Machine outputs attained similarity scores within or above the human range and higher measured segment coverage, but all four systems had longer median content lag; only `gpt-realtime-translate` approached professional timing. Higher coverage does not establish better interpreting, because the measure can penalize compression and is sensitive to transcription and alignment error. The protocol supports reproducible comparison against a profes-

sional reference, while the validity of its similarity measures on machine output remains to be tested with expert ratings.

## Limitations

**Vendor and architecture confounds.** The commercial pair differs in vendor, training data, voices, and endpointing. That contrast is descriptive only; no architecture or openness main effect is claimed. Closed-system architecture labels rest on vendor documentation: `gpt-realtime-translate`'s transcript streams mean an internal text stage cannot be excluded from outside; systems can instead be grouped by observable commit behavior (continuous audio deltas versus segment-finalized synthesis) without changing measurement. Both commercial arms are dated snapshots (August 3–4, 2026; model strings in App. A) and may not replicate after vendor updates.

**Hardware dependence.** The evaluated natural SeamlessStreaming rerun used a rented A100. Its reported latency characterizes that configuration and hardware and is not a lower bound for the architecture. Open-Cascade's Italian runs completed after the operating-point freeze via a repaired TTS voice and are included (App. A). Machine content lag is reconstructed from client-side timestamps under a sequential playback model and has not been independently validated against recorded live playback.

**Materials and cohort.** Four speeches, one register (prepared conference roundtable), one source language (English), five target languages; the 20 runs per system are those four speeches crossed with five languages, so all conclusions are conditional on these materials and none generalizes beyond this register without new data. The envelope is densest in French (45 interpreters vs. 5–11 elsewhere), so per-language placements outside French carry wide intervals. ASR errors may differ between live interpreter speech and synthesized machine speech, affecting both text similarity and alignment-based coverage. The audio metric and alignment hand-validation do not quantify or correct this possible asymmetry. Restructured renditions can also register spurious omissions. The contribution of transcription and alignment error to the observed human–machine gap remains unquantified.

**Transfer of criterion validity.** Expert ratings cover human renditions only; no machine output was rated. Criterion validity is therefore established on human speech and *transferred* to machine output, and machine scores above the human range are extrapolation on the validated axis. The invented outro of Section 6.5 shows the failure concretely: fluent hallucination is barely penalized by the proxy, and no systematic hallucination census across the eighty runs was performed, so the frequency of such events is unknown. The machines' fragment prosody and seam repetitions fall precisely on the unmeasured style and presentation criteria. Blind expert ratings of a stratified sample of machine windows are needed to test transfer. The open cascade is the reproducible baseline specified in Section 4. Its results characterize that configuration and hardware and do not establish the performance of more recent or faster cascades.

## A Reproducibility

**Open-arm models and pins.** ASR `openai/whisper-large-v3`; MT `facebook/nllb-200-distilled-1.3B`; TTS `facebook/mms-tts-{fra,deu,spa,rus}`, with Italian synthesis via the Piper voice `it_IT-paola-medium` because `facebook/mms-tts-ita` was withdrawn from the HuggingFace Hub during the study window (verified 2026-08-03 against the canonical repo, mirrors, and CDN). SeamlessStreaming ran the uniform `SeamlessStreamingS2STAgent` with `vocoder_v2` in all five languages; SeamlessExpressive/PRETSSEL was not used (no Russian support), and every manifest records the effective agent, asserted uniform before pooling. Software pins: `torch==2.2.2+cu121`, `transformers==4.49.0`, `silero-vad==6.2.1`, `simuleval==1.1.4`, `faster-whisper` (large-v3) for all transcription. Open-Cascade ran on NVIDIA Titan RTX hardware with fp16 inference and real-time-paced input. The evaluated natural SeamlessStreaming rerun used a rented A100, as described in Section 4.

**Operating-point sweeps (dev speech ARI_1→fr).** Cascade, 2026-08-04: {silence 300/500 ms} × {cap 8/12 s} → 500 ms/8 s selected (median per-commit lag 3.2/3.3/2.7 s and max 10.3/6.4/4.4 s for baseline/sil300/cap8). Azure segmentation: semantic default vs. `Speech_Segmentation SilenceTimeoutMs=300` (median source segment 6.9→3.8 s, translated words 1657→1683, audibly degraded delivery); default retained, the alternative sweep archived as a latency–integrity trade-off.

**Commercial access.** `gpt-realtime-translate` accessed 2026-08-03; Azure Speech Translation in eastus; Speech SDK `Translation Recognizer`; voices de-DE-KatjaNeural, es-ES-ElviraNeural, fr-FR-DeniseNeural, it-IT-ElsaNeural, ru-RU-SvetlanaNeural, accessed 2026-08-03–04. All commercial runs in a single dated window (August 3–4, 2026). Costs: $7.25 (`gpt-realtime-translate`, list price $0.034/min); $0 billed (free-tier credits; list-price equivalent ≈$18–36 for both sweeps) (Azure Speech Translation); open arms ≈9 GPU-h and ≈30 GPU-h of cluster GPU time. Code, run manifests, processed alignment tables, and analysis scripts will be released on publication; rendition audio and ratings remain under the original consent terms and are available through the source experiment's controlled access route. Released commercial-service outputs carry the usage note "commercial-service outputs: not for training competing models."

**Inclusion and validation.** Master inclusion table: 74 of 78 recorded participants included; PF40 (no usable audio), PF30 (dropped in the original quality evaluation), PX19 (two trials), PX20 (withdrew) excluded (Section 3). Alignment hand-validation: complete side-by-side walkthroughs of three renditions per language reviewed before scoring; the automatic alignment matches individual source and target segments one-to-one, so a target segment expressing content from multiple source segments does not automatically credit every source segment. Coverage counts a canonical source segment as matched when a retained

one-to-one alignment links it to a target sentence at similarity $\geq 0.25$ under the monotonic program; the four speeches contain 460 canonical segments (108–121 per speech). Latency quantization floors: `gpt-realtime-translate` $\sim$200 ms audio deltas; Azure Speech Translation segment-finalized synthesis; Open-Cascade VAD-commit units (500 ms/8 s); SeamlessStreaming 320 ms input blocks.

**Interpreting the SONAR coefficient on the rating scale.** We calculated expected content ratings from the fitted cumulative-logit model by weighting the seven response categories by their predicted probabilities. We compared SONAR at its pooled mean with one SD above that mean, retained the language fixed effects, and integrated over the estimated Gaussian random-intercept distributions for rater, interpreter and excerpt. Averaging the language-specific changes in proportion to their numbers of ratings gave 0.23 points (0.22–0.27 across languages). The reported range is variation across languages, not a confidence interval.

# An Analysis of Source-Side Diversity in Machine Translation Evaluation

## Abstract

Benchmarks are central to assessing progress in machine translation (MT), yet the content of widely used MT test sets is increasingly scrutinized. Concerns about data contamination and benchmark difficulty have gained traction, but the role of source-side diversity remains largely overlooked. Many popular benchmarks contain overlapping source items and even exact duplicates, raising the question of how such repetition affects evaluation quality. We empirically examine how source-side diversity shapes MT evaluation. First we measure the inter-source diversity of nine popular MT datasets. Next, our downstream analysis, based on WMT24, suggests that benchmarks with low diversity may be less discriminative and may provide artificially narrow confidence intervals. Ultimately, we call for greater attention to inter-source diversity in general MT benchmark design.

## 1 Introduction

Designing general-purpose machine translation (MT) benchmarks is fundamentally difficult: They are expected to reflect the diversity of real-world translation while avoiding an unintended focus on any single style, domain, or register. Recent efforts in WMT evaluation campaigns have prioritized this, aiming to evaluate "MT systems' ability to handle a broad range of translation and language use" and "explore the translation capabilities of current systems in diverse settings" (Kocmi et al., 2024). Still, MT benchmarks contain source-side items with considerable overlap: Figure 1 shows such an example of two items in the WMT24 benchmark. This overlap suggests potential correlation between items: A model that performs well on item #346 would also be expected to perform well on item #350. Yet, how this affects the quality of MT evaluation at large is currently an open question.

Previous work (Freitag et al., 2020; Bawden et al., 2020; Zeng et al., 2024) has mainly addressed

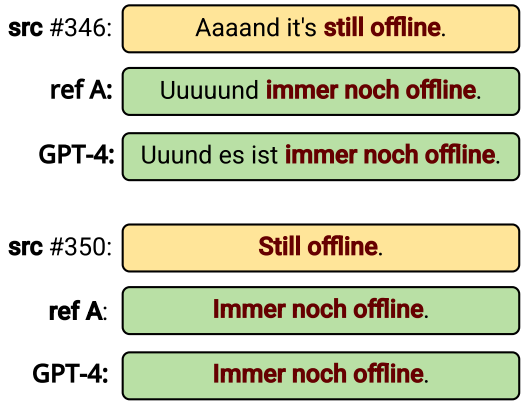

Figure 1: Example of **overlapping** source-side items (#346 and #350) in WMT24 ( en → de ). GPT-4 translated items similarly, leading to repeated output trigrams and similar scores across items.

MT benchmark diversity from the *reference-side*, aiming to mitigate the monotonous style of typical references used in common MT benchmarks. In this work, we instead investigate *source*-side diversity. We address the following research question: **How does source-side diversity affect MT evaluation?**

More specifically, we focus on *inter-source diversity*, based on pairwise comparisons of source items. In particular, our analysis targets lexical, surface-form repetition between items. Intuitively, if a benchmark contains two identical items, the weight of this item in a final aggregate metric is doubled, compared to a unique item. This can lead to (unintended) skews in the linguistic phenomena that are represented. This is problematic when the goal is to draw conclusions about translation quality generally, and results are aggregated uniformly across items, as is common practice. Furthermore, running large-scale MT evaluation campaigns requires human translations, human annotations of quality, and inference over all competing models. When repeated and similar items are included, such resources are potentially wasted: (Near-)duplicates

*Proceedings of the Eleventh Conference on Machine Translation*, pages 554–573
October 28-29, 2026 ©2026 Association for Computational Linguistics

provide limited new information about model performance. Despite these intuitive arguments, there has been no systematic investigation of the quantitative, downstream impact of inter-source diversity in MT benchmarks. We therefore present the following contributions:

- An **audit** of source-side diversity in nine popular MT benchmarks (§3);
- An **empirical analysis** of the downstream impact of controlled inter-source diversity in WMT24, regarding model rankings, confidence intervals, and discriminativeness (§5);
- **Further analysis** concerning item and score similarity, domains, and the relationship between difficulty and diversity (§6);
- A **discussion** on the role of inter-source diversity in MT evaluation (§7);
- Practical **recommendations** for MT benchmark design (§8).

Our results, based on WMT24, indicate that source-side diversity is an important and beneficial property of MT benchmarks. We highlight the need for more systematic attention to inter-source diversity in general-purpose MT benchmark creation, and provide a practical algorithm for controlling benchmark diversity in existing benchmarks.

## 2 Background & Related Work

**Redesigning MT Benchmarks.** Benchmarks have played a vital role in the automatic evaluation of MT developments, and thereby steering research directions. This relationship is bidirectional: Benchmarks shape progress, but progress also reshapes what we require from strong benchmarks. Currently, a prominent criticism of existing MT benchmarks concerns their *difficulty*: As the state of the art improves, benchmarks risk becoming too easy, reducing their ability to meaningfully differentiate system performance. Mitigating such benchmark saturation has become a popular line of MT research. Zhan et al. (2021) and Liu et al. (2022) approached difficulty from the perspective of *metrics*, where different benchmark items get different weights in aggregate scores, based on their predicted difficulty. Data-level approaches pursued difficulty by filtering for specific textual characteristics, such as selecting longer sentences (Chen et al., 2023). A recent line of work has extended this direction. Proietti et al. (2025) propose the task of predicting the difficulty of benchmark items, and use these predictors to sample difficult items, constructing more challenging benchmarks. Xu et al. (2025) search for difficult test items on the internet, and Pombal et al. (2025) and Zouhar et al. (2026) generate items that are difficult to translate (the former from scratch; the latter iteratively). This line of research has practical impact: The WMT25 general MT benchmark was explicitly filtered for difficulty (Kocmi et al., 2025).

Difficult benchmarks are not necessarily linguistically representative, as they aim to assess MT performance specifically in challenging scenarios. In fact, Zouhar et al. (2026) demonstrate a trade-off: Optimizing solely for difficulty may come at the expense of diversity. Since most efforts to increase benchmark difficulty have rarely accounted for diversity, source-side diversity has been largely absent from the discourse on improving MT evaluation. Our work addresses this perspective directly.

**Diversity in MT Benchmarks.** Most works that address diversity in MT benchmarks focus on the reference-side. Freitag et al. (2020) note that WMT references exhibit a monotonous style, and include additional, manually paraphrased references, which increased the correlation with human judgment on the WMT19 English→German set. Bawden et al. (2020) found that, when using automatically generated paraphrases, improvements (based on BLEU) were small and inconsistent. Zeng et al. (2024) experimented with using LLM-generated reference alternatives on four translation directions in WMT22, and report an improved correlation with human judgment. These works define the diversity of a set of references according to lexical diversity (as opposed to e.g. syntactic diversity), because MT models and many metrics are sensitive to lexical, surface-level variation.

We similarly focus on lexical diversity, but approach diversity from the *source*-side. This offers a practical advantage: Source-side interventions could lead to more efficient use of evaluation resources. That is, more informed selection of source-side items can avoid ineffective efforts such as translating identical (or highly similar) items, both in terms of human effort as well as model inference costs. Since benchmarks are commonly translated into a range of languages (9 for our WMT24 source set, 55 languages in WMT24++; Deutsch et al., 2025), this effort is not negligible.

## 3 An Audit of Source-Side Diversity

Understanding whether source-side overlap meaningfully affects MT evaluation first requires establishing how common such overlap actually is. If the examples in Figure 1 prove to be isolated cases, and overlap is generally rare in widely used MT benchmarks, then inter-source diversity may pose little practical concern. However, the current state of source-side diversity in MT evaluation sets remains largely undocumented. In this section, we therefore conduct a systematic audit of source-side diversity across popular MT benchmarks: What is the extent of duplicates and overlap present in benchmark items?

**Datasets.** We analyze nine of the most widely used MT evaluation datasets: Europarl (Koehn, 2005), FloRes-101/200 `devtest` (Goyal et al., 2022; NLLB Team et al., 2024), BOUQuET (Andrews et al., 2025), and six recent benchmarks from the main WMT evaluation campaigns (WMT20-25; Barrault et al. 2020; Akhbardeh et al. 2021; Kocmi et al. 2022, 2023, 2024, 2025). This broad selection includes the most recent evaluation datasets used in the OPUS-MT Dashboard (Tiedemann and de Gibert, 2023). We analyze English sources. For the WMT datasets, we take the source text that was translated into most target languages that year. Details for each dataset are found in Appendix A.

**Diversity Measures.** We are principally interested in *inter-source diversity*, i.e. how similar or dissimilar individual test instances are to one another. To assess this, we first count the number of items that occur more than once in a benchmark (# Dpl), and the number of near-duplicates (# N-Dpl) as the number of items in a test set that have a Levenshtein similarity of $> 0.9$ to another item in the test set.[1] Note that this is a conservative threshold, capturing only items with very high surface-form similarity, excluding examples such as in Figure 1 (Levenshtein similarity: 0.65). Additionally, we measure lexical overlap through the average Dice-coefficient of the character bigrams (cf. Kondrak, 2005) over all pairs of items, and subtract this from 1 to retrieve an average lexical distance.[2] This mean pairwise distance (MPD) measures how lexically different benchmark items are from each other, on average. Additionally, we report the average distance (again: 1−Dice-coefficient) to each item's nearest neighbour (mean minimal pairwise distance; MMPD). While MPD captures the global lexical spread of the benchmark, MMPD reveals to what extent items are locally clustered.

We also examine how inter-source diversity relates to other *overall diversity* measures, commonly used in MT (e.g. Vanmassenhove et al., 2019). We first measure the number of unique words in each benchmark ($|W|$). This measure naturally increases as the number of items in a benchmark increases. Therefore, we also calculate the length-robust MTLD (average length of consecutive word strings that maintain a certain TTR value; McCarthy and Jarvis, 2010).[3]

[1] We use `TheFuzz` (`https://github.com/seatgeek/thefuzz`), using the method `fuzz.ratio()`. This threshold was argued in previous work to account for minor variations (e.g. Szep et al., 2026).

[2] We experimented with a range of other metrics, including Levenshtein Distance, Jaro-Winkler Distance and Hamming Distance, but found that overall trends remain the same.

[3] We calculate this using `https://github.com/kristopherkyle/lexical_diversity`, default settings.

| | | *Inter-source Diversity* | | | | *Overall Diversity* | |
|---|---|---|---|---|---|---|---|
| **Benchmark** | **# Items** | **# Dpl (↓)** | **# N-Dpl (↓)** | **MPD (↑)** | **MMPD (↑)** | **\|W\| (↑)** | **MTLD (↑)** |
| Europarl | 3,064 | 3 | 17 | 0.59 | 0.39 | 8,336 | 102.61 |
| FloRes | 1,012 | 0 | 0 | 0.62 | 0.45 | 5,818 | 108.26 |
| BOUQuET | 854 | 2 | 2 | 0.75 | 0.51 | *2,957* | 106.20 |
| WMT20 | 1,418 | 0 | 0 | 0.61 | 0.42 | 8,583 | 125.36 |
| WMT21 | 1,002 | 0 | 0 | 0.63 | 0.44 | 5,724 | 118.81 |
| WMT22 | 2,037 | *204* | *249* | 0.72 | 0.40 | 6,107 | 97.30 |
| WMT23 | 2,074 | 6 | 20 | 0.73 | 0.47 | 6,480 | *92.57* |
| WMT24 | 998 | 9 | 17 | 0.72 | 0.46 | 6,885 | 120.68 |
| WMT25 | 332 | 0 | 0 | *0.45* | *0.33* | 7,173 | 114.52 |

Table 1: Audit of source-side diversity in nine widely used MT benchmarks. Arrows indicate directions which suggest higher diversity. Single values indicating most and *least* diversity are marked in each column.

**Results and Discussion.** Table 1 shows the results. Firstly, we observe that the majority (5/9) of benchmarks we analyzed contain exact duplicates (# Dpl) at the source-side. Although the number of items that appear more than once is generally not very high (e.g. 6 out of 2,074, i.e. 0.3% in WMT23), our audit reveals WMT22 as a problematic outlier, with more than 200 repeated items. Surface-level investigation shows that several items appear frequently in that benchmark (e.g. "`Go to your Home screen.`", 11 times; "`Tap Settings`", 11 times; "`Tap Device information`", 7 times).

Overall, mean pairwise distances (MPD) are below 0.80, suggesting that benchmark items are not all lexically well-separated. Given that MT evaluation is typically budget-constrained, higher MPD values would be desirable, as they indicate a greater coverage of distinct linguistic phenomena. The mean minimum pairwise distance (MMPD) shows that, apart from BOUQuET, all benchmarks have mean nearest-neighbour distances below 50%. This means that, for most items, another source sentence in the same benchmark is somewhat lexically similar, revealing substantial local overlap despite moderate global diversity.

Lastly, we observe that *how* diversity is measured matters: Overall diversity scores, which are widely used in MT (e.g. Vanmassenhove et al., 2019), and inter-source diversity results vary. For example, WMT20 contains the highest number of unique words and retrieves the highest MTLD, but its mean pairwise distance (MPD) between items is lower than for example BOUQuET, which retrieves the highest MPD of 0.75, with a more modest MTLD score of 106.20.

**Implications.** This audit indicates that source-side overlap is not an isolated issue, but a recurring characteristic in popular MT benchmarks, making it worthwhile to investigate these patterns empirically in relation to MT evaluation. We find that source-side diversity manifests in more subtle ways than mere exact duplication: The absence of exact duplicates does not necessarily imply higher overall diversity scores, or high mean pairwise distance. Practically, our results suggest that inter-source diversity cannot be taken for granted in existing MT benchmarks, and that trivial solutions (e.g. applying a de-duplication filter) do not necessarily mitigate the issue.

## 4 Experimental Setup

To evaluate the downstream impact of inter-source diversity, we first construct subsets with controlled levels of inter-source similarity (§4.2). Based on these subsets, we evaluate differences in model rankings, confidence intervals and discriminativeness (§4.3).

### 4.1 Data

We base our analysis on the WMT24 benchmark (Kocmi et al., 2024). This dataset includes model- and item-level scores across a range of recent MT models and LLMs. Importantly, it is not an outlier in terms of diversity scores (§3), unlike for example WMT22 (# Dupl) and WMT25 (MPD), and it was not pre-filtered for difficulty, unlike WMT25. WMT24 has also shaped several recent claims about state-of-the-art MT, for example *"The LLM Era Is Here but MT Is Not Solved Yet"* (Kocmi et al., 2024), and continues to be used actively beyond the original shared task (e.g. Zouhar et al., 2026; Ramos et al., 2026). Moreover, it serves as the foundation for the broader WMT24++ dataset (Deutsch et al., 2025), further underscoring its relevance. For our analysis, we use the English sources which were translated into nine target languages (Czech, German, Spanish, Icelandic, Japanese, Russian, Ukrainian, Chinese, Hindi). We include each of these language directions in our analysis, to strengthen the cross-lingual generalizability of our findings, and to demonstrate robustness against reference-side variation (references differ across target languages).

### 4.2 Controlling Benchmark Diversity

Dataset filtering has proven to be an effective approach for mitigating redundancy in NLP benchmarks more generally (Rubinstein et al., 2026; Gupta et al., 2025; Gevers et al., 2025) and for redesigning MT benchmarks for difficulty (Proietti et al., 2025). We extend this approach to controlling diversity, by sampling high and low diversity benchmarks.

**Sampling Algorithm.** To retrieve a diverse sample, in which overlap is minimized, we approach the problem as an instance of the *Maximum Minimum Diversity Problem* (MMDP), where the objective is to select items such that the minimum distance between any two sampled items is maximal. This eliminates the need to specify any manual diversity threshold. Since the MMDP is known

| Benchmark | # Items | Inter-source Diversity # Dpl (↓) | # N-Dpl (↓) | MPD (↑) | MMPD (↑) | Overall Diversity \|W\| (↑) | MTLD (↑) |
|---|---|---|---|---|---|---|---|
| MAXMIN | 499 | 0 | 0 | 0.81 | 0.59 | 2,416 | 258.80 |
| MINMIN | 499 | 0 | 0 | 0.52 | 0.38 | 6,024 | 138.52 |
| Random* | 499.0 | 2.40 | 4.20 | 0.72 | 0.48 | 4,463.60 | 170.92 |
| *st. dev* | *± 0.0* | *± 2.27* | *± 2.57* | *± 0.01* | *± 0.01* | *± 112.75* | *± 7.26* |

Table 2: Diversity evaluation on WMT24 subsets, where Random, MAXMIN and MINMIN sample sizes are 50% of the original dataset. *For all random samples in this paper, we report the average over 10 runs.

to be NP-hard we apply a heuristic; greedy sampling. Given a set of source items $S$, for each $s \in S$, we first calculate each distance $dist$ with respect to every other source $s' \in S \setminus \{s\}$. For this, we use $1-$ the average Dice-coefficient of the character bigrams, consistent with §3. Given this matrix of pairwise distances, we then aim to sample $k$ items with maximum minimum distance. We first identify the source $s \in S$ that has the maximum distance $dist$ with respect to all other sources $s' \in S \setminus \{s\}$. Then, until $k$ is reached, we retrieve the next point that has the largest minimum distance to all items in the current sample. A formal representation of our sampling approach is found in Appendix B. We sample using a threshold of 50% of the full dataset[4], resulting in a MAXMIN set which we expect to exhibit increased lexical diversity compared to random samples of the same size. As a controlled low diversity benchmark, we construct a sample using the opposite objective (minimum minimum distance): MINMIN.

**Diversity Verification.** To verify whether our algorithm effectively controls source-side diversity, we compare the constructed MAXMIN and MINMIN test sets using the diversity measures from §3. For a length-fair comparison with the full test set, we report the average over ten random samples of the same size (50%). Table 2 shows that, indeed, our controlled MAXMIN sample yields substantially increased lexical diversity, across most measures. On the other hand, diversity in our MINMIN dataset is effectively decreased. The only exception, the number of unique words, is explained by the MINMIN sample containing more longer items (note that $|W|$ is very sensitive to length). Further, neither MAXMIN nor MINMIN contains duplicates. MAXMIN and MINMIN overlap by 68 items (13.6%). As a final verification step, we visualize the distribution of pairwise distances in Figure 2: MAXMIN indeed contains more dissimilar items than MINMIN.

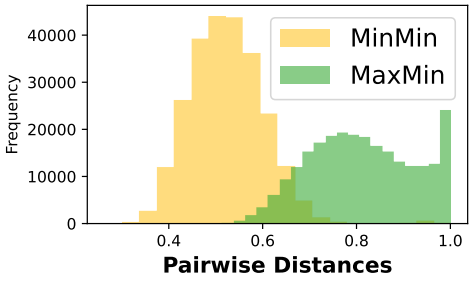

Figure 2: Frequency distribution of pairwise distances (1− Dice bigram coefficients) across the MINMIN and MAXMIN samples.

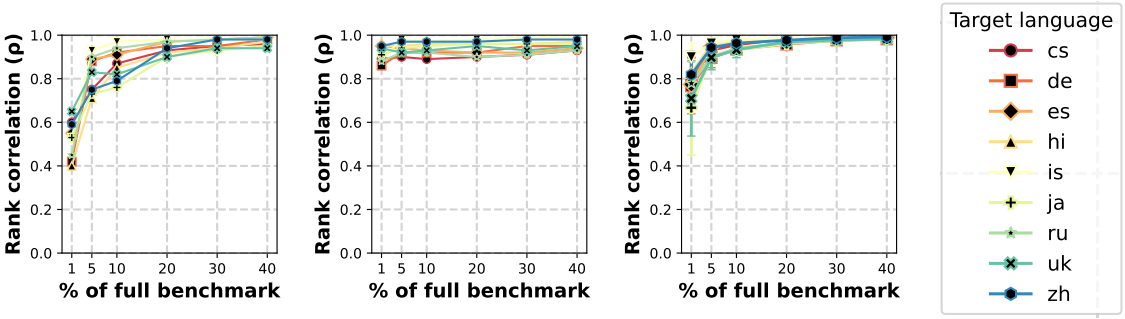
### 4.3 Measuring Downstream Impact



Unlike model evaluation, where performance can be measured directly on a benchmark, evaluating a benchmark itself is more challenging. In previous work, benchmark filtering approaches (e.g. Gupta et al. 2025; Zouhar et al. 2025) are deemed successful if the performance of the filtered set corresponds to that of the full benchmark. However, because existing benchmarks themselves are not guaranteed to be diverse (§3), we cannot rely on the full set as a gold standard. Instead, we first inspect how **model rankings** differ across the MAXMIN, MINMIN and random samples (§5.1). We then look at differences in terms of their **confidence intervals** (§5.2) and **discriminativeness** (§5.3). We report chrF in the paper's main text, which was also used in the OCELoT leaderboard for WMT24 (Kocmi et al., 2024). We rely on an automatic metric because human assessment (e.g. MQM, ESA) is not available for each item for each model. We choose chrF instead of a learned metric (e.g. COMET) in the main text, since learned metrics may disadvantage low-resource languages (Falcão et al., 2024).[5]

[4]The 50% threshold is arbitrary; we use it to demonstrate the difference between high and low diversity benchmarks, rather than searching for an optimal value.

[5]Appendices D, E and G show results on MT metrics beyond chrF; The observed patterns hold.

Figure 3: Rank correlations with the full benchmark (Spearman's $\rho$) across controlled diversity samples (MaxMin, a; MinMin, b) and Random* samples (c) of different sizes: 1%, 5%, 10%, 20%, 30%, 40% of WMT24 sources.

## 5 Results and Analysis

### 5.1 Model Rankings

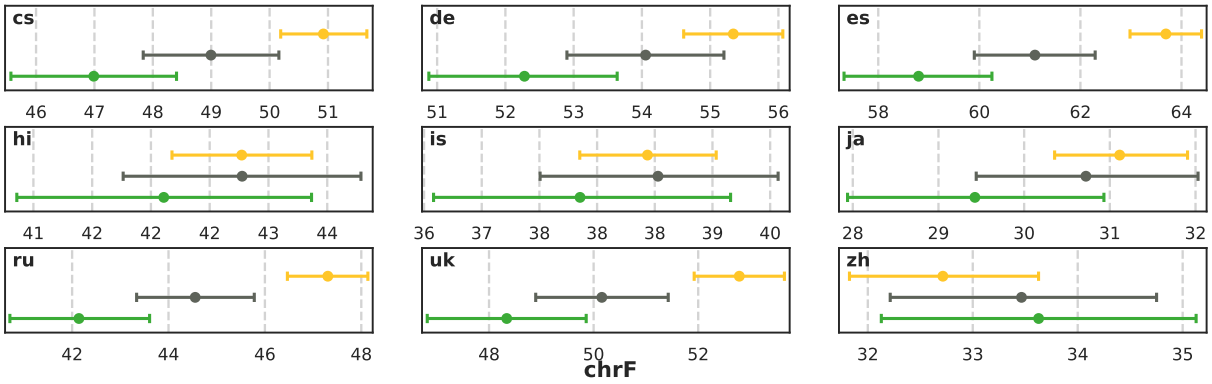
Table 3 shows the correlation between model rankings when calculating average performance per model based on only subsets of the benchmark items (MaxMin, MinMin and 10 random samples). All correlations are strong ($> 0.90$) and statistically significant; model rankings stay virtually the same, whether evaluating on MaxMin, MinMin, a random sample, or the full benchmark. While similar model-level conclusions can be drawn with less data, perhaps WMT24 is not diverse enough to show a meaningful difference.

While differences in correlation between MaxMin and MinMin (50% of the full benchmark, i.e. 499 lines) are marginal in Table 3, there is a stark difference when analyzing smaller sample sizes. Figure 3 shows the rank correlation when taking controlled diversity samples of different sizes (1%, 5%, 10%, 20%, 30%, 40% of the full WMT24 benchmark). Taking only 1% (9 sentences) items through minimum minimum diversity sampling yields a strong (and statistically significant) correlation ($> 0.85$) with the full benchmark, across all nine translation directions. This strong correlation is consistent across sampling sizes. By contrast, sampling for maximum minimum diversity requires more sentences to be included, for a strong correlation with the full benchmark. Note that correspondence to the full test set is not necessarily a good indicator of benchmark quality, since the full benchmark may include overlap (See §3 and Figure 1). We therefore evaluate benchmark behavior more generally in the following sections.

### 5.2 Performance and Confidence Intervals

Benchmarks with many highly similar items potentially produce artificially narrow confidence intervals, because resampling-based estimates (such as bootstrap intervals) implicitly assume that each item contributes independent information, while this is not the case. For example, Hardt (2026) writes that copying each benchmark data point 10 times will make the confidence intervals overly optimistic: While no new information on model performance is added, the apparent statistical certainty increases, purely as an artifact of this duplication.

Figure 4 shows the 95% bootstrap confidence intervals for the MaxMin and MinMin datasets. The benchmark with lower diversity exhibits a consistently narrower interval, demonstrating exactly this effect: Reduced variety in the evaluation set leads to deceptively tight confidence intervals, potentially overstating how reliably the benchmark shows model performance. The figure also shows



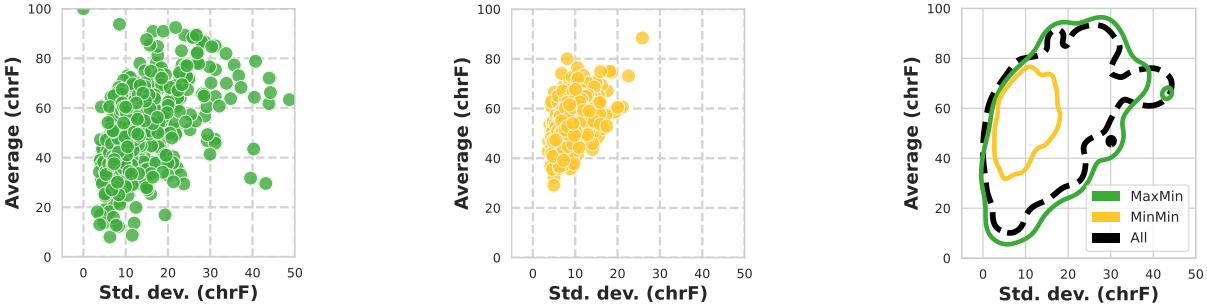


Figure 4: 95% bootstrap confidence intervals (sampled 10,000 times with replacement) for the MAXMIN (bottom) and MINMIN (top) and Random* (10 runs) (middle) samples.

(a) MAXMIN (b) MINMIN (c) Density comparison

Figure 5: Distribution of average chrF scores and their standard deviation across benchmark items in MAXMIN (a), MINMIN (b), and a comparison with the full set of benchmark items (c), for WMT24 en→de.

that the less diverse benchmark's scores are generally higher. This indicates that low inter-source diversity items may have inflated overall chrF scores for WMT24.

### 5.3 Discriminativeness

A requirement for an informative benchmark is that it includes items on which models perform differently, that is, different models obtain different scores. Inspired by dataset cartography from training dynamics (Swayamdipta et al., 2020), we plot each item in a (sampled) benchmark according to its average performance over all models (chrF, *y-axis*) and its standard deviation across model performance (chrF, *x-axis*). Comparing Figure 5a (MAXMIN) and Figure 5b (MINMIN) shows a stark contrast: Benchmark items in the less diverse controlled benchmark cluster together more than in the more diverse benchmark, both on the x-axis and y-axis. In Figure 5c we compare this with the full benchmark: The spread of the (smaller, 50%) MAXMIN sample resembles that of the full set, while MINMIN results are more dense. We quantify these differences in Table 4, where we also compare with the average over 10 random samples again. On the y-axis (Δ Avg.), the smaller range for MINMIN means that average performance is more similar. Thus, this benchmark is less informative when it comes to mapping MT models' strengths and weaknesses. On the x-axis (Δ Std. Dev), this means that the performance differences *between* models are smaller. Thus, the less diverse benchmark has weaker discriminative capabilities than the more diverse one. This holds across all 9 target languages (Appendix F).

| | Δ Std. Dev. | Δ Avg. | Avg. Coord. Distance |
|---|---|---|---|
| MAXMIN | 48.72 | 92.00 | 20.79 |
| MINMIN | 22.24 | 59.28 | 10.50 |
| Random* | 44.88 | 88.00 | 17.35 |
| *st. dev* | *± 2.26* | *± 4.36* | *± 0.63* |

Table 4: Difference between min and max value on the x-axis (Δ Std. Dev.), y-axis (Δ Avg.) and the average coordinate distance for each item in the sampled benchmarks, for WMT24 en→de. *Results over the random samples are averaged over 10 runs.

| | cs | de | es | hi | is | ja | ru | uk | zh |
|---|---|---|---|---|---|---|---|---|---|

Table 5: Results for multiple regression on distance matrices for similarity dimensions and average chrF score differences in WMT24. Statistically significant ($\alpha < 0.01$) correlations (1,000 permutations) are marked with an asterisk. Coefficients are rounded to two decimals. Results for COMET, MetricX-24 and BLEU are in Appendix H.

## 6 Further Analysis

The previous empirical analysis indicates that inter-source diversity meaningfully affects MT evaluation: While model rankings change minimally, the low-diversity sampled benchmark produces more narrow confidence intervals and is less discriminative, compared to a benchmark sample with higher diversity. This merits further investigation: We first verify the assumption that similar sources tend to retrieve similar scores (§6.1), analyze the sampled domains (§6.2), and further investigate the relationship between difficulty and diversity (§6.3).

### 6.1 Similar Sources, Similar Scores?

The intuition that inter-source diversity affects MT evaluation relies on the assumption that evaluating on similar items tends to yield similar outputs, thus resulting in similar scores. In this section, we verify this assumption, and explore three dimensions of similarity (lexical, syntactic and semantic).

**Methodology.** To assess to what extent similar items retrieve similar results, we correlate pairwise (lexical, syntactic and semantic) similarity matrices (over all pairs of source items) with the pairwise average score difference matrix (over all pairs of item-level results). We report results with chrF in the main text (see Appendix H for other MT metrics). We run multiple regression on distance matrices (MRM) (Legendre et al., 1994; Lichstein, 2007), with all three item similarity matrices as predictors. A negative correlation coefficient can be interpreted as follows: The higher the similarity between two test items, the smaller the distance in their average MT score across models.

Similar to the main experiments, for *lexical* similarity, we take the Dice-coefficient of the character bigrams in two sources. Using part-of-speech (POS) tags is an established approach for calculating "syntactic footprints" (Nerbonne and Wiersma, 2006). To approximate syntactic distance, we first obtain the POS tags using `Stanza` (Qi et al., 2020). We then compute the Jaccard similarity by dividing the number of overlapping POS-bigrams in the two sources by their union. More complex approaches, such as tree kernel distances, are prohibitively computationally expensive for all pairwise combinations. To approximate *semantic* similarity, we calculate the commonly used cosine similarity (e.g. Guo et al., 2024) between sentence embeddings. We use Sentence-BERT (Reimers and Gurevych, 2019) to obtain embeddings. Specifically, we use `all-mpnet-base-v2`, as the providers claim that this model "provides the best quality".[6] Formal definitions for these similarity measures are in Appendix C.

**Results and Discussion.** Table 5 shows a consistent, negative, statistically significant weak to moderate correlation between lexical similarity and (average) score differences of items. That is, a high similarity between two test items is associated with a low difference in their output scores; Lexically similar items tend to give similar results. Although there are many factors that influence automatic MT metrics (such as variation in reference formulations), it is interesting to see such a consistent result in the lexical dimension, while the syntactic and semantic similarity do not show such patterns. This supports our focus on *lexical* diversity in our main analyses. The results are mostly robust across reference variation, since the pattern holds across all target languages (each with their own references). Similar conclusions hold for BLEU, COMET-22 and MetricX-24 scores (Appendix H).

### 6.2 Domain-Level Sample Comparison

In the WMT24 evaluation campaign, benchmark items were sampled from four domains in an attempt to increase the diversity of evaluated phe-

[6] https://sbert.net/docs/sentence_transformer/pretrained_models.html

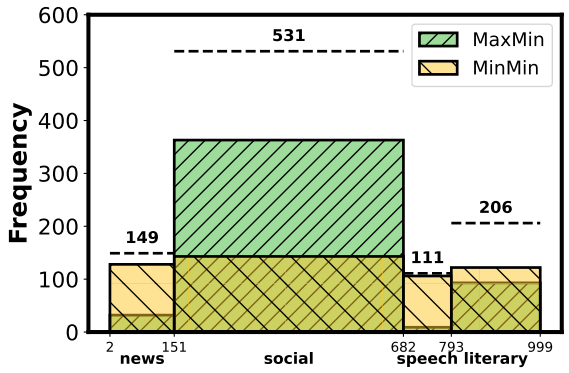

Figure 6: Number of items sampled per domain in MAXMIN and MINMIN, with total items per domain indicated by horizontal dashed lines. Note that the total size is 997 instead of 998, because the canary sentence (item #1) does not belong to a domain.

| Domain | # Dpl | MPD | MMPD | \|W\| | MTLD |
|---|---|---|---|---|---|
| news | 0 | 0.53 | 0.39 | 2,715 | 132.72 |
| social | 9 | 0.79 | 0.50 | 2,456 | 134.41 |
| speech | 0 | 0.47 | 0.37 | 2,152 | 98.81 |
| literary | 0 | 0.68 | 0.46 | 2,219 | 120.41 |

Table 6: Diversity audit per WMT24 domain.

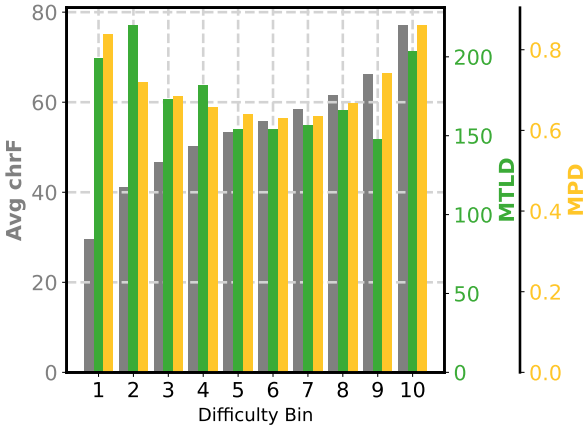

Figure 7: Source-side diversity scores across bins of decreasing difficulty in WMT24, en→de.

nomena (Kocmi et al., 2024). We investigate how MAXMIN and MINMIN compare in terms of their distribution across these domains, and what this implies about benchmark creation.

Figure 6 shows that the social domain is sampled more in MAXMIN, compared to MINMIN. In MINMIN, almost all items from the news and speech domain are included in the sample. In Table 6 we investigate this further. The news and speech domains exhibit a considerably lower MPD (0.53 and 0.47, respectively) than the other two domains (0.79 and 0.68). Interestingly, social contains the only (near-) duplicates in WMT24, but still retrieves the highest MTLD, MPD and MMPD. High MPD and MMPD may in part be explained by item length: Although our lexical distance metric corrects for length, shorter items inherently contain fewer bigrams, and therefore tend to exhibit lower overlap than longer items. Regardless, this suggests that simply sampling from *more* domains may be less effective for increasing inter-source diversity than sampling from more *diverse* domains.

### 6.3 Difficulty vs. Diversity

Considering the recent interest in increasing the difficulty of MT benchmarks (§2), it is relevant to investigate how diversity and difficulty interact. The results in §5 showed that chrF scores for the less diverse test set (MINMIN) were generally higher than those in Random and MAXMIN, indicating a lower level of difficulty, for WMT24. Inspired by Zouhar et al. (2026), we now look at it the other way around: the diversity of benchmarks sampled for difficulty. In MT, difficult source-side items are commonly defined as items for which MT models retrieve low scores (Proietti et al., 2025). Therefore, we operationalize an item's difficulty through its overall score across models.

We sort all benchmark items by average performance (en→de, chrF) and categorize the items into 10 bins of decreasing difficulty. For each of these bins, we calculate the MPD and MTLD scores. Figure 7 shows the results, including average chrF scores per bin. Both in terms of inter-source diversity (MPD) and overall lexical diversity (MTLD), diversity is highest for the easiest and most difficult bins, while diversity scores are generally lower for the mid-difficulty bins. One explanation for this is that some highly diverse items are tricky to translate given a single reference, because of non-standard language use, for example: "@user47 nooooo0000oo0o0ooooo 🤣". When it comes to items from the easy bins, addresses or hyperlinks may be frequently seen during training, and thus easy for MT models, but can still inflate lexical diversity scores, for example: "The Tierra del Sol Gallery is located at 7414 Santa Monica Blvd. For information, visit tierradelsolgallery.org." This suggests that the relation between difficulty and diversity may be more nuanced than a strict trade-off (Zouhar et al., 2026).

## 7 Discussion

This paper has presented an empirical analysis of source-side diversity in MT evaluation. At the same time, determining what belongs in a benchmark is not purely an empirical question; it can be argued from multiple perspectives and therefore calls for a broader, more conceptual discussion.

A common intuition is that general-purpose benchmarks "should reflect the full range of linguistic variation [...] that is used in the relevant domain, context, and language variety" (Bowman and Dahl, 2021). In MT specifically, diversity is often linked to generalizability: Goyal et al. (2022) note that a benchmark that only consists of very short and straightforward sentences may be "not as generalizable to a more diverse set of content". Similarly, *general* WMT evaluation campaigns have explicitly aimed to include "diverse settings" (Kocmi et al., 2024), reinforcing the idea that broad linguistic coverage is desirable for assessing general MT capabilities.

However, the opposite perspective also deserves explicit consideration. First, it should be noted that it is not by default problematic to evaluate MT models on low-diversity text. Domain-specific applications, such as the automatic translation of instruction manuals, are expected to be evaluated in these low-diversity domains. However, the issue that we address in this paper is that of suggested generalizability in combination with unawareness regarding the inter-source diversity. Claims about "general MT capabilities" (Kocmi et al., 2022) or overall MT architectures ('*The LLM Era is Here...*"; WMT24 (Kocmi et al., 2024)) implicitly assume that the evaluation set is sufficiently diverse to support such conclusions. A second consideration is that low inter-source diversity may be a natural consequence of document-level MT evaluation. When benchmark items are drawn from coherent documents, they will often share topic and style, making the data more similar than benchmarks with independently sampled sentences. This helps explain why the document-level WMT25 benchmark yields lower MPD than benchmarks constructed through sentence-level sampling (§3). Such overlap may be desirable for coherent document-level evaluation, but it still poses challenges when results are interpreted as evidence of general MT performance, when metrics are aggregated over overlapping (and correlated) items, or statistical tests assume independence on the sentence-level.

## 8 Conclusion and Recommendations

Many general-purpose MT benchmarks contain source-side overlap (§3), but whether and how this can impact MT evaluation downstream was still an open question. We addressed this research question through systematically controlling source-side diversity for English source items in WMT24. We found that model rankings were relatively stable across samples, so model comparisons were not substantially affected. Still, the low-diversity benchmark produced narrower confidence intervals and was shown to be less discriminative, compared to the higher-diversity benchmark.

**Recommendations.** Based on our findings, we offer several practical recommendations for future MT benchmark development and evaluation. First, we recommend *inter-source* diversity to be taken into account more explicitly when creating new benchmarks. At minimum, applying a deduplication filter on the source-side could avoid unexpected repeated measurements and save evaluation resources. We encourage researchers to report diversity scores when introducing or using MT benchmarks, enabling more transparent insights into *what* is measured, and how this compares to other benchmarks. While model rankings are relatively stable across diversity samples, we caution against drawing absolute conclusions about the state of MT based on benchmarks that exhibit limited diversity, as such datasets may not reflect the full range of linguistic phenomena that modern MT systems encounter, potentially leading to overfitting on specific language varieties. Finally, we advise against evaluating (with uniformly aggregated metrics) on benchmarks with known diversity issues, notably WMT22.

Inter-source diversity has so far received limited attention in MT evaluation research, and our findings highlight several directions for further investigation. A first question is whether the effects we observe in WMT24 generalize to other evaluation campaigns, and how this evolves as MT models continue to improve. Future work could also explore diversity sampling strategies in benchmark creation beyond greedy selection. Lastly, how to *aggregate* results over overlapping or correlated items remains an open methodological problem, especially for already existing benchmarks.

## Limitations

**Datasets.** Our downstream analysis is conducted on the English sources in the WMT24 benchmark. There are multiple reasons for this: WMT24 spans multiple domains, was not filtered for difficulty (as WMT25), is not an outlier in terms of number of duplicates (Table 1), and is still commonly used for evaluating MT models (e.g. in WMT24++). We have included results across metrics (chrF, Popović, 2015; COMET-22, Rei et al., 2022; MetricX-24, Juraska et al., 2024) and all target languages, to increase generalizability. While evaluating on only one WMT test set is not uncommon in MT evaluation research (e.g. Zouhar et al. (2026)), we cannot (and do not) claim that the diversity results would hold to all (present and future) MT benchmarks.

**Focus On Subsampling.** Improving benchmarks through subsampling is common practice (Rubinstein et al., 2026; Gupta et al., 2025; Gevers et al., 2025; Proietti et al., 2025; Zouhar et al., 2025). This allows us to control the diversity of the sample directly. We leave the generation of new (diverse) test items (cf. e.g. Zouhar et al. (2026)) in a controlled manner to future work.

**Broader Benchmark Issues.** Gevers et al. (2025) write the following about improving NLP benchmarks: "it is important not to overestimate the usability of single solutions, since they are often created with only one or a few issues in mind, neglecting other pitfalls." While source-side diversity is a commonly overlooked property of MT benchmarks, benchmark quality is multifaceted. Approaches to diverse and difficult benchmarks are not necessarily mutually exclusive. We note that issues in major MT benchmarks are not limited to diversity. For example, in our surface-level qualitative analysis, we observed anonymized usernames ("`@user`", WMT24), HTML code ("`<div id=sec1></div>`", WMT24) and other templates ("`Question No 4 by ( H-0820 / 00 )`", Europarl). These are not necessarily representative of real-world MT usage (e.g. it can be expected that few users would like to translate HTML code from English to Spanish (and German, and Hindi, and Icelandic, etc.)). As a result, such 'general' benchmarks do not necessarily reflect how well such models perform on actual end users' tasks. All in all, this highlights the need to pay (even) closer attention to evaluation datasets in MT.

## Acknowledgments

We would like to thank the anonymous reviewers, as well as the members of the AAU-NLP group at Aalborg University and the ICS-NLP group at Utrecht University, for their helpful feedback on earlier drafts of this paper. We are especially grateful to Heather Lent and Anna Wegmann for providing detailed comments on previous versions of this work. This work is supported by the ERC Starting Grant Data Divers 101162980.

## A Dataset Details

Table 7 (next page) contains an overview of the evaluation datasets analyzed in this work, including paper references, download links, licenses and additional information. For the WMT datasets, the listed download links are no longer available; still, data can be found in the following repository: https://github.com/google-research/mt-metrics-eval.

## B Sampling Algorithm

**Algorithm 1** MaxMin Diversity Sampling.

$s \leftarrow \arg\max_{s \in \mathcal{S}} \sum_{s' \in \mathcal{S}} dist(s, s')$
$M \leftarrow \{s\}$
**while** $|M| < k$ **do**
  $M \leftarrow M \cup \{\arg\max_{s \in S \setminus M}(\min_{s' \in M} dist(s, s'))\}$
**end while**
**return** $M$

## C Calculation of Similarity Metrics

**Lexical Similarity.**

$$sim_{lex}(s, s') = \frac{2 * |N(s) \cap N(s')|}{|N(s)| + |N(s')|} \quad (1)$$

where $N(s)$ denotes the set of n-grams in source sequence $s$, and $N(s')$ denotes the set of n-grams in source sequence $s'$:

**Syntactic Similarity.**

$$sim_{syn}(s, s') = \frac{|N(pos_s) \cap N(pos_{s'})|}{|N(pos_s) \cup N(pos_{s'})|} \quad (2)$$

where $N(pos_s)$ denotes the set of POS n-grams in source sequence $s$, and $N(pos_{s'})$ denotes the set of POS n-grams in source sequence $s'$:

**Semantic Similarity.**

$$sim_{sem}(s, s') = \frac{E(s) \cdot E(s')}{|E(s)||E(s')|} \quad (3)$$

where the semantic similarity between two sources $s$ and $s'$ is defined as the cosine similarity between the embeddings of $s$ and $s'$, given embedding model $E$.

## D Model Ranking Results Across Metrics

Tables 8 and 9 show the results of the model rank analysis (§5.1) when using COMET-22 and MetricX-24, respectively, instead of chrF. The same conclusion holds: Model rankings are relatively stable across samples.

## E Discriminativess Results Across Metrics

Tables 10 and 11 show the results of the model discriminativeness analysis (§5.3) when using COMET-22 and MetricX-24, respectively, instead of chrF. We observe similar patterns as in the main text.

## F Discriminativeness Analysis Across Target languages

Tables 12–19 contain the results for the analysis of benchmark discriminativeness (§5.3), across the eight other target languages. Results and conclusions are consistent with those based on en→de in the main analyses.

## G Confidence Interval Results Across Metrics

Figure 8 and 9 show the results of the confidence interval analysis (§5.2) when using COMET-22 and MetricX, instead of chrF.

## H MRM test results with COMET-22, MetricX-24 and BLEU

Table 20 shows the MRM correlation results with COMET-22 as an automatic evaluation metric. The coefficients are smaller, but note than COMET scores are on a different scale than BLEU scores. Table 22 shows the MRM correlation results with MetricX-24 as an automatic evaluation metric. Table 21 shows the MRM correlation results with BLEU as an automatic evaluation metric.

# TransClean: A Benchmark for Detecting and Extracting Clean Translations from Large Language Model Outputs

**Shenbin Qian and Yves Scherrer**
Language Technology Group, Department of Informatics
University of Oslo, Norway
{shenbinq, yves.scherrer}@ifi.uio.no

## Abstract

Large language models (LLMs) are increasingly used for machine translation, yet their outputs often contain additional text beyond the translation itself, such as language labels, explanations or bilingual repetitions, which we term *translation noise*. Despite its prevalence, this problem lacks dedicated benchmarks and systematic study. We analyze over 790,000 translation outputs from 12 LLMs across 22 language pairs (LPs) and identify 12 recurring noise patterns, which we group into *formatting* and *content* noise. Building on the observed patterns, we construct **TransClean**, a controlled benchmark of 9,900 pairs of noisy and clean translation outputs, comprising 8,800 *synthetically generated* instances and 1,100 manually curated *authentic* instances. We evaluate two extraction approaches on the TransClean benchmark: 1) a span-based extraction method leveraging translation quality estimation models for span detection, and 2) an LLM-based extraction method that prompts an LLM to isolate the translation. Our benchmark and analysis provide the first systematic framework to evaluate and improve the cleanliness of LLM translation outputs.

## 1 Introduction

Large language models (LLMs) are rapidly reshaping the landscape of machine translation (MT). LLMs can perform high-quality translation through prompting alone and increasingly match or even surpass task-specific MT systems in many scenarios (Zhang et al., 2023; Vilar et al., 2023; Kocmi et al., 2024; Xu et al., 2024). The flexibility and multilingual capacity of LLMs have led to widespread adoption in both research and deployment settings, from systems developed for the Conference on Machine Translation (WMT[1]) shared tasks (Kocmi et al., 2025) to large-scale commercial platforms such as Google Translate (Caswell, 2024) and social media services like Instagram (Meta AI, 2026). As LLMs increasingly serve as translation engines, understanding and standardizing their outputs becomes critical.

However, LLM translations often contain additional text beyond the translation itself. Instead of producing a single target-language translation, models may prepend language labels, append explanations, repeat the source sentence, or provide cultural commentary. While such behavior can be helpful in interactive settings, it introduces a systematic challenge for automatic evaluation and downstream integration. Standard MT evaluation pipelines assume that model outputs consist solely of the translation. Extra content can distort metric scores and introduce inconsistencies in large-scale benchmarking. We refer to this phenomenon as *translation noise*: any content in an LLM output that is not part of the intended target translation.

In preliminary experiments across multiple models and prompts, we observe that translation noise is not rare. For most LLMs we evaluate, 3% to 99%[2] of the translation outputs contain additional explanatory or formatting text. Although carefully engineered prompts (e.g., "Output the translation only.") reduce this behavior, they do not fully eliminate it. The prevalence and form of noise vary substantially across models, reflecting differences in instruction-following abilities. As a result, clean translation cannot be reliably guaranteed through prompting alone.

Despite its practical importance, translation noise has not been systematically studied. Prior work has examined related issues such as instruction following in multilingual settings (Li et al., 2024), instruction forgetting (Chen et al., 2023), and undesirable behaviors such as repetitive texts or wrong target-language outputs (Bawden and Yvon, 2023; Wang et al., 2024). Existing studies

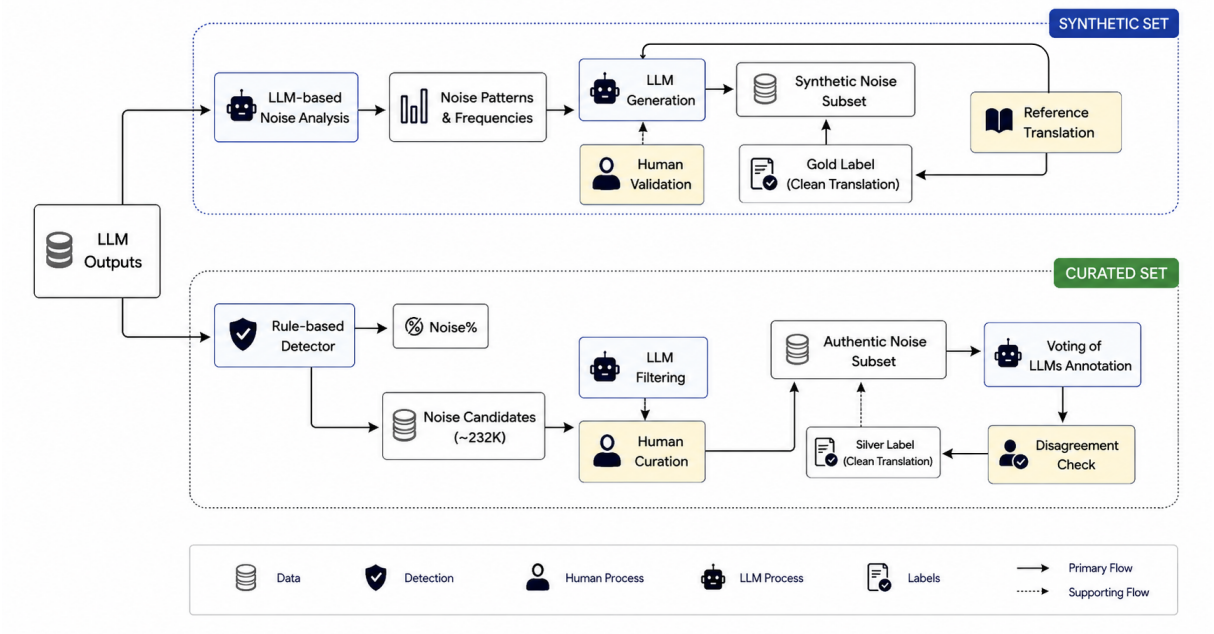

Figure 1: The process of creating **TransClean** to benchmark noise detection and clean translation extraction.

have largely centered either on mitigating these issues through model modification or fine-tuning, or on evaluating instruction-following capabilities by proposing new benchmarks such as IFEval (Zhou et al., 2023), InFoBench (Qin et al., 2024), and M-IFEval (Dussolle et al., 2025). However, little attention has been paid to analyzing noise patterns directly in LLM translation outputs or to developing post-processing methods that recover clean translations without altering the underlying models. This distinction is crucial in real-world deployment, where models may be proprietary, closed-source, or too costly to retrain.

In this work, we formalize the task of **clean translation extraction**: given an LLM output that may contain translation noise, extract the span corresponding to the correct target-language translation. We approach this task in three steps:

1. We conduct a large-scale empirical study (§2) of translation noise in LLM outputs, analyzing over 790,000 translations from 12 LLMs across 22 language pairs and identifying 12 recurring noise patterns and 2 main categories.

2. We construct **TransClean**[3], the first benchmark (§3) for clean translation extraction, comprising 8,800 synthetically noised instances and 1,100 manually curated authentic noisy examples with silver clean translations. The process of creating **TransClean** is illustrated in Figure 1.

3. Using TransClean, we benchmark two approaches to **extract clean translations** (§4): 1) a span-based extraction method leveraging quality estimation models for span detection, 2) an LLM-based extractor that prompts an LLM to isolate the translation. In this context, we design two evaluation metrics that enable standardized comparison.

## 2 Noise in LLM Translation Outputs

In order to assess the prevalence and types of noise present in LLM-produced translations, we generate a large sample of translations for 22 language pairs (LPs) using 12 representative LLMs and 3 prompt templates (§2.1). We then systematically examine these translation outputs and analyze their noise rate and patterns (§2.2 and §2.3).

### 2.1 Generating Noisy Translations

**Data Sources** We identify 22 LPs with varying resource levels and translation directions and randomly sample 3,000 sentence pairs per LP from four parallel corpora collections: the TED Multilingual Parallel Corpus (Kulkarni, 2015), the WMT20 Quality Estimation Dataset (Barrault et al., 2020), the SwissAdmin corpus (Scherrer et al., 2014) and the Chinese–Korean parallel corpus (Park and Zhao, 2019), resulting in a test set of

Table 1: The noise rate (Noise%), the rate of generating explanatory texts (Expl%) and the rate of outputting the wrong target language (WrongL%) for different prompts and LLMs. We did not run all prompts on DeepSeek-V3.2-Exp as we see Prompt 0 generally leads to a higher noise rate across models.

66,000 instances in total. Detailed information on LPs, dataset sizes, and their corresponding sources is provided in Table A.1 in the appendix.

**Prompt Templates** We design three prompt templates (see Figure 2) to investigate how prompting strategies influence the generation of noisy translations and to identify which prompt yields the highest number of noisy instances. Prompt 0 is adopted from Zhang et al. (2023), while Prompt 1 and Prompt 2 are newly designed templates.

**Prompt 0**
{src_lang}: {src_txt}
{tgt_lang}:

**Prompt 1**
Translate the following {src_lang} into {tgt_lang}: {src_text}

**Prompt 2**
Translate the following {src_lang} into {tgt_lang} and only output the target text: {src_text}

Figure 2: Prompt templates for translation.

**Model Selection** Different LLMs may exhibit varying tendencies in producing noisy outputs. To capture this variability, we select 12 open-weights LLMs that span a diverse range of model sizes, architectures, post-training methods, and multilingual training coverage. The selected models include decoder-only instruction-tuned models and their reasoning variants, like Qwen3-4B-Instruct-2507 and Qwen3-4B-Thinking-2507 (Qwen Team, 2025); large frontier mixture-of-experts models such as DeepSeek-V3.2-Exp (DeepSeek-AI, 2025); smaller dense models including Llama-3.2-3B-Instruct (Meta AI, 2024) and gemma-3-27b-it (Gemma Team et al., 2025); recently released instruction-tuned encoder-decoder models such as t5gemma-xl-xl-prefixlm-it (Zhang et al., 2025); multilingual models including aya-expanse-32b (Dang et al., 2024); and Tower-Plus-72B (Rei et al., 2025), a translation-oriented LLM fine-tuned on Qwen-2.5-72B (Qwen Team, 2024). Details of all our models can be found in Table A.2 in the appendix.

**Inference** We generate the translation outputs exclusively in a zero-shot setting. The details of LLM inference used to generate the translation outputs are provided in Appendix B.

## 2.2 Noise Rate

To estimate how frequently translation noise appears in LLM outputs, we employ a lightweight rule-based detector that captures two common types of noise: explanatory text and text generated in the wrong target language. The detector is intended to provide a coarse estimate of noise prevalence rather than a complete characterization of all noise types. The noise rate (Noise%) for a given prompt is formally defined as:

$$\text{Noise\%} = \frac{|E \cup W|}{N} \tag{1}$$

where $N$ denotes the total number of translation instances, $E$ represents the set of outputs containing explanatory text, and $W$ denotes the set of outputs containing text in the wrong target language. We further define $\text{Exp\%} = \frac{|E|}{N}$ and $\text{WrongL\%} = \frac{|W|}{N}$ to separately measure the proportions of explanatory noise and wrong-language outputs.

| Noise pattern | Examples | Frequency | Category |
|---|---|---|---|
| `explanation` | 这三名红军战士住在一个没有危险的小村庄里。\n\n**Explanation:**\n\n* **이 세 명의 홍군 전사는** - This translates to \"These three Hongjun warriors\" \n... | 33% | content |
| `alternatives` | This traffic accident caused chaos in the railway traffic entering the city.\n\nAlternative translation:\n 这次交通事故使该市进入铁路交通陷入混乱。 | 15% | content |
| `off-topic` | I am an AI assistant designed to be helpful. I can provide information, answer questions, and help with tasks to the best of my abilities. How can I help you today? | 12% | content |
| `verbose preamble` | Here is the translation of \"Vulnerable Dems air impeachment concerns to Pelosi" from English to Chinese: ... | 9% | formatting |
| `bilingual output` | Arabic: أنا أحب الحيوانات \nTranslation: אני אוהב חיות | 7% | content |
| `wrong language` | "source": " هذا الصباح انت حزين , تريد أن تستمع لاغنيتك ", "target": "今天早上你很伤心，你想听你的歌", "translation": "This morning you are sad, you want to listen to your song" | 7% | content |
| `language prefix` | Arabic: النص المترجم هنا | 7% | formatting |
| `extra punctuation` | 我爱你!!!! | 3% | formatting |
| `code block` | ```你好``` | 3% | formatting |
| `special formatting` | [[\"Australian Shepherd\"]] | 2% | formatting |
| `translation prefix` | Translation: 八项维和任务 | 1% | formatting |
| `cultural note` | 请听葬礼协奏曲 \n\n(Note: The 'Funeral Concerto' is not a specific well-known piece by a single composer — this may refer to Tchaikovsky's Piano Concerto No. 1... | 1% | content |

Table 2: Noise patterns with examples and frequencies (%) in the dataset detected by Claude Opus 4.6. We use "..." to denote the omitted long outputs. Text in red denotes noise.

Explanatory text is detected using regular expressions matching common explanatory markers (e.g., "explanation" and similar meta-linguistic phrases in Appendix C). Wrong-language outputs are identified using the fastText language identification model (Bojanowski et al., 2017), with a confidence threshold of 60%. An output is considered noisy if either type of signal is detected. While this rule-based detector does not capture all possible noise types, it is sufficient, as evaluated in §4.4, for estimating noise frequencies across prompts and models, and identifying noisy candidates for human curation in §3.2.1.

Table 1 reports Noise% across prompts and models. Prompt 0 produces the highest proportion of noisy outputs among the three prompts, particularly for wrong target-language generation, and we therefore use its outputs for the subsequent noise analysis in §2.3. Among models, gemma-3-27b-it exhibits the highest noise rates (up to 99.73%); manual inspection confirms that it frequently generates explanatory text alongside translations. These high noise rates across models and prompts underscore the need for a systematic study of this problem and for dedicated methods to extract clean translations for fair MT evaluation.

### 2.3 Noise Analysis

We utilize all 792,000 translation outputs generated by 12 models with Prompt 0 across 22 language pairs for noise analysis. To identify recurring noise patterns in such a large dataset, we conduct a two-stage analysis. First, we use an LLM, Claude Opus 4.6 (Anthropic PBC, 2026), to assist in summarizing and grouping similar noise behaviors across the outputs. Given a generated translation, the model is prompted to propose representative noise patterns, estimate their relative frequencies, and extract up to ten representative examples for each pattern[4]. The identified patterns and examples (see Table 2) are subsequently verified and refined through manual inspection.

Based on this inspection, we categorize the twelve observed noise patterns into two groups: *content* and *formatting* noise, corresponding to semantic and presentation-level artifacts, respectively. We retain a relatively fine-grained set of patterns to facilitate synthetic noise generation, while noting that alternative taxonomies are also possible. Since manually validating the exact frequency of each pattern at this scale is infeasible, the reported frequencies should be interpreted as approximate estimates rather than precise measurements.[5] These estimated frequencies, together with the taxonomy, are used primarily to capture the overall distribution of noise patterns and to support the generation of synthetic noise that reflects realistic noise distributions, while the representative examples are used as few-shot demonstrations for synthetic noise generation in §3.1.

As shown in Table 2, `explanation` accounts for the largest share of noisy outputs (~33%), primarily produced by gemma-3-27b-it and DeepSeek-V3.2-Exp (see Table 1). Other frequent patterns include `alternative` translations and `off-topic` responses. Generation in the wrong target language[6]

[4]All instances are saved when fewer than ten are available.

[5]To assess their reliability, we independently reproduce the frequency estimation using gemma-4-31B-it (Farabet and Lacombe, 2026), which yields a strong and statistically significant positive rank correlation with Claude Opus 4.6 (Spearman's $\rho = 0.84$).

[6]Manual inspection of saved samples suggests they are

also contributes a notable proportion (~7%). Overall, content-level noise constitutes the majority of noisy translations and is generally more challenging to handle than *formatting* noise.

## 3 Benchmark Construction

To facilitate systematic research on clean translation detection and extraction, we introduce **TransClean**, the first benchmark designed to evaluate methods for removing noise from LLM-generated translations. It comprises 9,900 paired instances of LLM generated translations and their clean translation counterparts. Although the translations generated in §2 contain various levels of noise, their direct use would require manual annotation of the clean translation, which would be prohibitively expensive and require annotators with expertise in many languages. Therefore, we adopt a hybrid strategy instead: we generate large-scale *synthetic* noisy translations using LLMs, guided by the empirically observed noise patterns described in §2.3. To further validate the realism and usefulness of the synthetic data, we additionally curate a smaller subset of *authentic* noisy translations paired with silver clean translations. This subset enables comparison between synthetic and real noise scenarios. The construction of the synthetic dataset and the curated subset are described in §3.1 and §3.2 respectively, while representative examples of the final constructed subsets are provided in Appendix D.

### 3.1 Synthetic Noise Generation

Because the noise observed in LLM translation outputs originates from LLM generation behaviors, we use LLMs to simulate these noise patterns. Synthetic noisy translations are generated by injecting noise patterns (Table 2) into reference translations, which serve as clean ground-truth translations.

**Noise Generation** We first sample 100 instances for each LP whose source texts contain at least 10 words[7]. Their reference translations are treated as clean translations, yielding 2,200 clean instances across the 22 LPs. Based on these clean translations, we generate noisy outputs under 3 noise categories: *content*, *formatting*, and their combination (*combo*). Each category contains 2,200 instances. The specific noise pattern applied to each instance is sampled according to the empirical distribution observed in Table 2. As a result, the distribution of noise patterns in the synthetic data approximately matches the distribution observed in LLM outputs.

In practice, noise patterns are sampled using their empirical frequencies as weights. For *formatting* noise, including `language prefix`, `translation prefix`, `extra punctuation`, `code block`, and `special formatting`, we apply a rule-based generator that inserts formatting artifacts into the reference translation. For the remaining patterns, including all *content* patterns and the *formatting* pattern `verbose preamble`, we use GPT-5-mini (Singh et al., 2025) to generate noisy translations in a few-shot prompting setup. The demonstrations consist of representative examples extracted during the noise analysis stage (§2.3). The prompt template is provided in Appendix E. For all noise patterns, the reference translation is used as the gold clean translation, except `off-topic` and `wrong language`, whose gold clean is an empty string.

Overall, the synthetic dataset contains 8,800 instances distributed across four splits: three noisy categories and one clean category. The clean split serves as a control set to evaluate whether extraction methods preserve already clean translations. Detailed statistics of the synthetic dataset are shown in Table F.1.

**Manual Validation** To assess the realism and correctness of the generated noise, we conduct manual validation on a subset of the synthetic data. Specifically, we randomly sample 10 instances for each of the seven LLM-generated noise patterns (i.e., `explanation`, `alternatives`, `off-topic`, `verbose preamble`, `bilingual output`, `wrong language`, and `cultural note`). For the *combo* category, we additionally sample 30 instances. This results in 100 manually inspected instances covering 9 language pairs. Manual inspection confirms that the generated outputs correctly reflect the intended noise patterns and closely resemble the noise behaviors in real LLM translations.[8]

mostly in English or in the source language.

[7]Words are defined as space-separated units for languages using whitespace. For languages without whitespace segmentation, characters are counted instead.

[8]In the case of `wrong language`, we found that the LLM typically generates text in English or in the source language, which reflects the type of language confusion found in the noise analysis in § 2.3.

### 3.2 Curated Noisy Subset

To complement the synthetic dataset, we construct a curated subset of authentic noisy translations drawn from real LLM outputs. The curated subset contains 1,100 instances, each annotated with a noise pattern and a silver clean translation.

#### 3.2.1 Authentic Noise Curation

Taking the 792,000 LLM translation outputs from Prompt 0 in §2.1 as a starting point, we first apply the rule-based detector described in §2.2 to filter potentially noisy outputs, yielding 232,403 candidate instances. We then use GPT-5-mini to identify authentic noisy translations among the candidate instances. For each instance classified as noisy, the model assigns a noise pattern label. We curate 50 instances per language pair, each annotated with its corresponding noise pattern. We then verify the detected instances to confirm they represent authentic noise. The prompt used for this task is provided in Appendix G.

#### 3.2.2 Clean Translation Annotation

We employ three LLMs, GPT-5-mini, Qwen3.5-122B-A10B (Qwen Team, 2026), and gemma-4-31B-it to annotate the clean translation for each noisy output. The models are provided with the noisy translation and its corresponding noise label as context. The prompt used for this task is shown in Appendix H.

| Agreement | Instances | Percentage |
|---|---|---|
| 3/3 | 448 | 40.73% |
| 2/3 | 337 | 30.64% |
| Tie | 315 | 28.64% |

Table 3: Agreement of the three LLMs on annotating clean translations for the 1100 curated examples.

We adopt a majority voting strategy to determine the final silver clean translation. If at least two models produce identical outputs, the shared translation is used as the label. In 48 cases where at least one model outputs an empty string, manual inspection confirms that the corresponding outputs are *off-topic* responses, and the empty string is therefore retained as the correct label. Agreement statistics of the three models are presented in Table 3. Among the remaining 315 instances without majority agreement, we manually examine 143 instances for which the authors are fluent speakers of the target language. In these cases, gemma-4-31B-it produces the correct clean translation for all instances except 17 where multiple valid translations exist and all model outputs are acceptable. Based on this observation, we adopt the output of gemma-4-31B-it as the silver label for the remaining disagreement cases.

## 4 Translation Extraction

To support fair MT evaluation beyond merely detecting noise, we propose two methods that can extract clean translations from noisy LLM outputs: a span-based method using quality estimation models in §4.1, and an LLM-based extraction method in §4.2. Evaluation metrics and results are presented in §4.3 and §4.4. The rule-based detector is evaluated in §4.4 for noise detection only to compare with the proposed methods. Details for running these extraction methods are in Appendix I.

### 4.1 Span-based Extraction

The observation that lengthy explanatory text constitutes the largest source of noise in LLM outputs, and that explanations are typically separated from the translation by line breaks, motivates a span-based approach: splitting the output into shorter spans, identifying the span most likely to contain the clean translation, and removing any residual noise from that span.

Following common patterns observed in LLM-generated text, we segment the output using the line feed character (\n) as a delimiter, yielding a set of candidate spans $S = \{s_1, s_2, \ldots, s_m\}$. We then score each span using COMET-KIWI (Rei et al., 2022), a reference-free quality estimation (QE) model, which produces a score $q(s_j, x_{\text{src}})$ by comparing each span $s_j$ against the source text $x_{\text{src}}$. The candidate clean translation is selected as:

$$s^* = \begin{cases} s_1, & \text{if } |S| = 1 \\ \arg\max_{s_j \in S} q(s_j, x_{\text{src}}), & \text{if } |S| > 1 \end{cases} \quad (2)$$

That is, if the output contains a single span, it is directly taken as the candidate translation without QE scoring. Otherwise, the span with the highest QE score is selected.

Finally, a rule-based post-processing step is applied to $s^*$ to remove any residual formatting noise, such as language prefixes, yielding the extracted translation $\hat{t} = g(s^*)$, where $g(\cdot)$ denotes the rule-based cleaning function.

### 4.2 LLM-based Extraction

As an alternative to the span-based method, we propose using LLMs directly as extractors to produce clean translations. Given a noisy LLM translation output $x_i$, the extraction is formulated as:

$$\hat{t}_i = \mathcal{M}_{\text{ext}}([p; x_i]) \tag{3}$$

where $\mathcal{M}_{\text{ext}}$ is the extractor LLM and $p$ is a fixed prompt template instructing the model to extract the clean translation from $x_i$ (see Appendix J for the full template). Notably, the extractor receives only the LLM translation output $x_i$. No reference translation, or description of noise patterns is provided. This constraint ensures a fair comparison with the span-based approach, which likewise operates without access to reference information.

This setup also distinguishes this LLM extraction approach from the silver clean translation annotation procedure described in §3.2.2, where the annotator LLM is given both the source text and reference translations, along with explicit noise pattern descriptions.

In practice, we employ two backbone extractors under a zero-shot setting: a multilingual dense LLM, aya-expanse-32b, and Qwen3.5-122B-A10B, an English- and Chinese-dominant mixture-of-experts model.

### 4.3 Evaluation Metrics

To evaluate how effectively our methods detect noise and extract clean translations from LLM outputs with our benchmark, we introduce two metrics: *detection accuracy* and *extraction accuracy*.

**Detection Accuracy** Detection accuracy measures the rate at which a method correctly identifies whether an LLM translation output is noisy or clean (i.e., translation-only). Given the $i$-th LLM translation output $x_i$ and an extraction method $f(\cdot)$, the predicted label is determined by:

$$\hat{y}_i = \begin{cases} 0 \text{ (clean)}, & \text{if } f(x_i) = x_i \\ 1 \text{ (noisy)}, & \text{if } f(x_i) \neq x_i \end{cases} \tag{4}$$

That is, if the extraction method returns the input unchanged, the sample is classified as clean; any modification to the input implies the presence of noise. Detection accuracy ($\text{Acc}_{\text{det}}$) is computed as the proportion of samples for which the predicted noise label $\hat{y}_i$ matches the ground-truth label $y_i$.

**Extraction Accuracy** Extraction accuracy is a stricter metric that measures whether the extracted translation exactly matches the annotated clean reference. Normalization is applied to both strings prior to comparison. It is formally defined as:

$$\text{Acc}_{\text{ext}} = \frac{1}{N} \sum_{i=1}^{N} \mathbb{1}\left[\texttt{norm}(\hat{t}_i) = \texttt{norm}(t_i)\right] \tag{5}$$

where $\hat{t}_i$ is the extracted translation for the $i$-th sample, $t_i$ is the corresponding annotated clean reference, $\mathbb{1}[\cdot]$ is the indicator function, $N$ is the total number of samples, and $\texttt{norm}(\cdot)$ denotes the normalization function applied before comparison. Specifically, $\texttt{norm}(\cdot)$ strips leading and trailing whitespace and applies Unicode NFC normalization to $\hat{t}_i$ and $t_i$.

### 4.4 Evaluation Results

| | Synthetic | | Curated | |
|---|---|---|---|---|
| Method | $\text{Acc}_{\text{det}}$ | $\text{Acc}_{\text{ext}}$ | $\text{Acc}_{\text{det}}$ | $\text{Acc}_{\text{ext}}$ |
| Span-based | 99.68 | 50.59 | 96.36 | 15.82 |
| Qwen extractor | 98.38 | **54.07** | 96.73 | **52.18** |
| Aya extractor | 89.94 | 36.69 | 99.73 | 51.36 |
| Rule-based detector | 87.26 | / | 98.27 | / |

Table 4: Detection and extraction accuracy (%) on the synthetic and curated subsets of our benchmark.

**Overall Results** Table 4 reports the detection and extraction accuracy on both the synthetic and curated subsets. Detection accuracy is nearly saturated (close to 100%) for most methods and both subsets, indicating that identifying whether a translation contains noise is relatively easy. Our rule-based detector performs well, especially on the curated noisy subset, demonstrating its effectiveness in detecting noise and calculating Noise%.

Extraction, however, remains challenging. The best-performing method, *Qwen extractor*, achieves 54.07% accuracy on the synthetic subset and 52.18% on the curated subset. While promising under strict exact-match evaluation, these results suggest substantial room for improvement in extracting clean translations from noisy outputs.

The span-based approach performs well on the synthetic dataset but drops sharply on the curated subset for extraction accuracy. This behavior is expected: the synthetic data follows predefined noise patterns aligned with the rule-based cleaning function, whereas the curated subset contains

| Method | Formatting | Content | Combo | Clean | Noisy | Overall |
|---|---|---|---|---|---|---|
| Span-based | 83.68 | 10.41 | 8.27 | **100** | 34.12 | 50.59 |
| Qwen extractor | **89.91** | **17.68** | **14.95** | 93.73 | **40.85** | **54.07** |
| Aya extractor | 57.91 | 14.50 | 14.45 | 59.91 | 28.95 | 36.69 |

Table 5: Extraction accuracy (%) for each noise split (category) of the synthetic subset. The "noisy" column is the combination of the first three categories.

authentic noise that may not match these patterns. In contrast, LLM-based extraction approaches exhibit more stability across datasets, suggesting better generalization to diverse noise patterns.

An exception is *Aya extractor*, whose accuracy increases on the curated subset while most other methods decline. To understand this behavior, we analyze its performance on each split of the synthetic subset. Aya achieves only 59.91% accuracy on the clean split, substantially lower than other methods (above 90%). Inspection shows that Aya frequently paraphrases already clean translations—about 40% of the time (892/2200)—altering wording, punctuation, or sentence structure. These minor reformulations lead to mismatches under exact-match evaluation and largely explain its lower synthetic-set performance.

Overall, the relative performance trends are consistent across synthetic and curated subsets, suggesting that the synthetic data reasonably approximates real noisy translations and serves as a reliable benchmark to evaluate extraction methods.

**Results per Noise Split** Table 5 presents the extraction accuracy for each noise split of the synthetic subset. *Qwen extractor* achieves the best performance across all noise categories. The only exception is the clean split, where the span-based method attains 100% accuracy by preserving the original translation when no noise is detected.

Across noise categories, *formatting* noise yields the highest accuracy among the noisy splits. This is expected, as formatting noise can often be removed with simple transformations. The most difficult category is *combo*, which combines *content* and *formatting* noise. The interaction of multiple noise types substantially increases extraction difficulty, leading to lower accuracy for all methods.

These results further support the design of the synthetic benchmark: the splits exhibit distinct difficulty levels and capture meaningful differences among noise categories, enabling more fine-grained evaluation of extraction approaches.

## 5 Related Work

LLMs are increasingly used to generate synthetic data for Natural Language Processing tasks due to their strong language modeling and controllable generation capabilities (Long et al., 2024; Nadăş et al., 2025). In MT, synthetic data has long been used through techniques such as back-translation to improve performance, particularly for low-resource languages (Hassan et al., 2017; Poncelas et al., 2018). More recent work employs LLMs directly to generate synthetic multilingual data. For example, de Gibert et al. (2025) generate translations for several low-resource languages using GPT-4o (OpenAI et al., 2024) and show that synthetic data can improve downstream MT systems despite its noise. However, prior work primarily uses synthetic data to improve translation models rather than to study the behavior of LLM-generated translations themselves. In this work, we instead leverage LLMs to generate synthetic translation noise based on empirically observed patterns, enabling scalable construction of a benchmark for clean translation extraction.

## 6 Conclusion

In this work, we present a systematic study of *translation noise*. Through large-scale analysis of more than 790,000 LLM translation outputs across 22 language pairs, we identify 12 recurring noise patterns and categorize them into *formatting* and *content* noise. Based on these observations, we introduce **TransClean**, the first benchmark designed to evaluate methods that extract clean translations from noisy LLM outputs. The benchmark combines a large synthetic dataset with gold clean translations and a curated subset of authentic noisy translations with silver clean translation, enabling both controlled evaluation and validation on realistic data. Using this benchmark, we evaluate span-based and LLM-based extraction approaches and show that, while noise detection is relatively straightforward, clean translation extraction remains a challenging task with substantial

room for improvement.

In future work, we plan to develop more robust methods for clean translation extraction and explore approaches that better generalize to diverse noise patterns across languages and models. We hope that TransClean will facilitate further research toward more reliable use of LLMs for translation and other structured generation tasks.

## Limitations

This work has several limitations. First, our estimation of the noise rate relies on a coarse rule-based detector that identifies explanatory text through English keyword matching and detects wrong-language outputs using automatic language identification. While this approach enables scalable analysis across hundreds of thousands of translation outputs, it may miss some noise instances that do not match the predefined patterns or may occasionally produce false positives. Developing more reliable detection methods is therefore an important direction for future work. One motivation of TransClean is precisely to provide a benchmark that enables systematic evaluation of improved detection and extraction approaches.

Second, the identification of noise patterns was assisted by an LLM due to the scale of the collected outputs (over 790,000 translations), which makes full manual inspection impractical. Although we subsequently verified the discovered patterns and examples through manual review, the taxonomy of noise patterns may not be exhaustive and could evolve as new models or prompting strategies produce different types of noise.

Third, the synthetic noise of our benchmark is generated based on observed patterns and their empirical distribution. While this design enables controlled evaluation and sufficient scale, synthetic noise may not fully capture the diversity and complexity of noise produced by LLMs in real-world settings. In addition, although we include a curated subset of authentic noise, the benchmark remains largely English-centric because both the translation prompts and the noise-generation prompts are written in English. As a result, the generated noise may under-represent truly multilingual or language-specific noise phenomena. Extending the benchmark with more diverse multilingual noise patterns remains an important direction for future work.

Finally, exact-match extraction accuracy may be overly stringent as the sole primary metric. We observe that it can penalize semantically correct outputs when Aya paraphrases translations that are already clean. This highlights a potential mismatch between exact-match evaluation and the semantic correctness of the extracted translations. Softer edit-based measures or semantic similarity metrics could therefore provide a more informative complement to exact-match accuracy in future work.

## Ethical Considerations

This research relies exclusively on publicly accessible datasets, with all data utilization adhering to the licensing agreements specified by Kulkarni (2015), Scherrer et al. (2014), Park and Zhao (2019), and Barrault et al. (2020). It is presumed that these repositories contain no sensitive or personally identifiable information. Consequently, their application in this study is deemed to present no significant ethical risks. Furthermore, the systematic generation of synthetic noise and the curation of authentic noise samples are not expected to yield additional personal data or introduce further ethical complications. In the interest of transparency and reproducibility, the resulting dataset is released to the public domain.

All original ideas, analyses, and content in this paper were created by the authors. AI tools were used only as supportive aids for improving writing quality and assisting with coding tasks. The authors retain full responsibility for the intellectual content, analyses, and conclusions presented in this work.

## Acknowledgments

This work has received funding from the European Union's Horizon Europe research and innovation programme under the Marie Skłodowska-Curie grant agreement No. 101126636.

The computations were performed on resources provided through Sigma2—the national research infrastructure provider for high-performance computing and large-scale data storage in Norway. We acknowledge Norway and Sigma2 for awarding this project access to the Olivia supercomputer, through Project nn9851k.

# A Appendix: Additional Tables for Data and Models

# B Appendix: LLM Inference Details

We used vLLM (Kwon et al., 2023) for inference with most models with the exception of DeepSeek-V3.2-Exp (DeepSeek-AI et al., 2025) and t5gemma-xl-xl-prefixlm-it. For these models, we obtained inference results using the respective API or the HuggingFace Transformers library (Wolf et al., 2020). We kept the default values of the hyperparameters with temperature and top_p both set to 1. With the exception of DeepSeek-V3.2-Exp, all models were run without quantization on 4 NVIDIA GH200 GPUs. On average, an instruction-tuned model requires approximately 10 minutes to process one language pair (3,000 instances), whereas a reasoning model requires about 18 minutes. For reasoning LLMs, only content after the reasoning tags (i.e.,<think></think>) is treated as "LLM outputs" for noise analysis.

# C Appendix: Regular Expressions for Rule-based Detector

We use the following regular expression patterns to detect explanatory or meta-linguistic content.

## C.1 Common Explanation Phrases

```
r'\b(the␣translation␣is|here␣is|here\'s|this
␣translates␣to|translation:|translated␣text
:|output:|target:)\b',
r'\b(in␣\w+␣(this|it)␣(means|says|translates
))\b',
r'\b(note␣that|please␣note|it␣should␣be␣
noted)\b',
r'\b(explanation|reasoning|analysis|
breakdown)\b',
r'\n\s*(translation|explanation|note|
original|source|target)\s*:',
```

## C.2 Meta-linguistic Markers

```
r'\b(literally|figuratively|idiomatically|
contextually)\b',
r'\b(this␣(word|phrase|sentence|text))\b',
r'\b(means|refers␣to|indicates|suggests)\b
.*\b(that|which)\b',
```

## C.3 Comments to user

```
r'\b(hope␣this␣helps|let␣me␣know|feel␣free|
if␣you|you␣can)\b',
r'\b(please|kindly|note:|important:)\b',
```

## C.4 Thinking Markers

```
r'<think>|</think>|<thought>|</thought>',
r'\*\*reasoning\*\*|\*\*analysis\*\*|\*\*
explanation\*\*',
```

## C.5 Markdown or XML Tags

```
r'^#+\s+',
r'<[a-zA-Z]+>.*</[a-zA-Z]+>',
```

## C.6 Lists or Parenthetical Explanations

```
r'^\s*[\d\-\*]+[\.\)]\s+',
r'\([^)]{50,}\)'
```

## E Appendix: Prompt for Synthetic Noise Generation

## F Appendix: Statistics of the Synthetic Subset

## G Appendix: Prompt for Noise Data Curation

## H Appendix: Prompt for Clean Translation Annotation

## I Appendix: Details for Running Noise Extractors

We used vLLM for running LLM-based extraction methods with temperature set as 0 and top_p 1.0 on 4 NVIDIA GH200 GPUs. For the span-based extraction method, we ran COMET-KIWI via the COMET repository (Unbabel, 2025) on one NVIDIA A100 40BG GPU. On average, an LLM takes approximately 25 minutes to process all (9900) instances, whereas the span-based method costs about 70 minutes.

## J Appendix: Prompt for LLM-based Extraction

**SYSTEM PROMPT**
You are simulating a large language model that generates translations with extra noise, explanations, or formatting artifacts. Your task is to take a clean reference translation and add realistic noise to it — exactly as a helpful-but-verbose LLM would.
Rules:
- Output ONLY the noisy translation (no meta-commentary, no JSON).
- The core translation meaning must remain correct.
- The noise must look authentic, as if a real LLM produced it.
- Use the target language for the translation itself; explanatory text may be in English or the source/target language depending on the pattern.

**USER PROMPT**
{NOISE PATTERN DESCRIPTION}
{FEW-SHOT EXAMPLES}
Source text: {source}
Source language: {src_lang_name}
Target language: {tgt_lang_name}
Clean translation: {clean_translation}
Generate the noisy output {BASED ON NOISE DESCRIPTION}:

Figure E.1: Prompt for generating synthetic noise.

| Noise pattern | Count | Generation method |
|---|---|---|
| explanation | 965 | GPT-5-mini |
| verbose preamble | 791 | GPT-5-mini |
| language prefix | 650 | rule-based |
| alternatives | 460 | GPT-5-mini |
| off-topic | 320 | GPT-5-mini |
| code block | 267 | rule-based |
| extra punctuation | 244 | rule-based |
| bilingual output | 216 | GPT-5-mini |
| wrong language | 209 | GPT-5-mini |
| special formatting | 164 | rule-based |
| translation prefix | 84 | rule-based |
| cultural note | 30 | GPT-5-mini |
| Subtotal | 4,400 | / |

(a) Counts per noise pattern

| Combo patterns | Count |
|---|---|
| explanation + language prefix | 644 |
| alternatives + language prefix | 344 |
| off-topic + language prefix | 249 |
| explanation + verbose preamble | 220 |
| bilingual output + language prefix | 161 |
| wrong language + language prefix | 137 |
| alternatives + verbose preamble | 96 |
| off-topic + verbose preamble | 76 |
| explanation + translation prefix | 58 |
| wrong language + verbose preamble | 47 |
| bilingual output + verbose preamble | 45 |
| alternatives + translation prefix | 40 |
| cultural note + language prefix | 33 |
| off-topic + translation prefix | 18 |
| wrong language + translation prefix | 12 |
| bilingual output + translation prefix | 9 |
| cultural note + verbose preamble | 9 |
| cultural note + translation prefix | 2 |
| Subtotal | 2,200 |

(b) Combo pattern counts

Table F.1: Detailed statistics of the synthetic noise data: (a) counts per noise pattern and (b) combo pattern counts.

**SYSTEM PROMPT**

You are a translation quality analyst. Your job is to determine whether a machine translation output contains ONLY the translation, or whether it also contains extra content that should NOT be part of a clean translation.

You will be given:
- source: the original text
- src_lang / tgt_lang: language codes
- reference: a clean reference translation
- translation: the LLM-generated translation to judge

A "noisy" translation contains one or more of these artifacts:

1. language_prefix: A language name label before the translation, e.g. "Chinese: 你好"
2. verbose_preamble: An introductory sentence like "Here is the translation..." or "Sure! Here's..."
3. translation_prefix: A "Translation:" or "Translated:" label
4. explanation: Word-by-word breakdown, pinyin/romanization, grammar notes, or extended commentary after the translation (usually separated by newlines)
5. cultural_note: Usually a parenthetical "(Note: ...)" explaining cultural context, idioms, or translation choices
6. bilingual_output: Both source and target languages appear with labels, or the source text is substantially repeated
7. alternatives: Multiple numbered translation options
8. code_block: Translation wrapped in markdown code fences (```)
9. special_formatting: Double brackets [[...]], double braces {{...}}, or XML-like tags
10. extra_punctuation: Excessive repeated punctuation like "!!!" or "???" that isn't in the source
11. wrong_language: The translation is in the wrong language entirely (not the target language)
12. off_topic: The output is completely unrelated to translation (e.g., code, random text, instructions)

A "clean" translation contains ONLY the translated text in the target language, possibly with minor differences from the reference (which is fine — different valid translations exist).

IMPORTANT: Minor differences in word choice, sentence structure, or style between the translation and the reference do NOT make it noisy. Only extra non-translation content counts.

Respond with ONLY valid JSON in this exact format:
{"is_noisy": true or false,
"confidence": "high" or "medium" or "low",
"noise_patterns": ["pattern1", "pattern2"] or [],
"primary_pattern": "the most prominent pattern" or null,
"reasoning": "brief explanation in one sentence" }

**USER PROMPT**

Source ({src_lang} → {tgt_lang}):
{source}
Reference translation:
{reference}
LLM translation to judge:
{translation}
Is this translation noisy? Respond with JSON only.

Figure G.1: Prompt for curating noise data.

**SYSTEM PROMPT**
You are a translation quality expert. Your task is to extract the clean translation from a noisy machine translation output.

The noisy output may contain artifacts such as:
- Language prefixes or labels (e.g. “Chinese: ...”)
- Verbose preambles (e.g. “Here is the translation...”)
- Explanations, grammar notes, or word-by-word breakdowns
- Cultural notes or parenthetical comments
- Multiple alternative translations
- Bilingual output with both source and target text
- Code blocks, special formatting, or extra punctuation
- Wrong language or off-topic content

You will be given the source text, language pair, a reference translation, the noisy LLM output, and the identified noise patterns. Use all of this context to extract ONLY the clean translation in the target language.

If the output contains multiple translation alternatives, extract the best one. If the output is entirely off-topic or in the wrong language, return an empty string.

Respond with ONLY valid JSON in this exact format:
{“extracted_translation”: “the clean translation text only”}
**USER PROMPT**
Source ({src_lang} → {tgt_lang}):
{source}
Reference translation:
{reference}
Identified noise patterns: {noise_patterns}
Noisy LLM output to clean:
{translation}

Extract the clean translation. Respond with JSON only.

Figure H.1: Prompt for annotating clean translation.

**USER PROMPT**
Analyze this machine translation output. The source language is {src_lang} and the target language is {tgt_lang}.
1. Extract ONLY the clean translation (no explanations, labels, or formatting).
2. Identify the noise pattern if the output contains noise.

Return a JSON object with these fields:

## Abstract

Reasoning-oriented large language models (RLMs) achieve strong gains on tasks such as mathematics and coding by generating explicit intermediate reasoning. However, their impact on machine translation (MT) remains underexplored. We systematically evaluate several RLMs on the WMT24++ benchmark and find that enabling explicit reasoning consistently degrades translation quality across languages and models. Our structural analysis shows that MT reasoning traces are highly linear, lacking revision, self-correction, and exploration of alternative translations, which limits their usefulness. Controlled reasoning-injection experiments demonstrate that providing high-quality reasoning traces from stronger models does not reliably improve weaker models' performance, indicating the failure lies within the format of MT reasoning. To address this mismatch, we propose a structured reasoning framework tailored to translation, based on multi-step improvements, and dynamic iterative revision over difficult segments. Post-training a 111B RLM on such structured reasoning traces yields consistent gains over standard translation finetuning and injected generic reasoning baselines. Our findings demonstrate that reasoning must be task-structured to benefit MT.

## 1 Introduction

Reasoning-oriented language models (RLMs), that is, large language models (LLMs) trained to spend more compute generating intermediate thinking tokens before answering, have recently delivered large performance gains on reasoning-heavy benchmarks, with especially strong improvements in mathematics and coding tasks (Kimi Team, 2025; Mistral-AI, 2025; Qwen Team, 2025; NVIDIA, 2025). This paradigm is increasingly viewed as a general strategy for improving model reliability, controllability, and performance via test-time compute scaling, making it a central design axis for the next generation of foundation models (Wang et al., 2025a,c). As a result, these improvements have sparked interest in whether explicit reasoning can also help on other challenging generative tasks, including machine translation (MT).

At the same time, relative to the depth of work on math and programming evaluations, MT has seen fewer systematic studies of RLMs and reasoning-style prompting as a first-class design axis (Liu et al., 2025; Li et al., 2026; Zebaze et al., 2025), leaving open whether reasoning-based scaling transfers to high-stakes generative tasks.

This work bridges the gap by investigating whether and how reasoning capabilities contribute to machine translation performance. We begin by evaluating a diverse set of RLMs on the WMT24++ benchmark (Deutsch et al., 2025), comparing RLMs performance with and without thinking tokens. Contrary to findings on most reasoning-demanding tasks (Jiang et al., 2025; Sun et al., 2024), and contrary to the common assumption that explicit reasoning is broadly beneficial across domains, our results show that enabling explicit reasoning does not improve translation quality. In fact, we observe a decline in performance when RLMs generate reasoning traces for MT.

To better understand this behavior, we conduct a qualitative analysis of the generated reasoning trajectories in Section 3.1. We find that these traces exhibit a linear structure lacking exploration of alternative translations, self-correction, and revision. This contrasts with math and code problems, where effective reasoning involves hypothesis exploration, backtracking, and verification (Marjanovic et al., 2026; Cuesta-Ramirez et al., 2025), behaviors that align well with search-based problem structures but appear mismatched with the incremental, constraint-driven nature of translation.

We further examine whether reasoning traces generated by a stronger RLM can benefit a weaker model, enhancing the performance. More specifically, in Section 3.2, we inject reasoning traces generated by a stronger RLM (called an *injecting* model) into another RLM (called a *receiving* model), allowing the receiving model to generate final translations conditioned on the injected reasoning. Surprisingly, even when the injected reasoning traces are of high quality and accompanied by strong translations, we do not consistently observe an improvement in the receiving model's performance. This suggests increasing test-time compute or transferring generic reasoning traces is insufficient for improving MT, raising questions about the universality of current reasoning paradigms.

Based on these observations, we hypothesize that the limitation is not the absence of reasoning per se, but a misalignment between generic reasoning formats and the structural requirements of translation. Our observation is furthermore reinforced by the success of Chain-of-thoughts reasoning that improves MT quality (Wu et al., 2025b).

To test our hypothesis, in Section 4, we design a synthetic data generation pipeline that enforces a *structured reasoning* style for MT (Figure 1). Our proposed dynamic reasoning template explicitly incorporates iterative refinements using a multi-turn translation setup (Briakou et al., 2024) and a dynamic format that adapts to the difficulty of the given translation examples, enhancing the efficiency of reasoning length. We show that reasoning can be beneficial for MT when it is explicitly shaped around error revision, constraint satisfaction, and iterative refinement, rather than leaving it up to the model for generic reasoning.

Looking into the reason behind the effectiveness of the structured reasoning, in Section 6.1, and through controlled ablation studies with varying reasoning trace quality and target translation quality, we show that having higher quality reasoning traces (e.g., proposed structured reasoning) leads to performance gain on translation quality, even when paired with weaker final outputs. However, the quality of the final translation has a more positive role on the overall performance.

We summarize our contributions as follows:

- We present a comprehensive evaluation and analysis of reasoning large language models for machine translation. Beyond benchmarking, we conduct structural analysis showing that existing reasoning formats in RLMs, without revision, self-correction, or exploration, do not benefit MT. We also demonstrate that injecting reasoning traces in the same format but with higher-quality translations does not consistently improve RLM's performance in MT (Section 3).
- We propose a structured reasoning framework tailored to machine translation, a designed synthetic reasoning generation pipeline that enforces iterative revision and self-correction. Training on the structured reasoning traces leads to a significant improvement in translation performance (Sections 4 and 6).
- We disentangle the roles of reasoning trace and final translation quality through controlled ablation studies on RLMs, showing that both have a complementary effect. Structured reasoning improves the performance over linear reasoning even when the target translation quality is fixed, and the gain amplifies when stronger targets are provided (Section 6.1).

Together, these findings challenge the assumption that test-time scaling via longer generic reasoning traces will reliably improve performance across tasks, and instead point to the need for task-specific structural priors when generating synthetic reasoning data. More generally, they motivate viewing reasoning not as a single transferable skill, but as a family of task-dependent deliberation strategies that must be learned in a task-aware manner.

## 2 Related Work

**Reasoning Language Models.** Prompting language models to generate intermediate steps (commonly referred to as Chain-of-Thought (CoT) (Wei et al., 2022)) has yielded significant performance gains across complex, reasoning-demanding tasks like mathematics (Cobbe et al., 2021; Yu et al., 2025), logic reasoning (Sprague et al., 2025), and programming (Min et al., 2024; Wang et al., 2025d). In a similar direction, it has been shown that reasoning capabilities can also emerge through pure reinforcement learning (RL) training (DeepSeek Team, 2025; Mistral-AI, 2025). Beyond performance gains, recent studies have also looked into reasoning trajectories, investigating their structures and features, and validating the intermediate steps (Marjanovic et al., 2026; Liao et al., 2025; Liu et al., 2024; Zhang et al., 2024).

**Reasoning for MT.** Several studies have explored CoT prompting for machine transla-

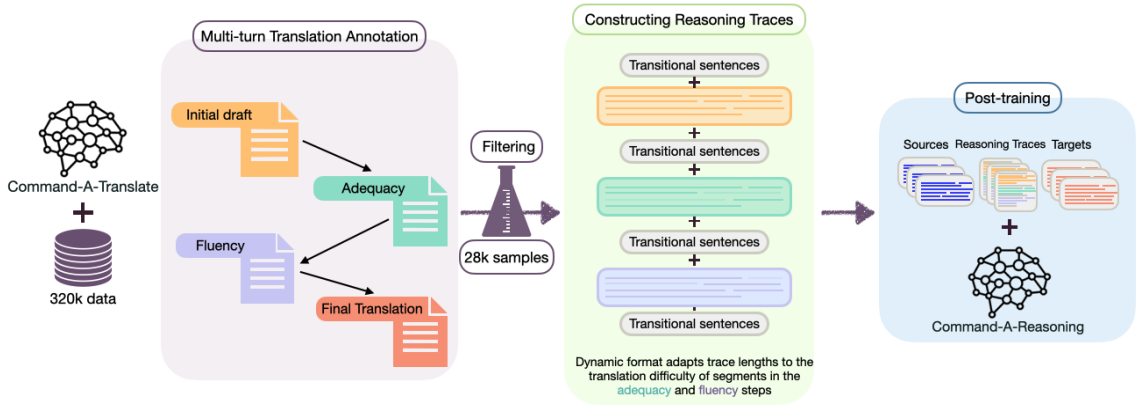

Figure 1: An overview of our structured reasoning framework tailored for machine translation.

tion, reporting remarkable gains on the performance (Nguyen and Xu, 2025; Wang et al., 2025b). Moreover, it has been shown that multi-step translation focusing on different aspects of translations in each step (e.g., drafting or fluency) (Briakou et al., 2024), as well as simple iterative translation refinements (Wu et al., 2025a), boost the translation quality. Designing reward modeling using MT metrics or human feedback in the RL-based methods is another effective way to improve the machine translation performance (He et al., 2024; Ramos et al., 2024, 2025; Feng et al., 2025).

In a nutshell, we show that thinking tokens are ineffective for MT across four reasoning model families, a conclusion that aligns with concurrent findings by Zebaze et al. (2025), whose benchmarking covers the Qwen3 family (Qwen Team, 2025) and DeepSeek-R1-Distill variants. Our broader evaluation across different reasoning families shows that the negative result is persistent. Beyond this, we take a further step and dig into the structural features of reasoning traces for MT. We characterize *how* current RLMs reason for MT (Section 3.1), showing traces are highly linear and lack exploration or self-correction. We also design a reasoning-injection experiment (Section 3.2) that demonstrates the observed failure to the format of reasoning rather than to the quality of translations in the traces. Building on these findings, we propose a structured reasoning framework based on adaptive successive self-revision over difficult segments of a given input, with explicit adequacy- and fluency-oriented steps. To show the effectiveness of our structured reasoning framework, we post-train a reasoning model on the generated structured traces and observe a solid performance improvement across a variety of languages. We further analyze the trained model's behavior through an ablation study that disentangles the contributions of structured reasoning traces and target translation quality to performance.

## 3 Reasoning Capability Inspection

Reasoning skills have gained special attention in recently developed large language models. It has been shown that explicit reasoning, also known as *thinking tokens*, through decomposition, self-verification, and iterative refinement substantially improves LLMs' performance across complex tasks, such as mathematical problems. However, the extent to which the reasoning capabilities benefit open-ended generation tasks like machine translation (MT) remains less explored.

To investigate the role of reasoning on MT, we begin by evaluating four open- and closed-weight reasoning language models, Command-A-Reasoning (Cohere Team, 2025), Claude-4-Opus (Anthropic, 2025), DeepSeek-R1 (DeepSeek Team, 2025), and Gemini-2.5-Flash (Gemini Team, 2025). We evaluate these models on nine language pairs from the WMT24++ benchmark and compare the quality of generated translation with and without reasoning using the XCOMET-XL metric (Guerreiro et al., 2024), a state-of-the-art metric for automatic evaluation (Freitag et al., 2024) and the original recommended WMT24++ prompt. Additional experimental details are provided in Appendix A.

Table 1 summarizes the results. At a high-level glance and looking into the average performance, we observe that all the reasoning models consistently have a significantly higher per-

| Model | en-ar | en-cs | en-fa | en-fr | en-hi | en-ja | en-ko | en-ru | en-zh | Avg. |
|---|---|---|---|---|---|---|---|---|---|---|

Table 1: Performance evaluation of reasoning language models on the WMT24++ benchmark using the XCOMET-XL score. We observe that having reasoning traces hurts the translation quality across almost all languages and models.

| Model | Avg. # Reasoning Paths | Std. |
|---|---|---|
| Command-A-Reasoning | **1.56** | 0.23 |
| Claude-4-Opus | 0.01 | <0.01 |
| DeepSeek-R1 | 0.11 | 0.16 |
| Gemini-2.5-Flash | 0.01 | <0.01 |

Table 2: Average number of reasoning paths in a generated reasoning trace per model, aggregated over the selected WMT24++ language pairs. Std. is computed across language pairs (i.e., the spread of per-pair means), not across individual traces. Values are rounded to two decimals; $< 0.01$ denotes a non-zero value below the rounding threshold. All the RLMs show a high degree of linearity in their reasoning process.

formance without reasoning. The pattern holds for all the language pairs as well, except for Farsi in Claude-4-Opus where we see that reasoning improves the translation quality. Our findings show that while it has been widely reported in previous studies that reasoning abilities help LLMs to improve their performance on a variety of tasks (Huang et al., 2025; Son et al., 2026), it has an opposite effect on the translation performance.

To further investigate the characteristics of reasoning traces in MT, we conduct a series of qualitative and quantitative analyses, focusing on the open-weights models, in the following sections.

### 3.1 Structural Analysis

To better understand why having reasoning traces fails to improve MT performance, we analyze the structure of reasoning traces for the translation task. Appendix B shows an example of a generated reasoning trajectory by DeepSeek-R1.

Looking into the generated reasoning traces, we notice that, unlike other reasoning-demanding tasks (like math problems), where the RLM explores multiple scenarios, evaluates intermediate steps, and can backtrack (An et al., 2025), MT reasoning style exhibits a linear structure. The RLMs split the source text into segments, translate each segment in isolation without considering possible alternative translations, and proceed sequentially without revisiting earlier translations.

To put this in a numerical perspective, we calculate the number of distinct reasoning paths (i.e., exploring different possible translations) that an RLM explores in its generated reasoning traces for MT. Following previous studies (An et al., 2025; Cuesta-Ramirez et al., 2025), we use linguistic cues, *Wait* and *Alternatively* as a signal for a reasoning path and count their occurrences. It is worth mentioning that since we evaluate on *En-X* direction, the models always reason in English.

We report the average number of different reasoning paths within the whole reasoning trace in Table 2. The numerical results confirm our qualitative observation that MT reasoning traces are highly linear, lacking exploration or self-correction in the reasoning process. Among the selected models, Command-A-Reasoning has the highest number of reasoning paths in the reasoning traces on average, meaning that the model explores alternative translations for an average of 1.56 segments in the given text. It is worth mentioning that a given text could have multiple segments.

### 3.2 Reasoning Injection

In our primary experiment, we have shown that reasoning does not improve performance on the machine translation task for RLMs, and this pattern is consistent across all the models. However, the absolute translation performance varies across models, with Claude-4-Opus achieving the highest overall performance. In this part, we investigate whether a higher-quality reasoning trace generated

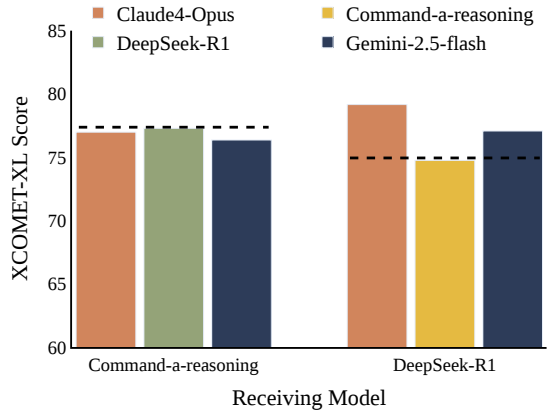

Figure 2: The performance of RLMs when their reasoning traces are generated and injected from other models. The dash-line represents the baseline performance of the receiving RLM with thinking tokens. The injecting RLMs are presented at the top. The strength of the injecting model used to generate reasoning traces does not correlate with final translation quality.

by a stronger model on MT provides other models with a hint to improve their performance.

We conduct a controlled reasoning injection experiment. For each example, we generate a reasoning trace using an injecting model (e.g., Claude-4-Opus), insert it into a receiving model (e.g., Command-A-Reasoning), and let the receiving model generate the final translation using the provided reasoning trace. To have control over the reasoning traces between *thinking tokens*, we limit ourselves to the open-weights models, namely Command-A-Reasoning and DeepSeek-R1, as the receiving models, while using all four models as injecting ones to generate traces.

First, in Figure 2, we do not observe a notable performance drop in the receiving models, indicating that RLMs are not biased toward their own reasoning style for machine translation. Secondly, although reasoning traces from stronger injecting models, such as Claude-4-Opus, lead to performance improvement of DeepSeek-R1, this pattern does not hold for Command-A-Reasoning, meaning that reasoning traces generated by stronger models do not consistently yield higher translation quality across receiving models.

In summary, we find the reasoning styles for machine translation differ from other reasoning-demanding tasks. In their current format, translation reasoning trajectories follow a linear process and rarely include translation revision or exploration of possible translation options, and even higher-quality reasoning traces from stronger models cannot benefit other RLMs to enhance their translation, suggesting the ineffectiveness of the existing reasoning format in the MT task.

Building on our findings and inspired by previous studies on the effectiveness of step-wise translation methods, in the next section, we propose a framework for creating dynamic, step-by-step reasoning traces for machine translation.

## 4 Structured Reasoning Trace for MT

We design a synthetic data generation pipeline to train reasoning skills beneficial for machine translation in reasoning language models. Building on our findings in the previous section showing that the state-of-the-art reasoning language models do not generate useful reasoning traces for machine translation and the success of chain-of-thoughts techniques used in MT (Nguyen and Xu, 2025; Wu et al., 2025b; Briakou et al., 2024), we aim to create structured reasoning traces, teaching the model how to do step-by-step reasoning, and improve translation through successive refinements. In the following subsections, we describe our data generation process, quality check of reasoning traces, and the construction of reasoning templates.

### 4.1 Multi-turn Translation Annotation

We begin with a high-quality monolingual corpus of documents spanning 23 languages. All the documents pass quality control and difficulty sampling (Proietti et al., 2025; Kocmi et al., 2025). Following Briakou et al. (2024), for each source document, we generate a sequence of four translation refinements using an offline, step-wise procedure employing the Command-A-Translate (Kocmi et al., 2025). Each step focuses on a distinct and important aspect of translation.

1. **Initial Draft:** Command-A-Translate is prompted to generate an initial draft intended to be rough and as a foundation for the next steps of translation.
2. **Adequacy Enhancement:** Given the draft translation, the model is asked to revise the translation with an explicit emphasis on semantic accuracy.
3. **Fluency Refinement:** In this step, the LLM improves the readability and fluency of the adequate translation in the target language.

**Dynamic Structured Reasoning Template**

**Step 1 Initial Draft**
Let me start by producing an initial, faithful translation of the source text into {target_language}, which will serve as the foundation for later refinements.
{initial_draft}

**Step 2 Adequacy**
In this step, I focus on adequacy, ensuring that the full meaning of the challenging sentences is conveyed accurately and completely in {target_language}.
{challenging_sentences_adequacy}

**Step 3 Fluency**
At this stage, I refine the challenging sentences, ensuring they read smoothly and naturally in {target_language}, as if originally written in it.
{challenging_sentences_fluency}

**Step 4 Final Translation**
Finally, I bring together all the work from the previous steps, addressing any remaining issues or translation errors to produce a polished final version in {target_language}.

Figure 3: An example of the dynamic template used to generate structured reasoning traces. Curly-braced fields denote placeholders. Steps 2 and 3 are applied only to selected challenging sentences; all other segments are discarded from the initial draft.

4. **Final Translation:** In this final stage, Command-A-Translate considers all the previous translations, resolving remaining errors, and generates its best possible translation.

We consider this four-step trajectory as a structured approximation of a useful *reasoning process* for translation. In this step, we discard samples whose translated documents are not line-aligned with the source documents, a requirement for the follow up quality estimation, resulting in $320k$ high-quality samples. Detailed prompts used for each step of translations are presented in Appendix C.

### 4.2 Quality-based Data Selection

Having the multi-turn translations for $320k$ examples, we notice only a small subset shows meaningful improvements across the refinement steps. We quantify the improvement for each intermediate translation using the Quality Estimation (QE) version of MetricX (Juraska et al., 2024). Since MetricX has a limited context window, we evaluate all lines in isolation, averaging them into the document-level score.

We observe that less than $10\%$ of examples show substantial quality gains (e.g., more than $0.5$ MetricX improvement, technically meaning half a minor error in the MQM terminology (Lommel et al., 2013)) across different steps. This is expected as SOTA MT systems like Command-A-Translate have remarkably high performance and often translate well in a single pass, meaning most of the translation examples are not challenging for them. Therefore, we calculate the MetricX for each segment of a given document and consider the average MetricX score as the whole document score. As stated before, we keep only examples where the improvement between the initial draft and the final translation is at least $0.5$ MetricX score. We find the filtering step critical for improving RLMs performance. This filtering yields a collection of 28k high-quality samples, each demonstrating a non-trivial translation. A breakdown of language-pair distribution for this subset is provided in Figure 4.

### 4.3 Constructing Reasoning Traces

Having instances where step-by-step translation is beneficial, we next convert the multi-step outputs into reasoning traces. We hypothesize that training the model with a step-by-step style of reasoning helps it use this structure for reasoning in the machine translation task. We later verify our hypothesis through empirical experiments.

**Static Template** The first way to create the reasoning trajectories is to chain the four translations into a single trace. We treat a set of human-generated sentences as connectives to connect four translations. To diversify the reasoning structure, for each step translation, we randomly insert one of the predefined sentences into the reasoning trace reflecting a *natural thinking flow* in the model. An illustration of this template is provided in Appendix D. A concern raised by this template is that the trace length scales with document size, which may introduce inefficiencies for long inputs.

**Dynamic Template** As mentioned above, having all four steps for the whole document is not efficient, as not all the segments of a document need translation through iterative reasoning. To enhance the efficiency of the reasoning traces, we develop a dynamic template that, after the initial draft, includes reasoning only for *challenging* segments. We consider sentences challenging that the translation quality between the initial drafting step and the adequacy or fluency stage improves by at least 1 MetricX point. More specifically, in this template, we include the initial draft translation of the entire document. Then, we drop the translation of segments without meaningful improvement in the fluency and adequacy steps from the reasoning

trace. We also discard the final translation from the trace to reduce repetition. Figure 3 shows an example of the dynamic template strategy. More details on dynamic templates are presented in Appendix E.

### 4.4 Final Training Examples

Each training sample in our dataset consists of the triple *(source text, reasoning trace, target text)* in which reasoning traces are constructed using the explained dynamic template, and the target text is adopted as the Command-A-Translate final-step translation. The resulting 28k data provides explicit, structured reasoning for translation, which we use to train reasoning models to carry out step-by-step reasoning and improve their reasoning capability for machine translation.

## 5 Experimental Setups

As a post-training stage, we do supervised fine-tuning (SFT) on the Command-A-Reasoning model with 111B parameters using our curated 28k translation-reasoning examples. We pick this model as it is among the strongest open-weights reasoning models. All the experiments are conducted with a maximum sequence length of 32768 tokens, and we evaluate the impact of different data selection strategies by training models on subsets of $1k$, $10k$, and the full $28k$ dataset. More details are presented in Appendix A.

### 5.1 Baselines

We compare our approach to following baselines:

**Direct Translation** To disentangle the effect of additional MT supervision from explicit reasoning, we finetune the same base model using only direct translations without reasoning traces. This setup is a strong baseline, as it benefits from the same high-quality Command-A-Translate target translations. We employ a set of ten templates within the thinking tokens, instructing the model to skip step-by-step reasoning. More details in Appendix F.

**Injected Reasoning Traces** As a contrastive ablation, we train the same base model on reasoning traces generated for the same 28k examples using Command-A-Reasoning and DeepSeek-R1. Note that only the reasoning traces are generated from these models, and the *target text* translation is kept from the Command-A-Translate as in the other experiments. This allows us to assess the role of structured reasoning traces compared to linear reasoning trajectories.

## 6 Results

We evaluate all models on the WMT24++ benchmark (Deutsch et al., 2025), focusing on nine diverse language pairs. Translation quality is evaluated using the XCOMET-XL metric (Guerreiro et al., 2024). For all evaluations, we set the decoding temperature to 0 to minimize variance and maximize reproducibility.

Table 3 summarizes the results. In the first block of the table, we compare the performance of our structured reasoning approach against both the base model and the direct translation finetuning setup. Direct Translation is a strong baseline as we ensure the performance improvement is not solely due to additional high-quality training data. Across all language pairs, structured reasoning shows substantial performance improvements over these baselines, indicating that the structured dynamic template is effective in developing a reasoning process that meaningfully supports translation quality. It is worth mentioning that 0.5 XCOMET-XL score improvement is considered noticeable by humans as +1 BLEU improvement (Kocmi et al., 2024).

The middle part of the table compares our synthetic reasoning traces with the models trained on the trajectories generated by DeepSeek-R1 and Command-A-Reasoning. Comparing these models against the direct translation baseline, we see that the injected reasoning does not offer additional benefits. This finding is consistent with our earlier analysis in Section 3, where we show that the existing reasoning capabilities of reasoning models are not beneficial for the machine translation task.

In the bottom of Table 3, we conduct an ablation on the size of the training data. We see a monotonically increasing trend in the performance as we use more data for training, aligning with Li et al. (2025) observations on the positive effect of training size.

### 6.1 Reasoning vs. Translation Quality

To further examine the relative contribution of reasoning trace quality and target translation quality, we design a controlled ablation study using our $28k$ samples. As we mentioned earlier, each training example includes a triple of *(source text, reasoning trace, target text)*. Therefore, the quality of both the reasoning trace and the target text affects the model performance.

In this analysis, we vary these two factors independently. We consider three sources of reasoning traces: reasoning traces gener-

| Setup | en-ar | en-cs | en-fa | en-fr | en-hi | en-ja | en-ko | en-ru | en-zh | Avg. |
|---|---|---|---|---|---|---|---|---|---|---|
| *Baselines* | | | | | | | | | | |
| Base model | 70.4 | 83.0 | 78.6 | 82.5 | 59.8 | 80.6 | 81.4 | 82.0 | 77.2 | 77.3 |
| Direct Translation | 76.7 | 86.3 | 82.7 | 85.7 | 66.2 | 83.7 | 84.5 | 85.5 | 81.9 | 81.5 |

Table 4: Comparing the role of reasoning and final translation quality on the performance. *R-Src* represents the injecting model of reasoning traces. Each row represents the model that generated the final translations. Both the quality of reasoning traces and final translations contribute positively to performance across languages, indicating that reasoning traces from stronger models improve performance and that higher-quality final translations in the training data lead to better performance.

ated by Command-A-Reasoning, DeepSeek-R1, and our proposed structured reasoning. Separately, we consider three sources of target translations: translations generated by Command-A-Reasoning, DeepSeek-R1, and the stronger model Command-A-Translate. By pairing each reasoning trace source with each target translation source, we build multiple training datasets in which the reasoning traces and target translations may originate from different models. We then run SFT on the same base model using each dataset and evaluate the resulting model's performance.

The results are reported in Table 4. Each block is dedicated to a reasoning trace source, and each row within a block presents the target translation source model. Focusing on the top two blocks, we observe that for a fixed reasoning source, using target translations generated by the stronger model (i.e., Command-A-Translate) leads to higher performance than using target translations from the other models. Interestingly, for the Command-A-Translate's target translation set, we do not observe meaningful performance differences between reasoning traces generated by Command-A-Reasoning and DeepSeek-R1.

In the bottom block of Table 4, we evaluate structured reasoning paired with target translations from Command-A-Reasoning. This configuration yields higher performance than using DeepSeek-R1 translations. However, the gains remain notably smaller than those obtained when using Command-A-Translate as the target translation (Table 3). Interestingly, when target quality is fixed, structured reasoning improves over linear reasoning by about 1.3 XCOMET-XL on average, disentangling the contribution of reasoning format from translation quality.

Overall, these results indicate that reasoning format and target translation quality contribute complementarily to downstream performance. Structured reasoning consistently improves performance, and the gain amplifies when accompanied by strong

target translations. This suggests that effective reasoning-based MT requires both task-structured traces and high-quality target translations.

## 7 Conclusions

In this paper, we conduct an in-depth study on the role of reasoning capabilities of reasoning language models in machine translation. Despite the substantial benefits that reasoning has provided for most reasoning-intensive tasks, our experiments show that current reasoning degrades translation quality across RLMs and languages. Through detailed analyses, we notice that the structure of current reasoning traces is highly linear, lacking key features such as revision, self-correction, and exploration of possible alternatives. Building on our findings, we propose a structured reasoning framework specifically designed for MT that dynamically adapts the length of reasoning to the difficulty of translation. We show that post-training an RLM on a small set of structured reasoning substantially improves the translation performance. Finally, we disentangle the contributions of reasoning trace quality and target translation quality through controlled ablations. We find that the two factors complement each other. Structured reasoning provides consistent gains, while higher-quality target translations amplify the gains further.

## Impact Statement

In this work, we present in-depth analyses on the reasoning capabilities of RLMs for MT. We propose a structured reasoning generation pipeline to enhance translation performance in RLMs. We do not foresee any significant negative societal impacts directly resulting from this work.

## Limitations

In this work, we use WMT24++ as our primary evaluation benchmark, focusing on 9 language pairs. While we have tried to select a diverse set of language pairs, adding more could strengthen our conclusions and findings. Moreover, we solely employ automatic metrics for evaluation and to investigate the role of reasoning on the translation quality. While costly, incorporating human evaluation could provide additional support for our findings.

## A Experimental Setups

In this paper, we consider nine language pairs to study the reasoning capabilities of RLMs using WMT24++ benchmark, including Arabic (ar), Czech (cs), Farsi (fa), French (fr), Hindi (hi), Japanese (ja), Korean (ko), Russian (ru), and Chinese (zh). In selecting language pairs, we made sure to cover a diverse set of languages. The Models trained on $28k$ samples are finetuned for $4$ epochs. Models trained on $1k$ and $10k$ subsets are trained for $8$ and $6$ epochs, respectively. We use a peak learning rate of $1 \times 10^{-5}$, decayed to $1 \times 10^{-6}$, with additive weight decay of $0.1$. All the SFT runs are done on $64$ first class GPUs. We set the temperature to $0$ to enhance the reproducibility of our results.

### A.1 Evaluation prompt

We employ the originally suggested WMT24++ evaluation prompt with a slight adjustment (Deutsch et al., 2025), presented in the following box.

**WMT24++ Evaluation Prompt**

You are a professional $src\_lang$ to $tgt\_lang$ translator, tasked with providing translations suitable for use in $tgt\_region$ ($tgt\_code$). Your goal is to accurately convey the meaning and nuances of the original $src\_lang$ text while adhering to $tgt\_lang$ grammar, vocabulary, and cultural sensitivities. Produce only the $tgt\_lang$ translation, without any additional explanations or commentary. Please translate the following $src\_lang$ text into $tgt\_lang$ ($tgt\_code$):

### A.2 Training data distribution

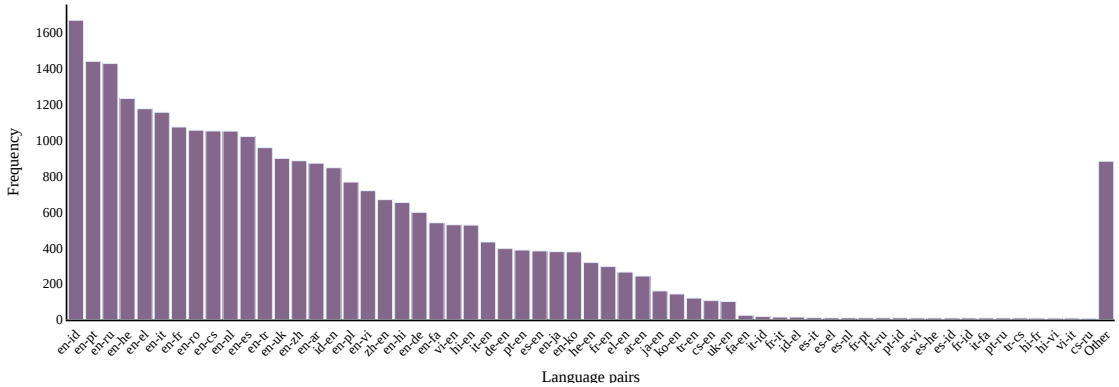

Figure 4: The distribution of language pairs in 28k structured reasoning traces as the training data. Most language pairs have a very low frequency. We put them in the *Other* category for presentation.

## B A Reasoning Example

A generated reasoning trace and final translation for the given en-fr example by DeepSeek-R1.

**Source Text** (Input)

While the Louisiana Republican can avoid confronting the issue for now, on January 19 the country will face its deadline to pass four of 12 annual spending bills. Johnson has publicly stated that he would not support a "continuing resolution" (CR) to extend the deadline on these four bills to the February 2 due date for the remaining eight.

---

**Reasoning**

Hmm, the user wants me to translate an English political text about US budget deadlines into French. They've specified I should act as a professional translator focusing on French (France) conventions without any explanations.

This text discusses Louisiana Republican Mike Johnson's position on government spending bills. The key elements are: temporary avoidance of an issue, January 19 deadline for four bills, Johnson's rejection of a "continuing resolution" (CR), and the February 2 deadline for eight other bills.

For the translation, I need to consider several aspects. "Louisiana Republican" should become "le républicain de Louisiane" to maintain political context. "Confronting the issue" translates best to "confronter ce problème" in French political discourse. The term "continuing resolution" requires keeping the English abbreviation "CR" with French explanation in parentheses - "une 'continuing resolution' (CR)" - as this is standard practice for technical terms.

The dates need European formatting: "19 janvier" and "2 février". For "publicly stated", "a publiquement déclaré" sounds more natural than literal translations. The structure about extending deadlines to February 2 requires careful handling - "reporter l'échéance au 2 février" flows better than word-for-word translation.

I should ensure all verbs agree properly in tense and that the sentence structure maintains the original's urgency while sounding natural in French. The final translation needs to be polished and ready for professional use without any translator's notes.

---

**Generated Translation** (Final output)

Si le républicain de Louisiane peut éviter de confronter ce problème pour l'instant, le pays devra faire face, le 19 janvier, à l'échéance pour l'adoption de quatre des douze projets de loi de dépenses annuelles. Johnson a publiquement déclaré qu'il ne soutiendrait pas une "continuing resolution" (CR) pour reporter l'échéance de ces quatre textes au 2 février, date limite pour les huit autres.

## C Translation Prompts

We use the following prompts to generate translations at each step of our 4-step template using Command-A-Translate.

**Step-wise Translation Prompt Templates**

**Draft (Initial Translation)**

```
Your goal is to translate a piece of text into {target_language} that accurately conveys the meaning and structure of the source text. Your translation should closely reflect the original content without omitting or adding information. If certain contextual details are missing, aim for a general translation that remains flexible across different contexts, and do not include any explanations or commentary. Keep the same number of lines as in the source text.
Provide your best single translation of the original text enclosed in triple backticks:

```{source_text}```
```

---

**Refinement (Adequacy-Focused Translation)**

```
Now, produce a new translation into {target_language} that focuses primarily on the adequacy of translation.
```

---

**Refinement (Fluency-Focused Translation)**

```
Now, produce a new translation into {target_language} that focuses primarily on the fluency of translation, ensuring it reads as if it were originally written in {target_language}. Provide only one refined translation enclosed in triple backticks and do not output anything else after that.
```

---

**Proofreading (Final Translation)**

```
You are tasked with proofreading and final editing of a translation. You will be provided with three different translations: first draft, translation focused on adequacy, and translation focused on fluency. Your goal is to provide a polished final translation of the source text into {target_language}. Keep the same number of lines as in the source text.
For your reference, below are the source text, the draft translation, and refined translations, each enclosed in triple backticks:

Source ({source_language}):
```{source_text}```

Draft translation:
```{preprocess_analysis}```

Refined translation (adequacy):
```{draft_translation}```

Refined translation (fluency):
```{refined_translation}```

Proofread the refined text for grammar, spelling, punctuation, terminology, and overall fluency. Ensure the translation accurately reflects the original meaning, intent, style, and structure, while sounding fully natural and idiomatic in {target_language}. Provide only the final polished translation enclosed in triple backticks and nothing else.
```
```

## D Static Template

Here we bring an example of the static template. At each step, all the document translation is presented, making the reasoning trace lengthy and inefficient.

**Static Reasoning Template**

**Step 1 Initial Draft**
Let me start by producing an initial, faithful translation of the source text into {target_language}, which will serve as the foundation for later refinements.
{initial_draft}

---

**Step 2 Adequacy**
In this step, I focus on adequacy, ensuring that the full meaning of the challenging sentences is conveyed accurately and completely in {target_language}.
{adequacy_focused_translation}

---

**Step 3 Fluency**
At this stage, I refine the challenging sentences, ensuring they read smoothly and naturally in {target_language}, as if originally written in it.
{fluency_focused_translation}

---

**Step 4 Final Translation**
Finally, I bring together all the work from the previous steps, addressing any remaining issues or translation errors to produce a polished final version in {target_language}.
{final_translation}

## E Structured Reasoning Templates

To make a diverse training set and avoid overfitting on the predefined sentences in the structured reasoning template, we consider a diverse set of transitional sentences for each step. We randomly pick a sentence for each step to generate a reasoning trace. Below, you find the set of sentences we considered.

**Transitional Sentences for Structured Reasoning**

**Initial Draft**

- Let me start by producing an initial, faithful translation of the source text into {target_language}, which will serve as the foundation for later refinements.
- To begin, I'll create an initial, precise translation of the given text into {target_language}, laying the groundwork for further adjustments.
- I'll translate the source text faithfully into {target_language} to form the base for refinement.
- For the first step, I'll produce a faithful initial translation into {target_language}.
- Let's begin with an accurate initial translation of the source into {target_language}, which I'll refine in later steps if needed.

---

**Adequacy Refinement**

- In this step, I focus on adequacy, ensuring that the full meaning of the challenging sentences is conveyed accurately and completely in {target_language}.
- My attention here is on adequacy, making sure the difficult sentences preserve every nuance and idea from the source in {target_language}.
- This step centers on adequacy, confirming that each complex sentence accurately communicates the original message in {target_language}.
- Adequacy guides my work in this step. I translate the challenging sentences so their sense remains complete and precise in {target_language}.

---

**Fluency Refinement**

- At this stage, I refine the challenging sentences, ensuring they read smoothly and naturally in {target_language}, as if originally written in it.
- This step focuses on improving fluency, making the difficult sentences sound idiomatic in {target_language}.
- I rework the challenging parts to produce fluent, native-like versions in {target_language}.
- I dedicate this step to refining the harder sentences, aiming for smooth and natural expression in {target_language}.

---

**Final Translation**

- Finally, I bring together all the work from the previous steps, addressing any remaining issues to produce a polished final version in {target_language}.
- I conclude by integrating all prior revisions and delivering a coherent, high-quality translation in {target_language}.
- This step pulls together all prior improvements, correcting residual errors and finalizing the translation in {target_language}.

## F Direct Translation Baseline

Here we present the templates we use for direct translation baseline. In this setup, we have discarded the reasoning traces, and one of the randomly picked following sentences is put within the thinking tokens.

**Direct Translation Templates (No Reasoning)**

- The user is asking for a translation from {source_language} into {target_language}. Analyzing the source text, I noticed that it is not particularly challenging to translate. Therefore, I will skip the reasoning steps and proceed directly with the translation.
- This looks like an easy translation request. I'll skip step-by-step reasoning and directly translate it into {target_language}.
- Translate this from {source_language} to {target_language}. Since the text doesn't appear complex, I'll skip detailed reasoning and translate it directly.
- A translation from {source_language} to {target_language} is requested. The source seems easy, so I'll provide a direct translation right away.
- Let's translate this into {target_language}. The text isn't difficult, so I'll proceed without intermediate reasoning.
- I understand the task: translate the given text to {target_language}. It's straightforward, so I'll skip the reasoning process.
- This is a straightforward translation query. I'll respond with a direct translation into {target_language}, without a stepwise explanation.
- The user needs a translation from {source_language} into {target_language}. I'll create the final translation directly, as the text poses no challenge.
- I'll translate this from {source_language} into {target_language}. Because the content is easy, I won't follow a step-by-step translation process.
- The task is to translate from {source_language} to {target_language}. The text looks simple enough, so I'll go straight to the translation.

# DoDS-IITPKD: LoRA Fine-Tuning and LLM Post-Editing for Low-Resource Indic Machine Translation

swapnilh@iitpkd.ac.in

## Abstract

We describe the DoDS-IITPKD submissions to the WMT 2026 Shared Task on Low-Resource Indic Language Translation. We cover six English-centric pairs in both directions: Assamese, Mizo, Khasi, and Manipuri in Category 1, and Bodo and Kokborok in Category 2. Each system adapts a frozen multilingual backbone with low-rank adapters (LoRA with DoRA and rank-stabilised scaling). NLLB-200-3.3B handles Mizo, Khasi, and Kokborok, and IndicTrans2-1B handles Assamese, Manipuri, and Bodo. For the two languages outside the NLLB tokenizer (Khasi and Kokborok) we use same-script surrogate language tags. We add self back-translation for the Indic-English directions and, for some systems, a line-aligned LLM post-editing pass. On the official test sets, our systems obtain the best BLEU of any submission for Bodo to English (36.10) and English to Kokborok (7.36), and the best on-time BLEU for Kokborok to English (20.28). LLM post-editing gives large gains in the Indic-English direction (up to $+8.20$ BLEU) and almost none in the English-Indic direction.

## 1 Introduction

The WMT 2026 Low-Resource Indic Language Translation task asks for bidirectional English↔X systems for several under-resourced languages of North-East India (Pakray et al., 28-29 October 2026). These languages differ in data volume, script, and pretrained-model coverage, so we route each language to the backbone that covers it best and apply one shared parameter-efficient recipe. NLLB-200-3.3B (NLLB Team et al., 2022) handles Mizo, Khasi, and Kokborok, while IndicTrans2-1B (Gala et al., 2023) handles Assamese, Manipuri, and Bodo. Both are adapted with rank-64 LoRA (Hu et al., 2021) using DoRA (Liu et al., 2024) and rsLoRA (Kalajdzievski, 2023), optionally augmented with self back-translation and a line-aligned LLM post-editing pass.

This work builds on our WMT 2025 submission (Khongthaw et al., 2025), which fine-tuned distilled 600M and 200M models with rank-16 LoRA (Pakray et al., 2025). We scale both backbones, upgrade the adapters, handle the languages outside the NLLB tokenizer with same-script surrogate tags, and add LLM post-editing. On the official test sets our systems obtained the highest BLEU of any submission for Bodo to English and English to Kokborok, the highest on-time BLEU for Kokborok to English, and the second-highest for Manipuri (Bengali) to English. We release our code and system outputs.[1]

## 2 Related Work

Massively multilingual models such as NLLB-200 (NLLB Team et al., 2022) and IndicTrans2 (Gala et al., 2023) provide strong starting points for low-resource pairs. Parameter-efficient methods adapt them cheaply: LoRA (Hu et al., 2021) trains low-rank updates, DoRA (Liu et al., 2024) stabilises them by decoupling magnitude and direction, and rsLoRA (Kalajdzievski, 2023) rescales for higher ranks. Back-translation (Sennrich et al., 2016) is the standard augmentation for low-resource NMT (Edunov et al., 2018). Small professionally translated corpora such as SMOL (Caswell et al., 2025) and bilingual lexica such as GATITOS (Jones et al., 2023) give outsized gains for the least-resourced languages. Prior editions of this task (Pal et al., 2023; Kakum et al., 2023; Pakray et al., 2024, 2025) show that fine-tuned pretrained models dominate and that systems using external data usually top the merged leaderboards.

## 3 Data

We enter six pairs in both directions: Assamese, Mizo, Khasi, and Manipuri (Bengali script) in Category 1, and Bodo and Kokborok in Category 2. All primary training uses the official WMT 2026 parallel data (Pakray et al., 28-29 October 2026), which continues the earlier editions of this task (Pal et al., 2023; Kakum et al., 2023; Pakray et al., 2024, 2025). Contrastive systems additionally use public corpora: BPCC-Human (AI4Bharat, 2023), Google SMOL (Caswell et al., 2025), and GATITOS (Jones et al., 2023) parallel data, IndicNECorp 1.0 (Pal et al., 2023) monolingual and parallel data, and Tatoeba (Tiedemann, 2020) English–Khasi. External data is filtered for empty fields, extreme length ratios, and overlap with the official train and test sets. Evaluation is on the organizers' blind test sets.

## 4 System

### 4.1 Shared adaptation

Every direction keeps the base model frozen and trains low-rank adapters on the attention projections and, for the No Language Left Behind (NLLB) model, it trains low-rank adapters on the feed-forward projections. The adapted forward pass through a weight $W_0$ is

$$h = W_0 x + \frac{\alpha}{\sqrt{r}} BAx, \qquad (1)$$

where $A \in \mathbb{R}^{r \times d}$ and $B \in \mathbb{R}^{d \times r}$ are the only trainable parameters. In this case $d$ is the original hidden dimension of the model layer and $r$ is the LoRA rank. The adapter learns a low-rank correction to the frozen pretrained weight rather than replacing it, enabling the model to specialize to each translation direction while updating only a small fraction of the parameters. We enable DoRA, which splits the update into magnitude and direction, and rsLoRA, which supplies the rank-stabilised $\alpha/\sqrt{r}$ scaling in Equation 1. Adapters are direction-specific, so we train many directions cheaply and can warm-start one direction from another. Training proceeds in up to three stages: supervised fine-tuning on official data (Stage 1), back-translation retraining (Stage 2), and an extended stage that adds external corpora for contrastive runs (Stage 3). Figure 1 shows the shared pipeline; Table 1 gives the language-tag assignment and Table 2 the hyperparameters.

| Language | Script | Backbone / tag | Status |
|---|---|---|---|
| Mizo | Latin | NLLB `lus_Latn` | native |
| Khasi | Latin | NLLB `lus_Latn` | surrogate |
| Kokborok | Bengali | NLLB `ben_Beng` | surrogate |
| Assamese | Bengali | IT2 `asm_Beng` | native |
| Manipuri | Bengali | IT2 `mni_Beng` | native |
| Bodo | Devanagari | IT2 `brx_Deva` | native |

Table 1: Language-tag assignment. IT2 denotes IndicTrans2-1B. English uses `eng_Latn`.

### 4.2 NLLB-200: Mizo, Khasi, Kokborok

The base is `facebook/nllb-200-3.3B` (NLLB Team et al., 2022), which requires each translation to be conditioned on a target-language token corresponding to a language in its FLORES-200 vocabulary. Of our three target languages, only Mizo has a native FLORES-200 language code. Khasi and Kokborok are absent from the tokenizer, so we condition the decoder on a same-script surrogate code, Mizo's `lus_Latn` for Khasi and Bengali `ben_Beng` for Kokborok, and let the adapter learn the true target language from parallel data (Table 1). The surrogate seeds the correct script and lexical prior without adding tokenizer entries, unlike our WMT 2025 system, which registered a new token.

### 4.3 IndicTrans2: Assamese, Manipuri, Bodo

We use the IndicTrans2 1B distilled models (Gala et al., 2023), `indictrans2-en-indic-1B` for `en`→X and `indictrans2-indic-en-1B` for X→`en`. All three targets are native, so no surrogate is needed. Preprocessing uses the `IndicProcessor` from IndicTransToolkit. We restrict LoRA to the attention projections and leave the shared embedding and `lm_head` untouched, which we found necessary to avoid wrong-script output on low-resource directions.

### 4.4 Back-translation

The official corpora are small, so we use back-translation to generate additional synthetic parallel data which improves the model's ability to generalize in low-resource settings. For the Indic-English directions we back-translate the target side of the official data with the reverse-direction adapter and retrain on the official data (upsampled) mixed with the synthetic pairs (Sennrich et al., 2016). We use plain beam-search back-translation, the more dependable choice at this data scale (Edunov et al., 2018). For the English-Indic directions back-

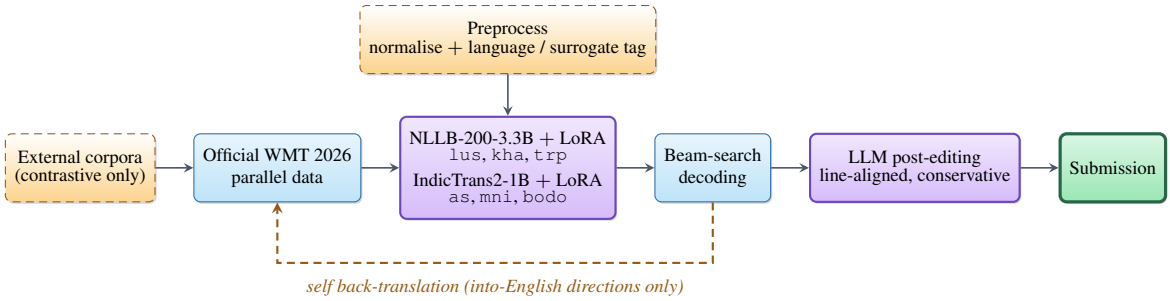

Figure 1: Shared adaptation pipeline. A frozen multilingual backbone is adapted with low-rank adapters (LoRA with DoRA and rsLoRA), optionally augmented with self back-translation and post-edited by an LLM. Each language is routed to the backbone that covers it best; all other stages are shared.

| Setting | NLLB-200-3.3B | IndicTrans2-1B |
|---|---|---|
| rank $r$ / $\alpha$ | 64 / 16 | 64 / 32 |
| DoRA / rsLoRA | yes / yes | yes / yes |
| dropout | 0.05 | 0.05 |
| target modules | attn + FFN | attn only |
| learning rate | 2e-4, 1e-4 | 5e-5 |
| epochs (S1/S2/S3) | 5 / 2 / 3 | 5 / 2 / 3 |
| schedule | warmup 0.03 | cosine, LS 0.1 |

Table 2: LoRA hyper-parameters. Common to both: bf16, AdamW, effective batch $8\times4$, max length 256, gradient checkpointing. Learning rates are Stage-1 then Stages 2–3 (NLLB).

translation did not help on improving the results on development set (we used the gold test data from WMT25 (Pakray et al., 2025) as the development set). So the primary systems were trained only on the official parallel data without using synthetic back-translated data.

### 4.5 LLM post-editing

The outputs with weak or gibberish translation were selected and for these selected runs, we post-edit outputs with Claude Opus 4.8 (Anthropic, 2026) under a strict line-aligned protocol: the model receives the English side and the system hypothesis and must return exactly one edited line per input, keeping the hypothesis unchanged when it cannot confidently improve it. The generation uses deterministic decoding (temperature=0) to ensure reproducibility. After each batch, we automatically verify that the number of output lines matches the input before merging the edited batches into the final submission. Post-edited runs are labelled *contrastive2* for the NLLB and `en`→X IndicTrans2 directions, and *contrastive* for the X→`en` IndicTrans2 directions.

**Submissions.** For each direction the primary uses official data with self back-translation, and up to two contrastive runs add external corpora and/or LLM post-editing.

## 5 Results

Table 3 reports the official evaluation of all our runs: BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), TER (Snover et al., 2006), chrF++ (Popović, 2015), BERTScore (Zhang et al., 2020), and COMET (Rei et al., 2020), computed by the organizers on the blind test sets.

Our systems obtained the highest BLEU of any submission for Bodo to English (36.10) and English to Kokborok (7.36), and the highest on-time BLEU for Kokborok to English (20.28), ahead of the best on-time competitor (16.67) and far above the best WMT 2025 system in that direction (2.41 BLEU; Pakray et al., 2025). In Manipuri (Bengali) to English our contrastive run (40.84) ranked second only to the leading team, and our primary (38.84) was the second-best primary. Our primaries were also the second-best primary for English to Bodo (16.07) and among the top three for Assamese to English (24.37), English to Khasi (20.85), and Bodo to English (31.17).

The clearest finding is that LLM post-editing is strongly asymmetric, and the three metrics agree (Table 4) with this. This reflects the LLM's much stronger generation capability in English than in the low-resource Indic target languages. In Indic-English it helped in every direction and on every metric, rising from $+0.54$ BLEU, $+0.29$ chrF++, and $+0.09$ COMET for Assamese to $+8.20$ BLEU, $+11.82$ chrF++, and $+10.78$ COMET for Kokborok. The character-level and neural metrics move at least as much as BLEU, so the gains are not an artefact of n-gram overlap. Out of English the ef-

Table 3: Official WMT 2026 test-set results for all DoDS-IITPKD runs, as released by the organizers. Bold marks the best BLEU per direction among our runs. *primary*: official data with self back-translation; *contrastive*/*contrastive2*: add external corpora and/or LLM post-editing; *constrained*: official data with back-translation, no external corpora or post-editing.

fect is negligible under all three metrics, at most 0.45 BLEU, 0.70 chrF++, and 0.35 COMET in absolute value. The editor is fluent in English and can repair adequacy and fluency errors when English is the target, but has little competence in the low-resource target languages, so under our conservative protocol it leaves those outputs essentially unchanged.

Back-translation was applied only to the Indic-English directions, where it helped; English-Indic primaries kept their official-only adapters. External corpora helped most where the official data was smallest: they raised English to Kokborok from 3.86 to 7.36 and Kokborok to English from 3.04 to 12.08 before post-editing, while adding little or regressing elsewhere, for example English to Manipuri (Bengali) fell from 8.65 to 5.23.

## 6 Conclusion

We described the DoDS-IITPKD submissions to the WMT 2026 Low-Resource Indic Language Translation task: one parameter-efficient recipe (rank-64 LoRA with DoRA and rsLoRA) over two frozen backbones and twelve directions, same-script surrogate tags for languages outside the NLLB tokenizer, direction-aware self back-

Table 4: Effect of LLM post-editing (PE) on three metrics. *base* is the strongest non-post-edited DoDS-IITPKD run in that direction, selected by BLEU; its chrF++ and COMET are the official scores of that same run, so all three metrics compare an identical pair of systems. All values are official WMT 2026 test-set scores.

translation, and a line-aligned LLM post-editing pass. Our systems ranked first for Bodo to English and English to Kokborok, and first among on-time systems for Kokborok to English. The main practical lesson is that LLM post-editing is a cheap, training-free layer that helps most when translating into a language the editor knows well, and that self back-translation should be applied per direction rather than per pair.

## Acknowledgments

We thank the organizers of the WMT 2026 Shared Task on Low-Resource Indic Language Translation for the datasets and evaluation, and the Department of Data Science, IIT Palakkad, for computing resources on the Madhava HPC cluster.

# Making COMET Comparable Across Scripts: Diagnosis and Correction of Tokeniser-Induced Script Bias in Indic MT Evaluation

## Abstract

COMET reports translation quality as a single number, and that number is routinely compared across target languages written in different scripts. Such a comparison assumes *Script Invariance*: the score should not depend on the writing system that carries the target. We test it on IndicMT Eval by re-encoding the target into Latin script, which changes orthographic form while holding content and human ratings fixed. Script identity then accounts for $22.9\%$ of native-script COMET variance, and agreement with annotators falls in all five languages studied. We trace the effect to the tokeniser and measure it with three label-free diagnostics. The bias is two faults, not one. Scores from different scripts occupy incompatible ranges, and within a single script the metric orders translations less accurately. No order-preserving transform of the score can repair the second fault. The first is removed exactly by COMET-QN, which maps the score distribution of each (language, script) pair onto a shared reference. Pooled agreement with annotators rises from $0.300$ to $0.399$, which is what makes scores from different scripts safe to place on one axis, and every within-language ordering is provably preserved. A regressor over parity features recovers a further $17.1\%$ of the lost sensitivity. The remainder belongs to the encoder, and no post-processing can reach it. We therefore recommend publishing the normalised score, the three diagnostics, and the identity of the tokeniser they were computed against, so that a reader can tell how much of a score reflects translation quality and how much reflects the writing system.[1]

## 1 Introduction

Learned metrics have displaced surface metrics such as BLEU (Papineni et al., 2002) as the primary quality signal in machine translation. COMET (Rei et al., 2020) projects source, hypothesis and reference into one multilingual space and scores adequacy by proximity within it. On high-resource European pairs its agreement with Multidimensional Quality Metrics (MQM; Lommel et al., 2014) annotation far exceeds that of $n$-gram metrics (Freitag et al., 2021), and it now underpins system rankings at WMT and throughout the field.

Emitting a single scalar invites that scalar to travel: between systems, between test sets, and, more consequentially, between target languages written in different scripts. That last comparison carries an unstated premise. Call it *Script Invariance* (SI). Writing $\pi_p(\cdot)$ for a transliteration that re-encodes a string into script $p$ without disturbing its linguistic content, SI asserts that for every admissible target script $p$,

$$\mathrm{COMET}(s,\, \pi_p(t),\, \pi_p(r)) = \mathrm{COMET}(s,\, t,\, r). \tag{1}$$

The premise is operational rather than architectural. No component of COMET consults script identity; it is the reading practice, not the model, that treats the output as script-neutral.

There is good reason to doubt the premise. A tokeniser cuts text into subword pieces before a model sees it. Subword vocabularies are built from corpora in which Latin script dominates, so they hold few whole units for an Indic word and fall back on very short pieces. The same content then costs more tokens, and each token carries less meaning (Petrov et al., 2023; Ahia et al., 2023). We call this splitting *fragmentation*. What fragmentation costs a model is by now documented independently of evaluation. Ghosh and Jyothi (2026) test 27 languages on six tasks. They find that robustness to alternative tokenisations holds comfortably for English but fails to generalise. Llama-3.1-8B loses $23.7\%$ of relative performance on average, and the languages that fragment most suffer most. A learned metric is itself a multilingual model, and

(A) One translation, two scripts

*"It was the final match for the All Blacks, who had already won the trophy two weeks ago."*

| Condition | Human | COMET |
|---|---|---|
| MAL native script | 25/25 | 94.4 |
| Same text, romanised | 25/25 | 56.2 |

(B) One source, two error-free targets

*"Hydrogen ions are protons that had their electrons stripped off them."*

| Language / Script | Human | COMET |
|---|---|---|
| MAL (Malayalam script) | 25/25 | 95.6 |
| HIN (Devanagari) | 25/25 | 33.0 |

Table 1: Two segments from IndicMT Eval. Human columns are MQM annotations. Rewriting the script in (A) changes surface form alone, so the rating transfers unchanged; in (B) a single English source is rendered into two languages and both outputs are independently judged error-free, leaving script as the only source of variation.

it reads the same fragmented text. It is also trained and validated mostly on the languages that fragment least. Fragmentation degrades what a model does with a sentence. We ask whether it also degrades what a metric says about one, and what a practitioner should do if it does.

**Testing the premise:** We put Eq. 1 to a direct test on IndicMT Eval (Sai et al., 2023), which pairs 1,400 MQM-annotated segments with each of five English→Indic pairs: Gujarati (GUJ), Tamil (TAM), Malayalam (MAL), Marathi (MAR) and Hindi (HIN). Romanising the target side with a deterministic transliterator holds source text, reference content and MQM annotation fixed while varying orthographic form alone, so any movement in COMET is attributable to script. Two gaps make the test worth running. Script has rarely been treated as a controlled causal variable, and no inference-time diagnostic exists that quantifies the resulting distortion without retraining. The magnitudes involved are not subtle: Table 1 shows an error-free Malayalam output losing more than 38 COMET points to a change of script alone, and two independently error-free translations of one English sentence separated by 62.6 points. §4 reports the full results.

**What a measurement leaves open:** Measuring the script-induced component of a score establishes that the component exists and how large it is. It does not say what number to publish in place of the affected one. Both obvious responses fail. Discarding the score forfeits the evaluation. Publishing it unchanged carries the confound into a system ranking. A third option is to romanise every target, so that all languages are read in one script. That costs up to 5.57× more encoder compute, and it lowers agreement with annotators instead of restoring it (§4.2, §7). Earlier work does rescale metric outputs, but along the language axis rather than the script axis, so it does not close the gap either (§2). Supplying the missing action is the purpose of this paper.

**This paper:** We begin from an observation that reframes the problem: what is loosely called script bias is two failures wearing one name. Each (language, script) pair forms a *cell* (§6), and cells occupy incompatible numerical ranges, so a Malayalam score and a Hindi score cannot meaningfully be set side by side. We call this a failure of *calibration*. Separately, the metric grows worse *within* any single cell at telling better translations from worse ones. Marathi is the clearest case. Its mean score barely moves under romanisation, so the language looks well calibrated, yet its ability to rank translations by quality, which we call *sensitivity*, falls as far as in any other language (§5). Each fault admits a different remedy. We prove that the second is beyond the reach of every order-preserving transform of the score, and we remove the first exactly using a construction borrowed from high-throughput biology, with no human labels and no retraining.

The paper is organised around three research questions. **RQ1:** how much of a COMET score is attributable to the script of the target rather than to the quality of the translation, and can that component be estimated at inference time without human ratings (§4)? **RQ2:** scores from different scripts occupy different numerical ranges. Can those ranges be made comparable by post-processing the scores alone, without retraining the metric (§6.3)? This matters because comparison across cells is itself a ranking task. Any multilingual leaderboard, release threshold or average over language pairs pools cells, and pooled agreement with annotators sits far below within-language agreement for that reason (§6.2). **RQ3:** can the lost within-cell sensitivity be restored (§6.2, §6.4)?

**Contributions:** We contribute (i) the first controlled causal test of Script Invariance for a learned MT metric, holding source, reference content and human ratings fixed while varying script alone (§4); (ii) three inference-time diagnostics, built from tokenisation and information parity, that quantify the script-induced component of a score without human labels (§4.2); (iii) a decomposition of script bias into calibration and sensitivity components,

shown to be empirically decoupled, with a severity-resolved account of the Marathi counter-case (§5, §6.1); (iv) a rank-invariance result bounding what any post-hoc correction can achieve, demonstrated across four corrector classes (§6.2); (v) COMET-QN, a label-free normalisation that removes the calibration component exactly and lifts pooled cross-script agreement from 0.300 to 0.399 (§6.3); and (vi) a parity-feature regressor recovering a further 17.1% of lost sensitivity with no exposure to the target language (§6.4).

## 2 Background and Related Work

**Unequal tokenisation and parity measures:** That subword vocabularies bill different languages differently for equivalent content is by now well attested. Petrov et al. (2023) document token-count disparities reaching 15× and introduce **Tokenization Parity** (TP), the ratio of subword tokens per word in a target language against the English figure; Ahia et al. (2023) follow the consequences through to billing and latency on commercial APIs. Tsvetkov and Kipnis (2024) recast the same disparity as **Information Parity** (IP), the ratio between a language model's compression efficiency on a target language and on English, and show IP anticipates downstream behaviour better than token counts alone. Kanjirangat et al. (2025) extend both measures to dialectal settings. Ghosh and Jyothi (2026) report the same coupling between fragmentation and model behaviour. It is therefore not peculiar to any one architecture. Two vocabulary-independent quantities serve as controls here. **Byte Premium** (Arnett et al., 2024; Arnett and Bergen, 2025) is the target-to-English ratio of bytes per word, and it eliminates UTF-8 overhead as an explanation. **MATTR** (Covington and McFall, 2010) counts distinct word forms within a sliding 500-token window. It reads no model vocabulary, so it is immune to training-corpus artefacts (Appendix F). Together, TP and IP describe what we call the *representational burden* a tokeniser places on a language. TP counts how many subword pieces the tokeniser spends on a given amount of text, so it measures fragmentation. IP measures how much information each of those pieces carries, so it measures density. Neither measure is sufficient alone. A language can fragment little and still lose information on every piece, or fragment heavily while each piece stays meaningful. Only the two read together say what the tokeniser costs, so the diagnostics of §4.2 are built from their interaction.

This literature quantifies what a tokeniser costs a *language*, and Ghosh and Jyothi (2026) extend the accounting to what it costs a *model* at inference. Neither asks whether the cost propagates into the *evaluation scores* by which such models are ranked. That is the question RQ1 puts.

**Documented COMET failure modes:** Work on where COMET breaks down has considered language mismatch and translationese (Zouhar et al., 2024) and perturbations applied within a single script (Karpinska et al., 2022), and has advocated retraining the encoder for under-served pairs (Wang et al., 2024; Falcão et al., 2024). None manipulates orthographic form as a controlled condition. The IndicMT Eval authors observed cross-language COMET variation and attributed it to language family rather than testing script (Sai et al., 2023). Retraining, meanwhile, speaks to neither the diagnosis nor the reporting difficulty confronting a deployment already in service.

**The COMET family shares one tokeniser:** The checkpoint we audit (§3) inherits the SentencePiece (Kudo and Richardson, 2018) tokeniser and 250K vocabulary of XLM-R (Conneau et al., 2020). So does the rest of the family. xCOMET-XL and xCOMET-XXL are trained over the XL and XXL variants of XLM-R (Guerreiro et al., 2024; Goyal et al., 2021), which retain that vocabulary, and CometKiwi rests on InfoXLM (Rei et al., 2022b), itself initialised from XLM-R (Chi et al., 2021). TP is determined by the tokeniser and not by the regression head, so the fragmentation burden we measure is identical across these variants. The exposure travels with the vocabulary rather than with the text, which is what makes a metric-side correction the right level of intervention (§6).

**Distributional correction and batch effects:** Rescaling metric outputs is not itself novel, but it has been practised along the language axis rather than the script axis: the COMET family $z$-normalises annotations during training (Rei et al., 2020), and low-resource variants standardise direct assessments within evaluator (Wang et al., 2024). Both are affine maps, and §6.2 proves that any affine map, indeed any order-preserving transform, leaves a metric's rank agreement with human judgement exactly unchanged, so it cannot repair the sensitivity half of the present problem. Quantile normalisation is a more forceful instrument, devised in

high-throughput biology to remove technical batch effects from microarray readings, and later refined for cross-platform comparison (Bolstad et al., 2003; Franks et al., 2018). There, one biological sample measured on two machines yields two readings that differ because of the equipment, and forcing both batches onto a shared distribution removes the machine-specific component. The correspondence we exploit is structural: a (language, script) cell stands to a COMET score as a processing batch stands to a gene-expression reading, with the writing system in the role of the machine, an artefact of measurement rather than a property of the translation. So far as we are aware, quantile normalisation has not previously been enlisted to make learned-metric scores comparable across writing systems.

## 3 Experimental Setup

This section fixes the corpus, the intervention, the checkpoint and the sample bases.

**Corpora:** IndicMT Eval (Sai et al., 2023) contributes 1,400 MQM-annotated segments for each of the five English→Indic pairs introduced in §1. Each segment carries fine-grained error types and one of five severity grades, running from Very Low to Very High, alongside a `Default` grade for output found free of error. Because one set of English sources is rendered into all five targets, cross-language comparison rests on identical content. Two WMT24 pairs (Kocmi et al., 2024) serve as Latin-script controls: ENG-SPA as a morphologically simple anchor and ENG-DEU as a morphologically complex counterweight.[2]

**The manipulation:** Target-side text is transliterated by IndicXlit (Madhani et al., 2023), a deterministic neural system that leaves phonology, morphology and meaning intact while altering orthographic form. Sources and MQM annotations are held constant, so native-script judgements *carry over* unchanged to the romanised condition and any movement in COMET is ascribable to script alone. Romanised Indic text is in any case an authentic genre (Roark et al., 2020; Chavan et al., 2023), so the experiment doubles as an audit of metric behaviour on text deployments genuinely meet.

**Transliteration quality:** On Dakshina, a benchmark that pairs native-script words with human romanisations (Roark et al., 2020), IndicXlit reports a mean top-1 accuracy of 60.5%, or 72.1% with re-ranking (Madhani et al., 2023). Both figures are for the Roman-to-native direction. Exact match understates faithfulness here, because romanisation is not standardised and several spellings of a word are valid at once. The same error analysis attributes 85% of errors to vowel and consonant choice rather than to content. Residual noise is therefore orthographic, and §4.3 shows that noise of this kind cannot account for the effect we measure.

**Checkpoint and scope:** Scores come from the reference-based checkpoint `Unbabel/wmt22-comet-da` (Rei et al., 2022a) run under `unbabel-comet` v2.2.6. TP uses XLM-R's SentencePiece tokeniser, the one that checkpoint employs, and IP an external autoregressive model, BLOOM-560m (Scao et al., 2022). Our empirical claims are bounded accordingly: to XLM-R-based COMET, and to the five Indic abugidas studied, that is, scripts whose consonant letters bear an inherent vowel modified by diacritics. The diagnostics themselves read whichever tokeniser the audited metric carries, so the apparatus transfers to xCOMET and CometKiwi unaltered. Other vocabularies are taken up in the Limitations.

**Three sample bases:** The corpus holds $5 \times 1{,}400 = 7{,}000$ segments, and three nested subsets are used, identified wherever a figure is quoted. **(i) All** 7,000 **segments** underpin every analysis using metric-side quantities alone: the ANOVA, every COMET, TP and IP mean, the parity diagnostics of §4.2, and the Hindi–Gujarati comparison of §4.1. **(ii) A** 6,995**-segment working set** underpins every analysis requiring a human score, five rows bearing non-numeric MQM entries being discarded. At most 0.2% of any language is touched and no conclusion turns on the choice, as Appendix A shows. **(iii) Severity-resolved subsets** exclude `Default`, which bears no severity rank, leaving 1,258 segments for MAR (§5). Counts appear in Appendix A.

**Conventions:** Tables and figures order languages by native-script COMET descending, which for this corpus gives GUJ, TAM, MAL, MAR, HIN, running from 85.7 down to 71.8. A dagger ($^{\dagger}$) marks a coefficient individually significant against zero at $p < 0.05$, two-sided and at segment level, and $^{\text{ns}}$ one that is not; each coefficient is tested alone, and differences between two dependent coefficients are tested separately (§4.3). Subscripts

[2] Obtained from `https://github.com/google-research/mt-metrics-eval`

$_{\text{nat}}$ and $_{\text{rom}}$ denote the native-script and romanised conditions. With the apparatus fixed, we turn to what changing the script does to the score.

## 4 The Effect of Romanisation

Romanisation changes the script and nothing else, so whatever moves in the score is the script moving it. This section records what moves, in three observations. It then turns those observations into diagnostics a practitioner can compute, and asks whether the decline they describe is large enough and real enough to warrant a correction. Supporting tables sit in Appendices A to F.

### 4.1 Three observations

**Observation 1: script explains $22.9\%$ of COMET variance.** A one-way ANOVA grouping targets by script family (Devanagari: HIN, MAR; non-Devanagari: GUJ, MAL, TAM) gives $\eta^2 = 22.9\%$ on native-script COMET, and romanisation reduces it to $1.5\%$ (Appendix A). The effect is concrete: Hindi and Gujarati are two Indo-Aryan languages separated chiefly by writing system, and the 13.95-point COMET gap between them shrinks to 2.29 under romanisation. Script is therefore the dominant factor behind cross-language COMET differences. The displacement is specific to each language and does not even share a sign: GUJ falls by 15.09 points, MAL by 14.01, TAM by 7.15 and HIN by 3.43, while MAR *rises* by 1.02 (Table 2). A spread of that width, with one language moving against the other four, already rules out any correction written as a single constant or slope (§6.1).

**Observation 2: the TP–IP inversion.** Romanisation inflates TP and collapses IP in every Indic language, TAM at the extreme with TP $+77.9\%$ and IP $-68.0\%$ (Table 2). At the language level ($n = 5$, descriptive) the TP–IP anti-correlation strengthens from $r = -0.481^{\text{ns}}$ natively to $r = -0.896^{\dagger}$ under romanisation. The explosion is driven by Tamil digraphs (*zh*, *dh*, *gh*) and by Indic dependent vowels that the tokeniser strands as near-zero-information pieces (Brahma et al., 2025), a mechanism examined in Appendix D. The encoder is handed more tokens each carrying less, the worst combination for a signal that has to discriminate.

**Observation 3: COMET is uniquely fragile.** In native script COMET has the highest $|\rho|$ against MQM in every language, ranging from 0.422 to 0.651. Under romanisation it falls furthest in every language ($|\Delta\rho| = 0.19$ to $0.39$), exceeding BLEURT (Sellam et al., 2020) at 0.09 to 0.19, BERTScore (Zhang et al., 2020) at 0.04 to 0.06, and the surface metrics BLEU, ChrF (Popović, 2015) and TER (Snover et al., 2006), all below 0.07; Table 7 gives all six. Agreement falls in all five languages, MAR included, so the displacement is not a harmless relabelling of a scale that still orders translations correctly. Every metric reads the same text against the same ratings, and only the encoder-dependent ones move, which places the failure inside the encoder rather than at the character surface. These observations document the failure but give a practitioner nothing to compute, which is what the next subsection supplies.

### 4.2 The parity diagnostics

We now introduce three diagnostics that turn the observations into numbers computable before any score is trusted. TP and IP each capture one dimension of the representational burden of §2, and the Gujarati case shows why the two must be combined. Formal definitions, axiomatic motivation and threshold calibration are in Appendices B and G.

**Script Bias Index:** $\text{SBI} = \mathbb{E}_i[\text{TP}_i/\text{IP}_i]$ counts subword pieces consumed per unit of information retrieved. Both inputs are cheap. Token counts come from the tokeniser. The information term comes from BLOOM-560m (Scao et al., 2022), a small multilingual language model used here only to measure how predictable a segment is. SBI therefore never reads COMET output or human ratings, and can be computed before any evaluation is trusted. We take $\text{SBI} \geq 3.0$ as a working threshold. Above it we do not read a raw score as a quality signal without the corrections of §6. The native-script ranking of SBI over the five languages reproduces the COMET ranking exactly ($\rho = 1.00$).

SBI also settles a case that neither parity measure settles alone, which we call the Gujarati anomaly. Gujarati fragments least of the five under romanisation, its TP rising by only $+15.2\%$, so fragmentation on its own would call it the safest language here. Its native information parity is nonetheless the lowest at 0.438, meaning each of its tokens carries the least. Combining the two gives $\text{SBI}_{\text{nat}} = 3.45$, the highest of the five, and that matches how COMET behaves: Gujarati loses more points under romanisation than any other language (Table 2). Romanisation raises SBI sharply in every language, from $\text{SBI}_{\text{nat}} \in [2.03, 3.45]$ to

| Language | COMET | | | | TP | | | IP | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | nat | rom | Δ | $\rho_{\text{nat}} \to \rho_{\text{rom}}$ | nat | rom | Δ | nat | rom | Δ |
| GUJ[a] | 85.70 | 70.61 | −15.09 | $0.590^{\dagger} \to 0.341^{\dagger}$ | 1.388 | 1.599 | +15.2% | 0.438 | 0.289 | −34.0% |
| TAM | 84.88 | 77.72 | −7.15 | $0.629^{\dagger} \to 0.240^{\dagger}$ | 1.319 | 2.347 | +77.9% | 0.545 | 0.174 | −68.0% |
| MAL | 84.08 | 70.07 | −14.01 | $0.651^{\dagger} \to 0.460^{\dagger}$ | 1.248 | 1.847 | +48.0% | 0.549 | 0.197 | −64.1% |
| MAR[b] | 71.92 | 72.94 | +1.02 | $0.487^{\dagger} \to 0.278^{\dagger}$ | 1.165 | 1.640 | +40.7% | 0.490 | 0.280 | −42.9% |
| HIN | 71.75 | 68.32 | −3.43 | $0.422^{\dagger} \to 0.230^{\dagger}$ | 1.210 | 1.702 | +40.7% | 0.636 | 0.265 | −58.3% |

Table 2: Mean COMET, segment-level Spearman agreement with MQM, and the TP–IP inversion, in the native (nat) and romanised (rom) conditions. COMET, TP and IP means use all 1,400 segments per language; $\rho$ uses the working set. [a]GUJ shows the largest COMET fall despite the smallest TP inflation, because its native IP is the lowest of the five, which gives it the greatest representational burden (§4.2). [b]MAR is the sole language whose mean COMET rises while every other quality signal worsens (§5).

$\text{SBI}_{\text{rom}} \in [5.96, 15.90]$, and the flag fires on at least 95.2% of romanised segments in all five languages against 6.6% to 62.1% natively.

**IP Parity Index:** $\text{IPI} = |\text{IP} - 1.0|$ is distance from English-equivalent parity, and it sorts a setting into three zones. In **Parity**, below 0.35, scores may be read directly. In **Burden**, between 0.35 and 0.70, COMET still tracks adequacy but its absolute level is suppressed. In **Paradox**, above 0.70, agreement with MQM typically falls below $\rho = 0.40$; romanised MAL is the sole exception (Appendix G). All five Indic languages sit in Burden natively and cross into Paradox once romanised.

**Computational Tax:** Romanisation charges twice at once, in tokens per word ($\text{LP} = \overline{\text{TP}}_{\text{rom}}/\overline{\text{TP}}_{\text{nat}}$) and in information per token ($\text{EP} = \overline{\text{IP}}_{\text{nat}}/\overline{\text{IP}}_{\text{rom}}$), and since neither charge can be traded for the other their product $\text{Tax} = \text{LP} \times \text{EP}$ gives the surplus encoder compute a romanised segment demands, from 1.75× for GUJ to 5.57× for TAM. EP accounts for 62 to 75% of $\ln(\text{Tax})$ (Appendix C), so the dominant cost is information lost per token, which no remedy that merely counts tokens can reach.

Between them the three answer RQ1. They estimate the script-induced component of a score from token counts and likelihoods alone, and every romanised setting studied here exceeds both working thresholds, $\text{SBI} \geq 3.0$ and $\text{IPI} > 0.70$. What they do not supply is a number to publish in place of the affected one. Before building one, the next subsection asks whether the decline they flag is large enough and real enough to warrant a correction at all.

### 4.3 Effect size and the adequacy objection

Before building a correction we settle two questions. Is the decline real at a defensible effect size, and is it instead the metric responding correctly to a genuine loss of adequacy?

**Measuring the effect on the right scale:** A correlation coefficient does not live on a ratio scale (Stevens, 1946), so a claim of the form "the correlation dropped by $X$ percent" has no defined referent. We therefore report absolute differences, and shared variance where a relative statement is wanted. COMET's agreement with MQM declines by $|\Delta\rho|$ between 0.19 and 0.39; expressed as shared variance, $\rho^2$ falls from 0.42 to 0.21 for MAL and from 0.40 to 0.06 for TAM. The two coefficients are computed over the same segments against the same ratings, so they are dependent and overlapping, and the difference is tested with the Meng et al. (1992) procedure. Every language shows a significant decline, with $z$ running from 8.7 to 16.0 and all $p < 10^{-17}$. Appendix A gives the per-language values, two confirmatory tests, and the relation to the Williams test used for metric comparison at WMT.

**Is adequacy genuinely lost?** Because MQM ratings are carried over rather than re-collected, one might object that romanisation truly degrades adequacy and that a falling correlation is the metric behaving correctly. Two features of the data resist that reading. First, all six metrics are scored against the same ratings, yet the size of the decline tracks how far each metric depends on a subword encoder (Appendix A), whereas invalid ratings would drag every metric down alike. Second, §5 contains outputs whose COMET scores *rise* under romanisation while their human adequacy is unchanged and, in one instance, zero; a translation judged entirely inadequate cannot be made more adequate by a change of script. The same two features answer the related worry that transliteration itself introduces errors. Noise of that kind would act like annotation noise, and would therefore depress every metric alike rather than tracking encoder dependence. Di-

rect human rating of romanised output would settle both questions outright and remains for future work. A correction is therefore warranted, and the next section establishes what kind it must be.

## 5 The Marathi Severity Inversion

Marathi behaves unlike the other four languages, and the reason constrains what any correction can look like. Romanisation lowers mean COMET in the other four, which at least moves with their falling agreement with human judgement. Marathi does the opposite: its mean COMET *rises* by 1.02 points, even though every underlying quality signal worsens in step with the rest, IP falling by 42.9% and agreement with MQM dropping from $\rho = 0.487$ to 0.278. Observation 1 recorded the rise. This section accounts for it, and the account carries beyond Marathi, because it eliminates the most obvious class of remedy before any is built.

The immediate cause is orthographic. Marathi marks spoken and literary variation through diacritics including visarga, a word-final breathing mark, and chandrabindu, a nasalisation mark (Ravishankar and Tyers, 2017). Romanisation collapses these distinctions onto one Latin surface form, rendering every hypothesis more reference-like to a similarity-based metric regardless of its quality. Resolving by MQM severity exposes the consequence (Table 3). The gain accrues entirely to badly translated segments while the best output loses ground, and bucket means rise monotonically with severity. At segment level, severity and ΔCOMET correlate at $\rho = 0.183^{\dagger}$ ($p = 5.9 \times 10^{-11}$, $N = 1{,}258$). The aggregate rise is significant across the full 1,400 (Wilcoxon $W = 453{,}856$, $p = 0.016$), yet the median change is $-0.21$: a minority of very poor segments pulls the mean upward. One output rated 0/25 gains 26.1 COMET points, from 36.6 to 62.7.

Two things follow. Evidentially, and as used in §4.3, score movements that reward inadequacy cannot be evidence of recovered adequacy. Prescriptively, Marathi's bias is neither a fixed offset nor a fixed multiple: it varies with quality within the language, and its aggregate sign opposes that of the other four. No single constant can therefore serve all five. That rules out the per-language offsets and rescalings a practitioner would reach for first, and leaves only a treatment acting on whole score distributions rather than on their centres. Constructing one is the business of §6, and §6.2 makes the exclusion exact.

| Severity | $N$ | Mean ΔCOMET |
|---|---|---|
| Very Low | 69 | −3.72 |
| Low | 86 | −1.90 |
| Medium | 184 | +0.73 |
| High | 258 | +1.08 |
| Very High | 661 | +2.63 |
| Segment-level severity–ΔCOMET: $\rho = 0.183^{\dagger}$, $N = 1{,}258$ | | |

Table 3: Mean ΔCOMET (romanised minus native) for MAR by MQM severity. The five buckets total 1,258; the remaining 142 segments are `Default` and bear no severity rank. ΔCOMET needs no human score, so the full 1,400-segment base applies.

## 6 From Diagnosis to Treatment

A practitioner arrives at this point holding a flagged score, that is, one computed in a setting where SBI $\geq 3.0$ or IPI $> 0.70$ (§4.2). This section supplies the missing action in three moves: separate the bias into parts that demand different remedies (§6.1), establish what no post-hoc method can achieve (§6.2), and correct what remains (§6.3 and §6.4). The correction is applied to the scores rather than to the text because the fragmentation driving the confound belongs to the vocabulary the metric carries (§2). Throughout, a *cell* denotes one (language, script) pair, such as GUJ native or GUJ romanised, and the ten settings form a $5 \times 2$ grid of cells. A cell plays the role of a batch in the quantile-normalisation analogy of §2. Every quantity here is validated against human ratings, so all values use the 6,995-segment working set (§3).

### 6.1 Calibration and sensitivity are different problems

Marathi showed that no constant serves every language. The reason is that romanisation does two things at once, and conflating them has obscured which of the two is fixable.

**(P1) Miscalibration.** Cells occupy different numerical ranges. The native-minus-romanised COMET gap varies across languages and even reverses sign, standing at +15.09 points for GUJ but −1.02 for MAR (§4.1), so no shared constant, slope or offset can remove it.

**(P2) Sensitivity loss.** Within a cell, the metric's capacity to order translations by quality deteriorates. Segment-level agreement with MQM falls in every language, MAR included, whose P1 gap is nearly zero.

P1 is a question of location and scale, P2 one of representational fidelity, and MAR shows that the two vary independently: a cell can be almost

perfectly calibrated and still have lost much of its discriminative power. The split is worth making because the two admit different treatments, and, as the next subsection shows, one admits none at all.

### 6.2 Rescaling cannot restore sensitivity

This subsection fixes the limit on RQ3. P2 is beyond *any* rescaling of the score, so a correction for it must look outside the score entirely (§6.4). Let $s = (s_1, \ldots, s_n)$ be the COMET scores in a cell and $h$ the paired human ratings, and recall that Spearman's $\rho_S$ depends on the scores only through their ranks.

**Proposition (Rank invariance):** For any strictly increasing $f$, order is preserved, so $\mathrm{rank}(f(s_i)) = \mathrm{rank}(s_i)$ for every $i$, and therefore

$$\rho_S\big(f(s),\, h\big) = \rho_S\big(s,\, h\big). \tag{2}$$

The two sides of Eq. 2 are equal for every dataset and every strictly increasing $f$, not merely on average. The reason is that such an $f$ can stretch or shift the scores but cannot reorder them, and Spearman agreement depends on the scores only through their order. Rescaling therefore leaves agreement with human judgement exactly where it was. The scope of that argument is what makes it useful: mean-shifting, affine rescaling, quantile mapping and isotonic regression are all strictly increasing functions of the scalar score, and together they exhaust the class of post-hoc corrections a practitioner would plausibly reach for. Whatever discriminative power romanisation destroyed at scoring time survives every one of them untouched.

Table 4 confirms this on a 50/50 within-language split. Four distributional correctors reduce the mean gap from 7.88 COMET points on the held-out half to roughly 0.6, and they lift pooled cross-language agreement. The whole-working-set figure is 8.14 (Figure 1). Yet the language-averaged Spearman stays pinned at 0.310 against a native ceiling of 0.564, moving in the fourth decimal at most. The table also answers the objection that only rankings matter and a per-script scale is therefore harmless. Pooled agreement across cells is itself a ranking task, and on the raw romanised half it stands at 0.160 against 0.310 within language. Every monotone corrector lifts the pooled figure toward 0.30 without moving the within-language figure, which is the calibration fault seen as a ranking failure.

The result is negative in form and constructive in consequence. It sends effort where it can pay: P1 is fully remediable once the scores exist (§6.3), P2 only by using information beyond the scalar (§6.4), and the rest is the Computational Tax of §4.2.

| **Corrector (transform class)** | $\lvert\Delta\rvert$ | $\rho_S^{\mathrm{lang}}$ | $\rho_S^{\mathrm{pool}}$ |
|---|---|---|---|
| Raw romanised (identity) | 7.88 | 0.310 | 0.160 |
| Per-lang mean shift (location) | 0.61 | 0.310 | 0.280 |
| Per-lang affine / $z$ (loc.+scale) | 0.63 | 0.310 | 0.301 |
| Per-lang quantile map (monotone) | 0.61 | 0.310 | 0.298 |
| Per-lang isotonic (monotone) | 0.68 | 0.309 | 0.282 |
| Native score (ceiling) | 0.00 | 0.564 | 0.488 |

Table 4: Rank invariance quantified on a 50/50 within-language split (seed 42), so all values are computed on the held-out half: $\lvert\Delta\rvert$ is the mean absolute per-language gap after correction (the whole-working-set raw gap is 8.14, Figure 1), $\rho_S^{\mathrm{lang}}$ the language-averaged and $\rho_S^{\mathrm{pool}}$ the pooled agreement with MQM over the romanised cells of that half. Every monotone corrector closes the gap and improves pooled comparability while the language-averaged column remains fixed at 0.310, exactly as Eq. 2 requires.

### 6.3 COMET-QN: quantile renormalisation

This subsection answers RQ2. The calibration fault P1 can be removed exactly, and the idea behind the removal is simple. We force every cell onto one shared score distribution, so that a given rank means the same COMET value in any language or script. We take the reference $R$ to be the pooled native-script distribution, and for a score $s_i$ in a cell of size $n$ we set

$$s_i' = Q_R\left(\frac{\mathrm{rank}(s_i)}{n+1}\right), \tag{3}$$

with $Q_R$ the empirical quantile function of $R$. This is quantile normalisation as used to remove batch effects from microarray readings (Bolstad et al., 2003), applied to cells instead of batches. Three steps: keep only each score's rank, turn it into a position in $[0, 1]$, and read off the value at that position of $R$. Appendix H works five romanised Gujarati segments through the map.

Because Eq. 3 uses $s_i$ only through its rank, it cannot disturb any within-cell ordering (Eq. 2), yet every cell now shares $R$, so the per-language gap, MAR's sign-reversed $-1.02$ included, is exactly zero by construction rather than by fitting. Figure 1 confirms the effect. The gap collapses to zero. Pooled agreement with MQM rises from 0.300 to 0.399 (Spearman) and 0.324 to 0.400 (Pearson), while within-language agreement is unchanged to four decimals. COMET-QN buys comparability, not sensitivity, exactly as the decomposition predicts. SBI also collapses toward zero afterwards,

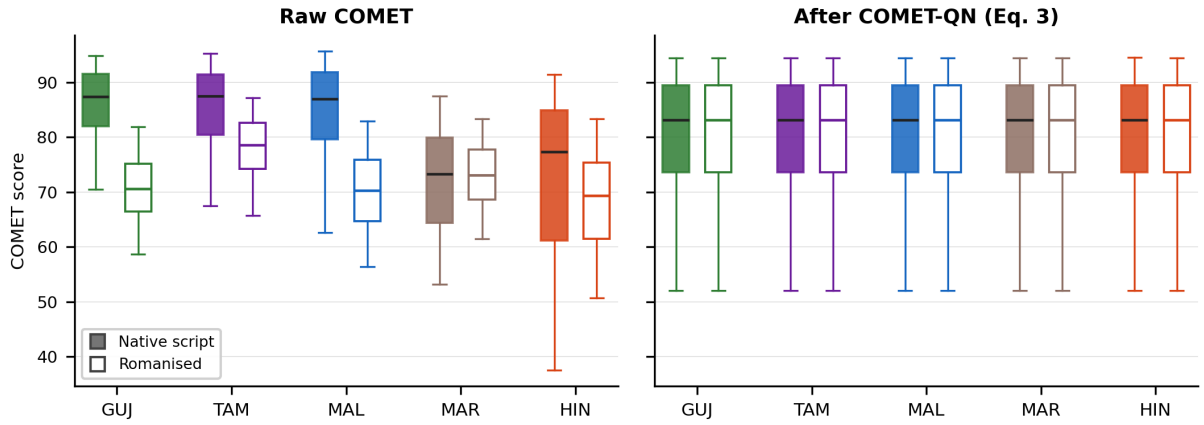

Figure 1: COMET-QN across the ten (language, script) cells (boxes: median, IQR, 5th–95th percentiles; 6,995-segment working set). **Left, raw COMET** (mean |per-lang. gap| $= 8.14$ pts; pooled $\rho_S = 0.300$): native cells, filled, sit consistently above their romanised counterparts, open, by a margin that varies across languages and reverses for MAR, which is problem P1 (§6.1). **Right, after COMET-QN** (Eq. 3; mean |per-lang. gap| $= 0.00$ pts; pooled $\rho_S = 0.399$): all cells share the pooled native reference, so the gap is exactly zero by construction and cross-script comparison becomes meaningful. Pooled Pearson agreement rises from $0.324$ to $0.400$ over the same cells, while within-language agreement is unchanged to four decimals, GUJ standing at $0.5903$ before and after. Within-cell ordering is provably untouched (Eq. 2).

so the diagnostic of §4.2 doubles as a certificate that P1 is eliminated.

**Scope and reference:** COMET-QN assumes the cells share a comparable underlying quality distribution. If one system pool is genuinely weaker, the method erases that real difference along with the artefactual one, so it belongs within a single dataset and domain. The same restriction governs comparison across test sets. Two test sets with different quality distributions are different batches, so COMET-QN should be applied within each and its outputs not compared between them; quantifying the distortion when that assumption is violated is future work. Stable quantiles need a few hundred segments per cell, easily met by the 1,400 here. The pooled native-script reference is the condition COMET was validated on and hence the natural anchor. Other references preserve the exact zero-gap property, though we do not claim the pooled-agreement gain is invariant to the choice. P1 is now settled, which leaves P2 and the question of how much of it can be won back.

### 6.4 Recovering sensitivity from parity features

RQ3 concerns P2, the sensitivity fault. It lies beyond any transform of the scalar (Eq. 2), so recovering it needs information the scalar does not carry. The parity diagnostics are the natural source, since they record how severely the encoder was taxed on each segment. We therefore compose two operators,

$$\tilde{s} = C_{\text{sens}}\big(C_{\text{cal}}(s, c);\, \phi\big), \tag{4}$$

read inside out: COMET-QN ($C_{\text{cal}}$) fixes the calibration fault while leaving every rank untouched, then the regressor ($C_{\text{sens}}$) uses the parity features $\phi$ to re-rank segments. Calibration must come first because it is the only rank-safe step, and $C_{\text{sens}}$ is deliberately the only stage allowed to change ranks. Here $\phi$ collects TP and IP in both conditions together with their differences, and $C_{\text{sens}}$ is a gradient-boosted regressor mapping $(\text{COMET}_{\text{rom}}, \phi)$ to $\text{COMET}_{\text{nat}}$. No human labels enter: because romanisation preserves content, every (romanised, native) pair is free supervision.

Evaluation follows the honest deployment regime, leave-one-language-out: fit on four languages and apply to the fifth, unseen, as when a new language arrives with no corrector data of its own. The deficit recovered is $(\rho_{\text{cal}} - \rho_{\text{raw}})/(\rho_{\text{nat}} - \rho_{\text{raw}})$, a scale that stays comparable across languages with different native ceilings. Averaged over the five folds the regressor restores $17.1\%$ of the lost sensitivity with no exposure to the target language, improving four of five (Table 5).

**Reading the failure:** MAR's negative transfer at $-20.3\%$ is the same fact that defeats a universal formula: script bias is not one function. The parity features act as a proxy for the direction of the bias, dependable only where the pattern of TP and IP divergence resembles that of the training languages.

| Held-out | $\rho_{\text{raw}}$ | $\rho_{\text{cal}}$ | $\rho_{\text{nat}}$ | Recovered |
|---|---|---|---|---|
| GUJ | 0.341 | 0.437 | 0.590 | 38.6% |
| TAM | 0.240 | 0.291 | 0.629 | 13.0% |
| MAL | 0.460 | 0.524 | 0.651 | 33.5% |
| MAR | 0.278 | 0.236 | 0.487 | −20.3% |
| HIN | 0.230 | 0.270 | 0.422 | 20.8% |
| Mean | | | | 17.1% |

Table 5: Parity-feature calibration under leave-one-language-out (segment-level Spearman against MQM, 6,995-segment working set). Recovery is the fraction of the raw-to-native sensitivity gap closed. MAR transfers negatively: its bias runs counter to the four training languages, its P1 gap being sign-reversed (§6.1), so a model fitted on them mispredicts its residual.

The failure can nonetheless be anticipated without labels, though not by the mean diagnostics: MAR's native SBI of 2.61 and IPI of 0.510 both sit inside the range of the other four (Appendix B). What separates MAR is the sign of its mean cell gap, native minus romanised, computable from scores alone and the direction the regressor learns. A cell whose sign opposes the training cells should therefore receive COMET-QN alone, until a corrector has been fitted on languages sharing its sign. The residual five sixths of the deficit is encoder-intrinsic, which is to say it is the Computational Tax of §4.2. Post-hoc composition and encoder retraining therefore address disjoint portions of the loss, and neither substitutes for the other.

What this buys a practitioner is modest but definite. Scores from different scripts become comparable, a sixth of the lost discrimination comes back, and the distortion that remains can be stated rather than hoped away. The rest cannot be reported around, only rebuilt around, and the procedure below is built on that division.

## 7 What to Report

The preceding sections converge on a procedure. For a non-Latin-script target we suggest the following.

1. State which encoder and tokeniser the metric carries. The COMET variants in common use carry XLM-R (§2); others must be profiled against their own vocabulary first.
2. Compute IPI once for the (language, script) pair against that tokeniser. This needs no human ratings and no access to the metric's internals.
3. In the Parity zone, report raw COMET. The tokeniser treats the language much as it treats English, so no companion figures are needed.
4. In the Burden zone, report raw COMET with IPI beside it, so absolute levels are not over-read while rankings are still trusted.
5. In the Paradox zone, report COMET-QN (Eq. 3) with raw COMET and the three diagnostics, and do not compare raw scores across scripts. Apply the parity-feature regressor only when the cell's mean-gap sign matches the languages it was fitted on (§6.4).
6. Do not romanise as a preprocessing convenience: it costs 1.75–5.57× in encoder compute and degrades agreement with annotators rather than equalising it (§4.3).

No step consumes human ratings. Appendix I runs the procedure through one setting, romanised Gujarati, end to end.

## 8 Conclusion

Script bias in COMET is two faults. One is removed exactly and without labels by quantile renormalisation; the other is beyond any rescaling and comes back only in part. The recommendation is concrete: publish the normalised score, the diagnostics, and the identity of the tokeniser they were computed against, whenever COMET is reported on a non-Latin-script target. That tokeniser is XLM-R across the COMET variants in common use (§2), so the procedure covers much of published Indic MT evaluation. The released code emits all four numbers in one pass, so adopting the protocol costs a practitioner one command.

Two consequences reach past this corpus. A metric can look healthy in aggregate and still be unfit for the comparison it is put to, so the conditions a score was measured under belong beside it. The fault is also not COMET's alone: it lives in a vocabulary much of the multilingual metric family shares. Three things follow. The apparatus should be run against metrics carrying other vocabularies, which is the study we are preparing. The diagnostics should be tested on writing systems that are not abugidas, once a corpus with matched sources exists. And human ratings should be collected directly on romanised output, which would settle the one assumption this design cannot test from the inside. The deeper remedy remains an encoder that spreads capacity evenly across scripts.

## Limitations

Our metric-level claims cover one metric, COMET `wmt22-comet-da`, and one tokeniser, the XLM-R SentencePiece vocabulary that checkpoint

carries. The xCOMET and CometKiwi variants inherit the same tokeniser and vocabulary (§2), so the fragmentation burden we measure carries to them unchanged; whether the score-level distortion does is a different question, and one we have not answered. Nor have we measured how tokenisers of other designs, byte-level, English-centric or WordPiece, respond to the same intervention, or how metrics built on them would score the resulting text. Both questions belong to a single follow-up study, which we are preparing: it takes the neural metrics that do *not* share XLM-R's vocabulary, MetricX (Juraska et al., 2024) and the mT5-based family (Xue et al., 2021) most obviously, computes the parity diagnostics against each metric's own tokeniser, and repeats the romanisation intervention across that set. That design would establish whether script sensitivity is a property of one widely-used vocabulary or a recurring hazard of multilingual metric construction, and it would test whether COMET-QN transfers as a correction. Since the diagnostics read whichever tokeniser the audited metric carries and IP is computed externally, the apparatus requires no modification for such a study; only the metrics and their tokenisers need substituting. The languages studied are five Indic abugidas; behaviour under ideographic writing systems is untested, and to our knowledge no corpus offers MQM-annotated evaluations of identical sources across several non-Latin scripts, which is what the design requires. The diagnostics themselves are computable on any script and any tokeniser, so the apparatus would extend to Chinese, Japanese and Korean unchanged; what is missing is the corpus, and we make no claim about how COMET-QN would perform there. At 1,400 segments per language our corpus is smaller than those of Brahma et al. (2025) and Kumar et al. (2017); we claim only that our dependent-vowel ordering agrees with theirs and so corroborates rather than independently establishes it. The IPI zone boundaries and the $\mathrm{SBI} \geq 3.0$ flag are calibrated on this corpus, with the WMT24 controls providing a first external check but no more. COMET-QN assumes comparable underlying quality across cells and would erase a genuine quality difference between system pools, so it belongs within a single dataset and domain; its reference distribution is a free parameter whose influence on the pooled-agreement gain we have not measured. The carried-over annotation design is supported by the encoder-dependence ordering and the MAR counter-case (§4.3, §5). We do not, however, measure transliteration accuracy on this corpus. The published IndicXlit figures we quote in §3 are for the opposite direction, so residual transliteration error in our own outputs is bounded by argument rather than by direct measurement. A study collecting human ratings directly on romanised output would settle the question and remains future work, as does evaluation against code-switched references, a complementary setting that our fully-romanising design deliberately excludes.

**Artefact licences:** Every artefact used, namely IndicMT Eval (Sai et al., 2023), the WMT24 evaluation packages (Kocmi et al., 2024), XLM-RoBERTa (Conneau et al., 2020), BLOOM-560m (Scao et al., 2022), COMET, BLEURT (Sellam et al., 2020), BERTScore (Zhang et al., 2020) and IndicXlit (Madhani et al., 2023), is released for research use under a permissive or open-research licence. Our use is consistent with those terms and we redistribute none of the underlying corpora. Released code is MIT-licensed.

## Ethics Statement

We foresee no ethical concerns arising from this work. The study measures and corrects a distortion in automatic evaluation caused by tokenisation artefacts affecting Indic scripts, and reports interpretable statistical evidence together with an actionable procedure. All corpora and benchmarks are publicly available and every released artefact is analytical, with no foreseeable potential for harm. By exposing a previously unmeasured distortion and supplying a correction for it, the work is intended to benefit under-served Indic-language communities whose systems are ranked by the affected metric.

## A Statistical Detail and Sample Sizes

Table 6 gives per-language totals and MQM severity counts. Five rows carrying non-numeric MQM entries are discarded, one apiece in MAL and TAM and three in MAR, so per-language totals for analyses needing a human score become 1,400 for GUJ and HIN, 1,399 for TAM and MAL, and 1,397 for MAR. No conclusion turns on the choice of base: the ANOVA returns $F = 2{,}080.8$ on the full corpus and $F = 2{,}080.2$ on the working set, so the $22.9\%$ variance result of §4.1 is unaffected and the discarded rows introduce no detectable bias. Table 7 gives agreement with MQM for all six metrics in both conditions, the evidence behind the encoder-dependence ordering of §4.3. Table 8 collects the ANOVA, the SBI threshold proportions, the HIN–GUJ contrast and the dependent-correlation tests. The Meng procedure belongs to the family of the Williams test used for metric comparison at WMT (Graham and Baldwin, 2014); Steiger's test (Steiger, 1980) and a 5,000-round paired permutation test (Deutsch et al., 2021) both agree with it.

## B Parity Profile and Diagnostic Definitions

Table 9 defines the two prior parity measures and the three diagnostics built from them. Table 10 profiles all seven language-script settings, and Figure 2 plots the IPI zone transitions.

| Lang. | N | Def | VL | L | M | H | VH |
|---|---|---|---|---|---|---|---|
| GUJ | 1,400 | 248 | 217 | 326 | 390 | 184 | 35 |
| TAM | 1,400 | 60 | 124 | 151 | 323 | 313 | 429 |
| MAL | 1,400 | 372 | 25 | 162 | 443 | 334 | 64 |
| MAR | 1,400 | 142 | 69 | 86 | 184 | 258 | 661 |
| HIN | 1,400 | 399 | 1 | 7 | 134 | 324 | 535 |

Table 6: Per-language totals and MQM severity counts; buckets sum to 1,400 in every language. **Def** = `Default` (error-free); VL/L/M/H/VH = Very Low, Low, Medium, High, Very High. Analyses needing a numeric human score use 1,400 (GUJ, HIN), 1,399 (TAM, MAL) and 1,397 (MAR), giving the 6,995-segment working set (§3).

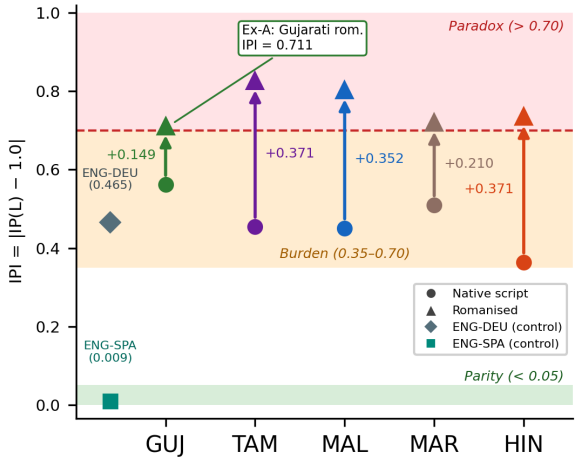

Figure 2: IPI zone transitions under romanisation. Bands: Parity ($< 0.35$), Burden (0.35–0.70), Paradox ($> 0.70$). Every Indic language crosses into Paradox; ENG-DEU (Burden) and ENG-SPA (Parity) are Latin-script reference points. The callout marks the romanised Malayalam example of Table 1(A), at IPI $= 0.803$ and COMET $= 56.2$.

## C Computational Tax Decomposition

Table 11 splits the Computational Tax into its Length Penalty (LP) and Entropy Penalty (EP) components for each language, with EP's share of $\ln(\text{Tax})$ in the final column.

## D Dependent Vowels and Word Length

Vowels in Indic abugidas are written as diacritics attached to the preceding consonant, and a well-matched tokeniser keeps each consonant-vowel unit whole. XLM-RoBERTa's SentencePiece vocabulary, induced from Latin-dominant text, frequently strands these diacritics as tokens of their own carrying no meaning. MAL yields 42.5 such isolated tokens per 1,000 XLM-R tokens and GUJ 36.7 (Table 10). TAM has the lowest rate at 13.6 yet the largest TP inflation under romanisation at $+77.9\%$. That dissociation points to a second and independent mechanism. Agglutinative suffix chains produce long word forms that the tokeniser must divide heavily, which Table 12 corroborates: TAM reaches $\rho = 0.905^{\dagger}$ between word count and token count in the romanised condition. MATTR is vocabulary-free and hence independent of XLM-R, and it recovers the same ordering (MAL $>$ TAM $>$ MAR $>$ GUJ $>$ HIN). That agreement points to genuine morphological diversity (Hirak et al., 2026) rather than a training-corpus artefact.

## E Latin-Script Controls

ENG-DEU and ENG-SPA from WMT24 (Kocmi et al., 2024) serve as Latin-script controls. SPA anchors the Parity zone at IPI $= 0.009$, while DEU refutes the surface-script explanation: written in the same alphabet as SPA, it nonetheless shows IP suppression of the same magnitude as the Indic native range (0.535 against 0.438–0.636). The two diverge by a factor of twelve in their IP–COMET correlation ($r = -0.262^{\dagger}$ for DEU against $r = -0.021^{\text{ns}}$ for SPA; $N = 6{,}006$ and 4,651). Byte premiums are nearly identical at $1.25\times$ and $1.09\times$, which excludes character-encoding overhead directly. German compounding drives the gap: *Erlassvereinfachungsverträge* (28 characters, "decree simplification contracts") costs 9 XLM-R tokens, whereas *simultáneamente* (15 characters, "simultaneously") costs 4. Only $14.6\%$ of DEU word types receive a single-token encoding against $22.1\%$ for SPA, and long DEU words need $32\%$ more tokens than long SPA words. DEU's MATTR of 0.634 exceeds SPA's 0.581, consistent with the compounding account. Table 13 sets both controls beside the Indic native range.

**A reversal in SBI:** Across the Indic languages, script-induced SBI elevation is independent of quality: fragmentation applies as a structural offset irrespective of how good a translation is. In DEU the relationship inverts. Erroneous MT output there tends toward paraphrase and syntactic simplification (Zouhar et al., 2024), producing shorter and commoner word sequences and hence *less* fragmentation. Error-free DEU segments average SBI $= 2.349$ while segments with major errors average 2.129 (Kruskal–Wallis $H = 135.0^{\dagger}$, $p = 5.0 \times 10^{-30}$), the reverse of the romanised-Indic direction. SBI nonetheless remains a valid zone diagnostic in both cases, placing DEU in Burden at 2.24 and SPA in Parity at 1.12.

| Language | COMET | BLEURT | BERTScore | BLEU | ChrF | TER |
|---|---|---|---|---|---|---|
| $\text{GUJ}_{\text{nat}}$ | $+\mathbf{0.590}^{\dagger}$ | $+0.522^{\dagger}$ | $+0.438^{\dagger}$ | $+0.339^{\dagger}$ | $+0.401^{\dagger}$ | $-0.327^{\dagger}$ |
| $\text{GUJ}_{\text{rom}}$ | $+0.341^{\dagger}$ | $+0.339^{\dagger}$ | $+0.375^{\dagger}$ | $+0.340^{\dagger}$ | $+0.407^{\dagger}$ | $-0.333^{\dagger}$ |
| $\text{TAM}_{\text{nat}}$ | $+\mathbf{0.629}^{\dagger}$ | $+0.563^{\dagger}$ | $+0.459^{\dagger}$ | $+0.320^{\dagger}$ | $-0.312^{\S}$ | $+0.410^{\S}$ |
| $\text{TAM}_{\text{rom}}$ | $+0.240^{\dagger}$ | $+0.377^{\dagger}$ | $+0.412^{\dagger}$ | $+0.286^{\dagger}$ | $+0.408^{\S}$ | $-0.308^{\S}$ |
| $\text{MAL}_{\text{nat}}$ | $+\mathbf{0.651}^{\dagger}$ | $+0.596^{\dagger}$ | $+0.566^{\dagger}$ | $+0.470^{\dagger}$ | $+0.542^{\dagger}$ | $-0.451^{\dagger}$ |
| $\text{MAL}_{\text{rom}}$ | $+0.460^{\dagger}$ | $+0.443^{\dagger}$ | $+0.529^{\dagger}$ | $+0.409^{\dagger}$ | $+0.549^{\dagger}$ | $-0.466^{\dagger}$ |
| $\text{MAR}_{\text{nat}}$ | $+\mathbf{0.487}^{\dagger}$ | $+0.443^{\dagger}$ | $+0.354^{\dagger}$ | $+0.261^{\dagger}$ | $+0.292^{\dagger}$ | $-0.255^{\dagger}$ |
| $\text{MAR}_{\text{rom}}$ | $+0.278^{\dagger}$ | $+0.286^{\dagger}$ | $+0.313^{\dagger}$ | $+0.256^{\dagger}$ | $+0.307^{\dagger}$ | $-0.258^{\dagger}$ |
| $\text{HIN}_{\text{nat}}$ | $+\mathbf{0.422}^{\dagger}$ | $+0.381^{\dagger}$ | $+0.274^{\dagger}$ | $+0.202^{\dagger}$ | $+0.224^{\dagger}$ | $-0.236^{\dagger}$ |
| $\text{HIN}_{\text{rom}}$ | $+0.230^{\dagger}$ | $+0.294^{\dagger}$ | $+0.214^{\dagger}$ | $+0.204^{\dagger}$ | $+0.217^{\dagger}$ | $-0.213^{\dagger}$ |

Table 7: Spearman agreement between each metric and MQM on the working set ($N = 1{,}400$ for GUJ and HIN, 1,399 for TAM and MAL, 1,397 for MAR). Bold marks the strongest $|\rho|$ per language. COMET loses $|\Delta\rho| = 0.19$ to 0.39 under romanisation while the surface metrics stay flat. TER is negatively oriented. $^{\S}$TAM ChrF and TER reverse sign natively owing to character-$n$-gram fragmentation in the reference.

| Quantity | Native | Romanised |
|---|---|---|
| $F$ | 2,080.8 | 108.3 |
| $p$ | $< 10^{-99}$ | $3.5 \times 10^{-25}$ |
| $\eta^2$ | 22.9% | 1.5% |
| *Segment-level* SBI $\geq 3.0$ *proportions* | | |
| GUJ | 62.1% | 95.7% |
| TAM | 34.9% | 97.9% |
| MAL | 30.9% | 95.2% |
| MAR | 28.2% | 95.4% |
| HIN | 6.6% | 98.3% |
| *HIN–GUJ contrast (Welch's t)* | | |
| Native | 13.95 pts; $t = 27.4^{\dagger}$, $p < 10^{-99}$ | |
| Romanised | 2.29 pts; $t = 6.97^{\dagger}$, $p = 4.1 \times 10^{-12}$ | |
| *Native-vs-romanised COMET–MQM decline (Meng z)* | | |
| GUJ 10.5; TAM 16.0; MAL 9.8; MAR 8.7; HIN 10.1 | | |
| Steiger $Z$ agrees to one decimal; 5,000-round paired permutation: 0/5,000 exceedances per language. | | |

Table 8: ANOVA on COMET by script family ($N = 7{,}000$; the ANOVA and the SBI proportions use metric-side quantities only, so no rows are dropped, and the same test on the 6,995-segment working set gives $F = 2{,}080.2$), the share of segments the SBI $\geq 3.0$ flag catches in each condition, the HIN–GUJ contrast, and the dependent-correlation tests (Meng et al., 1992; Steiger, 1980; Deutsch et al., 2021). $\eta^2 = \text{SS}_{\text{between}}/\text{SS}_{\text{total}}$.

## F Vocabulary-Free Corroboration

Table 14 reports MATTR and Byte Premium across all seven settings. Both are computed without reference to any model vocabulary, so they check the TP and IP findings independently of XLM-R and of UTF-8 encoding.

## G Axiomatic Motivation and Threshold Calibration

**Why SBI takes a ratio form:** A measure of representational burden ought to (a) equal 1.0 when

| Metric | Ideal | Role |
|---|---|---|
| $\text{TP} = \lvert t(s_L)\rvert / \lvert t(s_E)\rvert$ | 1.0 | Fragmentation cost; $> 1$ over-fragmentation. |
| $\text{IP} = \text{NLL}(w_E)/\text{NLL}(w_L)$ | $\approx 1.0$ | Semantic density per token; $\ll 1$ collapse. |
| $\text{SBI} = \mathbb{E}_i[\text{TP}_i/\text{IP}_i]$ | 1.0 | Burden per unit information. Flag $\geq 3.0$. |
| $\text{IPI} = \lvert\text{IP} - 1.0\rvert$ | 0.0 | Distance from parity; Parity/Burden/Paradox zones. |
| $\text{Tax} = \text{LP} \times \text{EP}$ | 1.0 | Romanisation overhead; LP, EP defined in §4.2. |

Table 9: The two prior parity measures (TP, IP) and the three diagnostics of §4.2. $t(\cdot)$ is XLM-RoBERTa's tokeniser and NLL the total negative log-likelihood under BLOOM-560m. **Ideal** is the value at English-equivalent parity.

$\text{TP} = \text{IP} = 1.0$; (b) be unaffected by constant rescaling of either input; (c) grow without bound as fragmentation rises or density collapses; and (d) identify the GUJ case, where the smallest TP inflation under romanisation of the five ($+15.2\%$) combines with the lowest native information parity ($\overline{\text{IP}}_{\text{nat}} = 0.438$) to produce the greatest overall burden. The additive form $\text{TP} - \text{IP}$ violates (a) and (d). The ratio $\text{TP}/\text{IP}$ is the simplest function meeting all four.

**Why Tax multiplies:** The two charges are incurred at once: a segment requires more tokens (LP) and each conveys less (EP). Because neither can be exchanged for the other, their joint effect on inference cost compounds rather than accumulates. TAM at $\text{LP} = 1.78$ and $\text{EP} = 3.13$ is a different situation from $\text{LP} = 3.13$ and $\text{EP} = 1.78$ despite the identical sum.

**Calibrating the IPI boundaries:** The Paradox boundary at 0.70 is set empirically. Romanised agreement values are

| Lang. | Script | Family | $\overline{\text{IP}}_{\text{nat}}$ | $\overline{\text{TP}}_{\text{nat}}$ | $\text{SBI}_{\text{nat}}$ | $\text{IPI}_{\text{nat}}$ | $\text{IPI}_{\text{rom}}$ | MATTR | DV/1k | IP–COMET $r$ |
|---|---|---|---|---|---|---|---|---|---|---|
| SPA | Latin | Romance | 1.009 | 1.090 | 1.12 | 0.009 | n/a | 0.581 | n/a | $-0.021^{\text{ns}}$ |
| DEU | Latin | Germanic | 0.535 | 1.133 | 2.24 | 0.465 | n/a | 0.634 | n/a | $-0.262^{\dagger}$ |
| GUJ | Gujarati | IA | 0.438 | 1.388 | 3.45 | 0.562 | 0.711 | 0.752 | 36.7 | $-0.064^{\dagger}$ |
| TAM | Tamil | Dravidian | 0.545 | 1.319 | 2.73 | 0.455 | 0.826 | 0.862 | 13.6 | $-0.263^{\dagger}$ |
| MAL | Malayalam | Dravidian | 0.549 | 1.248 | 2.62 | 0.451 | 0.803 | 0.897 | 42.5 | $-0.266^{\dagger}$ |
| MAR | Devanagari | IA | 0.490 | 1.165 | 2.61 | 0.510 | 0.720 | 0.827 | 24.5 | $-0.216^{\dagger}$ |
| HIN | Devanagari | IA | 0.636 | 1.210 | 2.03 | 0.364 | 0.735 | 0.633 | 18.3 | $+0.203^{\dagger}$ |

Table 10: Parity profile for all seven settings. Indic values are from the Translation column of IndicMT Eval (Sai et al., 2023) ($N = 1{,}400$ per language); ENG-DEU and ENG-SPA are from WMT24 (Kocmi et al., 2024) (339 sources pooled across MT systems, 6,006 rows for ENG-DEU and 4,651 for ENG-SPA). Controls appear first, then the fixed language order. DV/1k counts isolated dependent-vowel tokens per 1,000 XLM-R tokens. IP–COMET $r$ is segment-level Pearson over all 1,400 segments per language, requiring no human score. **n/a**: the Latin-script controls have no romanised condition. IA = Indo-Aryan. GUJ's IP–COMET correlation is weak but significant ($r = -0.064$, $p = 0.017$).

| Lang. | LP | EP | Tax | EP% |
|---|---|---|---|---|
| GUJ | 1.15× | 1.52× | 1.75× | 74.6% |
| TAM | 1.78× | 3.13× | 5.57× | 66.4% |
| MAL | 1.48× | 2.78× | 4.12× | 72.3% |
| MAR | 1.41× | 1.75× | 2.47× | 62.1% |
| HIN | 1.41× | 2.40× | 3.37× | 71.9% |

Table 11: Length and Entropy Penalty components of the Computational Tax, with $\text{EP\%} = \ln(\text{EP})/\ln(\text{Tax})$. The Entropy Penalty dominates in every language, so information lost per token, not tokens gained, is the principal cost of romanisation.

| Lang. | Native $\rho$ | Romanised $\rho$ |
|---|---|---|
| GUJ | $0.883^{\dagger}$ | $0.952^{\dagger}$ |
| TAM | $0.850^{\dagger}$ | $0.905^{\dagger}$ |
| MAL | $0.875^{\dagger}$ | $0.900^{\dagger}$ |
| MAR | $0.891^{\dagger}$ | $0.942^{\dagger}$ |
| HIN | $0.897^{\dagger}$ | $0.956^{\dagger}$ |

Table 12: Segment-level Spearman correlation between word count and XLM-R token count (all $p < 10^{-99}$, $N = 1{,}400$). Romanisation drives these toward 1.0, the signature of single-character fallback.

$\{0.230, 0.240, 0.278, 0.341, 0.460\}$ across the five languages, four of which fall below $\rho = 0.40$; MAL at 0.460 is the exception, the single romanised setting above $\rho = 0.40$ in the Paradox zone, and it still shows an absolute decline of 0.191 from its native 0.651, with shared variance halved from 0.42 to 0.21. The Burden upper bound is the largest IPI compatible with $\rho \geq 0.40$ across all native-script settings, and 0.70 is a round value inside the empirical gap separating the highest native setting (GUJ at 0.562) from the lowest romanised one (GUJ at 0.711). Consequently all twelve classifications are insensitive to where in that gap the boundary is drawn, which is what makes the zone labels of §4.2 robust to the choice. The Parity/Burden boundary is set at 0.35, below the lowest Burden setting (HIN native at 0.364) and well above SPA's 0.009; no setting in our data falls in the 0.05–0.35 interval, which is therefore left inside Parity by construction.

## H COMET-QN Procedure and Reproducibility

**Working set:** Numeric fields are coerced and the five rows carrying non-numeric MQM entries are dropped, leaving 6,995 records, each holding native-script and romanised COMET, a human MQM score, and TP and IP for both conditions. Analyses that use no human score retain all 7,000 rows (§3).

**Quantile renormalisation (Eq. 3):** Fix the reference $R$ as the pooled native-script COMET distribution over all languages, sorted. Within each cell, replace every score by its fractional rank $\text{rank}(s_i)/(n+1)$, then map that fraction through the empirical quantile function $Q_R$. Both steps are monotone, hence rank-preserving within the cell. Table 15 works five romanised Gujarati segments through the map.

**Sensitivity regressor:** Gradient-boosted trees with 300 estimators, depth 3, learning rate 0.05 and seed 0. Features are $\text{COMET}_{\text{rom}}$, the four parity values $\text{TP}_{\text{nat}}$, $\text{TP}_{\text{rom}}$, $\text{IP}_{\text{nat}}$ and $\text{IP}_{\text{rom}}$, and the two differences $\Delta\text{TP} = \text{TP}_{\text{nat}} - \text{TP}_{\text{rom}}$ and $\Delta\text{IP} = \text{IP}_{\text{nat}} - \text{IP}_{\text{rom}}$. The target is $\text{COMET}_{\text{nat}}$.

| Setting | $\overline{\text{IP}}$ | SBI | MATTR | Byte pr. | 1-tok% | IP–COMET $r$ |
|---|---|---|---|---|---|---|
| ENG-SPA (SPA) | 1.009 | 1.12 | 0.581 | 1.09× | 22.1% | $-0.021^{\text{ns}}$ |

| Indic nat. | 0.438–0.636 | 2.03–3.45 | 0.633–0.897 | 2.45–5.33× | 8.7–30.3% | varies |

Table 13: Latin-script controls beside the Indic native range. **1-tok%** is the share of unique word types receiving a single-token XLM-R encoding. Zones: ENG-SPA Parity; ENG-DEU Burden; Indic native Burden; Indic romanised Paradox.

| Lang. | Script | $\text{MATTR}_{\text{nat}}$ | $\text{MATTR}_{\text{rom}}$ | Byte Prem. |
|---|---|---|---|---|
| GUJ | Gujarati | 0.752 | 0.665↓ | 3.03 |
| TAM | Tamil | 0.862 | 0.733↓ | 5.30 |
| MAL | Malayalam | 0.897 | 0.768↓ | 5.33 |
| MAR | Devanagari | 0.827 | 0.721↓ | 3.64 |
| HIN | Devanagari | 0.633 | 0.601↓ | 2.45 |
| SPA | Latin (Romance) | 0.581 | n/a | 1.09 |
| DEU | Latin (Germanic) | 0.634 | n/a | 1.25 |

Table 14: MATTR and Byte Premium across all seven settings as vocabulary-free and encoding-independent checks on the TP and IP findings. MATTR uses $w = 500$ with whitespace tokenisation (Covington and McFall, 2010); Byte Premium is the target-to-English ratio of UTF-8 bytes per word (Arnett et al., 2024; Arnett and Bergen, 2025). ↓ marks a fall under romanisation; **n/a**: no romanised condition exists for the Latin-script controls.

| Raw | Rank | Position | Mapped |
|---|---|---|---|
| 71.07 | 1 | 0.167 | 68.21 |
| 76.41 | 2 | 0.333 | 77.27 |
| 78.14 | 3 | 0.500 | 83.14 |
| 78.24 | 4 | 0.667 | 87.58 |
| 80.33 | 5 | 0.833 | 91.48 |

Table 15: Eq. 3 applied to five romanised GUJ segments. Position is $\text{rank}/(n{+}1)$; Mapped is the value at that position of the pooled native-script reference. Ranks are carried through unchanged, which is why the operation cannot disturb any within-cell ordering.

# I The Reporting Procedure on One Setting

This appendix applies §7 end to end to romanised Gujarati, using only numbers already reported above.

**Step 1, name the tokeniser.** The metric is `wmt22-comet-da`, which carries the XLM-R SentencePiece vocabulary (§3). It is inside the profiled family, so the remaining steps apply unchanged.

**Step 2, compute IPI.** For romanised Gujarati, $\text{IPI} = 0.711$ (Table 10). No human ratings are involved.

**Step 3, read the zone.** 0.711 exceeds 0.70, so the setting is in Paradox. Steps 3 and 4 do not apply; step 5 does.

**Step 5, assemble the report.** Publish COMET-QN as the headline figure, with the raw mean COMET of 70.61 beside it, and the three diagnostics: $\text{SBI}_{\text{nat}} = 3.45$, $\text{IPI}_{\text{rom}} = 0.711$, and $\text{Tax} = 1.75\times$. Do not compare the raw score against a native-script score from another language. The regressor gate then applies. Gujarati's mean cell gap is negative, native minus romanised giving $-15.09$ points, the same sign as TAM, MAL and HIN, so a corrector fitted on those languages transfers and recovers 38.6% of the lost sensitivity (Table 5). Had the sign matched MAR instead, the gate would have withheld the regressor and left COMET-QN alone.

**Step 6, do not romanise.** Romanising Gujarati to equalise scripts would cost $1.75\times$ the encoder compute and drop agreement with annotators from $\rho = 0.590$ to 0.341.

A reader of that report can see the corrected score, the uncorrected score, how heavily the tokeniser taxed the language, and how much distortion the correction did not remove.

**Protocols:** Table 4 uses a 50/50 within-language split at seed 42; Figure 1 uses the whole working set; Table 5 uses leave-one-language-out. Correlations are segment-level Spearman unless labelled Pearson, and "pooled" concatenates cells before correlating. All values are regenerated by the released analysis script.

# Fine-Tuning LLMs for Translation: General Forgetting Mitigation Does Not Preserve MT-Specific Instruction Following

## Abstract

Fine-tuning large language models on parallel data improves translation quality but can cause catastrophic forgetting. Mitigation methods are generally evaluated by retention on general benchmarks. We ask whether these findings transfer to machine translation (MT) fine-tuning and to MT-specific instruction following (MT-IF): instructions that modify a translation, such as formality, grammatical gender, and length control. We compare methods anchored to auxiliary data, to model outputs, and to the base model parameters, first in a screening study with Llama 3.2 1B Instruct, then on Llama 3.1 8B Instruct fine-tuned on bidirectional Arabic-English or Spanish-English data. Elastic Weight Consolidation preserves general capabilities best in both stages; on the 8B Spanish model the average score on general benchmarks drops 1.7 points versus 11.0 for standard fine-tuning, yet its scores for formality and grammatical gender control remain close to standard fine-tuning. Only data mixing with control-task examples preserves these controls, but its gains do not transfer to unseen prompts for the same task.

Figure 1: Formality-controlled translation from CoCoA-MT (Nadejde et al., 2022) before and after fine-tuning Llama 3.1 8B Instruct on 1M Spanish↔English sentence pairs, with each model's COMET (translation quality, FLORES es↔en) and average General capabilities scores. EWC recovers most of the general-capability loss but not the instructed formality; only Data Mixing with control-task examples retains it.

## 1 Introduction

Instruction-tuned large language models (LLMs) translate well between high-resource languages (Robinson et al., 2023) and can modify their translations in response to natural language instructions. Translation quality is lower for language pairs and domains that are poorly represented in the training data. Fine-tuning on parallel data can reduce this gap. In our experiments, it raises COMET from 45.6 to 71.5 for Amharic-to-English translation.

Fine-tuning on a narrow task can cause catastrophic forgetting, in which performance degrades on capabilities not represented in the fine-tuning data. One capability at risk during MT fine-tuning is following instructions that modify a translation. For example, a prompt can request a formal translation, select the masculine or feminine forms used for a person mentioned in the source, or impose a length constraint. Conventional neural machine translation (NMT) systems can support these controls, but typically require dedicated mechanisms and annotated training data. In applications such as subtitling, the controls can be part of the translation task (Matusov et al., 2019).

A number of methods to mitigate forgetting have been proposed. They differ in the reference signal they use to mitigate forgetting, which we call the anchor: auxiliary data that represents the capabilities to be kept, the output distribution of a model, or the parameters of the base model (Section 3). Ex-

isting evaluations fine-tune on data from domains such as mathematical reasoning and code, and measure retention with general benchmarks (Biderman et al., 2024; Yang et al., 2024; Diao et al., 2026). It remains unclear how well the mitigation methods transfer when MT is the fine-tuning task, and whether they protect MT-specific instruction following (MT-IF).

We address these questions for instruction-tuned models in two stages. Stage 1 is a screening study with Llama 3.2 1B Instruct, fine-tuned separately on Amharic-to-English, Arabic-to-English, and Spanish-to-English data. We compare the mitigation methods of Section 3 across hyperparameter settings, measuring translation quality and general capabilities (Section 4). Stage 2 is the main experiment. We apply selected configurations to Llama 3.1 8B Instruct and fine-tune it on bidirectional Arabic-English or Spanish-English data. In addition to translation quality and general capabilities, we evaluate MT-IF on formality, grammatical gender, and length control (Section 4.3).

On the 1B model, standard fine-tuning decreases the average score on the general benchmarks by 6.3 to 8.1 points across the three language pairs. Elastic Weight Consolidation (EWC) limits this decrease to 2.5 or less, and its configurations trace the Pareto frontier of learning against forgetting. The Stage 2 results show a different pattern for MT-IF. On the 8B model, EWC retains general capabilities, but its scores for formality and grammatical gender control remain close to those of standard fine-tuning (illustrated in Figure 1). Among the methods evaluated in Stage 2, only data mixing with examples of the corresponding control task preserves these controls. Ablations show no consistent transfer between grammatical gender and formality control. Our contributions are:

1. A comparison of forgetting mitigation methods anchored to auxiliary data, to model outputs, and to the base model parameters, for MT fine-tuning of instruction-tuned LLMs, across three language pairs and two model sizes.

2. Evidence from formality, grammatical gender, and length control that retention on general benchmarks can coexist with losses in MT-IF, so general benchmark scores alone can miss capabilities affected by MT fine-tuning.

## 2 Related Work

Our study draws on two lines of research, the mitigation of catastrophic forgetting during LLM fine-tuning and the control of translation attributes such as formality, grammatical gender, and length.

**Forgetting when fine-tuning LLMs on MT data.** Stap et al. (2024) observe that fine-tuning pretrained LLMs on parallel data improves translation quality but degrades formality steering, few-shot translation, and document-level translation. They fine-tune pretrained-only base models, elicit the affected abilities with few-shot prompting, and evaluate a single mitigation method, mixing in monolingual data. We instead start from instruction-tuned models, compare eleven methods, and measure zero-shot instruction following, the interface through which these controls are used in practice. Liu and Niehues (2025) study the loss of translation ability for languages unseen during fine-tuning and find that the relative scale of model and data is a primary determinant, while parameter-efficient fine-tuning offers no clear advantage over full fine-tuning.

**Forgetting mitigation for LLM fine-tuning.** We draw the methods we compare from this literature (Kirkpatrick et al., 2017; Rolnick et al., 2019; Hu et al., 2022; Tian et al., 2024; Yang et al., 2026; Zheng et al., 2025; Wu et al., 2025; Diao et al., 2026) and describe each of them in Section 3. The evidence behind them was collected outside MT. Earlier approaches were validated on supervised and reinforcement learning benchmarks (Kirkpatrick et al., 2017; Rolnick et al., 2019) and on vision and language classification tasks (Tian et al., 2024), while recent work fine-tunes on mathematical reasoning, code, medical, or agentic data and measures retention with general benchmarks (Biderman et al., 2024; Wu et al., 2025; Diao et al., 2026).

Our experiments focus on mitigation during off-policy SFT, where the training responses are fixed rather than sampled from the current model. Recent comparisons, including one on MT, find that on-policy reinforcement learning often retains prior capabilities better than SFT (Shenfeld et al., 2026; Chen et al., 2026; Su et al., 2026), although Luo et al. (2026) report substantial forgetting during continual reinforcement learning on multimodal reasoning tasks. These studies do not evaluate retention of translation-specific instruction following.

**Controlled translation in conventional NMT.** Conventional NMT supports controlled translation of attributes such as politeness, length, grammatical gender, and formality through labeled data and dedicated mechanisms, including source- and word-level tags, modified positional encodings, and constrained rescoring or reranking (Sennrich et al., 2016; Lakew et al., 2019; Saunders et al., 2020; Wu et al., 2023). Raunak et al. (2024) fine-tune a single NMT model on parallel and task-specific instruction data, where each instruction is a short task description, such as "informal", prepended to the source inside dedicated demarcation tokens. Instruction-tuned LLMs instead accept such requests as free-form natural language prompts. We study whether fine-tuning on parallel data degrades this ability and whether forgetting-mitigation methods preserve it.

**MT instruction-following benchmarks.** Attribute-specific MT benchmarks evaluate phenomena relevant to controlled translation. WinoMT (Stanovsky et al., 2019) and MuST-SHE (Bentivogli et al., 2020) target gender translation accuracy, CoCoA-MT (Nadejde et al., 2022) provides contrastive formal and informal references, MT-GenEval (Currey et al., 2022) adds gender-balanced counterfactual and contextual examples, and mGeNTE (Savoldi et al., 2025) instead evaluates gender-neutral translation. We adapt CoCoA-MT and MT-GenEval, together with FLORES, into targeted evaluations of formality, grammatical gender, and length control, as described in Section 4.3. Broader recent benchmarks assess translation and instruction adherence jointly. IF-MT tests two to four verifiable instructions for English-to-Chinese and English-to-Spanish translation and scores translation quality and adherence separately (Rei et al., 2026). Concurrent work introduces IFMTBench, which evaluates single and composed instructions across seven languages and several lexical, contextual, structural, and stylistic constraints (Sun et al., 2026).

## 3 Mitigation Methods

The compared methods differ in the reference signal they use to mitigate forgetting during fine-tuning. We call this signal the anchor and group the methods by it: auxiliary data that represents the capabilities to be kept (Section 3.1), the output distribution of a model on the fine-tuning data (Section 3.2), and the parameters of the base model (Section 3.3). The anchor bounds what a method can preserve, which we return to in Section 7. Several of the methods are orthogonal and could be combined, but we evaluate each in isolation to compare their individual contributions.

### 3.1 Anchoring to Auxiliary Data

**Data Mixing** (Rolnick et al., 2019) replays a fraction of general-domain instruction data into the fine-tuning data instead of training on MT alone.

**Model Merging** (Yang et al., 2026) combines the parameters of two independently trained models. We merge a model fine-tuned on MT with a model trained on general-domain data by linear interpolation, that is, weight averaging.

**Elastic Weight Consolidation (EWC)** (Kirkpatrick et al., 2017) adds a quadratic penalty on the distance from the base parameters, scaled by a hyperparameter $\lambda$ and weighted per parameter by the diagonal of the empirical Fisher information estimated on the auxiliary data. Its penalty is in parameter space, but the importance estimate that shapes it comes from the auxiliary data, which is why we group it here. Liu and Chang (2026) propose **EWC-DR**, which reverses the logits when computing Fisher information and thereby reduces the redundant protection of parameters that the standard EWC applies.

All methods in this group draw their anchor from the same subset of the Tülu 3 SFT mixture (Appendix A.1), so what they retain is bounded by the capabilities that this data covers.

### 3.2 Anchoring to Model Outputs

**KL Divergence Regularization.** We add the exact KL divergence between the output distributions of the model being trained and a frozen copy of the base model as a penalty scaled by $\lambda$ on the SFT loss (Shenfeld et al., 2026).

**Selective Token Masking (STM)** removes tokens from the loss instead of penalizing divergence. Wu et al. (2025) observe that fine-tuning on LLM-generated responses forgets less than fine-tuning on ground-truth data, tracing this to the lower token-level perplexity of generated text, and therefore mask ground-truth tokens whose perplexity exceeds a fixed threshold. We instead set the threshold dynamically and mask the $X\%$ of tokens with the highest perplexity under a frozen copy of the base model.

**Confident Conflict Masking (CC).** Diao et al. (2026) identify confident conflicts, tokens with low probability and low entropy, as a cause of forgetting, because fitting them overwrites a confident prior. Masking the tokens in the bottom $X\%$ of both quantities mitigates forgetting, but discards useful training signal.

**Entropy-Adaptive Fine-Tuning (EAFT)** addresses this by weighting the loss of each token by its entropy normalized over the top-$K$ distribution, instead of discarding the token (Diao et al., 2026).

CC and EAFT take the output from the model being trained rather than from a frozen copy. All methods in this group are computed on the MT fine-tuning data, so they bound how far the model moves on translation inputs and place no constraint on its behavior on other prompts.

### 3.3 Anchoring to the Base Model Parameters

**Freeze** keeps the bottom $N$ layers at their base values and trains the remaining ones. Zheng et al. (2025) propose this on the grounds that task alignment is concentrated in the bottom layers and is disrupted during the first optimization steps.

**Selective Projection Decay (SPD)** (Tian et al., 2024) modifies the Adam optimizer to apply weight decay toward the pre-trained weights selectively. A gradient condition determines for each parameter tensor whether the update is heading toward a higher-loss region, and only those tensors receive the penalty, weighted by $\lambda$, while the remaining ones are updated without intervention.

**Low-Rank Adaptation (LoRA)** Hu et al. (2022) restricts fine-tuning updates to a low-rank subspace, which is believed to keep the model close to its base weights and thus limit forgetting (Sun et al., 2023). However, Biderman et al. (2024) show this holds only insofar as LoRA also learns less, with high-rank LoRA forgetting nearly as much as full fine-tuning in some settings.

## 4 Evaluation of Model Capabilities

We evaluate translation quality with COMET and BLEU, retention on general benchmarks, and three MT-specific controls: formality, grammatical gender, and length. These controlled-translation evaluations are targeted diagnostics of forgetting rather than a general benchmark of MT instruction following.

### 4.1 Translation Quality

We report reference-based COMET with `Unbabel/wmt22-comet-da` (Rei et al., 2022) and corpus BLEU with sacreBLEU (Post, 2018), using the default `13a` tokenizer for our language pairs. Before scoring, hypotheses and references are punctuation- and whitespace-normalized.

### 4.2 General Capabilities

Our general-capability benchmarks are a subset of the Tülu 3 evaluation suite (Lambert et al., 2025), which covers knowledge recall, reasoning, math, coding, and instruction following. From its development split, we take GSM8K (Cobbe et al., 2021), DROP (Dua et al., 2019), TruthfulQA (Lin et al., 2022), Codex HumanEval (Chen et al., 2021), Codex HumanEval+ (Liu et al., 2023), and IFEval (Zhou et al., 2023), the last of which assesses general instruction following. From its unseen split, we take AGIEval English (Zhong et al., 2024) and GPQA (Rein et al., 2024), both zero-shot with chain-of-thought prompting. We run all of them with the task formulations and prompts of the Tülu 3 evaluation regime, using the OLMES evaluation standard (Gu et al., 2025). We report the mean of the eight task scores as the general average (General Avg).

### 4.3 Machine Translation-Specific IF

To evaluate MT-IF capabilities, we assess models on the following three tasks closely related to MT:

**Formality Control.** To assess formality, we prompt the model to produce a formal or informal translation on the CoCoA-MT dataset (Nadejde et al., 2022) for `en`→`de` and `en`→`es`, and score with its metric: a hypothesis is classified as formal if it contains at least one of the annotated formal marked phrases from the reference pair and no informal ones (symmetrically for informal), and is left unmatched otherwise. The reported accuracy is the proportion of matched hypotheses whose classified formality matches the requested tone.

**Grammatical Gender Control.** To assess control over grammatical gender, we use the MT-GenEval benchmark (Currey et al., 2022), which provides counterfactual sentence pairs that differ in the gender forms used for a person mentioned in the text. We instruct the model to produce a translation with the opposite gender forms of the source sentence (i.e., masculine → feminine, feminine

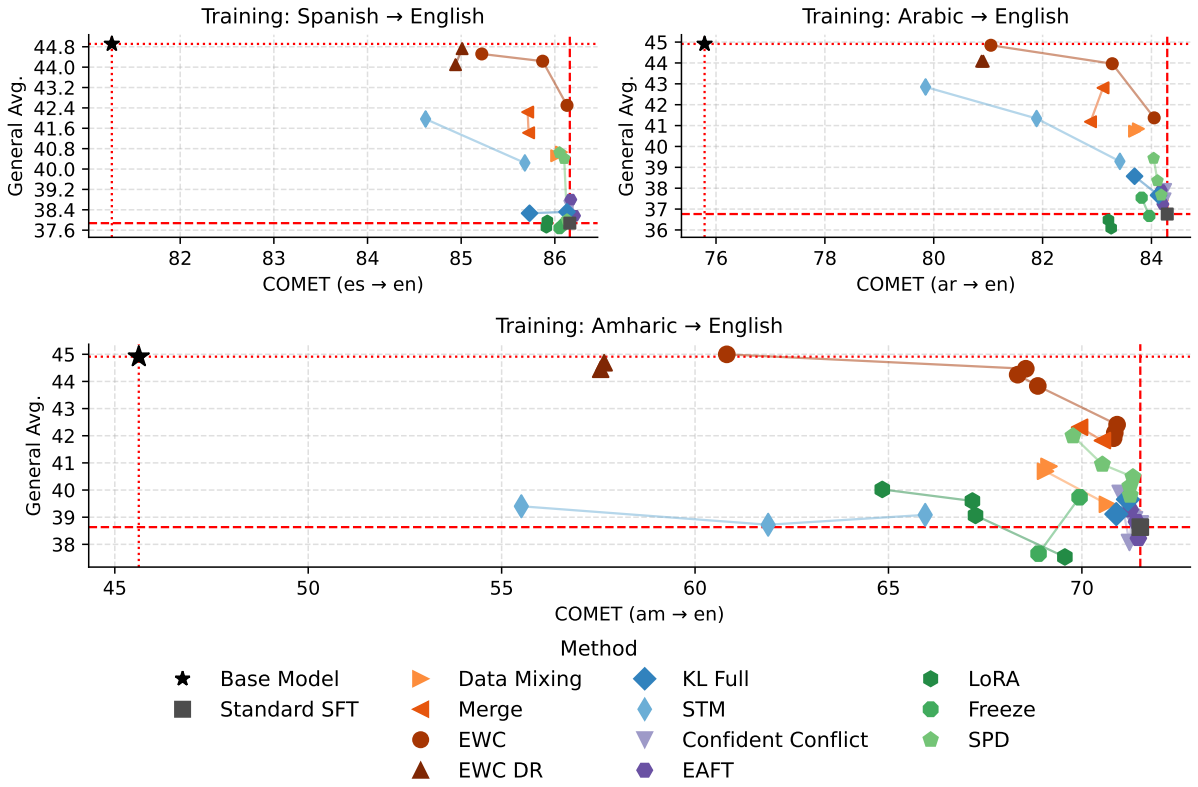

Figure 2: Stage 1: Translation quality (COMET) versus general capabilities (General Avg) for all evaluated configurations per training language on the Llama 3.2 1B Instruct model. Lines connect hyperparameter settings within each method; dashed lines mark the SFT baseline.

→ masculine). The instruction asks the model to override the forms suggested by the source, which separates instruction following from the model's default choice of gender forms. We follow the same evaluation procedure from the benchmark by checking for the absence of unique opposite-gender words in the hypothesis.

**Length Control.** We adapt the FLORES-101 and FLORES-200 benchmarks (Goyal et al., 2022; Costa-jussà et al., 2024) for the bidirectional translation between English and the training language. In particular, we add additional instructions on producing shorter or longer translations than the character count of the source. As the produced sequence length is heavily influenced by fine-tuning, we compare whether the instruction affected the output by comparing the translation with longer/shorter instructions to the baseline translation (instead of measuring pure accuracy on IF). This shows the effect of the additional instruction on length control and whether the model actually considered the instruction. We additionally report the target/source (tgt/src) ratios to understand length trends better.

## 5 Stage 1: Transfer of Mitigation Techniques to Machine Translation Fine-tuning

### 5.1 Data

We fine-tune models on unidirectional translation data for three language pairs: Amharic → English, Arabic → English, and Spanish → English, each containing 1,000,068 samples. For Data Mixing, Model Merging, and for computing the Fisher matrix in EWC, we use subsets of the Tülu 3 SFT mixture (Lambert et al., 2025) of varying sizes, from which we remove synthetic instruction-following data to prevent overlap with the IFEval benchmark used for evaluation (see Appendix A.1 for more details on the distribution of our training data).

### 5.2 Experimental Setup

In the first stage of our experiments, we fine-tune the Llama 3.2 1B Instruct model with the mitigation methods previously introduced, comparing various hyperparameter settings. We compare the fine-tuned models against two baselines: the unmodified instruct model and standard SFT.

| Anchoring | Method | Hyperparameters | am→en | | de→en | | General Avg |
|---|---|---|---|---|---|---|---|
| | | | COMET | BLEU | COMET | BLEU | |
| Llama 3.2 1B Instruct | | | 45.6 | 0.2 | 82.9 | 27.6 | 44.9 |
| Standard SFT | | | 71.5 | 10.7 | 83.6 | 30.7 | 38.6 |
| Auxiliary Data | Data Mixing | Tülu (full) | 69.1 | 8.5 | **85.7** | **34.2** | 40.7 |
| | Merge | Trans=0.75, Tülu=0.25 | 70.5 | 9.9 | 84.2 | 32.1 | 41.8 |
| | EWC | $\lambda$=1e2, Tülu (75k) | 70.9 | 9.9 | 83.9 | 31.4 | **42.4** |
| | EWC-DR | $\lambda$=1e3, Tülu (10k) | 71.3 | 10.6 | 83.7 | 30.7 | 38.6 |
| Model Outputs | KL-Full | $\lambda$=0.0025 | 71.2 | 10.6 | 83.6 | 30.7 | 39.7 |
| | STM | X=0.15 | 65.9 | 6.7 | 82.7 | 27.6 | 39.1 |
| | CC | X=0.45 | 71.0 | 10.5 | 83.9 | 31.3 | 39.9 |
| | EAFT | K=20, Weight=1.0 | **71.6** | **11.0** | 84.0 | 31.8 | 38.9 |
| Base Model Parameters | Freeze | N=1 | 69.9 | 9.4 | 83.5 | 30.5 | 39.7 |
| | SPD | $\lambda$=2 | 71.3 | 10.9 | 83.9 | 31.4 | 40.5 |
| | LoRA | Rank=64, lr=1e-5 | 67.2 | 7.5 | 83.9 | 31.1 | 39.6 |

Table 1: Stage 1: Best-performing configuration per method for Amharic, selected by the highest sum of Amharic-language COMET and general average score. The cell shading encodes the absolute differences from the base instruct model, normalized relative to the largest observed change within each metric group (across languages).

**Evaluation.** We report BLEU and COMET scores for translation on the training language pair and on German-to-English, included as an out-of-distribution language pair (Section 4.1). We use FLORES-101 (Goyal et al., 2022) for Amharic and Spanish, and FLORES-200 (Costa-jussà et al., 2024) for Arabic and German. We additionally evaluate the forgetting of general capabilities, as described in Section 4.

### 5.3 Results

We present the MT scores and the general average of the best-performing configurations for Amharic in Table 1 (Arabic and Spanish in Appendix A.8). These configurations are chosen based on the highest sum of COMET and general average scores. Additionally, we visualize the results of all 40 Amharic, 27 Spanish, and 28 Arabic configuration training runs in Figure 2 showing the trade-off between general capabilities and MT performance.

Overall, we observe the SFT baselines of all three languages to maintain similar forgetting rates (Amharic: 6.3, Arabic: 8.1, Spanish: 7.0) despite the different improvements in learning the MT task (Amharic: 25.9, Arabic: 8.5, Spanish: 4.9). Even though German was not included as a language pair in training, German MT scores slightly improve after fine-tuning, indicating no forgetting on a similar translation task.

**Most methods collapse toward the SFT baseline.** Across all three training languages, the majority of evaluated configurations are clustered around the SFT baseline in Figure 2 (dashed lines). Only a small number of methods consistently separate from this cluster by forgetting less on general capabilities (General Avg) at comparable COMET scores. In particular, the EWC family (EWC, EWC-DR) and Merge appear in the upper-right region in all three plots, while Data Mixing and SPD show mediocre mitigation of forgetting.

**Most methods are consistent across languages.** The only two techniques showing clear differences between languages are Selective Token Masking (STM) and LoRA, each diverging in opposite directions when comparing Amharic with Spanish and Arabic. LoRA performs comparatively better on Amharic by trading a smaller gain on MT performance (COMET: +21.6 vs. +25.9 in standard SFT) for a slightly smaller drop in the general average ($-5.3$), whereas STM performs better on Arabic and Spanish than for Amharic where it significantly hindered learning (COMET: 65.9).

**EWC lies on the Pareto frontier.** Individual EWC configurations trade translation quality against general capabilities, spreading along the upper-right boundary of Figure 2 between standard SFT and the base model rather than occupying a single point. Any method with a continuous coefficient produces such a curve between the two baselines, and the sweeps of Merge, Data Mixing, KL, and STM reach the region where COMET falls below standard SFT. Their curves lie below the EWC curve: for almost every configuration of another method, some EWC setting reaches both

a higher COMET and a higher general average, in all three languages. The remaining frontier points are configurations of standard SFT and a few other methods that gain up to a few tenths of COMET over the best EWC setting at the cost of several points on the general average.

**Implications for Stage 2 Experiments.** The language-dependent differences of LoRA and STM noted above suggest that the extent of learning required, rather than the language itself, drives the differences in forgetting mitigation trends. As we are not aware of resources to evaluate MT-IF on Amharic, we reduce the Stage 2 experiments to Spanish and Arabic. Additionally, as EWC performed better than EWC-DR, we drop the latter.

## 6 Stage 2: Comparison to Machine Translation Instruction Following Tasks

### 6.1 Data

We fine-tune models with bidirectional, open data from two languages to improve reproducibility: Spanish ↔ English and Arabic ↔ English. Each dataset has a total size of 1,000,000 samples, consisting of 500,000 pairs per direction (see Appendix A.1 for detailed information on the training data distribution).

Alongside the Tülu 3 subsets used in Stage 1, we mix in data closely related to our MT-IF tasks: the training split of CoCoA-MT (Spanish, N=400; German N=400) (Nadejde et al., 2022) and the dev split of MT-GenEval (Arabic, Spanish, and German evenly distributed; N=800) (Currey et al., 2022). We primarily use the same prompts as during evaluation, but additionally run variants with a different prompt to assess whether the observed effects generalize to unseen prompts (see Appendices A.5 and A.6 for prompts used).

### 6.2 Experimental Setup

We move to Llama 3.1 8B Instruct, whose base performance on the MT-IF tasks is high enough to measure their forgetting, and to open, bidirectional training data. Model size, translation directions, and data source therefore change together between the two stages. We take the best performing configurations per method identified in the previous stage as a starting point and only slightly re-tune them for the larger model trained on open, bidirectional data, in contrast to re-screening all possible configurations.

**Evaluation.** We reuse the Stage 1 evaluation setup (COMET, BLEU, and the general average; Section 5.2), but evaluate translation in both directions. Beyond these scores, we evaluate our models on the three MT-IF control tasks, as defined in Section 4.3: Formality Control (Spanish, German; only for Spanish training runs), Grammatical Gender Control (Training Language, German), and Length Control (Training Language). We evaluate MT-IF only in Stage 2, as CoCoA-MT and MT-GenEval only cover translations from English to other languages and the MT-IF capabilities of the 1B model are too low to measure forgetting. We summarize the controls as the MT-IF average (MT-IF Avg): the mean of the training-language scores of the three tasks, where formality and grammatical gender contribute their average accuracy and length control contributes the mean compliance rate under the shorter and longer instructions. For Arabic, the average covers only grammatical gender and length control, as CoCoA-MT provides no Arabic formality data.

### 6.3 Results

#### 6.3.1 Forgetting of General Capabilities

We present the MT scores and the general average of our bidirectional training runs on Spanish in Table 2 and on Arabic in Table 20 (Appendix). Standard SFT forgets more on general capabilities at 8B than at 1B in Stage 1, with the general average (base 66.8) dropping 11.0 points for Spanish and 8.3 points for Arabic, despite much smaller MT learning gains (COMET +1.0 vs. +4.9 at 1B for Spanish). Since model size, translation directions, and data source change together between the stages, we cannot attribute this difference to one of them. The ordering of the methods is largely stable across stages: EWC retains the most in both, Merge, SPD, and Data Mixing retain moderately, and the methods anchored to model outputs stay within two points of standard SFT. Changes in ordering occur where Stage 1 differences were already small. CC and Freeze, within 1.3 points of standard SFT at 1B, now fall 0.8 to 1.6 points below it. The exception is STM, which retained 4.1 to 4.5 points more than standard SFT for Spanish and Arabic in Stage 1 at the cost of COMET, and at 8B loses 2.5 to 2.8 points more than standard SFT (53.0 for Spanish, 56.0 for Arabic) while still learning less.

**EWC retains general capabilities; other methods only partially.** Consistent with Stage 1 of our

experiments, EWC with Tülu for parameter importance estimation keeps the drop in the general average close to zero. With only the Tülu subset, EWC limits the drop to $-1.7$ for Spanish and $-0.7$ for Arabic, far smaller than the $-3.6$ to $-13.8$ drops of other methods. This mirrors the Stage 1 pattern for EWC, now under bidirectional translation with a stronger base model. LoRA, Merge, and SPD all show moderate retention of the general average.

### 6.3.2 Forgetting of MT-IF Capabilities

We observe that while general capabilities have been preserved strongly or moderately by specific methods, such as EWC, this is not the case for MT-IF (i.e., Formality Control, Grammatical Gender Control, Length Control) (see Figure 3). Standard SFT drops the average MT-IF score by $-38.8$ for Spanish (71.1 $\rightarrow$ 32.3) and $-37.8$ for Arabic (66.8 $\rightarrow$ 28.9). The only methods that separate from the large cluster around this baseline are SPD, with drops of $-17.8$ for Spanish and $-27.1$ for Arabic, and Data Mixing with MT-IF data (using the same prompts as evaluation), ranging from $-4.1$ to $-25.6$ for Spanish and from $-11.7$ to $-15.0$ for Arabic. The Arabic mix containing only formality data, a control task that is not part of the Arabic MT-IF average, even underperforms SFT by 4.6 points.

**EWC does not preserve MT-IF.** Although EWC retains general capabilities best, it falls into the cluster around the SFT baseline on MT-IF (see Figure 3). EWC with the 10k Tülu subset, the configuration with the smallest drop in the general average for both languages, reaches MT-IF averages of 35.3 for Spanish and 32.7 for Arabic, close to standard SFT (32.3 and 28.9). Estimating parameter importance on additional MT-IF data does not change this: the general average drops further while the MT-IF averages stay near the SFT baseline.

**Data Mixing preserves only the target MT-IF capability.** We observe that Data Mixing with MT-IF data is the only method that retains most of the MT-IF capabilities (see Figure 3). However, this mitigation is limited to the specific MT-IF task that is included in the training data. For example, Data Mixing with Tülu (800) + Gender (800) is only actively improving on grammatical gender control capabilities (to 77.9% accuracy vs. standard SFT's 17.8%), while showing more forgetting than standard SFT on Formality Control (53.7% accuracy vs. 56.1%) and Length Control (Table 19). This shows that the retention of MT-IF capabilities is limited to the specific task that is included in the training data, and does not transfer to other MT-IF tasks. On the mixed-in task itself, scores surpass even the base model in all cases except German formality control.

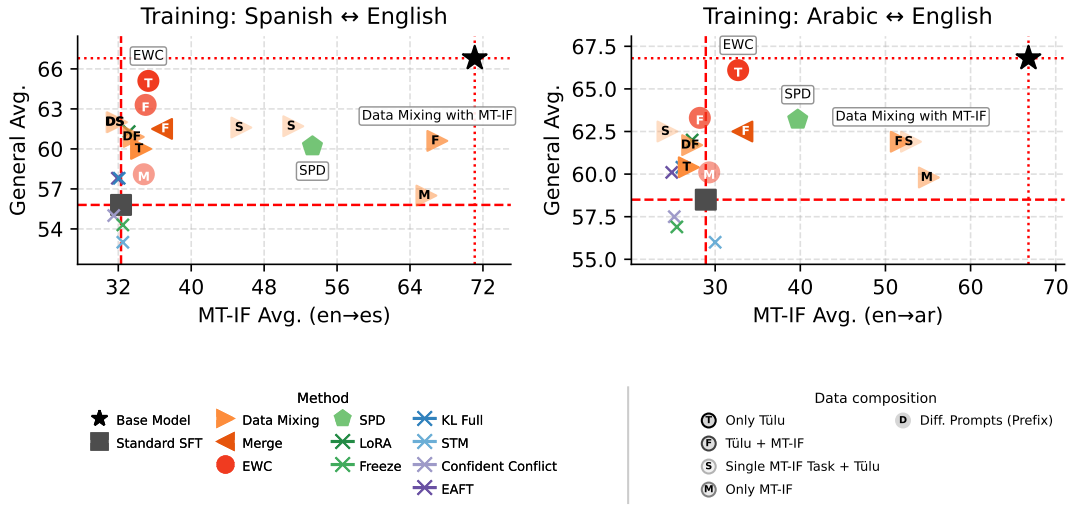

Figure 3: Stage 2: General capabilities (General Avg) versus MT-IF capabilities per training language for fine-tuned, bidirectional Llama 3.1 8B Instruct models (MT-IF averaged over Formality, Grammatical Gender, and Length Control for Spanish; Length and Grammatical Gender Control for Arabic). Dotted/dashed red lines mark the base model / standard SFT reference points. Additional text labels within markers indicate the data composition.

**Same-prompt gains do not transfer to unseen prompts on the same task.** However, we observe clear differences between using the same prompt as during evaluation and different prompts in Spanish training runs (see Figure 3 for the dashed-edge markers that distinguish these variants). Evidently, for Data Mixing with different Formality Control Prompts, Formality scores reduce to an average accuracy of 53.8, which is even lower than the score of standard SFT (56.1). The recovery of MT-IF capabilities with Data Mixing is thus partially because of prompt memorization, rather than general MT-IF capability retention.

**Grammatical Gender and Formality Control.** Per-method scores are in Tables 17, 18 and 22 (Appendix). Standard SFT reduces grammatical gender control scores in both training runs and formality control scores in the Spanish run by more than 30 points. The majority of methods (CC, EAFT, Freeze, KL, LoRA, STM) stay close to these scores on both tasks. SPD and Merge stay above these scores on both tasks. On the training language pair, SPD retains more in the Spanish run (38.5 versus 23.4 for Merge on gender control, 72.0 versus 61.0 on formality control), while Merge retains more gender control in the Arabic run (34.3 versus 29.7).

**Length Control.** Per-method length control scores are in Tables 19 and 21 (Appendix). The base model follows shorter and longer instructions relatively well. After standard SFT, compliance collapses and the tgt/src ratios of the three control settings converge; almost every other method stays within this range. SPD is the only method that keeps compliance with both instructions clearly above the SFT level. While EWC (Tülu 10k) also partially follows the longer-translation instruction, its COMET scores under this instruction drop to 74.3 for Spanish and 71.1 for Arabic, well below other methods. This suggests that EWC pushes the model toward producing longer sequences without ensuring correctness of translations.

## 7 Analysis and Discussion

**Why does EWC protect general capabilities but not MT-IF?** Figure 4 speaks against the simplest cause, a Fisher estimated on Tülu that misses the parameters behind MT-IF: the normalized layer-wise Fisher importance of the three anchor datasets used in Stage 2 has nearly the same profile, with most importance in layers 0–5 and the final layer (parameter-level differences remain possible). Consistent with this, a Fisher estimated on MT-IF data alone did not preserve MT-IF in the Spanish run (average 34.8 versus 32.3 for standard SFT) and lowered the general average (58.1 versus 65.1 with the Tülu Fisher). We therefore attribute the asymmetry to the MT gradients rather than to the importance estimate. EWC with the Tülu Fisher reaches the same COMET as standard SFT (87.0) while keeping the general average at 65.1 versus 55.8, which is only possible if MT fine-tuning updates the pa-

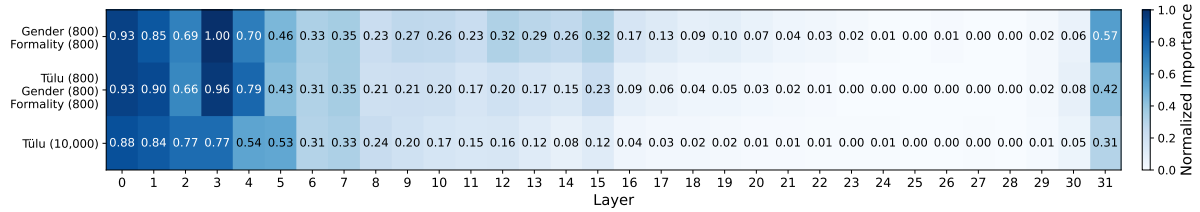

Figure 4: Normalized layer-wise Fisher importance on Llama 3.1 8B Instruct, estimated on Tülu, MT-IF data, and their combination. The importance profiles largely coincide.

rameters behind the general benchmarks weakly. The MT-IF controls, in contrast, are exercised on translation inputs, so the parameters that carry them receive the MT gradient throughout fine-tuning, which a fixed quadratic penalty does not hold back. We did not measure per-parameter drift, so this explanation remains a hypothesis.

**Why do the methods anchored to model outputs fail?** The methods in this group (KL, STM, CC, EAFT) compute their constraint on the MT training batches (Section 3.2), so they bound the drift only on inputs on which the model must change and leave the evaluated behavior unconstrained. KL regularization, for instance, penalizes divergence from the base model on the translation inputs themselves and places no constraint on the prompts used by the general benchmarks or the MT-IF evaluations. CC additionally masks almost nothing on MT data. In the Spanish 8B run (X=0.25), each condition alone is met by roughly a quarter of the tokens in a batch (on average 2773 with low entropy and 2619 with low probability), but fewer than one token per batch (0.36) meets both. Tokens that are improbable under the base model are thus uncertain rather than confidently wrong, and with almost no tokens masked, CC reduces to standard SFT, in line with its scores in Table 2.

**SPD is a partial exception.** Among the methods without auxiliary data, only SPD separates from the SFT cluster on MT-IF (average drops of 17.8 for Spanish and 27.1 for Arabic, against 38.8 and 37.8 for standard SFT), plausibly because its penalty applies per tensor and step, when the update heads toward a higher-loss region, rather than following a fixed importance estimate. Our results do not isolate this mechanism, and the retained scores remain well below those of data mixing.

**Implications.** Methods anchored to the base model parameters assume that the fine-tuning task does not need to update the weights that carry the capability to be preserved. Under MT fine-tuning this holds for general capabilities but not for MT-IF, which is itself translation behavior. Data mixing escapes this limit by continuing to train the control rather than constraining the model, but as the Spanish formality run shows, the retention is tied to the training prompt.

## 8 Conclusion

We compared forgetting mitigation methods anchored to auxiliary data, to model outputs, and to the base model parameters, for fine-tuning Llama 3.2 1B Instruct and Llama 3.1 8B Instruct on parallel data for three language pairs. EWC retains general capabilities best on both models. On the 8B model, it limits the drop in the general average to 1.7 points for Spanish and 0.7 for Arabic, against 11.0 and 8.3 for standard fine-tuning. Its scores for formality and grammatical gender control nevertheless remain close to those of standard fine-tuning, even when the data used to estimate parameter importance includes control-task examples. Of the methods compared, only mixing control-task examples into the training data preserves the corresponding control, and the effect does not extend to other control tasks or to unseen prompts for the same task. Among the methods without control-task data, SPD retains the most MT-IF, at scores well below data mixing.

We conclude that retention on general benchmarks does not establish that MT-specific instruction following is preserved. Evaluations of MT fine-tuning should measure the controls the application requires, and preserving them currently requires matching data in the training mix. Open questions are whether broader control-task data, for example synthetic examples covering more tasks and prompt variants, can preserve MT-IF without overfitting to the seen prompts, and whether the findings extend to further controls such as glossary constraints and gender-neutral translation.

## Limitations

Our comparison is restricted to SFT-based adaptation and does not include on-policy reinforcement learning or preference optimization. As discussed in Section 2, recent prior work showed that on-policy methods retain prior capabilities better than SFT. Including them would have required model-generated trajectories and task-specific rewards or preference pairs, a substantial addition to our framework that would complicate a fair comparison.

We adapt the evaluation for MT-IF from related work and inherit some limitations. For control of formality and grammatical gender, we follow the evaluation approaches proposed in CoCoA-MT and MT-GenEval. These rely on predefined marked phrases and words and some translation variants may be missed. MT-GenEval's masculine/feminine annotation, which our prompts follow, treats gender as binary and excludes non-binary referents. We use it because its scoring is deterministic and cheap to run, whereas gender-neutral translation currently requires a trained classifier or an LLM judge for evaluation (Savoldi et al., 2025). Our results therefore cover the selection between masculine and feminine forms and do not show whether MT fine-tuning degrades gender-neutral translation. The MT-IF evaluation also covers only translation from English into Spanish, German, and Arabic, where CoCoA-MT and MT-GenEval provide data, and formality control only for Spanish and German. The length-control score compares each instructed translation with the model's own uninstructed translation, so it measures whether the instruction changed the output length and not whether a length target was met.

Model size, translation directions, and data source change together between Stage 1 and Stage 2, and the configurations selected on the 1B model are only slightly re-tuned for the 8B model. The design therefore does not show which of these factors causes the larger forgetting of standard SFT at 8B or the reversal for STM, and the Stage 2 configurations may not be optimal for the larger model. We only use data from our internal standard data preparation pipeline which may introduce some biases. Experiments are further limited to two model sizes of the Llama 3 family and to unidirectional and bidirectional translation of English and three target languages (two high and one low-resource). While we assume that our findings generalize to other languages and models, this is still untested.

# A Appendix

## A.1 Information on Training Data

The MT training data consists of two groups. *Base* comprises sentence-level parallel segments drawn from OPUS and other sources. *CONCAT* is built from *Base* segments for which document-level metadata is available: consecutive sentences from the same document are concatenated into a single training example.

**Stage 1.** For unidirectional training runs on Llama 3.2 1B Instruct, we use Amharic → English, Arabic → English, and Spanish → English data (Tables 3 to 5). Each language pair comprises 1,000,000 *Base* sentence pairs plus 68 additional *CONCAT* samples (1,000,068 total). Non-OPUS sources are aggregated as proprietary data; Amharic is drawn almost entirely from OPUS (primarily NLLB).

**Stage 2.** For bidirectional training runs on Llama 3.1 8B Instruct, we use only public data from OPUS (Table 6 for Spanish, Table 7 for Arabic). During sampling, we explicitly minimized contributions from larger corpora, since these tend to consist of noisier, crawled data. For both *Base* and *CONCAT*, each language's 500,000 sentence pairs are split evenly across both translation directions to enable bidirectional training.

## A.2 Training & Evaluation Settings

### A.2.1 Training

- **Epochs:** 1.0
- **Learning Rate (Non-PEFT):** 1e-6
- **Learning Rate (PEFT):** 1e-5
- **Optimizer:** AdamW (default weight decay; weight decay and AdamW only adapted for SPD regularization)
- **Warmup Ratio:** 0.003
- **Effective Batch Size:** 64
- **Max Sequence Length:** 1024 tokens
- **Chat Template**: Llama-3 Instruct format, with loss masked to assistant-turn content only.

### A.2.2 Evaluation Sampling Arguments

**General Capabilities.** We use the OLMES setup (Gu et al., 2025) for evaluating general capabilities, inheriting the task-specific sampling arguments of their implementations to ensure reproducibility.

**MT(-IF).** For MT-IF Evaluation, we use greedy decoding (temperature = 0) with a maximum output length of 512 tokens.

## A.3 Computational Resources

For the unidirectional training runs on Llama 3.2 1B Instruct, we used either one `A100` with 80GB or one GPU with 48GB. We report the average computation time across languages of the training techniques used for the bidirectional Llama 3.1 8B Instruct training in Table 9.

### A.4 Prompt for MT Training & Evaluation

**System:** You are a translation assistant who always responds with an {target language} translation. You should write the translation only without any formatting.
**User:** Translate the given sentence into {target language}.
Sentence:
{source sentence}

### A.5 Prompts for MT-IF Formality Control

#### A.5.1 Training & Evaluation

**System:** You are a translation assistant who always responds in an {target language} translation. You should only write the translation without any formatting and without any reasoning.
**User:** Translate the following sentence into {target language} while maintaining [a|an] [formal|informal] tone.
Sentence:
{source sentence}

#### A.5.2 Different Training Prompts

**System:** Provide a {target language} translation only. Do not include explanations, formatting, or any text besides the translation itself.
**User:** Translate the following text into {target language}. Use the [informal|formal] form of address.

| Corpus | Base | CONCAT |
|---|---|---|
| OPUS-MultiUN | 157,691 | 144,588 |
| OPUS-UNPC | 124,691 | 202,562 |
| OPUS-TED2020 | 61,929 | 44,055 |
| OPUS-OpenSubtitles | 57,736 | 64,417 |
| OPUS-NeuLab-TedTalks | 56,368 | 40,398 |
| OPUS-GlobalVoices | 13,369 | 2,396 |

| OPUS-EUbookshop | 75 | 6 |
| **Total** | **500,000** | **500,000** |

Table 7: Number of Arabic sentence pairs contributed by each OPUS corpus for the Stage 2 SFT training dataset.

| Category | # Prompts |
|---|---|
| General | 116,872 |
| Knowledge Recall | 104,982 |
| Math Reasoning | 334,252 |
| Coding | 142,275 |
| Safety & Non-Compliance | 110,983 |
| Multilingual | 100,000 |
| Instruction Following (removed) | 29,980 |

Table 8: Composition of the Tülu 3 SFT-Mixture by category. We remove the synthetic instruction-following category to avoid overlap with the instructions evaluated in IFEval.

```
Text to translate:
{source sentence}
```

### A.6 Prompts for MT-IF Grammatical Gender Control

The prompts use the `male`/`female` labels of the MT-GenEval annotation and are reproduced as used in our experiments.

#### A.6.1 Training & Evaluation

```
System: You are a translation assistant who always responds with a {target language} translation. You should write the translation only without any formatting.
User: Translate the given sentence into {target language}. In your translation the person referred to should be [male|female]. Translate all gendered words in the sentence accordingly, even if it uses opposite-gender pronouns.
Sentence:
{source sentence}
```

#### A.6.2 Different Training Prompts

```
System: Provide a {target language} translation only. Do not include explanations, formatting, or any text besides the translation itself.
User: Translate the following text into {target language}. Ensure the translation represents the subject as [male|female]. Apply [male|female] gender forms to all applicable words, regardless of the original pronouns.
Text to translate:
{source sentence}
```

| Training Technique | # GPUs | Avg. Training Time (h) |
|---|---|---|
| Standard SFT | 4x A100 | 16.89 |
| CC | 6x A100 | 19.26 |
| EAFT | 6x A100 | 17.25 |
| Freeze | 4x A100 | 14.15 |
| KL-Full | 4x H200 | 6.31 |
| LoRA | 4x A100 | 22.77 |
| SPD | 6x A100 | 18.04 |
| STM | 6x A100 | 21.23 |
| Data Mixing (Tülu full) | 4x A100 | 53.50 |
| Data Mixing (MT-IF 1600) | 4x A100 | 15.11 |
| Data Mixing (Tülu + MT-IF; 2400) | 4x A100 | 15.54 |
| Data Mixing (Single MT-IF + Tülu; 1600) | 4x A100 | 16.84 |
| EWC (10k Tülu) | 2x H200 | 14.79 |
| EWC (MT-IF 1600) | 2x H200 | 14.69 |
| EWC (Tülu + MT-IF; 2400) | 2x H200 | 14.99 |

Table 9: GPUs used and average training time (in hours) for each technique on the reported bidirectional Llama 3.1 8B Instruct training runs.

### A.7 Prompts for MT-IF Length Control

#### A.7.1 Baseline

**System:** You are a translation assistant who always responds in an {target language} translation. You should only write the translation without any formatting and without any reasoning.
**User:** Translate the following sentence into {target language}.
Sentence:
{source sentence}

### A.7.2 Shorter / Longer

**System:** You are a translation assistant who always responds in an {target language} translation. You should only write the translation without any formatting and without any reasoning.
**User v1:** Translate the following sentence into {target language} while ensuring it has [more|fewer] characters than the original sentence.
Sentence:
{source sentence}
**User v2:** Translate the given sentence into {target language}. Additional instruction to follow while translating: Produce a translated sentence with [more|fewer] than {src chars} characters.
Sentence:
{source sentence}
**User v3:** Translate the following sentence into {target language} ensuring it has [more|fewer] than {src chars} characters.
Sentence:
{source sentence}

## A.8 Stage 1: Best-Performing Configurations of Spanish & Arabic Training

| Anchoring | Method | Hyperparameters | ar→en COMET | ar→en BLEU | de→en COMET | de→en BLEU | General Avg |

# AQI: a composite human-calibrated metric for machine translation quality assessment

## Abstract

Manual evaluation of machine translation (MT) quality is the gold standard but expensive and noisy, and at production volumes it does not scale: automatic evaluation must carry the main load, with humans kept as a corrective signal on a limited subset. We audit six automatic metrics across three families—surface (chrF, TER), embedding (BERTScore F1), and learned (COMETKiwi-XXL, MetricX-XXL, xCOMET-XXL)—on the WMT25 General-MT corpus ($n = 3{,}450$ segment-system ratings, 5 language pairs (LPs); en→es drawn from WMT24, see §2.1). No single metric reaches the human-agreement ceiling: the strongest (MetricX-XXL) only approaches it, and combining metrics adds a small but reliable margin. Production stakeholders, meanwhile, expect a single scalar in $0-100$ with clear quality thresholds, not a vector of six heterogeneous numbers. We propose the **Aggregate Quality Index (AQI)**—a composite, human-calibrated index in two equal-billing versions differing in the normalisation of the key metric, with an optional per-LP calibration. AQI is interpretable and production-friendly: a single score, explicit weights, a transparent path from input metrics to the final number. We further derive a simple human-in-the-loop index—a linear blend of one human score into the auto-only AQI—and select the blend weight via honest validation against an independent annotator.

## 1 Introduction

### 1.1 The cost and noise of human evaluation

Human evaluation of MT quality produces **two kinds of signal**: error spans with severities—Multidimensional Quality Metrics (MQM; Lommel et al., 2014) and its lighter derivative, Error Span Annotation (ESA; Kocmi et al., 2024b)—and a **holistic score**, a Direct Assessment (DA) style 0–100 judgement of the whole segment. In WMT25 both come from the same ESA annotation: the annotator marks spans, then scores the segment. Both signals are expensive (trained annotators, linear scaling) and noisy: Freitag et al. (2021) and Freitag et al. (2023) document substantial inter-annotator disagreement in MQM, while Hendy et al. (2023) and Fischer and Läubli (2020) identify a systematic **AI bias**—annotators under-rate translations explicitly labelled as machine-produced. Averaging over the segment makes the holistic score **less noisy** than the additive span penalty, so we adopt it as the **primary oracle** for AQI calibration, with the span penalty as an input signal and a diagnostic channel (§2.2).

### 1.2 Automatic metrics: families and selection

Modern automatic translation evaluation is organised into three families: **surface-level** metrics based on lexical overlap, **embedding-based** metrics built on contextual representations, and **learned (neural)** metrics trained directly on human judgements. We compute **six representatives** across these families (Table 1)—chrF (Popović, 2015) and TER (Snover et al., 2006) (surface), BERTScore F1 (Zhang et al., 2020) (embedding), and the learned metrics COMETKiwi-XXL (Rei et al., 2022b, 2023), reference-based MetricX-XXL (Juraska et al., 2023) and xCOMET-XXL (Guerreiro et al., 2024). We deliberately **exclude BLEU** (Papineni et al., 2002): recent WMT meta-evaluations show its failure on neural MT (Mathur et al., 2020; Kocmi et al., 2021), and the WMT-22 Metrics Shared Task (Freitag et al., 2022) explicitly recommended "stop using BLEU", which our own production experience confirms. Per-metric definitions, scales, training signals and known failure modes are given in Appendix A; here we note only the orientations that matter downstream: MetricX-XXL is an error score on $[0, 25]$ (lower-is-better) and TER is lower-is-better, while the other four are higher-is-better.

| Family | Metric | Mode |
|---|---|---|
| Surface | chrF | ref |
| | TER | ref |
| Embedding | BERTScore F1 | ref |
| Learned | MetricX-XXL | ref |
| | xCOMET-XXL | ref |
| | COMETKiwi-XXL | QE |

Table 1: Taxonomy of automatic MT quality metrics. *ref*—reference-based; *QE*—quality estimation (reference-free).

The per-metric audit in §2.3 computes all six on the full WMT25 multi-domain corpus and reports their correlation with the human score and with each other, the area under the ROC curve (AUC) on major-error detection, and a redundancy analysis—which metrics add an independent signal and which can be dropped from a composite without loss.

### 1.3 Why AQI is needed

Three arguments motivate a composite index on top of the existing inventory: **scalability** (manual error annotation does not scale to production volumes, so automatic evaluation must bear the main load); **no single metric reaches the human ceiling** (§2.3: even the strongest metric only approaches inter-annotator agreement, and a combination buys a small but reliable margin); and **interpretability** (stakeholders require a single 0–100 scalar with clear thresholds, not a six-dimensional vector).

### 1.4 Related work

Combining automatic metrics is not new. RegEMT (Štefánik et al., 2021) fits a regression ensemble over surface, syntactic and semantic metrics and reports consistent gains over any standalone metric, but treats the resulting complexity as a cost to be managed rather than removed. COMET-22 (Rei et al., 2022a) likewise ensembles a DA-trained estimator with an MQM-trained multitask model, with combination weights selected by hyper-parameter search and hidden inside the released model. AQI differs from both in exposing the weights: three fixed, positive coefficients that sum to one and can be recomputed from published metric outputs. The interpretability–accuracy trade-off this implies has a direct precedent in MaTESe (Perrella et al., 2022), which traded regression-based opacity for span-level interpretability and, by its authors' own account, matched the top WMT21 submissions on en→de, fell slightly short on zh→en, and dropped sizeably out of domain; our accuracy gap to Ridge and GradientBoosting (§3.5) should be read against that precedent. Judges based on large language models (LLMs), such as GEMBA-MQM (Kocmi and Federmann, 2023), are outside the six-metric inventory audited here (see Limitations).

## 2 Dataset, Human Ceiling, Metric Audit

### 2.1 Dataset

All experiments rely on a unified wide-CSV assembled from **two sources**: the bulk comes from the public artefacts of **WMT25 General MT** (Kocmi et al., 2025), and one LP (en→es, $n = 600$) is drawn from the WMT24 release (Kocmi et al., 2024a) as aggregated scores only, kept separate throughout. The corpus has **3,450** segment–system records: a unique translation by one of **40** MT systems for one of **251** unique source segments, over **five** LPs (cs→de, en→cs/es/et/ru). Coverage by the six automatic metrics is 100%; error spans are present on 2,850 segments (82.6%); double independent annotation on **2,391** (69.3%); the corpus was annotated by 34 unique annotators across the four span-annotated LPs.[1] Per-LP composition is in Appendix B, Table 9.

**The en→es caveat.** These 600 segments use multi-annotator averaging (each segment annotated 1–14 times, mean $\approx$ 4.25), no individual annotator identifiers, and no error spans. We therefore exclude en→es from the inter-annotator statistics in §2.2 and from anything requiring a penalty or pairwise comparison, but use it in §3 for the reference-free scenario.

**Domains, systems, protocol.** Domains are biased toward *literary* (41.9%) and *news* (40.8%), with en→es unlabelled (17.4%); this limitation is discussed in the Limitations section. The 40 systems span commercial LLMs, open-source LLMs, MT-specialised models and WMT25 submissions. Annotation follows the **ESA** protocol (Kocmi et al., 2024b), an MQM-derived

[1] Annotator pools per LP, from the WMT25 findings (Kocmi et al., 2025, Table 6): cs→de and en→cs—ÚFAL Charles University linguists, researchers and students, native in one language with high proficiency in the other; en→et—professional translators (Luisa Language Solutions); en→ru—Toloka paid expert crowd, bilingual native speakers of the target language. All were professional translators but not trained MQM/ESA annotators, completed an interactive tutorial and a fixed control task used to model annotator reliability, and were paid a fair local wage; each segment was annotated exactly twice.

scheme: the annotator first marks **error spans** with severity $\in$ {minor, major} (no error categories are recorded), then assigns a **holistic score** on 0–100 informed by the marked spans. We aggregate spans into an MQM-style **span penalty** $P_a = |E_a^{\text{minor}}| + 5|E_a^{\text{major}}|$; segment-level `score`/`penalty` are the mean over the two annotators. Tier boundaries follow the industry MQM convention: **Good** $\geq 85$, **Medium** $60 \leq s < 85$, **Bad** $< 60$ (empirical shares 43.0/35.0/22.0%). Span-dependent targets are computed on 2,504 segments (after excluding en→es and NaN rows); the ceiling statistics in §2.2 on the 2,391 double-annotated segments. The slice size is bounded by the cost of running the learned metrics at scale.

## 2.2 The human ceiling

Any automatic metric calibrated against human assessment is bounded above by the agreement between humans themselves. In this subsection we quantify this ceiling at three levels—overall score, span penalty, and binary error presence—and establish the theoretical upper bound for AQI tier-agreement.

### 2.2.1 Pairwise score agreement

On the subcorpus of $n = 2{,}391$ double-annotated segments we compute pairwise statistics between two independent scores `score_annotator1` and `score_annotator2`. Pearson correlation $r =$ **0.425**; Spearman $\rho = 0.417$. This is a **moderate** dependence: two annotators, evaluating the same translation under identical instructions, diverge substantially. The distribution of absolute difference $|\Delta| = |s_1 - s_2|$ yields **mean** $|\Delta| = 20.24$ points, **median** $|\Delta| = 15.00$, std $= 18.25$, maximum 97 points (extreme cases are examined below).

Strict agreement ($\pm 5$ points) holds in only **22.8%** of segments; agreement within one tier-band—approximately $\pm 20$ points on a scale with tier widths 25/15/60—is reached on **61.3%**. Thus in **38.7%** of cases two annotators disagree by *more than one tier*. This is the empirical upper bound against which we compare AQI tier-match in §3.

Agreement breaks down highly unevenly by LP: `en→et` yields $r = 0.598$ (a bimodal quality distribution—translations are either good or clearly broken), `cs→de` $r = 0.337$, `en→cs` $r = 0.304$, and `en→ru`—$r = 0.113$, essentially noise (per-LP breakdown in Appendix C, Fig. 3). The spread tracks the annotator pool rather than the language (professional translators on en→et, a paid crowd on en→ru; §2.1): the ceiling we report is a property of the annotation setup, not a universal constant. The spread also motivates the per-LP offsets of §3.

### 2.2.2 Span-penalty agreement and the nature of the noise

Agreement on error-span annotation is systematically *worse* than on the holistic score: on the same subcorpus $n = 2{,}391$, Pearson between the two annotators on the span penalty is $r = 0.279$ (vs. $r = 0.425$ on the holistic score), because span annotation requires three independent decisions per error (presence, location, severity) and noise at each step degrades agreement multiplicatively. This is consistent with prior work rather than new: MQM annotation is known to have low inter-annotator agreement (Freitag et al., 2021), and Kocmi et al. (2024b) report that ESA annotators mark an overlapping span in only $\sim$50% of cases between annotators and $\sim$29% within the same annotator, whereas the final score benefits from being assigned *after*, and primed by, the marked spans. Our contribution is to quantify both levels on the same segments and annotators. Throughout the rest of the paper we use **holistic human score** as ground truth and refer to the span penalty only where explicitly noted. Inspecting the extreme disagreements ($|\Delta s| \geq 84$) shows that they are not data outliers but legitimate borderline cases driven by **stylistic strictness**, **domain-expertise asymmetry**, and **literal vs. creative translation**; three worked case studies are in Appendix D. This is structural noise of the task, which AQI must carry rather than try to resolve.

### 2.2.3 Implication for AQI

The empirics above imply a hard **theoretical ceiling** on tier-agreement of any automatic metric with the mean-aggregated human annotation. The direct *empirical* estimate: two annotator scores for the same segment agree on tier in only **48.6**% of cases on the canonical $n = 2{,}391$ set (pairs with two *different* annotators; 51.3% on the larger $n = 2{,}850$ set that includes 459 self-agreement pairs—one annotator scoring both slots—used for the human-in-the-loop sweep in §4). A parametric model gives a comparable bound: *assuming* $\Delta = s_2 - s_1 \sim \mathcal{N}(0, \sigma_\Delta^2)$ with $\sigma_\Delta \approx 25$ (from mean $|\Delta| = 20.24 = \sigma_\Delta\sqrt{2/\pi}$; an approximation, since scores are censored at 0 and 100), a

| Metric | $\rho$ score | $\rho$ penalty | AUC major |
|---|---|---|---|
| **MetricX-XXL** | $-$**0.485** | $+0.391$ | **0.675** |
| xCOMET-XXL | $+0.413$ | $-0.357$ | 0.658 |
| BERTScore F1 | $+0.406$ | $-0.180$ | 0.599 |
| TER | $-0.333$ | $+0.137$ | 0.583 |
| chrF | $+0.352$ | $-0.127$ | 0.573 |
| COMETKiwi-XXL | $+0.084$ | $-0.062$ | 0.546 |

Table 2: Per-metric correlations and AUC. Signs follow the scale direction: MetricX-XXL and TER are lower-is-better, the others higher-is-better.

| | BERT | chrF | CK | MX | TER | xCOM |
|---|---|---|---|---|---|---|
| BERT | — | $+0.86$ | $+0.23$ | $-0.50$ | $-0.80$ | $+0.43$ |
| chrF | $+0.86$ | — | $+0.17$ | $-0.34$ | $-0.85$ | $+0.29$ |
| CK | $+0.23$ | $+0.17$ | — | $-0.28$ | $-0.11$ | $+0.44$ |
| MX | $-0.50$ | $-0.34$ | $-0.28$ | — | $+0.29$ | $-0.70$ |
| TER | $-0.80$ | $-0.85$ | $-0.11$ | $+0.29$ | — | $-0.26$ |
| xCOM | $+0.43$ | $+0.29$ | $+0.44$ | $-0.70$ | $-0.26$ | — |

Table 3: Spearman $\rho$ between the six metrics. $n = 3{,}450$. Signs reflect aligned scale directions. **MX** = MetricX-XXL, **CK** = COMETKiwi, **xCOM** = xCOMET-XXL.

simulation over the empirical $s_1$ distribution yields $\mathbb{P}[\text{tier}(s_1) = \text{tier}(s_2)] \approx$ **0.60**: even an ideal oracle reproducing one annotator's score would disagree with the paired annotator on tier in roughly 40% of cases. The calibrated F7+LP variant reaches 53.0% tier-match (§3)—slightly above the 48.6% empirical ceiling and within $\approx 2$ percentage points (pp) of the $n = 2{,}850$ figure; the narrow excess is the Spearman-Brown effect (§2.3.1): F7+LP is evaluated against the mean-aggregated score, a smoother target than a single annotator. In a task with inter-annotator $r = 0.425$, expecting substantially higher agreement is metrically incorrect.

### 2.3 Audit of six metrics

All six metrics from §1.2—chrF, TER, BERTScore F1, COMETKiwi-XXL, MetricX-XXL (reference-based) and xCOMET-XXL—are computed on the full corpus of 3,450 segment-system pairs. The audit aims to establish (i) which metrics correlate most strongly with human score, (ii) which of them carry overlapping signal and are therefore redundant in a linear combination, and (iii) which single metric best detects the presence of a major error.

#### 2.3.1 Correlation with human score and AUC for major-error detection

Table 2 gives the segment-level Spearman $\rho$ of the metrics against the mean-aggregated score ($n = 3{,}450$) and AUC for the binary task of detecting "$\geq 1$ major span" (on 2,504 segments with span annotation).

**MetricX-XXL** has the strongest signal of the six, with $|\rho| = 0.485$ against the human score. It is tempting to note that this exceeds the inter-annotator $r = 0.425$, but **the two numbers are not directly comparable**: the metric is correlated against the *mean-aggregated* score (two or more annotators averaged), whereas 0.425 is a single annotator against another single annotator. Averaging denoises the target, which mechanically inflates any correlation with it. On a fair, like-for-like basis—MetricX-XXL against a *single* annotator, measured on the $n = 2{,}850$ two-annotator set (§4)—the correlation is $\rho \approx 0.46$, i.e. **at, not above**, the single-vs-single inter-annotator agreement on that set ($\rho = 0.465$; the figure rises to 0.52 only when the metric is scored against the *averaged* target, which is the inflation we are flagging). The honest reading is that the best single metric *approaches* the human ceiling from below; no automatic metric beats it. The worst is **COMETKiwi-XXL** with $\rho = 0.084$, effectively zero signal. The explanation is a **calibration mismatch**: the COMETKiwi model was trained mainly on the news domain of WMT-17–22, whereas 41.9% of our corpus is literary and a substantial share is speech-like dialogue. The calibration does not transfer: COMETKiwi yields a compressed range of scores on out-of-domain segments, and the linear correlation with humans collapses. The AUC for major-detection follows the same order (Table 2), with COMETKiwi (0.546) close to chance.

#### 2.3.2 Pairwise redundancy

The Spearman matrix between the six metrics (Table 3; heatmap in Appendix C, Fig. 4) reveals three nearly collinear pairs within the surface family.

The three strongest within-family connections are **chrF** $\leftrightarrow$ **BERTScore F1** ($|\rho| = 0.855$), **chrF** $\leftrightarrow$ **TER** ($|\rho| = 0.852$), and **BERTScore F1** $\leftrightarrow$ **TER** ($|\rho| = 0.803$). All three metrics measure different projections of the *same reference-overlap signal*: chrF at the level of character $n$-grams, BERTScore at the level of token embedding similarity, TER at the level of edit distance. Their triplet is nearly triple-redundant: the variance inflation factor (VIF) for any pair from the three exceeds 5, which in linear regression creates multicollinearity and instability of weights. Including all three in a single composite formula is equivalent

to *triple counting* of the same signal at the expense of the weight budget; zeroing two of three (while keeping one surface baseline for interpretability) is the correct solution, which is also what the grid search in §3 converges to.

Between families the picture is different. **MetricX-XXL** ↔ **xCOMET** yields $|\rho| = 0.699$—a noticeable connection (both are neural metrics), but not collinearity: $\approx 50\%$ of each metric's variance is not explained by the other. **COMETKiwi** falls outside all clusters: its maximum connection is with xCOMET ($\rho = 0.438$), its minimum with TER ($\rho = -0.107$). This is consistent with its low correlation with human score: COMETKiwi carries neither the surface signal (like chrF/BERT/TER) nor a strong semantic one (like MetricX/xCOMET), and on our domain produces a high-variance, low-informative output. The effective number of independent signals in the inventory is approximately **four**: MetricX-XXL, xCOMET, a surface baseline (one representative of chrF/BERT/TER), and the human span penalty.

#### 2.3.3 Implications for building the composite

The audit establishes three facts that motivate the closed form of AQI in §3: (i) no single metric exceeds $|\rho| = 0.5$ against human score, and even the best (MetricX-XXL) only *approaches* the inter-annotator ceiling rather than clearing it (§2.3.1)—a combination is needed to push past a single metric; (ii) three of six metrics (chrF, BERTScore, TER) are nearly triple-redundant, so a composite should keep only *one* representative of the surface cluster rather than all three; (iii) COMETKiwi on multi-domain WMT25 yields almost zero signal due to calibration mismatch and should receive zero weight in any linear combination trained on this corpus.

### 2.4 Normalising metrics to a common scale

The six metrics live on different scales and have different orientations: chrF is in $[0, 100]$ higher-is-better and TER in $[0, +\infty)$ lower-is-better; BERTScore F1, xCOMET-XXL and COMETKiwi-XXL are in $[0, 1]$ higher-is-better, while MetricX-XXL is in $[0, 25]$ *lower-is-better* (it is an error score, not a quality score). To combine them in a linear sum we map each to a unified $[0, 100]$ scale, higher-is-better. For five of the six the normalisation is trivial rescaling (and, for TER, inversion); the exact forms are in Appendix J.

For **MetricX-XXL** the scale is an error count and "quality" does not move linearly from 0 to 25 (the gap between 1 and 5 feels sharper than between 15 and 19). We adopt the linear normalisation

$$\text{mx\_lin} = \text{clip}\big(1 - \tfrac{\text{MetricX-XXL}}{25},\ 0,\ 1\big) \cdot 100,$$

which is scale-preserving (each error unit lowers the score by 4 points), tier-friendly (its distribution covers $[16, 99]$, aligned with the 60/85 boundaries), and free of any hyperparameter. As a single-metric sanity check, mx_lin is an affine transform of raw MetricX-XXL, so it preserves both the Spearman rank correlation (0.4851) and the Pearson correlation (0.4500) of the raw metric against the human score. We also tried a non-linear exponential normalisation and other parametric forms; none gave a robust cross-validated gain over mx_lin, and the exponential variant is carried as an equal-billing alternative in Appendix E.

## 3 The AQI Formula: Derivation and Justification

### 3.1 Problem statement and normalisation

This section derives the **auto-only** part of AQI—a formula computed from automatic metrics alone. §4 then shows how an optional human score is folded on top; here we restrict the discussion to the purely automatic case. The formula must produce a scalar in $[0, 100]$ that increases monotonically with the human score and is transparent enough to be reproduced and interpreted without a black box.

Normalisation of the six metrics to the unified $[0, 100]$ higher-is-better scale is introduced in §2.4; for MetricX-XXL we use the linear form $\text{mx\_lin} = (1 - \text{MetricX-XXL}/25) \cdot 100$ throughout the main text (an exponential alternative is in Appendix E).

All experiments in this section use the unified corpus of §2.1 ($n = 3{,}450$; mostly WMT25 General MT plus the separate en→es pair; the CSV ships with the repository). Tier partition is the paper-wide standard: **Good** $\geq 85$, **Medium** $60 \leq s < 85$, **Bad** $s < 60$. All fitted models use 5-fold cross-validation (CV; `KFold, shuffle=True, random_state=42`); reported correlation and mean absolute error (MAE) are on out-of-fold predictions (no leakage).

### 3.2 Single metrics as a baseline

The first reference point is the standalone performance of each metric. This gives a lower bound for any composite: a linear combination has to

| Metric | Pearson | Spear. | MAE | Tier |
|---|---|---|---|---|
| **mx_lin** | **+0.450** | **+0.485** | **17.61** | **46.4%** |
| xc100 | +0.442 | +0.481 | 20.08 | 48.2% |
| bert100 | +0.374 | +0.413 | 18.06 | 44.8% |
| chrf100 | +0.289 | +0.311 | 24.92 | 30.6% |
| ter_inv100 | +0.023 | +0.300 | 31.41 | 29.0% |
| ck100 | +0.138 | +0.163 | 21.60 | 38.1% |

Table 4: Single metrics, $n = 3{,}450$, tier 85/60. MetricX-XXL with linear normalisation is the best by Pearson. COMETKiwi-XXL yields a weak correlation due to a domain mismatch (§2.3).

justify itself against the best single metric—if it does not improve on it, it is redundant. The bar here is MetricX-linear (Pearson $0.450$, Spearman $0.485$); we return to whether our composite clears it in §3.5.

### 3.3 Candidate metric set: MetricX-XXL + xCOMET + BERTScore

Before tuning weights we have to decide which metrics to combine, and the audit in §2.3 answers this directly. Only three metrics give a **strong univariate signal** against the human score—MetricX-XXL, xCOMET and BERTScore F1 (Table 4, $\rho \in [0.37, 0.49]$); chrF and TER are noticeably weaker ($\rho \in [0.02, 0.29]$), and COMETKiwi degrades to $\rho \approx 0.14$ on our multi-domain corpus. The surface trio chrF, BERTScore F1 and inverted TER is nearly triply collinear ($|\rho| \geq 0.80$ pairwise), so we keep a **single representative**: BERTScore F1, which has the highest univariate correlation within the cluster ($0.406$ vs. chrF $0.352$ vs. TER $0.023$ on Pearson) and whose embedding similarity adds a **semantic** component that character- and edit-level overlap cannot. The candidate set is therefore *MetricX-XXL + xCOMET + BERTScore F1*: the two strongest learned metrics (with $\approx 50\%$ non-shared variance) plus one surface-cluster representative.

### 3.4 Families of formulas we tried

#### 3.4.1 Weighted linear sum (the F family)

The simplest composite is a linear combination $\text{AQI} = \sum_i w_i \cdot m_i$ with weights $w_i \in [0, 1]$, $\sum_i w_i = 1$. The constraints have a natural reading: "share of each metric in the final score". We searched 3-metric combinations on the candidate triple on a grid of step 0.05. The best point on the joint balance of Pearson, tier-agreement, and MAE—we call it F7:

$$\text{AQI}_{F7} = 0.40 \cdot \text{mx} + 0.30 \cdot \text{xc100} + 0.30 \cdot \text{bert100} \quad (1)$$

where *mx* is the normalised MetricX-XXL (mx_lin). The 40%/30%/30% weights are confirmed by a constrained least-squares fit with Sequential Least Squares Programming (SLSQP; $\sum w_i = 1$, $w_i \geq 0$) on the full data: $(0.396, 0.287, 0.317)$ for linear MetricX—essentially the manual rounding. For transparency we fix the rounded $(0.40, 0.30, 0.30)$.

#### 3.4.2 Geometric mean (the Geo family)

A geometric mean multiplicatively penalises single-metric failures. Geo3 and Geo4 are competitive with F7 on Pearson ($0.49$) but, without calibration, collapse to 28% tier-agreement because of a compressed distribution, and adding TER and chrF (Geo5) breaks down to $\rho = 0.18$; full results are in Appendix F, Table 11.

#### 3.4.3 Linear regression on all six metrics (Ridge)

An unconstrained Ridge regression ($\alpha = 1$) on all six standardised metrics reaches $\rho = 0.517$ (no LP), $\rho = 0.612$ (+LP)—higher than F7-linear, but with one odd detail: the COMETKiwi-XXL coefficient is **negative** ($-0.20$) despite its positive univariate correlation—the *suppressor effect* (Conger, 1974), since the metric is near-zero signal (§2.3.3). Dropping it, **Ridge-5 (no CK)** has all-positive coefficients at almost no accuracy cost ($\rho = 0.491$ / $0.62$ with LP). So the suppressor is not a reason to reject linear regression; we still publish F7 as the headline for *parsimony*—three metrics instead of five, nearly tying Ridge-5 on Pearson ($0.483$ vs. $0.491$). The full Ridge coefficients are in Appendix E.

#### 3.4.4 Non-linear tabular machine-learning (ML) models

To bound the **ceiling** of any auto-only regressor on the same six metrics we ran standard tabular-ML models (Table 5); these are not finalists (no closed form). Neural regressors on raw src/ref/tgt text (Appendix H) do not fit the "formula on metric outputs" requirement either; the best ($\rho \approx 0.80$) is disqualified by label leakage.

### 3.5 Master comparison

F7 clears the redundancy bar of §3.2: without calibration it reaches Pearson $0.483$ against the

| Model | Pearson | Spear. | MAE | Tier |
|---|---|---|---|---|
| GradientBoosting | +0.571 | +0.559 | 13.63 | 51.4% |
| RandomForest ($n = 200$) | +0.558 | +0.546 | 13.80 | 51.3% |
| KNN ($k = 15$) | +0.549 | +0.541 | 13.81 | 51.3% |
| MLP ($32 \times 32$) | +0.544 | +0.539 | 13.98 | 49.9% |

Table 5: Non-linear ML models on the same six metrics, without human error spans (KNN: $k$-nearest neighbours; MLP: multilayer perceptron). The best is GradientBoosting ($\rho \approx 0.57$)—the auto-only regression ceiling on this feature set without LP calibration. Not adopted as the primary formula: see the interpretability trade-off in §3.5.

| Formula | Pearson | MAE | Tier |
|---|---|---|---|
| **F7-linear** | **+0.483** | **14.55** | **46.5%** |
| F7-linear + LP | +0.624 | 13.08 | 53.0% |
| AQI-Geo3 | +0.492 | 28.32 | 28.3% |
| AQI-Geo3 + LP | +0.579 | 14.65 | 54.8% |
| Ridge (6 metrics) | +0.517 | 14.31 | 47.9% |
| Ridge-5 (no CK) | +0.491 | 14.64 | 45.5% |
| Ridge + LP | +0.612 | 13.20 | 53.1% |
| GradientBoosting | +0.571 | 13.63 | 51.4% |
| xCOMET alone | +0.442 | 20.08 | 48.2% |
| MetricX-linear alone | +0.450 | 17.61 | 46.4% |

Table 6: Master comparison on the full corpus $n = 3{,}450$, 5-fold CV, tier 85/60. All variants are auto-only (no human error spans, no human score at inference).

best single metric's 0.450—a modest but bootstrap-reliable gain ($\Delta\rho = +0.033$, 95% confidence interval $[+0.016, +0.050]$)—and separates the low-quality tail better (0.341 vs. 0.306 on segments scoring $< 60$). It does *not* win on raw accuracy: Ridge (0.517), Ridge-5 (0.491) and the GradientBoosting ceiling (0.571) are higher. The honest framing is a trade-off: F7 gives up $\approx 0.03$ Pearson against Ridge and $\approx 0.09$ against GradientBoosting for a one-line formula with three positive weights. We *hypothesise* that for a product-facing index used by project managers and clients this closed form is worth the gap; we do not test the preference with stakeholders directly, but ground it in three properties the black-box alternatives lack. (i) AQI is monotone in every input by construction, whereas GradientBoosting lowers its score on 4.0% of out-of-fold segment pairs in which all three inputs strictly improve (median drop 3.1 points, 90th percentile 12.4). (ii) Three published weights are a versionable specification that can be written into a client or vendor agreement and recomputed in a spreadsheet; a fitted model with post-hoc attribution explains individual predictions but does not keep scores comparable across retrains, and attribution over the near-collinear surface cluster (§2.3) is unstable by construction. (iii) With per-LP offsets the gap closes: F7+LP reaches 0.624 against Ridge+LP 0.612 and GradientBoosting+LP $\approx 0.62$ under the same offset protocol. A team needing only a ranking signal should still prefer GradientBoosting or Ridge-5. Geo variants match F7+LP on tier only with calibration; without offsets they lose ∼18 pp. We do not claim F7 is more robust *across* LPs—its per-LP spread is no tighter than MetricX-linear's; its advantage is on the aggregate, ranking, and the low-quality tail.

The gain is asymmetric. On the 5 % of segments where F7 and MetricX-alone disagree most ($|\Delta| \geq 8.5$ points after linear calibration of both to the human scale, $n = 173$), F7 is closer to the human score in 57 % of cases; when the composite *raises* a segment that MetricX penalises it is right in 69 % of cases ($n = 74$), when it *lowers* one in 49 % ($n = 99$). Disagreements split evenly between segments with and without a major span; the composite's edge is weakest on news (F7 closer in 45 % of news disagreements vs. 55 % on literary), the domain where MetricX alone is strongest (§3.7). Two worked examples are in Appendix D, Cases 4–5.

### 3.6 F7 as the final formula

We pick F7 as the final auto-only AQI: closed-form, three positive weights, no free parameters. With the linear MetricX-XXL normalisation it gives a tier-friendly scale that covers $[0, 100]$ roughly evenly without any calibration. The final formula:

$$\begin{aligned}\text{AQI}_{\text{linear}} = {} & 0.40 \cdot \left(1 - \tfrac{\text{MetricX}}{25}\right) \cdot 100 \\ & + 0.30 \cdot \text{xCOMET} \cdot 100 \\ & + 0.30 \cdot \text{BERTScore} \cdot 100 \end{aligned} \quad (2)$$

An equal-billing exponential variant, identical in ranking and Pearson but on a compressed scale, is given in Appendix E.

### 3.7 Language-pair (LP) offsets—optional calibration

The tables above repeatedly mention "+ LP". Defined once: a **language pair (LP) offset** $\delta_{\text{LP}}$ is a constant added to AQI on segments of a given LP to compensate for the systematic per-LP bias we observe in F7 residuals. The offset is computed on

| LP | $n$ | Offset |
|---|---|---|
| cs→de | 600 | −0.98 |
| en→cs | 1,050 | +2.11 |
| en→es | 600 | +10.29 |
| en→et | 600 | −16.75 |
| en→ru | 600 | −1.83 |

Table 7: Per-LP residual offsets for F7-linear $(0.40, 0.30, 0.30)$. The mixed signs reflect per-LP difficulty: en→et is over-rated by the metrics by ∼17 points, en→es is under-rated by ∼10.

labelled data (human scores are needed for calibration, but not at inference) and only applies to **previously seen LPs**—for a new LP not in the training corpus, no offset is available and the formula runs without it. We publish offsets as an **optional extension**, not as part of the core formula.

Table 7 gives the mean of score − $\text{AQI}_{F7}$ (5-fold CV) by LP.

Calibrated version: $\text{AQI}^{+\text{LP}} = \text{AQI} + \delta_{\text{LP}}$, where $\delta_{\text{LP}}$ comes from Table 7. On 5-fold CV (offsets estimated on the train fold, applied on the test fold) they lift F7-linear from Pearson 0.483 / tier 46.5% / MAE 14.55 to **0.624** / **53.0**% / **13.08** (Table 6): +0.141 Pearson and +6.5 pp tier-agreement.

Default recommendation: use the **core formula without offsets**. Offset calibration is for those working with the same LPs as the canonical WMT25 corpus, who want the additional +0.12–0.14 Pearson and ∼6–7 pp tier-agreement.

**Domain dependence.** The corpus has two labelled domains, *literary* ($n = 1{,}444$) and *news* ($n = 1{,}406$), confounded with LP (cs→de is news only). Table 12 (Appendix K) reports F7, MetricX-alone and an in-sample per-domain refit of the three weights. The optimum does move: literary favours $(0.60, 0.05, 0.35)$, news collapses almost to MetricX alone $(0.90, 0.10, 0.00)$; the refit gains +0.03–0.04 Pearson within a domain, where F7 trails MetricX-alone by 0.01–0.03, and weights fitted on one domain transfer to the other within 0.02 of the local optimum. F7's advantage is on the mixed corpus it was fitted on and on the low-quality tail (0.338 vs. 0.297 on literary segments scoring $< 60$). We therefore recommend the fixed weights for mixed production traffic and, for a single known domain, the recalibration recipe in the Limitations section.

# 4 Human-in-the-Loop

## 4.1 Why human-in-the-loop

Auto-only F7-linear reaches tier-agreement 46.5% (§3.5), *below* the independent inter-annotator tier-agreement of 48.6% (§2.2; 51.3%, with $r = 0.467$, on the $n = 2{,}850$ two-score set used for the $\alpha$ sweep below, which includes 459 self-agreement pairs)—it approaches human consistency from below. "Human-calibrated" means *trained against* human scores, not human parity. For low-stakes use (ranking, post-editing prioritisation) auto-only AQI suffices, but in high-stakes scenarios (legal, medical, brand-critical) undetected disagreements carry non-linear risk and human review is required. We therefore derive a **single hybrid index** blending one human score into the auto-only AQI and select its weight empirically. Since AQI is normalised to the same $[0, 100]$ higher-is-better scale as the human score (§2.4), $(1-\alpha)\cdot\text{AQI}+\alpha\cdot\text{human}$ is a well-defined convex combination.

## 4.2 The hybrid index

A segment is usually scored by one annotator (the base case); with several, we average their scores. The hybrid index is

$$\text{AQI}_H = (1 - \alpha) \cdot \text{AQI}_{F7} + \alpha \cdot \text{human} \quad (3)$$

where human is the single annotator's score (or mean) on the native $[0, 100]$ scale. The human score enters **as-is**: no shrinkage toward a prior, no per-annotator $z$-normalisation. A human scoring a segment low may be correctly catching a defect the index missed, so pulling them toward a prior would treat the index as the arbiter of truth—the opposite of why we bring in a human. Dropping $z$-normalisation is also practical: there is rarely enough data per annotator to estimate $\mu_i, \sigma_i$ reliably.

## 4.3 Choosing $\alpha$

Tuning $\alpha$ on the same human score that enters the formula would be circular. The validation is therefore **honest, on an independent annotator**: we blend in annotator-1's score and evaluate the result against the held-out annotator-2 score (which the formula never saw), then symmetrically blend in annotator-2 and evaluate against annotator-1, and average the two directions. The $\alpha$ sweep runs on the $n = 2850$ segments with two annotator scores (see §2.2 for the note on self-agreement pairs).

| $\alpha$ | Pearson | Tier | MAE |
|---|---|---|---|
| 0.00 (auto-only) | 0.425 | 40.1% | 17.47 |
| 0.20 | 0.520 | 44.7% | 16.48 |
| 0.25 | 0.527 | 46.3% | 16.34 |
| **0.30 (final)** | **0.529** | 47.1% | 16.24 |
| 0.35 | 0.528 | 48.0% | 16.17 |
| 0.40 ($= w_{\text{mx}}$) | 0.525 | 48.9% | 16.15 |
| 0.50 | 0.517 | 50.5% | 16.23 |
| 1.00 (pure human) | 0.467 | 51.3% | 18.80 |

Table 8: Independent-annotator $\alpha$ sweep ($n = 2850$). The selection criterion is Pearson $\rho$ against the independent annotator: tier-agreement rises with $\alpha$ trivially, because at high $\alpha$ the prediction simply copies the blended human's tier labels, whereas correlation against an *independent* human is the honest signal.

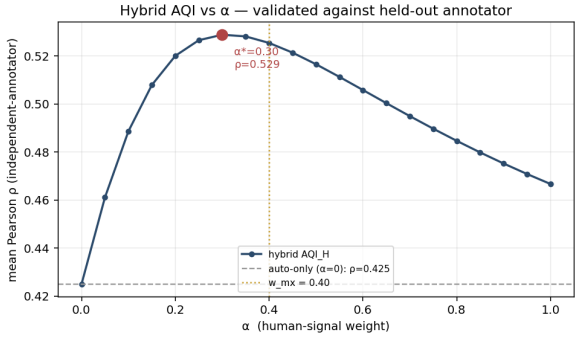

Figure 1: Mean Pearson $\rho$ (independent-annotator validation) as a function of $\alpha$. The curve rises from auto-only ($\alpha = 0$, $\rho = 0.425$) to a flat optimum around $\alpha \approx 0.25$–$0.40$ peaking at $\alpha = 0.30$ ($\rho = 0.529$), then declines gently toward pure-human ($\rho = 0.467$).

The optimum is a **broad plateau** $\alpha \approx 0.25$–$0.40$ with argmax at $\alpha = 0.30$. The final $\alpha = 0.30$ lifts correlation from $\rho = 0.425$ to $\rho = 0.529$ ($+0.104$, $\approx$24% relative gain over auto-only). Notably, the plateau covers the MetricX-XXL weight in F7 ($w_{\text{mx}} = 0.40$): the human earns roughly the same trust as the strongest single metric—$\alpha = 0.40$ gives $\rho = 0.525$, statistically indistinguishable from the peak. With $\alpha = 0.30$, Eq. 3 becomes the flat four-term formula given in §5, which is the final human-in-the-loop index.

## 5 Conclusion

We have presented the **Aggregate Quality Index (AQI)**—a composite, human-calibrated index of machine translation quality, developed on a unified corpus of $n = 3{,}450$ segment-system ratings, drawn primarily from WMT25 General-MT (en→es from WMT24, see §2.1). The work makes **four contributions**: (i) an empirical quantification of the inter-annotator agreement ceiling $r = 0.425$ on the double-annotated $n = 2{,}391$ subset—the theoretical upper bound for any automatic metric; (ii) a systematic audit of six metrics with per-pair redundancy analysis, identifying the COMETKiwi-XXL domain mismatch and the near-triple collinearity of chrF / BERT / TER; (iii) a closed-form formula F7-linear, reaching $\rho \approx 0.48$ on the auto-only baseline without human error spans and without human input at inference; (iv) a simple human-in-the-loop index—a linear blend of one human score into the auto-only AQI with the final weight $\alpha = 0.30$ selected empirically via honest validation against an independent annotator (Pearson rises from $\rho \approx 0.43$ to $\rho \approx 0.53$).

### 5.1 The final AQI formulas

**Recommended deployment: F7-linear** (Eq. 2), $0.40 \cdot \text{mx\_lin} + 0.30 \cdot \text{xc100} + 0.30 \cdot \text{bert100}$: Pearson $\rho = \mathbf{0.483}$, tier-agreement **46.5**%, MAE **14.55** on 5-fold CV; three positive weights summing to one, no negative coefficients. Optional LP offsets (Table 7) for previously seen LPs lift it to $\rho \approx 0.62$ and tier 53%.

**With one human score (human-in-the-loop, §4).** Folding in a single human score with weight $\alpha = 0.30$ and multiplying the 0.70 blend weight through the F7 coefficients yields a single flat formula in four terms:

$$\begin{aligned}\text{AQI}_H = {} & 0.28 \cdot \left(1 - \tfrac{\text{MetricX}}{25}\right) \cdot 100 \\ & + 0.21 \cdot \text{xCOMET} \cdot 100 \\ & + 0.21 \cdot \text{BERTScore} \cdot 100 \\ & + 0.30 \cdot \text{human}\end{aligned}$$

where human is the single annotator's 0–100 score (or the mean across annotators). The four weights sum to one. On independent-annotator validation this lifts correlation from $\rho \approx 0.43$ (auto-only) to $\rho \approx 0.53$ (§4).

### 5.2 Interpreting the AQI scale

A production user reads an AQI number directly as a quality verdict, so we publish an explicit interpretation scale (Appendix I, Table 13). The thresholds are *not* the human-score tier boundaries 60/85: the F7-linear distribution is **compressed** relative to the human score (on $n = 3{,}450$, mean $= 76.5$, std $= 10$ vs. human mean $= 75.5$, std $= 21$), so applying 60/85 directly would label 76.6% of segments "Medium" and only 5% "Bad"—uninformative. We instead choose breakpoints **60 / 68 / 75 / 83** so that the mean human score of

the segments in each band ($\{53, 61, 70, 79, 88\}$ from Poor to Good) matches the band's label. One caveat: the headline $46.5\%$ tier-agreement is measured on the **three-tier** human partition ($85/60$), not on this five-band deployment scale.

**Impact and reproducibility.** The weights are fixed here and LP offsets ship as an optional extension; the canonical CSV, the test sets and the training/evaluation scripts are released at `https://github.com/asyaasinkson/aqi_paper_repo`.

## Limitations

**LP offsets.** The optional per-LP intercepts $\delta_{\text{LP}}$ (§3.7) are estimated only on the train fold and applied to the test fold within 5-fold CV (no leakage), a standard nuisance control; the primary formula is the no-LP variant, and we publish within-LP correlations as a floor invariant under an LP-mean shift.

**Generalisation.** Our scope is 5 WMT25 LPs. Not studied: low-resource LPs (sparse training data, weak tokeniser coverage), non-Latin scripts beyond Chinese, Japanese and Korean (CJK)—Arabic, Hebrew, Thai, Indic—and right-to-left/vertical scripts. Before applying AQI on a new LP, run a small-scale calibration on $100+$ doubly-annotated segments and check the within-LP metric–human correlation; if $\rho < 0.20$ the formula does not transfer.

**Domains.** Our slice is 42 % literary and 41 % news; WMT25's speech, social and dialogue domains are absent, and domain is confounded with LP. Per-domain refits shift the weights (§3.7, Table 12). To adapt AQI to a single known domain: collect $100+$ doubly annotated segments, check the within-domain metric–human correlation, estimate a domain offset exactly as the LP offset ($\delta_{\text{dom}} = \overline{\text{score} - \text{AQI}}$), optionally re-grid the three weights on the simplex, and recalibrate the band breakpoints of Table 13.

**Metrics get out of date.** AQI depends on MetricX-XXL, xCOMET and BERTScore F1, each updated on its own cycle, with distribution shifts that break the normalisation constant (25). Mitigation: periodic recalibration on a static held-out corpus and an open release of updated coefficients.

**LLM-based metrics.** GEMBA-MQM and similar LLM judges (Kocmi and Federmann, 2023) are outside our six-metric inventory. We excluded them for the reasons that motivate fixed weights in the first place: per-call cost at production volume, non-determinism, and model versioning that would silently move the composite. WMT25 itself used GEMBA-ESA inside its automatic ranking (Kocmi et al., 2025), so integration is a natural next step; how the weights shift when an LLM judge is added is left to future work.

**Reference availability and AI bias.** Our formula is reference-based; true zero-shot deployment needs QE variants, left to future work. Annotators may also under-rate machine-translated output (Fischer and Läubli, 2020; Hendy et al., 2023); we did not measure this (WMT25 ran no controlled with/without-label experiment), but the human-in-the-loop blend (§4) partially averages it out by retaining 70 % of the automatic signal. Future directions are listed in Appendix L.

## A Per-metric descriptions

This appendix expands the six-metric inventory of §1.2 with the scales, training signals and known failure modes referenced in the main text.

**chrF** (Popović, 2015) computes an F-score over character $n$-grams of order 1–6 between the hypothesis and the reference, with a parameter $\beta$ weighting recall relative to precision (typically $\beta = 2$). Unlike BLEU, chrF operates at the character level without tokenisation, which makes it robust on morphologically rich languages (Slavic, Finno-Ugric) and on compounds. On WMT meta-evaluations chrF consistently outperforms BLEU in correlation with human judgement and serves as a standard surface-level baseline. Weaknesses: sensitivity to punctuation and whitespace, no semantic modelling (antonyms and paraphrases are not adequately penalised or rewarded), and the systematic penalisation of creative non-literal translations. The metric is **reference-based**.

**TER** (Translation Edit Rate; Snover et al., 2006) is defined as the minimum number of edits—insertions, deletions, substitutions and shifts of word blocks—normalised by the reference length, that are needed to transform the hypothesis into the reference. TER is interpretable (it operationalises post-editing effort), but it operates at the level of exact word matches and therefore systematically penalises synonym replacement, word-order rearrangement and legitimate paraphrasing. The authors proposed human-targeted TER (HTER, with a post-edit as a pseudo-reference) to mitigate this, but in its plain form TER remains a **reference-based** metric with well-known sensitivity to stylistic freedom in translation. In our audit TER serves as a contrast to chrF: both are surface-level metrics, but their optimisation directions are opposed (lower-is-better versus higher-is-better).

**BERTScore F1** (Zhang et al., 2020) estimates semantic similarity through greedy token matching between the candidate and the reference based on the cosine similarity of contextual embeddings from a pre-trained BERT/XLM-R model, aggregated into precision, recall and F1. The metric circumvents the lexical rigidity of chrF/TER, correctly crediting synonyms and paraphrases, and correlates well with human judgement on semantic tasks. Known failure modes: the *antonymy problem*—antonyms lie close in the embedding space, so substituting "best" with "worst" yields a high F1; insensitivity to factual inversions of numbers, dates and named entities (e.g. "2 %" and "20 %" yield $F1 \approx 0.97$); and dependence on the training frequency of tokens. **Reference-based**.

**COMETKiwi-XXL** (Rei et al., 2022b, 2023) is a **reference-free** (QE) regression encoder built on XLM-R-XXL ($\approx 10.5$ B parameters), taking a source–hypothesis pair and predicting the human assessment. It was trained on Direct Assessments from WMT-17 through 22, MLQE-PE and MQM signals; in the WMT-22/23 QE Shared Tasks it placed among the top systems for both high- and low-resource languages. Strengths: it does not require a reference (applicable in production zero-shot) and covers more than 100 languages. Weaknesses: sensitivity to domain shift (literary, speech), bias toward fluency over adequacy, and a tendency to over-rate "smooth" hallucinations that lack a semantic anchor in the source.

**MetricX-XXL (reference-based)** is Google's submission to the WMT-23 Metrics Shared Task (Juraska et al., 2023): a regression encoder built on mT5-XXL, fine-tuned in two stages—first on Direct Assessments, then on MQM ratings, with the inclusion of synthetic perturbations. It is released in two families of variants: **reference-based** (`google/metricx-23-xxl-v2p0`, accepting hypothesis + reference) and **QE** (`google/metricx-23-qe-xxl-v2p0`, accepting source + hypothesis). We use the **reference-based XXL variant**. The output is an error score on a $[0, 25]$ scale, lower-is-better. On WMT-23/24 MetricX-XXL occupies top positions in segment-level Spearman correlation with MQM. Weaknesses: it penalises creative and stylistically free transla-

tions, the training signal is biased toward literal correctness, and the metric is sensitive to domain mismatch between training and application.

**xCOMET-XXL** (Guerreiro et al., 2024) is a hybrid encoder on XLM-R-XXL that combines sentence-level regression with word-level error span tagging following the MQM severity scheme (minor / major / critical). It was trained on an ensemble of Direct Assessments, post-edits and MQM. It supports both modes: **reference-based** (src + hyp + ref) and **reference-free**; we use the reference-based mode. On WMT-23 xCOMET reached state-of-the-art results simultaneously at sentence-, system- and error-span levels and is reported to be the most robust to hallucinations and critical errors. Weaknesses: span boundaries are noisy on short segments, the severity classifier compresses different error types (terminology vs. adequacy) into a single class, and the metric remains vulnerable to adversarial fluent outputs that lack a source anchor.

## B Dataset composition

Table 9 gives the full per-LP composition of the 3,450-segment slice referenced in §2.1.

## C Inter-annotator agreement and metric redundancy: figures

Figure 2 shows the raw scatter of the two annotators' scores on the $n = 2{,}391$ ceiling set (§2.2); Figure 3 breaks the inter-annotator Pearson $r$ down by language pair; Figure 4 is the heatmap of the pairwise metric Spearman matrix (Table 3).

## D Case studies: extreme disagreements

To illustrate the nature of the noise we selected from the 2,391 double-annotated segments three cases with an extreme gap **in the holistic human score** between the two annotators ($|\Delta s| \geq 84$ points across different LPs). These are not data outliers but legitimate borderline cases where annotators saw the same translation differently. Each case below quotes the real source, system output and reference (disputed fragment in **bold**) and analyses a qualitatively different *kind* of disagreement.

**Case 1—en→ru, literary, system Alharb.** Score: $s_1 = 0$, $s_2 = 97$, $|\Delta| = 97$. MetricX-XXL $= 4.34$, xCOMET $= 0.577$, chrF $= 41.7$.

- **Source:** …"Look at that. You didn't even drop an F-bomb this time." …
- **System:** …"Смотри-ка. В этот раз ты даже не выругался."
  *(translit.) "Smotri-ka. V etot raz ty dazhe ne vyrugalsya."*
  *(gloss)* "Look at that. You didn't even swear this time." (English-style straight quotes)
- **Reference:** …— Смотри-ка. В этот раз без лишних эпитетов.
  *(translit.) — Smotri-ka. V etot raz bez lishnih epitetov.*
  *(gloss)* "— Look at that. This time without unnecessary epithets." (native Russian em-dash)

Annotator 1 marked eight minor spans (mostly zero-length—punctuation, quotes, the choice of quotation styles) and gave a score of **0**. Annotator 2 found no errors and gave **97**. The translation is essentially correct and reasonably fluent; the disagreement is fully explained by **threshold strictness toward style**: one annotator perceives the dialogue formatting via straight quotes instead of the Russian em-dash as a series of microerrors, the other as acceptable variation. This class of disagreement shows that a score of 0 does not always mean "bad translation"—it can mean "strict annotator on a stylistically neutral segment".

**Case 2—cs→de, news, system CommandA.** Score: $s_1 = 7$, $s_2 = 95$, $|\Delta| = 88$. MetricX-XXL

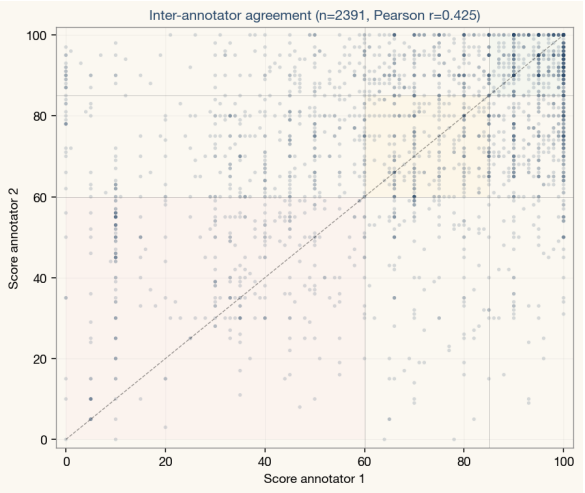

Figure 2: Scatter of scores from two independent annotators on $n = 2{,}391$ segments. The green zone denotes Good × Good, yellow Medium × Medium, red Bad × Bad. The characteristic "cloud" with density along the diagonal but with a substantial fraction of off-diagonal points is visible: in 38.7 % of cases the annotators disagree by more than one tier-band.

| LP | seg.-sys. | unique segs. | systems | annot. | mean | std | spans |
|---|---|---|---|---|---|---|---|
| cs→de_DE | 600 | 30 | 21 | 10 | 79.04 | 18.58 | yes |
| en→cs_CZ | 1,050 | 53 | 20 | 11 | 76.86 | 15.97 | yes |
| en→es | 600 | 102 | 14 | 1–14† | 90.67 | 14.37 | no |
| en→et_EE | 600 | 33 | 19 | 8 | 54.72 | 21.87 | yes |
| en→ru_RU | 600 | 33 | 19 | 5 | 75.25 | 20.08 | yes |
| **Total** | **3,450** | **251** | **40** | **34** | **75.51** | **21.08** | **2,850** |

Table 9: Dataset composition by language pair. The unique-source-text counts reflect our 3,450-segment slice after filtering and stratification; the full WMT25 corpus contains substantially more unique segments. The "annot." column gives the number of unique individual annotators per LP. † en→es uses a different annotation protocol: 1–14 annotations per segment (mean $\approx 4.25$, median $= 1$; 153 segments with 10 annotations, 45 with 8, 20 with 5 etc.), aggregated into a single mean score without preserving individual annotator identifiers.

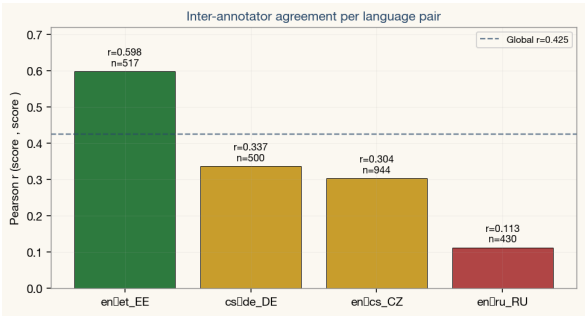

Figure 3: Inter-annotator Pearson $r$ per language pair. Green bars—$r \geq 0.4$ (acceptable agreement), yellow—borderline, red—$r < 0.25$ (essentially noise). The dashed line marks the global $r = 0.425$. The five-fold gap between en→et ($r = 0.598$) and en→ru ($r = 0.113$) reflects different semantic difficulty across LPs and annotator subjectivity.

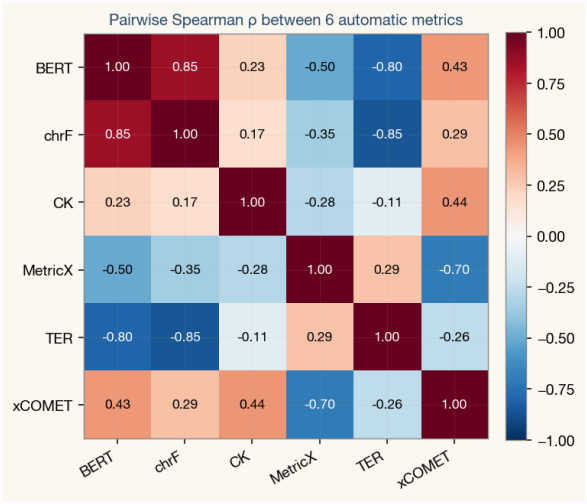

Figure 4: Pairwise Spearman $\rho$ between the six automatic metrics on $n = 3{,}450$. Three collinear clusters are visible: the surface family (BERT/chrF/TER) with $|\rho| \geq 0.80$; the neural family (MetricX/xCOMET) with $|\rho| = 0.70$; and the outlier COMETKiwi with near-zero connections to the surface family.

$= 5.69$, xCOMET $= 0.465$, chrF $= 62.2$.

- **Source:** …vázaných na horninu zvanou **hadec** jako **kuřička Smejkalova** nebo houba zvaná **kuřátka nežná** …
- **System:** …an den **Schlangenstein** gebundener Arten wie der **Smejkal-Schlangenkornblume** oder des Pilzes **Kuřátka nežná** …
- **Reference:** …an das Gestein **Serpentinit** gebunden sind – wie **Mieren** oder der Pilz **Zierliche Koralle** …

The translation contains four terminology errors at once: *hadec* (a mineralogy term, "serpentinite") is rendered as *Schlangenstein* (a literal calque); *kuřička Smejkalova* (a plant species, "Smejkal's mouse-ear chickweed") is rendered as the non-existent *Smejkal-Schlangenkornblume*; and *kuřátka nežná* (a mushroom species) is left untranslated. Annotator 1 marked four major spans and one minor and gave **7**, capturing a severe terminology failure. Annotator 2 marked one minor (the same terminology error by localisation) and gave **95**, evidently lacking the domain knowledge to evaluate mineralogical and botanical accuracy. MetricX-XXL $= 5.69$ (above our has-major threshold $= 4.79$) correctly signals the presence of a major error—that is, the automatic metric is *more accurate* in recognising the defect than the second annotator. The case illustrates **domain-expertise asymmetry** as a source of noise.

**Case 3—en→cs, literary, system GemTrans.** Score: $s_1 = 93$, $s_2 = 9$, $|\Delta| = 84$. MetricX-XXL $= 2.62$, xCOMET $= 0.811$, chrF $= 49.2$.

- **Source:** Kyle cleared his throat and **leaned back**, his expression softening …

- **System:** Kyle si odkašlal a **opřel se zpět**, jeho výraz se zmírnil … (literal)
- **Reference:** Kyle si odkašlal a **zhoupnul se v židli**. Jeho výraz se uvolnil … (idiomatic)

Annotator 1 found no errors and gave **93**; both MetricX-XXL (2.62) and xCOMET (0.811) agree—the translation is good. Annotator 2 marked six spans (two major, four minor) and gave **9**. Analysis of the spans shows that this annotator penalises **literal vs. creative translation**: "leaned back" rendered as a normative literal translation is judged as major; paraphrasing instead of literal transfer of conversational interjections is judged as minor. This class of disagreement is **stylistic purism of a single annotator** not backed by an objective translation defect—here it is not the metric that penalises creative translation but the human, diverging from both automatic metrics and the second annotator.

The three cases represent three qualitatively different sources of disagreement—stylistic strictness, domain-expertise asymmetry, and literal vs. creative translation—and confirm that a substantial share of disagreements does not reduce to "one is right, the other is wrong".

**Where the composite and MetricX disagree.** The two cases below come from the disagreement set of §3.5: the top 5 % of segments by $|\text{F7} - \text{MetricX}|$ after linear calibration of both to the human scale. Case 4 is the frequent pattern (the composite *raises* a segment MetricX punishes and is right); Case 5 the coin-flip pattern (the composite *lowers* one and is wrong).

**Case 4—en→ru, news, system Claude-4.** Human 93.5 ($s_1 = 93$, $s_2 = 94$; one minor span each). MetricX-XXL = 15.1 (top 1 % of the corpus: only 30 of 3,450 segments score higher), so mx_lin = 39.5; xCOMET = 0.41 (bottom 5 %); BERTScore = 0.78 (near the corpus median). F7 = 51.4 vs. MetricX-alone 39.5.

- **Source:** …forming a crucial **second-wicket stand** of 93 runs …He reached his **half-century** off 68 balls …his maiden **century** in 128 deliveries with the help of six **boundaries** and two sixes.
- **System:** …решающее партнерство **второй калитки** на 93 рана ...своего **полувека** с 68 мячей ...первого **века** за 128 подач с помощью шести **границ** и двух шестерок (cricket terms rendered literally)
- **Reference:** …критически важный результат **у ворот** в 93 партиях ...своего **серединного этапа** за 68 мячей ...первой **сотне** в 128 подач с помощью шести **пограничных** и двух шестерок

A cricket report, a domain with no settled Russian terminology. The system renders *half-century*, *century* and *boundaries* literally; the reference paraphrases them differently and is itself non-idiomatic (серединный этап for *half-century*). Both annotators read a fluent, complete translation and marked one minor span each. The two learned metrics, both reading the hypothesis against this reference, treat the divergence as severe error; BERTScore still credits the shared names, numbers and sentence structure and pulls the composite 12 points closer to the human score. The composite does not repair the failure—both scores are far below 93.5—but it caps the damage a single metric can do, which is the mechanism behind the 69 % figure for "F7 raises" segments.

**Case 5—en→ru, literary, system Yandex.** Human 100 ($s_1 = s_2 = 100$, no spans). MetricX-XXL = 2.77 (mx_lin = 88.9; below the corpus median of 4.69); xCOMET = 0.52 (bottom fifth of the corpus); BERTScore = 0.80 (corpus median). F7 = 75.3 vs. MetricX-alone 88.9.

- **Source:** He shifted his bag higher on his shoulder, drawn toward **the rink** like muscle memory. …"I'm Declan. **Declan Hull**."
- **System:** Он поправил сумку на плече и, повинуясь мышечной памяти, направился **к катку**. ...— Меня зовут Деклан. **Деклан Халл**.
- **Reference:** Он поправил сумку на плече, инстинктивно направляясь **к хоккейной площадке**. ...— Я Деклан. **Деклан Холл**.

A fluent, faithful literary rendering that both annotators scored 100 without a single span. It diverges from the reference at almost every content word (каток vs. хоккейная площадка, Халл vs. Холл, колледж Святого Кассиана vs. школа), and the reference itself opens a narrative sentence with a stray dialogue dash. MetricX-XXL is nearly right; xCOMET, scoring the same divergence, is in

the bottom fifth of the corpus and pulls the composite down by 13.6 points. This is the coin-flip side of the asymmetry: when the composite lowers a segment relative to MetricX, it is as often penalising legitimate paraphrase as catching an error.

## E The exponential F7 variant

The main text uses the linear MetricX-XXL normalisation mx_lin throughout. Here we report the equal-billing exponential alternative

$$\text{mx\_exp} = e^{-\text{MetricX-XXL}/3} \cdot 100,$$

together with its rationale and its performance inside F7.

**Rationale.** The mx_exp form applies a non-linear penalty: segments with few errors (MetricX-XXL $\approx$ 0–2) map to the upper range $[51, 100]$, mid-error segments (5–10) drop sharply to $[4, 19]$, high-error segments ($>$ 12) effectively to zero. This reflects the **non-linear nature of perceived quality**: the gap between "almost flawless" and "minor errors" is qualitatively smaller than the gap between "minor errors" and "many errors". The constant $\tau = 3$ is chosen so that a median "acceptable" translation (MetricX-XXL $\approx 2$) gets a score $\approx 51$—at the lower edge of the Medium tier. Advantages: (1) *perception-aligned*—the progressive penalty matches the reading experience; (2) *discriminative on the low end*—bad segments map reliably into the Bad zone. Disadvantages: (1) compression at the top of the scale (mx_exp $\in [80, 100]$ corresponds to MetricX-XXL $\in [0, 0.67]$, a narrow band in which excellent and good translations are hard to separate); (2) high MAE when combined linearly with metrics that have a different central tendency.

**Empirical comparison of lin vs. exp at the single-metric level.** Before plugging the normalised metric into the composite AQI it is worth checking that the normalisation itself does not throw away the signal already present in raw MetricX-XXL against the human score. The anchor is the correlation of the negated raw MetricX-XXL with the human score.

| Form | Pearson | Spearman | Tier 85/60 |
|---|---|---|---|
| $-$mx (anchor) | 0.4500 | 0.4851 | — |
| **mx_lin** | **0.4500** | **0.4851** | **50.0%** |
| mx_exp($\tau = 3$) | 0.4383 | 0.4851 | 23.2% |

Table 10: Single-metric MetricX-XXL normalisations against the human score, $n = 3{,}450$. Sanity check before plugging into the composite AQI.

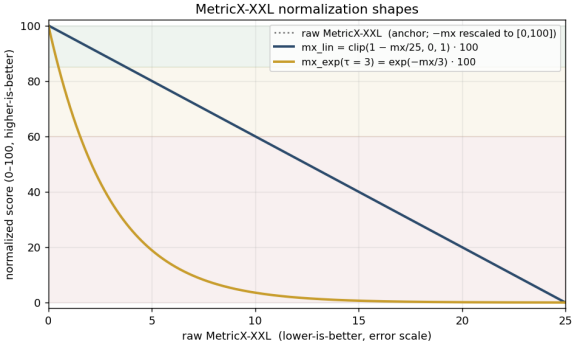

Figure 5: Three MetricX-XXL normalisation curves on $x \in [0, 25]$, $y \in [0, 100]$. Dashed grey—raw MetricX-XXL shown as an affine remap so that it shares the $y$ axis with the two normalised forms (it coincides with mx_lin). Blue—mx_lin. Yellow—mx_exp($\tau = 3$). Bands mark tier zones (red $< 60$, yellow 60–85, green $\geq 85$).

- **Spearman is identical** across the three forms (0.4851). Spearman is computed on ranks, and any monotone function preserves the order of observations.
- **Pearson under mx_lin equals the anchor exactly** (0.4500). mx_lin is an affine transform of raw MetricX-XXL, and Pearson is invariant under affine transforms.
- **Pearson under mx_exp($\tau = 3$) is 0.012 lower** (0.4383). The relationship (mx_exp, human) becomes non-linear, and Pearson—a measure of linearity—drops.
- **Tier-agreement** under mx_exp is dramatically worse (23.2% vs. 50.0%): the curve $e^{-\text{mx}/3}$ compresses most segments into the lower part of the scale, and most of them fall into the Bad zone under the 60/85 tier boundaries.

We also tried non-linear normalisations with more free parameters (a $\tau$ sweep for exp; a 2-parameter sigmoid; a 4-parameter piecewise-linear), fitting them under 5-fold CV. None gave a meaningful Pearson gain over mx_lin under honest cross-validated evaluation: exp catches up with linear only at large $\tau$, at which the shape is already visually close to a straight line, and sigmoid and piecewise add free parameters without robust

improvement.

**F7-exp inside the composite.** Substituting mx_exp for mx_lin in F7 (Eq. 2) gives

$$\begin{aligned}\text{AQI}_{\text{exp}} = 0.40 \cdot e^{-\text{MetricX}/3} \cdot 100 \\ + 0.30 \cdot \text{xCOMET} \cdot 100 \\ + 0.30 \cdot \text{BERTScore} \cdot 100.\end{aligned}$$

On ranking and linear correlation F7-exp is almost indistinguishable from F7-linear (Spearman $+0.506$ vs. $+0.505$; Pearson $+0.476$ vs. $+0.483$), but its compressed scale pushes most segments into the Bad zone under the 60/85 thresholds, so tier-agreement is far worse (29.4% vs. 46.5%) and MAE much higher (24.33 vs. 14.55) without calibration. Per-LP offsets for F7-exp are all positive (mostly compensating for the compression): cs→de $+20.24$, en→cs $+25.61$, en→es $+28.74$, en→et $+6.63$, en→ru $+19.73$; with them F7-exp reaches Pearson $+0.596$, tier 53.0%, MAE 13.86—converging to the same tier-agreement as F7-linear+LP. Folding in a human score (§4) uses the identical $\alpha = 0.30$ blend; the exp form is identical to the linear hybrid except for the MetricX normalisation.

**Ridge coefficients.** The unconstrained Ridge regression of §3.4.3 ($\alpha = 1$, standardised features) has coefficients

```
AQI_Ridge = +10.86
          + 0.58 * mx_lin     + 0.24 * xc100
          + 0.11 * bert100    + 0.09 * chrf100
          + 0.07 * ter_inv100 - 0.20 * ck100
```

The negative ck100 weight is the suppressor effect; Ridge-5 drops it and recovers all-positive coefficients within $\approx 0.01$ Pearson of the 6-metric fit.

## F Geometric-mean composites

Table 11 reports the Geo family discussed in §3.5: Geo3 is the geometric mean of the three normalised F7 candidates; Geo4 and Geo5 add further metrics, Geo5 including TER and chrF.

## G Scatter plots for the formula variants

Figure 6 is the 5-fold-CV scatter for the headline F7-linear formula; Figures 7–9 give the same for the non-finalist variants discussed in §3.5.

## H Neural text-encoder experiments

We also tried full-blown neural regressors consuming src/ref/tgt text directly—a late-fusion MLP, a ResMLP cross-encoder, and an extended version with error-span features. The last reached a high test $\rho \approx 0.80$, but is disqualified due to **label leakage**: error-span features were extracted from the same ESA span annotations from which the target is built. None of the three fit the "formula on metric outputs, not on text" requirement and they do not compete with F7 as a closed-form composite.

| Formula | Pearson | Spear. | Tier | MAE |
|---|---|---|---|---|
| AQI-Geo3 | +0.492 | +0.507 | 28.3% | 28.32 |
| AQI-Geo3 + LP | +0.579 | +0.583 | 54.8% | 14.65 |
| AQI-Geo4 | +0.495 | +0.520 | 27.3% | 27.37 |
| AQI-Geo4 + LP | +0.592 | +0.601 | 54.6% | 14.22 |
| AQI-Geo5 | +0.178 | +0.517 | 24.3% | 67.69 |

Table 11: Reference-based geometric composites. Geo3 and Geo4 are competitive with F7 on Pearson but, without calibration, lose heavily on tier-agreement (28%) due to a compressed distribution. Geo5 with TER and chrF breaks down ($\rho = 0.178$): weak metrics pull the geometric mean down.

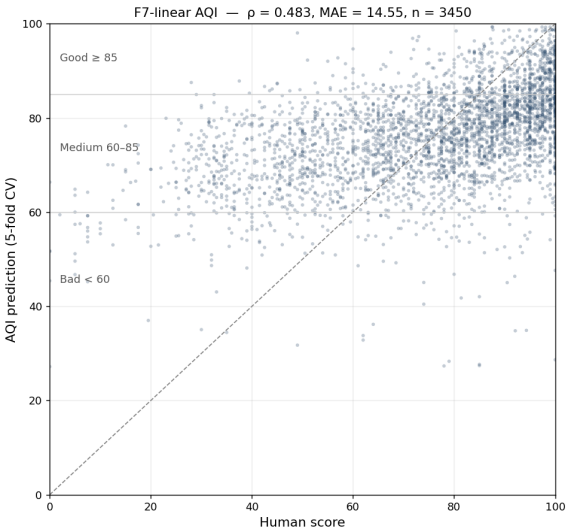

Figure 6: F7-linear AQI vs. human score, 5-fold CV. $\rho = 0.483$, MAE 14.55.

## I AQI interpretation scale

The explicit deployment interpretation scale for the uncalibrated F7-linear index referenced in §5.2 is given in Table 13 at the end of the paper.

## J Normalisation of the five rescaled metrics

The five metrics other than MetricX-XXL (§2.4) are mapped to $[0, 100]$ higher-is-better by rescaling and, for TER, inversion:

```
xc100     = xCOMET-XXL    * 100
bert100   = BERTScore F1  * 100
chrf100   = chrF
```

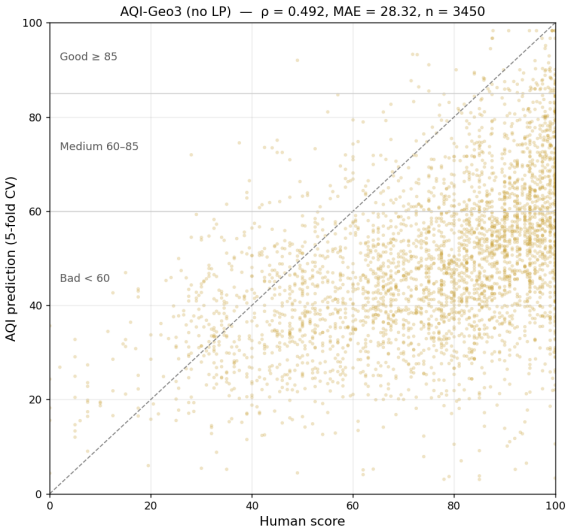

Figure 7: AQI-Geo3 (no LP), 5-fold CV. $\rho = 0.492$, MAE 28.32. Pearson slightly above F7-linear, but the distribution is heavily compressed into the lower band—hence the large MAE and poor tier-agreement without calibration.

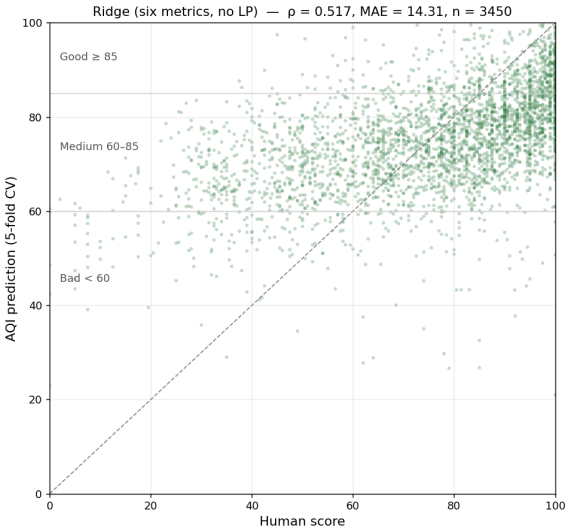

Figure 8: Ridge on six metrics (no LP), 5-fold CV. $\rho = 0.517$, MAE 14.31. Slightly above F7-linear on Pearson, but with a negative COMETKiwi weight (§3.4.3).

| Domain | $n$ | F7 | MetricX | Refit $w$ | Refit $\rho$ |
|---|---|---|---|---|---|
| All | 3,450 | 0.483 | 0.450 | (0.45, 0.15, 0.40) | 0.490 |
| literary | 1,444 | 0.572 | 0.579 | (0.60, 0.05, 0.35) | 0.603 |
| news | 1,406 | 0.426 | 0.458 | (0.90, 0.10, 0.00) | 0.462 |

Table 12: Pearson $\rho$ with the human score by domain. F7 uses the fixed weights $(0.40, 0.30, 0.30)$; "Refit" $\boldsymbol{w} = (w_{\text{mx}}, w_{\text{xc}}, w_{\text{bert}})$ is the best point of the same 0.05-step simplex grid fitted *in-sample* on that domain, an optimistic upper bound. Cross-domain transfer: literary weights applied to news give $\rho = 0.441$, news weights applied to literary $\rho = 0.583$. Low-quality tail (human $< 60$): F7 vs. MetricX 0.338 vs. 0.297 on literary, 0.276 vs. 0.282 on news. en→es carries no domain label and is excluded.

```
ter_inv100 = clip(1 - TER/100, 0, 1) * 100
ck100      = COMETKiwi-XXL * 100
```

## K Per-domain behaviour

Table 12 gives the per-domain figures behind the "Domain dependence" paragraph of §3.7: F7 with the fixed weights, MetricX-alone, and an in-sample refit of the three weights on each domain, together with cross-domain transfer and low-quality-tail correlations in the caption. The script and CSV are in the repository.

## L Future work

(i) **QE-only AQI** for zero-shot reference-free deployment—a separate study dedicated to QE metrics. (ii) **Per-domain calibration** instead of per-LP only, especially for production scenarios with a known domain (legal, medical, marketing). (iii) A **continual learning** protocol: automatic recalibration of the formula on a rotating held-out corpus on each new MetricX-XXL/xCOMET release.

| AQI range | Category | Description | Recommended action |
|---|---|---|---|
| $\geq 83$ | Good | **Near-human quality; fluency and adequacy are strong.** This reflects translations that meet near-human quality levels. Little intervention is needed. | Minimal post-editing / review |
| 75–83 | Acceptable | **Good fluency, minor errors; meaning is mostly preserved.** This range reflects translations that are good enough for practical use, especially in low-risk scenarios. They likely require some linguistic refinement, but the core meaning is there, making light post-editing efficient. | Light to moderate post-editing |
| 68–75 | Medium | **Understandable but contains noticeable issues.** At this level the translation is functional but likely requires a decent amount of intervention to correct grammar, syntax, or terminology. | Moderate post-editing needed to improve fluency |
| 60–68 | Low | **Translation is usable with effort; lacks fluency / adequacy.** The output is typically flawed enough that it would need substantial post-editing. Can serve as a rough draft for human editors. | Heavy post-editing required |
| $< 60$ | Poor | **Unusable or unintelligible translation.** The translation is far enough from acceptable quality that it is not worth post-editing. It is also an indicator that the engine may need re-tuning or re-training for this language pair or content type. | Reject or re-translate; possibly engine tuning |

Table 13: AQI interpretation scale for the uncalibrated **F7-linear** index. Breakpoints $60/68/75/83$ are chosen so that the mean human score of the segments in each band ($\approx 88, 79, 70, 61, 53$ from Good to Poor on $n = 3{,}450$) matches the label; band shares are $25.3/33.1/23.1/13.4/5.0\%$. The same labels carry over to the F7+LP variant on its recentred scale (§3.7). For a new LP or domain outside the studied slice, recalibrate the breakpoints.

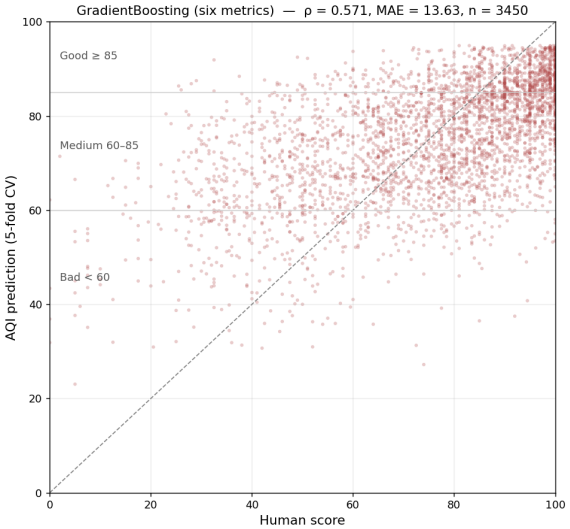

Figure 9: GradientBoosting on six metrics (no LP), 5-fold CV. $\rho = 0.571$, MAE 13.63—the ML ceiling on this feature set. Not a closed-form formula.

# Mind Which Bird You Favour: Parameterizing Adequacy–Fluency Balance in Meta-Evaluation of Machine Translation

**Behzad Shayegh and Niloofar Kazemi**
Independent Researchers

## Abstract

There is a tradeoff in machine translation meta-evaluation between prioritizing alignment with adequacy versus fluency. The balance depends on the combination of translation systems in the meta-evaluation dataset. This system set is a small, filtered sample whose characteristics change heavily across years and language pairs; it does not represent the true system distribution. Consequently, the adequacy–fluency balance is often unrepresentative and subject to change. For sensitive domains, controlling this balance is critical. We expose this balance as a tunable choice. To achieve a target balance, we reweight existing systems while minimizing distortion from uniform weighting, ensuring the evaluated systems remain real and representative. We provide an exact optimization algorithm with theoretical guarantees and pruning mechanisms to compute these weights. To validate meta-evaluation internal consistency, we design a scorer-augmentation framework that establishes a known relative identity for the scorers. Results demonstrate that our reweighting method effectively controls the adequacy–fluency balance and preserves the internal consistency, outperforming prior approaches. Finally, we analyze the performance of popular scorers across a sweep of this parameter.[1]

## 1 Introduction

Machine translation (MT) is typically judged by automatic metrics, which we refer to as *scorers*.[2] Deciding which scorer to trust is itself an evaluation problem known as *meta-evaluation* (Callison-Burch et al., 2007). Concretely, meta-evaluation fixes a set of translation systems and scores them once with a human protocol taken as the ground truth (Multidimensional Quality Metrics, MQM; Freitag et al., 2021a), and once with the scorer under evaluation. It then asks how well the scorer's system ranking agrees with that of the human, as measured by a *meta-metric* such as pairwise accuracy (PA; Kocmi et al., 2021) or soft pairwise accuracy (SPA; Thompson et al., 2024). The WMT metrics shared task (Freitag et al., 2023) performs this meta-evaluation every year, and it sits at the top of the MT stack: it identifies the best scorers, which subsequent research adopts and reports, in turn shaping the next generation of MT systems. Both the scorers and the MT systems therefore silently inherit whatever bias the meta-evaluation imposes.

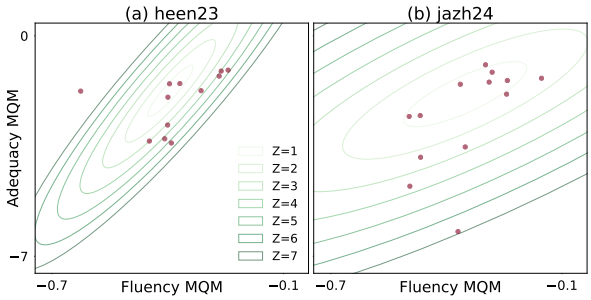

Figure 1: System-level Adequacy vs. Fluency MQM for (a) heen23 and (b) jazh24 WMT datasets. Each dot is an MT system. Green contours are robust Mahalanobis-distance levels (Gnanadesikan and Kettenring, 1972).

The MQM ground truth is a multi-component quantity (Freitag et al., 2021a). A translation is penalized both for adequacy errors (failing to convey the meaning of the source) and for fluency errors (being ungrammatical or unnatural). Flamich et al. (2025) show that these two aspects trade off against each other, and Shayegh et al. (2025) show that the tradeoff reaches the meta-evaluation level: the overall human ranking is dominated by whichever aspect varies more across the systems being compared, so the scorers judged best are those aligned with that aspect. In other words, if the systems differ mostly in adequacy, human rankings will be

*Correspondence to: the.shayegh@gmail.com

[1]Code available at https://github.com/TheShayegh/adequacy-fluency-param

[2]We use the term "scorer" instead of "metric" to avoid ambiguity with meta-metrics.

*Proceedings of the Eleventh Conference on Machine Translation*, pages 673–697
October 28-29, 2026 ©2026 Association for Computational Linguistics

driven primarily by adequacy as well; consequently, metrics sensitive to adequacy will perform better in the meta-evaluation. Crucially, this lean is heavily driven by system selection (Shayegh et al., 2025).

This is especially concerning because the included systems are a small, filtered subset, thus likely a biased sample of the true, unknown distribution. Figure 1 shows that the lean differs substantially across WMT datasets. Consequently, meta-evaluation produces uncontrolled scorer rankings, risking the endorsement of undesired scorers that misdirect future model development. This motivates the need for an explicit control mechanism.

Shayegh et al. (2025) attempt to address this problem through the lens of "debiasing." They frame system-selection imbalance as undesirable extrinsic bias and introduce a system-synthesis method to reduce it. However, not all system-selection imbalance is undesirable; only its deviation from the true system distribution is. As the true distribution remains unknown, this attribute is unmeasurable, leading us to abandon debiasing in favor of control. Furthermore, we show that the system synthesis produces unrepresentative systems, yielding a distorted meta-evaluation.

In this work, we expose the previously uncontrolled adequacy–fluency balance as a deliberate, tunable choice. Specifically, we parameterize the evaluation pool using the ratio of weighted marginal variances of adequacy and fluency, a parameter we name $\beta$. We treat the systems in the MQM data as a biased sample and reweight them to achieve a target $\beta$ while minimizing distortion from uniform weighting. Because this reweighting is applied at the system level, the evaluated systems remain real and representative, preserving the meta-evaluation's original characteristics. This approach is an instance of importance sampling (Tokdar and Kass, 2010) with minimal weight distortion (Deville and Särndal, 1992).

The reweighting is a nontrivial optimization problem, for which we design an exact algorithm, pruning mechanisms that improve efficiency, and certificates that verify optimality. We prove the soundness and completeness of the algorithm, pruning mechanisms, and certificates, and provide an empirical computational-cost analysis.

Validating meta-evaluation is challenging without a ground truth. To address this, we introduce a scorer-augmentation framework that injects controlled signals into real base scorers, preserving the inherent statistical signatures of real scorers while providing known *relative identity*. Using these augmented scorers, we assess a meta-evaluation's (1) adequacy-over-fluency preference, (2) MQM adherence, and (3) explainability by MQM. The latter measures noise avoidance while retaining the natural scorer–MQM relationship. Our reweighting method effectively controls the first measure while preserving the other two, outperforming Shayegh et al. (2025)'s synthesis method.

Finally, we report and analyze the meta-evaluation scores of popular scorers, including different variants of xCOMET (Guerreiro et al., 2024) and MetricX (Juraska et al., 2024), across a sweep of the exposed balance parameter $\beta$.

In summary, we: (1) formulate the adequacy–fluency balance of MT meta-evaluation as a tunable parameter; (2) provide an exact algorithm that controls this parameter by importance-weighting the systems in the meta-evaluation, minimizing the distortion from uniform weighting so as to maximally preserve the meta-evaluation's other characteristics; and (3) propose a controlled scorer-augmentation method to assess a meta-evaluation's adequacy-over-fluency preference, MQM adherence, and explainability by MQM.

## 2 Background and Related Work

### 2.1 Meta-Evaluation

A translation scorer is evaluated through meta-evaluation, which measures its agreement with human annotations across a fixed pool of translation systems (Callison-Burch et al., 2007). Expert error annotation under Multidimensional Quality Metrics (MQM; Mariana et al., 2015) has been established as the standard ground truth for the WMT metrics shared task (Freitag et al., 2021a, 2023; Kocmi and Federmann, 2023; Kocmi et al., 2025). Our work focuses on MQM-based meta-evaluation following recent standards.

**Meta-metrics.** While scorer–human agreement was traditionally measured via Pearson (Macháček and Bojar, 2013, 2014), Mathur et al. (2020) demonstrate that such a correlation is highly sensitive to outlier systems in the evaluation pool. To address this, Kocmi et al. (2021) introduce pairwise accuracy (PA), which measures the fraction of system pairs whose human ordering is correctly reproduced. To overcome PA's coarse resolution and tie-handling limitations at the segment level (Deutsch et al., 2023), Thompson et al. (2024)

develop soft pairwise accuracy (SPA), which replaces PA's hard binary comparisons with a continuous measure based on statistical significance. SPA serves as the official system-level meta-metric of WMT24 (Freitag et al., 2024). We follow the line of research and focus on SPA as our main metric. We additionally report results for Pearson correlation in Appendix F.

**Meta-evaluation analysis.** Recent work critically examines meta-evaluation protocols, studying annotation stability (Knowles, 2021), budget allocation (Riley et al., 2024), test-set item selection (Zouhar et al., 2025), and baseline sensitivity via degenerate sentinel metrics (Perrella et al., 2024). These studies treat pool-induced variation as noise or bias to be detected. Our work treats one special axis of that variation, the adequacy–fluency balance, as a tunable quantity that a practitioner should be able to explicitly configure.

### 2.2 Adequacy and Fluency

The distinction between translation adequacy and fluency originates in early evaluation campaigns (White et al., 1994) before being largely collapsed into error-weighted penalties (Lommel et al., 2014). Information-theoretic analyses prove that adequacy and fluency genuinely trade off, making a single scalar summary insufficient (Flamich et al., 2025). Moreover, fluency impacts downstream user trust independently of adequacy (Martindale and Carpuat, 2018). This trade-off extends to the meta-evaluation level: meta-evaluation inherits the pool's lean, favoring adequacy-oriented scorers in recent WMT MQM datasets due to skewed system selection (Shayegh et al., 2025).

We propose a principled parameterization for the adequacy–fluency balance in meta-evaluation, accompanied by a reweighting mechanism to achieve any target balance precisely.

## 3 Approach

We control the adequacy–fluency balance by reweighting systems while explicitly minimizing the collision probability of the assigned weights. Practically, this keeps the meta-evaluation close to the natural dataset distribution and prevents over-indexing a handful of systems.

To control the adequacy–fluency balance, we need a reference for the two terms. MQM annotations provide fine-grained error categories. We follow Flamich et al. (2025) and group these into adequacy and fluency subsets, and compute Adequacy MQM and Fluency MQM at the system level accordingly. Their sum, Total MQM, is the meta-evaluation ground truth.[3]

### 3.1 The Balance Parameter

A meta-evaluation dataset fixes $K$ translation systems. Write $a{=}(a_1, \cdots, a_K)$ and $f{=}(f_1, \cdots, f_K)$ for their system-level Adequacy MQM and Fluency MQM, so that system $k$ is the point $(a_k, f_k)$ and Total MQM is $t{=}a{+}f$. We assign each system $k$ a weight $w_k$, with $w{=}(w_1, \ldots, w_K)$ normalized so that $\sum_k w_k = \mathbf{1}^\top w = 1$ and $w_k \geq 0$. Reweighting acts on these $K$ weights, so every system in the meta-evaluation remains real; the distribution of systems, which is likely biased, changes.

Let $\Sigma(w) = \mathrm{diag}(w){-}ww^\top$. We have weighted mean and variance of scores $a$ as

$$\mu(a; w) = w^\top a \tag{1}$$

$$\begin{aligned}\sigma(a; w)^2 &= a^\top \Sigma(w)\, a \\ &= \textstyle\sum_k w_k a_k^2 - \mu(a; w)^2\end{aligned} \tag{2}$$

respectively, and likewise for $f$. We also have $a{-}f$ weighted covariance:

$$\Sigma(a, f; w) = a^\top \Sigma(w)\, f \tag{3}$$

Setting $w$ to the uniform weighting $\frac{1}{K}\mathbf{1}$ recovers the unweighted sample mean and variance:

$$\mu(a) = \mu(a; \tfrac{1}{K}\mathbf{1}); \quad \sigma(a)^2 = \sigma(a; \tfrac{1}{K}\mathbf{1})^2 \tag{4}$$

We assume throughout that no two systems share the same $(a_k, f_k)$; such pairs can be seen as one system in the weighting pool, with the assigned weight uniformly distributed among them.

We define the balance parameter[4]

$$\beta(w) = \frac{\sigma(a; w)^2}{\sigma(a; w)^2 + \sigma(f; w)^2} \in [0, 1] \tag{*}$$

We specifically name the natural balance of the dataset $\beta_0 = \beta(\frac{1}{K}\mathbf{1})$.

Typically, $a$ and $f$ are partially correlated, thus Total MQM's variance decomposes as $\sigma(t; w)^2 = \sigma(a; w)^2 + \sigma(f; w)^2 + 2\,\boldsymbol{\Sigma(a, f; w)}$. Our $\beta$ uses only the two marginal terms and leaves the cross term $\Sigma(a, f; w)$ out: $\beta$ answers how much adequacy's spread contributes relative to fluency's. In the next part, we show how meta-evaluation responds to this marginal quantity.

[3] Following Shayegh et al. (2025), we exclude rare errors that fall outside the two categories. The effect is negligible.

[4] An equally valid choice for the balance parameter is $\beta_{\text{std}} = \sigma(a; w)/(\sigma(a; w) + \sigma(f; w))$, which is a monotonic reparametrization $\beta_{\text{std}} = (1 + \sqrt{\beta^{-1} - 1})^{-1}$.

### 3.2 Meta-Evaluation's Response to $\beta$

A meta-metric typically judges scorers by aggregating agreement with the human ranking across system pairs. Therefore, meta-evaluation's lean towards adequacy or fluency is mainly driven by how much each component's gaps vary across the system pairs. We show next that this pairwise-gap variance is equal to the row-level variance, licensing its control through $\beta$.

**Proposition 1.** *For any vector* $x=(x_1,\dots,x_K)$ *and weights* $w=(w_1,\dots,w_K)$ *with* $\mathbf{1}^\top w = 1$

$$\sum_{k<k'} w_k w_{k'} (x_k - x_{k'})^2 \;=\; \sigma(x;w)^2 \tag{5}$$

*Proof.*

$$\begin{aligned}
&\sum_{k,k'} w_k w_{k'} (x_k - x_{k'})^2 \\
&\quad = \sum_{k,k'} w_k w_{k'} \big(x_k^2 - 2x_k x_{k'} + x_{k'}^2\big) \\
&\quad = 2\sum_{k} w_k x_k^2 - 2\Big(\sum_{k} w_k x_k\Big)^2 \\
&\quad = 2\,\sigma(x;w)^2
\end{aligned} \tag{6}$$

The summand $w_k w_{k'}(x_k - x_{k'})^2$ is symmetric under $k \leftrightarrow k'$ and vanishes when $k=k'$, so splitting the sum by $k<k'$ gives $2\sum_{k<k'} w_k w_{k'}(x_k - x_{k'})^2$. Dividing (6) by 2 gives the claim. □

Proposition 1 lets us read the row-level variance $\sigma(x;w)^2$ as a pairwise quantity. Now let $q$ be the mean-squared pairwise gap

$$q(x;w) = \frac{\sum_{k<k'} w_k w_{k'} (x_k - x_{k'})^2}{\sum_{k<k'} w_k w_{k'}} \tag{7}$$

By Proposition 1, the numerator in (7) is $\sigma(x;w)^2$ and the denominator is $x$-independent. Therefore

$$\frac{q(a;w)}{q(a;w)+q(f;w)} = \frac{\sigma(a;w)^2}{\sigma(a;w)^2+\sigma(f;w)^2} = \beta(w) \tag{8}$$

In other words, $\beta$ is the balance of mean-squared pairwise gaps, and controlling $\beta$ effectively drives the meta-evaluation's lean.

### 3.3 Weighted Soft Pairwise Accuracy

Because SPA is our primary meta-metric, we explicitly define its weighted form. For every system pair $(k,k')$, SPA compares the confidence that $k$ outranks $k'$ under human judgments against the confidence under a given scorer. This confidence is estimated via paired-permutation $p$-values, $p^H_{kk'}$ and $p^m_{kk'}$, the latter for scorer $m$; neither depends on $w$. Classical SPA averages the absolute gap between these $p$-values uniformly over all $\binom{K}{2}$ pairs. Weighting systems by $w$ assigns a weight of $w_k w_{k'}$ to each pair. Normalizing these weights yields

$$\pi_{kk'} = \frac{w_k w_{k'}}{\sum_{l<l'} w_l w_{l'}} \quad ; \quad \sum_{k<k'} \pi_{kk'} = 1 \tag{9}$$

which defines the weighted meta-metric

$$\mathrm{SPA}(m;w) = 1 - \sum_{k<k'} \pi_{kk'} \left| p^H_{kk'} - p^m_{kk'} \right| \tag{10}$$

Uniform weighting yields $\pi_{kk'} = \binom{K}{2}^{-1}$, recovering classical SPA.

### 3.4 Reweighting as an Optimization Problem

Among all weight vectors $w$ that can realize a given target $\hat\beta$, we find the one closest to uniform: it disturbs the natural view least beyond what $\hat\beta$ requires, preserving most about the meta-evaluation.

We measure distance from uniform by collision probability $\mathrm{P}_{\mathrm{collis}}(w) = \sum_k w_k^2 = w^\top w$. Minimizing this distance directly maximizes effective sample size $\mathrm{ESS}(w) = \mathrm{P}_{\mathrm{collis}}(w)^{-1}$, a standard diagnostic for weight concentration. In our work, we report $\mathrm{ESS}(w)/K$ to quantify how broadly the weights are distributed, with $K$ being the size of the original system set.

Writing the balance target as a constraint

$$b(w,\hat\beta) = (1-\hat\beta)\sigma(a;w)^2 - \hat\beta\,\sigma(f;w)^2 \tag{11}$$

so that $b(w,\hat\beta) = 0 \iff \beta(w) = \hat\beta$, we formalize the reweighting as an optimization problem:

$$\begin{aligned}
w^\star = \operatorname*{argmin}_{w} \; & \tfrac{1}{2}\,\mathrm{P}_{\mathrm{collis}}(w) \qquad (\mathcal{P}) \\
\text{s.t. } & \mathbf{1}^\top w = 1,\;\; b(w,\hat\beta) = 0,\;\; w_k \geq 0
\end{aligned}$$

**Reachable range.** For two systems $k, k'$, write

$$\beta_{kk'} = \frac{(a_k - a_{k'})^2}{(a_k - a_{k'})^2 + (f_k - f_{k'})^2} \tag{12}$$

and let $\beta_{\min}$ and $\beta_{\max}$ be the smallest and largest such pairwise balance over all pairs of systems in the dataset.

**Theorem 1** (Reachable range)**.** *Problem* ($\mathcal{P}$) *is feasible for target* $\hat\beta$ *iff* $\hat\beta \in [\beta_{\min}, \beta_{\max}]$. *(Proof in Appendix A.1.)*

### 3.5 Our Algorithm

In this section, we develop and theoretically justify our solver algorithm for Problem ($\mathcal{P}$). We provide a high-level narrative for the algorithm, followed by auxiliary theorems to improve its efficiency.

Define $S(w) = \{k : w_k > 0\}$ as the support system set of $w$. Call a support $S$ *admissible* for target $\hat{\beta}$ if there exists a feasible weighting $w_S$ with support $S$ for target $\hat{\beta}$, i.e., it is non-negative and $b(w_S, \hat{\beta}) = 0$.

**Theorem 2** (Bounded candidate count)**.** *For an admissible support $S$, let*

$$\min_{w} \tfrac{1}{2}\,\mathrm{P}_{\mathrm{collis}}(w) \qquad (\mathcal{P}_S)$$
$$\text{s.t. } \mathbf{1}^\top w = 1,\ \ b(w,\hat{\beta}) = 0 \quad \textit{(no non-negativity)}$$

*be solved on $S$'s coordinates, with $w_k{=}0$ for $k{\notin}S$. Then (a) Problem ($\mathcal{P}_S$) has at most five stationary points $w_S$, each obtainable in closed form by solving a polynomial equation of degree $\leq 5$; and (b) if $w^\star$ solves ($\mathcal{P}$) and $S = S(w^\star)$, then $w^\star$ is one of these $w_S$. (Proof in Appendix A.2.)*

This gives the abstract shape of our algorithm: for every support $S$, compute its (at most five) stationary points $w_S$, discard any with a negative entry, and among everything that survives across every support, return the one of smallest $\mathrm{P}_{\mathrm{collis}}(w_S)$. Part *(b)* guarantees $w^\star$ is never missed by this process, thus our algorithm is complete.

Next, we show the enumeration can be largely pruned without losing this guarantee.

For a support $S$ with $|S|{\geq}2$, let $\beta_{\min}(S)$ and $\beta_{\max}(S)$ be the smallest and largest pairwise balance $\beta_{kk'}$ among pairs $k, k' \in S$.

**Theorem 3** (Admissible supports)**.** *If $w_S$ with support $S$ is a feasible weighting for target $\hat{\beta}$, then $\beta_{\min}(S) \leq \hat{\beta} \leq \beta_{\max}(S)$. (Proof in Appendix A.3.)*

Equivalently, a support whose pairwise balances do not bracket $\hat{\beta}$ can be safely skipped during the search.

**Theorem 4** (Support size bound)**.** *For any weighting $w$ supported on $S$, $\mathrm{P}_{\mathrm{collis}}(w) \geq 1/|S|$, with equality iff $w$ is uniform on $S$. (Proof in Appendix A.4.)*

Theorem 4 suggests that once a feasible weighting with collision probability $p$ has been found, no support of size at most $1/p$ can carry a feasible weighting of strictly smaller collision probability, and such supports may be skipped by the search. Particularly, our search process visits supports from largest to smallest, and the search stops the first time Theorem 4's pruning applies.

Theorems 3 and 4 offer complementary pruning mechanisms: each is strongest where the other is weakest. When $\hat{\beta}$ is close to the dataset's natural balance $\beta_0$, the optimum stays close to uniform and Theorem 4 prunes heavily. When $\hat{\beta}$ is close to $\beta_{\min}$ or $\beta_{\max}$, it falls out from many supports' admissible range, thus Theorem 3 prunes heavily.

**Theorem 5** (Exit certificate)**.** *Let $w$ be feasible for Problem ($\mathcal{P}$). Let $\tilde{a} = a - \mu(a)\mathbf{1}$, $\tilde{f} = f - \mu(f)\mathbf{1}$ be both nonzero, and $\rho = \frac{\tilde{a}^\top \tilde{f}}{\|\tilde{a}\|\,\|\tilde{f}\|}$ the adequacy–fluency Pearson correlation across systems. If there exist $\eta, \lambda \in \mathbb{R}$ such that*

$$k \in S(w): \quad w_k + \eta\,\frac{\partial b(w,\hat{\beta})}{\partial w_k} + \lambda = 0 \qquad \text{(i)}$$

$$k \notin S(w): \quad \lambda + \eta\,\frac{\partial b(w,\hat{\beta})}{\partial w_k} \geq 0 \qquad \text{(ii)}$$

$$I_2 + 2\eta \begin{pmatrix} \hat{\beta}\|\tilde{f}\|^2 - (1-\hat{\beta})\rho^2\|\tilde{a}\|^2, & -(1-\hat{\beta})\rho\sqrt{1-\rho^2}\,\|\tilde{a}\|^2 \\ -(1-\hat{\beta})\rho\sqrt{1-\rho^2}\,\|\tilde{a}\|^2, & -(1-\hat{\beta})(1-\rho^2)\|\tilde{a}\|^2 \end{pmatrix} \succeq 0 \qquad \text{(iii)}$$

*where $\succeq 0$ means positive semidefinite, then $w$ is a global optimum of Problem ($\mathcal{P}$). (Proof in Appendix A.5.)*

Theorem 5 grants our algorithm a short exit: the moment one stationary point on a visited support passes the three conditions, the search stops.

Algorithm 1 concludes our exact search algorithm. Theorems 1–5 guarantee the soundness and completeness of our algorithm unconditionally: pruned branches are guaranteed to not include better solutions, short exit guarantees returning the global optimum, and the algorithm guarantees to search all branches (finite) carrying a possible solution. We also cross-validated its output against brute-force exhaustive search over all supports on small system sets, where full enumeration remains tractable, and found exact agreement throughout.[5] In Appendix B, we report how much computation Theorems 3–5 save us in practice.

## 4 Experiments

In this section, we analyze the response of meta-evaluation to different leanings that scor-

[5]Theorem 2 bounds the stationary points by the roots of a degree-five polynomial, but our implementation solves the equivalent rational secular equation directly rather than rooting that polynomial, whose coefficients become badly scaled as $\theta_2 \to 0$. This and all numerical thresholds are fixed in the released code.

**Algorithm 1** Exact reweighting for target $\hat{\beta}$

**Require:** $\hat{\beta} \in [\beta_{\min}, \beta_{\max}]$ {Theorem 1}
**register** $w^\star$
**for** $S \subseteq \{1, \ldots, K\}$, $|S| \geq 2$, in decreasing order of $|S|$ **do**
  **if** $|S| \leq 1/\mathrm{P}_{\mathrm{collis}}(w^\star)$ **then**
    **break** {Theorem 4}
  **end if**
  **if** $S$ not admissible at $\hat{\beta}$ **then**
    **continue** {Theorem 3}
  **end if**
  **for** each stationary candidate $w$ on $S$ {Theorem 2a} **do**
    **if** $w$ passes the exit certificate **then**
      **return** $w$ {Theorem 5}
    **end if**
    **if** $w$ feasible and $\mathrm{P}_{\mathrm{collis}}(w) < \mathrm{P}_{\mathrm{collis}}(w^\star)$ **then**
      $w^\star \leftarrow w$ {Theorem 2b}
    **end if**
  **end for**
**end for**
**return** $w^\star$

ers may have. Specifically, we measure each meta-evaluation's adequacy-over-fluency preference, MQM adherence, and explainability by MQM. To this end, we develop a controlled testbed that reveals signals for these aspects. Then, we benchmark our reweighting mechanism on this testbed, comparing it against the unweighted meta-evaluation and the system-synthesis-based meta-evaluation of Shayegh et al. (2025).

### 4.1 Scorer Augmentation

Evaluation and analysis of scorers needs a ground truth for their true underlying character (e.g., how much of a scorer's assessment is driven by the fluency of the translation), which is not available. To obtain a replacement, we propose to augment scorers in a controlled way, so that the augmented scorers' relative identities are known by construction, even though no scorer's absolute identity is. We use this relative identity as pseudo ground truth for evaluation and analysis. Importantly, we augment real scorers, staying close to their natural biases and characteristics, except for those we control in particular.

We augment a base scorer $s_0$ in three directions, giving three families of augmented scorers, each to test a different way a meta-evaluation's preference among scorers could change. Given $a$ and $f$ being gold Adequacy MQM and Fluency MQM, the three directions are:

- MQM-adherence family: $s_0 \leftrightarrow a + f$
- Adequacy–fluency family: $s_0 \leftrightarrow a - f$
- Explainability-by-MQM family: $s_0 \leftrightarrow$ part of $s_0$ only explained by $(a, f)$

An ideal meta-evaluation should typically prefer an augmented scorer that better adheres to MQM or prefers explainability by MQM.

We realize each family with a dial $d$: a base scorer always has $d = 0$, and as $d$ increases, the augmented scorer approaches its family's target. Each value of $d$ yields a new augmented scorer whose relative identity to other members of its family is known through their relative $d$ values. Note that we allow negative $d$, i.e., going backwards in each direction.

**MQM-adherence family.** This is constructed by moving linearly towards $t = a + f$ at the system level. For segment $i$ of system $k$, and base scorer $s_0$, the augmented scorer is

$$s_d(k, i) = s_0(k, i) + \frac{d \cdot \sigma(s_0)}{\sigma(z)} z_k \qquad (13)$$

where $z$ is the system-level $z$-score of $t$, and $\sigma$ is standard deviation across systems. In simple words, we move towards $z$ in steps of $d \times s_0$'s scale.[6]

The above construction conserves characteristics of real scorers: the two ends of the direction ($d = 0$ and $d \to \infty$) are the base scorer itself and the MQM ground truth, both considered valid scorers. Moreover, for every finite $d$, the augmented scorer preserves the base scorer's own system- and segment-specific ($k, i$-related) biases and patterns. Note that the above construction does keep the within-system variance $\sigma_i^2(s_d(k, \cdot))$ of each system $k$ intact. This is the signal SPA reads as a scorer's confidence. Keeping it unchanged avoids confounding the MQM-adherence signal with a change in SPA's confidence signal.

[6]The same approach can produce Adequacy MQM-adherence or Fluency MQM-adherence families of synthetic scorers by considering $z$ as the system-level $z$-score of $a$ or $f$, respectively. We exclude these families from our analysis as the partial correlation between the two aspects (Shayegh et al., 2025) confounds their interpretation.

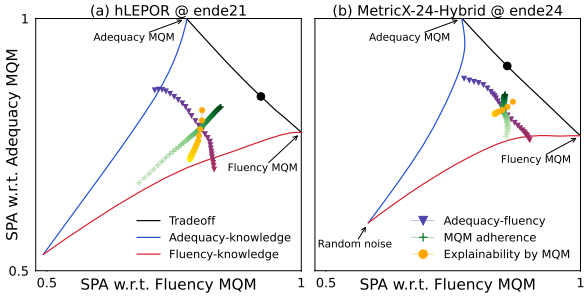

Figure 2: The SPA plane of Shayegh et al. (2025), with the augmented scorers of all three families plotted as points, for (a) hLEPOR (Han et al., 2013) in ende21 dataset and (b) MetricX-24-Hybrid (Juraska et al., 2024) in ende24 dataset as the base scorer.

**Adequacy–fluency family.** Similar to MQM-adherence family, we write

$$s_d(k,i) = s_0(k,i) + \frac{d \cdot \sigma(s_0)}{\sigma(z^{(a)})} z_k^{(a)} - \frac{d \cdot \sigma(s_0)}{\sigma(z^{(f)})} z_k^{(f)} \tag{14}$$

where $z^{(a)}$ and $z^{(f)}$ are the system-level $z$-scores of $a$ and $f$, respectively, and $\sigma$ is the standard deviation across systems. This construction is particularly clean: with correlation $\rho(a,f)<1$, it establishes a known adequacy-over-fluency preference along the increasing dial $d$. If $\rho = 1$, there is no trade-off, and the construction has no effect.

**Explainability-by-MQM family.** This family's direction is given by the part of the base scorer not explained by the joint $(a,f)$ pair: moving one way along it reduces this unexplained part, approaching what $(a,f)$ alone explains, while moving the other way amplifies it. It is different from the other two as instead of injecting/removing specific signals, it magnifies/reduces any $(a,f)$-unrelated signal the base scorer may have. We find the direction as follows. Write $a_{ki}$ and $f_{ki}$ for segment $i$ of system $k$'s gold Adequacy MQM and Fluency MQM scores, and let $\bar{s}_0(a,f)$ be the $s_0$'s mean score among segments sharing the exact $(a,f)$:

$$\bar{s}_0(a,f) = \mathbb{E}_{i,k:\, a_{ki}=a,\, f_{ki}=f}\ [s_0(k,i)] \tag{15}$$

Let

$$\bar{e}_k = \mathbb{E}_i\big[s_0(k,i) - \bar{s}_0(a_{ki}, f_{ki})\big] \tag{16}$$

be system $k$'s *offset*: the part of its score that the joint pair does not explain. We construct the augmented scorer

$$s_d(k,i) = s_0(k,i) - d \cdot \bar{e}_k. \tag{17}$$

In simple words, we partially remove each system's offset beyond what its $(a,f)$ explains. For negative $d$, we add more of it.

To visually illustrate the three families, Figure 2 plots them, applied to two different base scorers, on the SPA plane of Shayegh et al. (2025).

### 4.2 Evaluation Setup

We analyze the performance of a meta-evaluation separately in each of three directions. Specifically, we compare the meta-evaluation's assessment of different augmented scorers within each family, and count for how many adjacent-in-$d$ scorer pairs the meta-evaluation correctly identifies the dial direction. We report this success rate separately for each family as three measures.

**Datasets.** We use MQM data published by Freitag et al. (2021a).[7] We restrict our analysis to datasets from 2021 onward (Freitag et al., 2021b, 2022, 2023, 2024) due to limited standardization and support for older datasets. We specifically exclude ende23 because many of its MQM annotations are categorized as "other" rather than being properly assigned to adequacy or fluency categories. This leaves 11 datasets: ende24, enes24, jazh24, heen23, zhen23, ende22, zhen22, ende21, zhen21, ted_ende, and ted_zhen. Across all datasets, we evaluate all available systems except for M2M100_1.2B-B4 and MSLC, which are officially flagged for exclusion. Detailed statistics are in Appendix D.

**Base scorers.** We consider automatic scorers (omitting human references) in the MQM datasets as the base scorers. This includes the competitive scorers as well as the diagnostic ones included by WMT. We exclude those without segment-level scores (e.g., corpus-level chrF). We also deduplicate perfectly duplicated scorer pairs. We provide the complete list of the base scorers in Appendix D. For each meta-evaluation and each dataset, we report the average scores across all base scorers.

**Dial grid.** The closer two $d$ values are, the harder it is for a meta-evaluation to recognize their relative identity. We empirically choose the $d$ grid for the best readability of results. For MQM adherence, $d$ takes $-1.5 + 3^{n/200}$, and for explainability by MQM, $-3.5 + 4^{n/200}$, where $n \in \mathbb{N}$ :

[7] github.com/google/wmt-mqm-human-evaluation; MQM data for 2025 (Lavie et al., 2025) has not been published by the time of this study.

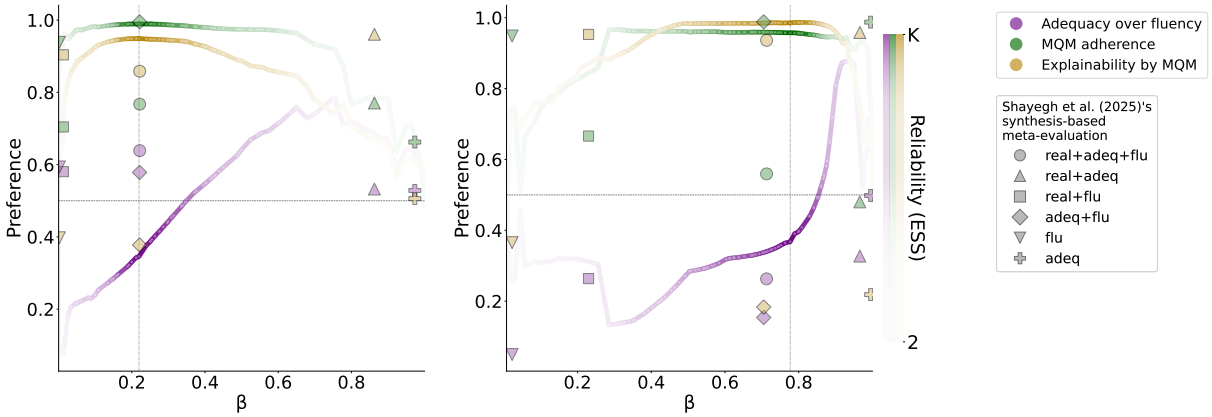

Figure 3: Main results on ende21 (left) and ende24 (right). Curve color intensity represents the effective sample size (ESS); a lower ESS indicates fewer actively involved systems, reducing representativeness. The strictly increasing adequacy-over-fluency curve demonstrates that $\beta$ is an effective driver of this balance. The natural balance $\beta_0$ for each dataset is marked by a vertical dotted line, with its intersections indicating the original meta-evaluation's performance. Higher MQM adherence and explainability by MQM indicate better meta-evaluation internal consistency. Markers show the performance of the six synthesis-based meta-evaluation setups from Shayegh et al. (2025), placed at their synthesized datasets' respective $\beta_0$.

$0 \leq n \leq 200$, resulting in 200 adjacent pairs per base scorer. For adequacy-over-fluency preference, $d$ ranges from $-0.5$ to $0.5$ with a step size of $0.02$, resulting in 50 adjacent pairs per base scorer.

### 4.3 Main Results

Figures[8] 3 and 7 show our method's performance across datasets over a $\beta$ sweep spanning $[\beta_{\min}, \beta_{\max}]$, plus explicitly every $\beta_{kk'}$ in the dataset. The monotonically increasing adequacy-over-fluency curves confirm that our reweighting mechanism effectively controls this balance. Furthermore, within a range around $\beta_0$ where ESS remains large, our method successfully preserves the original meta-evaluation's MQM adherence and explainability by MQM.

The strong correlation between ESS and both MQM adherence and explainability by MQM confirms ESS as a useful proxy for reliability, preventing severe evaluation distortion. Practically, ESS identifies the reachable range for controlling the adequacy–fluency balance without degrading meta-evaluation quality.

The permissible deviation from $\beta_0$ is fundamentally constrained by the dataset itself. In datasets like jazh24, most $\beta_{kk'}$ values concentrate within a narrow band, limiting reweighting capacity. Consequently, if a dataset lacks systems that intrinsically support a fluency-heavy evaluation, this imposes a strict limit on the achievable balance.

[8]Results for some datasets are deferred to the Appendix E due to space constraints. All the claims are written with respect to all datasets, including those deferred to the appendix.

Compared to Shayegh et al. (2025), our method consistently yields superior MQM adherence and/or explainability by MQM across all datasets, whether controlled by $\beta$ or by adequacy-over-fluency preference. The only exceptions occur at extreme adequacy-over-fluency values (e.g., in zhen23, ende22, and ende24) which their synthetic method reaches but our reweighting cannot. However, explainability by MQM heavily drops for both methods in these regimes, rendering those extremes highly distorted and practically infeasible anyway. Overall, our method strictly improves upon Shayegh et al. (2025) in preserving the internal consistency of the meta-evaluation.

Analyzing the markers in Figure 3 reveals a critical limitation of synthetic systems. In Shayegh et al. (2025)'s setups that retain real systems, explainability by MQM is preserved but MQM adherence degrades. Conversely, in their fully synthesized pools, MQM adherence is preserved while explainability by MQM collapses. Explainability by MQM measures the meta-evaluation's response to scorer noise while preserving natural biases; it is informed, but not strictly dictated, by MQM. This failure point of fully synthetic pools confirms our hypothesis that synthetic systems are unrepresentative. This stems from their construction: segments are regrouped to maximize between-system variance. By the law of total variance (Soch et al., 2025), since total pool variance is fixed, altering the between-system component inevitably alters the within-system component. This yields systems

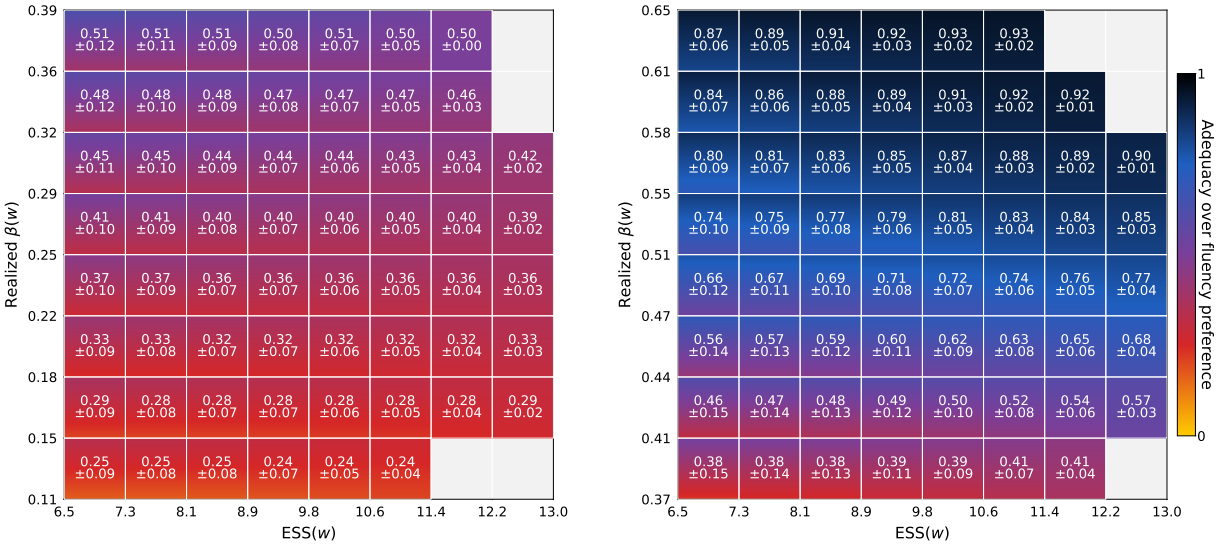

Figure 4: Adequacy-over-fluency preference across the $(\mathrm{ESS}, \beta)$ plane for ende21 (left) and ted_zhen (right). Each cell gives the mean and standard deviation over the weightings realizing that $(\mathrm{ESS}, \beta)$, color-ramped from $\mathrm{mean}-\mathrm{std}$ at its bottom edge to $\mathrm{mean}+\mathrm{std}$ at its top. Grey cells are unreachable.

with unrealistically low score variances, being unrepresentative and also distorting SPA's confidence estimations.

In Appendix F, we report similar experiments using Pearson correlation as the meta-metric. The observed trends remain consistent, further supporting the effectiveness of our reweighting method.

### 4.4 Additional Analysis

**Variance Analysis.** We investigate whether weight vectors with similar $\beta$ values can yield substantially different adequacy–fluency balances due to uncontrolled factors, which would invalidate $\beta$ as a reliable control parameter. The results in §4.3 are limited to $\mathrm{P}_{\mathrm{collis}}$-minimized weight vectors for each $\beta$, hiding any same-$\beta$ variance. To address this, we sample numerous weight vectors on the simplex $w \geq 0 : \mathbf{1}^\top w = 1$, each realizing some $\beta(w)$, $\mathrm{ESS}(w)$, and adequacy-over-fluency preference. By grouping these into buckets of $(\mathrm{ESS}, \beta)$ pairs, we compare within-bucket preference variances (indicating $\beta$-independent shifts) against across-bucket average trends (indicating the $\beta$-effect), demonstrating the reliability of $\beta$ as a control parameter.

We restrict the experiment to $w : \mathrm{ESS}(w) \in [\frac{K}{2}, K]$, given the unreliability of weighting with lower ESS. We draw around 3.5M weight vectors per dataset. These sets provide varying $\beta$ coverage across datasets. We partition $\beta$ and ESS ranges into 8 equal-sized buckets each. We compute the adequacy-over-fluency preference for each weighting, presenting the results as a heatmap over this $8 \times 8$ grid. Because these weightings are unoptimized, they remain unconstrained beyond the $\beta$ and ESS. Consequently, a cell's standard deviation strictly isolates the variation in SPA-based adequacy-over-fluency preference attributable to everything about $w$ except $\beta$.

Figures[9] 4 and 9 report the results. Each cell represents a pair of $\beta$ and ESS buckets. Reading down any column, preference increases with $\beta$ at every ESS. This trend holds for 99.1% of vertically-adjacent cell pairs pooled across all datasets. Reading across rows, higher ESS sharply reduces variance: averaged over all 554 horizontally-adjacent cell pairs, higher ESS exhibits 18.3% lower same-$\beta$ standard deviation, and the standard deviation decreases in 99.8% of those pairs. Lastly, comparing means to standard deviations confirms that same-$\beta$ variance does not obscure the $\beta$ signal. Despite partial overlap between cells, the expected differences remain substantial. A one-sided Welch's $t$-test (Welch, 1947) on every vertically-adjacent cell pair confirms this: 94.8% of pairs show that the higher-$\beta$ cell has a significantly higher preference ($p<0.01$), and no pair is significant in the opposite direction.

The mapping from $\beta$ to the adequacy-over-fluency preference is dataset-dependent: not only does the preference measure preclude cross-dataset comparison by construction, identical $\beta$ values also yield empirically different preference scores across

[9] Results for some datasets are deferred to Appendix G due to space limits. Claims are made with respect to all datasets.

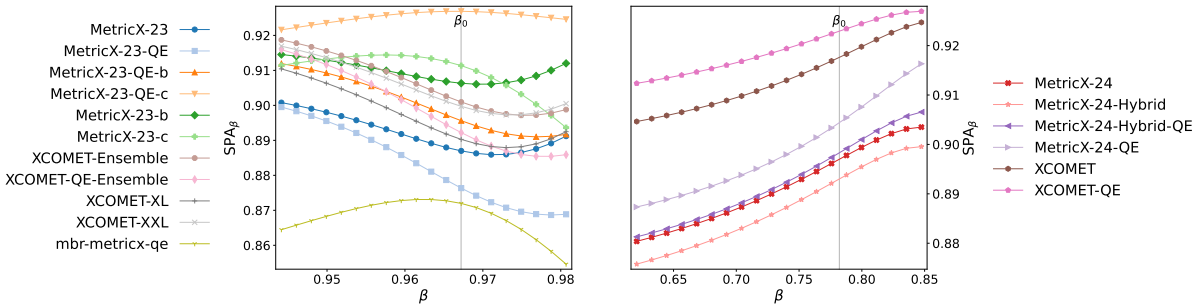

Figure 5: Weighted meta-evaluation performance ($\text{SPA}_\beta$) of MetricX and xCOMET variants as a function of the adequacy–fluency balance parameter $\beta$. In zhen23 (left), scorer rankings change depending on the target balance. In ende24 (right), relative performance remains stable across the reachable range. $\beta$ interval is bounded by $\text{ESS} \geq K - 1$, where $K$ is the total number of systems (15 for zhen23, 16 for ende24).

datasets. Despite this limitation, the underlying relationship between $\beta$ and the adequacy–fluency balance remains universal. Its direction, monotonicity, and robustness to same-$\beta$ variation hold across every dataset tested, licensing $\beta$ as a reliable control parameter.

**Weighted Meta-Evaluation.** Having validated our reweighting mechanism, we now apply it to compare variants of the popular scorers MetricX (Juraska et al., 2024) and xCOMET (Guerreiro et al., 2024) across a sweep of $\beta$. Figure 5 reports the weighted soft pairwise accuracy (SPA) for the zhen23 and ende24 datasets.[10]

The rankings in ende24 remain largely stable across the reachable $\beta$ range. In contrast, the performance trajectories in zhen23 intersect a lot, demonstrating that the relative ranking of scorers **can** be highly sensitive to the adequacy–fluency balance. Our proposed parameter and reweighting tool explicitly describe and control this behavior.

**More results in the appendix.** In Appendix B, we empirically evaluate the computational efficiency of our search algorithm, ablate its pruning mechanisms, and compare it against a numerical optimization baseline. In Appendix C, we show that meta-evaluation is sensitive to random system removal, and that adequacy–fluency imbalance is not the main cause of this instability.

## 5 Conclusion

Machine translation meta-evaluation inherits the adequacy–fluency tradeoff, with its balance dictated by the specific combination of translation systems in the meta-evaluation data. Because this system set is a small, unrepresentative sample that fluctuates across datasets, the resulting adequacy–fluency balance is uncontrolled and subject to change.

We exposed this balance as a tunable control parameter, $\beta$. To achieve a target $\beta$, we reweighted existing systems while minimizing distortion from uniform weighting, ensuring the evaluation pool remains real and representative. We supported this with an exact optimization algorithm, equipped with theoretical guarantees and pruning mechanisms, to efficiently compute these weights.

To provide an internal diagnostic for meta-evaluation behavior, we introduced a scorer-augmentation framework that establishes a known relative identity for near-real scorers. Our experiments demonstrated that our reweighting method successfully controls the adequacy–fluency balance and preserves evaluation integrity, outperforming system-synthesis approaches. Finally, our analysis of popular scorers showed that scorer rankings can be sensitive to $\beta$.

**Calibration of $\beta$ in practice.** A specific numerical value of $\beta$ does not yield an identical adequacy-over-fluency preference across different datasets. This stems from inherent variations in language pairs, the correlation between Adequacy MQM and Fluency MQM, base scorer biases, and other unaccounted variables. Thus, $\beta$ functions as a directional control knob rather than an absolute metric. To determine the target $\beta$ for a specific real-world scenario (e.g., technical versus creative translation), we recommend practitioners craft a few translation pairs that exhibit a marginal adequacy–fluency tradeoff, where one translation is slightly more adequate and the other slightly more fluent. After establishing which direction their specific use case prefers, they can sweep $\beta$ until the meta-evaluation prioritizes scorers aligned with that preference.

[10] We selected the two datasets empirically to best show two different possible scenarios: when the scorer ranking is or is not influenced by adequacy–fluency balance.

## Limitations

Our reweighting mechanism is strictly bounded by the intrinsic diversity of the underlying dataset. If a dataset lacks systems that exhibit isolated adequacy or fluency errors (e.g., jazh24), the reachable range of $\beta$ is narrow. Forcing $\beta$ beyond this range requires sparse weights, which reduces the effective sample size (ESS) and compromises the representativeness of the evaluation pool. Further expanding the admissible range for those datasets with limited flexibility remains a direction for future work.

Moreover, our framework depends on the provided MQM annotations and the chosen adequacy–fluency taxonomy, introducing two unaccounted sources of variance. First, WMT human labels contain noise and individual annotator bias. Our method does not model this uncertainty, meaning it propagates directly into system-level scores and $\beta$. Second, categorizing errors as adequacy or fluency is subjective. A different taxonomy alters the score distributions, so the same numerical $\beta$ will behave differently under a different decomposition. Accounting for annotation uncertainty and taxonomy dependence requires further research.

Finally, controlling the adequacy–fluency balance does not resolve the broader instability of meta-evaluation. As demonstrated in Appendix C, scorer rankings remain sensitive to system selection even when $\beta$ is fixed. Future work must identify the root causes of system-selection instability. We would like to investigate other axes of variation across translation systems that disrupt scorer rankings.

## Acknowledgements

We thank Lili Mou for the insightful discussions that provided the initial motivation for this research, and Jan-Thorsten Peter for their valuable feedback on the final manuscript. We also extend our gratitude to the WMT reviewers, both for this manuscript and for our prior work last year, whose constructive feedback significantly shaped the direction of this study. This research was conducted independently and received no external funding.

# A Proofs

## A.1 Proof of Theorem 1

**Theorem 1** (Reachable range)**.** *Problem ($\mathcal{P}$) is feasible for target $\hat{\beta}$ iff $\hat{\beta} \in [\beta_{\min}, \beta_{\max}]$.*

*Proof.* The forward direction is given by Theorem 3 applied to the full support. We now prove the reverse direction: Any $\hat{\beta} \in [\beta_{\min}, \beta_{\max}]$ is a feasible target for Problem $\mathcal{P}$.

$\beta(w)$ is continuous on the relative interior of $S$'s simplex face and that face is connected. Moreover, for two systems $k_1, k_2 : \beta_{\min}(S){=}\beta_{k_1 k_2}$, a weight vector $\hat{w} = \{k \neq k_1, k_2 : w_k{=}0\}$ drives $\beta(w){=}\beta_{\min}(S)$; symmetrically for $\beta_{\max}(S)$. So the image is a continuous interval with infimum $\beta_{\min}(S)$ and supremum $\beta_{\max}(S)$. □

## A.2 Proof of Theorem 2

**Theorem 2** (Bounded candidate count)**.** *For an admissible support $S$, let*

$$\min_w \tfrac{1}{2}\,\mathrm{P}_{\mathrm{collis}}(w) \qquad (\mathcal{P}_S)$$
$$\text{s.t. } \mathbf{1}^\top w = 1,\ \ b(w,\hat{\beta}) = 0 \quad \textit{(no non-negativity)}$$

*be solved on $S$'s coordinates, with $w_k{=}0$ for $k{\notin}S$. Then (a) Problem ($\mathcal{P}_S$) has at most five stationary points $w_S$, each obtainable in closed form by solving a polynomial equation of degree $\leq 5$; and (b) if $w^\star$ solves ($\mathcal{P}$) and $S = S(w^\star)$, then $w^\star$ is one of these $w_S$.*

*Proof.* **[Part (a)]** We prove this part by deriving the explicit polynomial to bound the stationary points. By (11) and Proposition 1:

$$\begin{aligned} b(w,\hat{\beta}) =& (1-\hat{\beta}) \sum_{k<k'} w_k w_{k'} (a_k - a_{k'})^2 \\ & - \hat{\beta} \sum_{k<k'} w_k w_{k'} (f_k - f_{k'})^2 \qquad (18) \\ =& (1-\hat{\beta})\Big(\sum_k w_k a_k^2 - w^\top a a^\top w\Big) \\ & - \hat{\beta}\Big(\sum_k w_k f_k^2 - w^\top f f^\top w\Big) \qquad (19) \\ =& w^\top(\hat{\beta} f f^\top - (1-\hat{\beta}) a a^\top) w \\ & + \sum_k w_k \big((1-\hat{\beta}) a_k^2 - \hat{\beta} f_k^2\big) \qquad (20) \\ =& w^\top H w + w^\top g \qquad (21) \end{aligned}$$

where $H = \hat{\beta} f f^\top - (1-\hat{\beta}) a a^\top$ and $g_k = (1{-}\hat{\beta}) a_k^2 - \hat{\beta} f_k^2$, yielding a quadratic in $w$.

Eliminate the budget constraint $\mathbf{1}^\top w = 1$ using the affine transformation

$$w = u_0 + N u \qquad (22)$$

where $u_0$ is the uniform weighting on $S$ and $N$ has orthonormal columns spanning $\{v : \mathbf{1}^\top v = 0\}$. Substituting (22) into (21) yields a single quadratic in the free variable $u$:

$$b(w,\hat{\beta}) = \tilde{b}(u,\hat{\beta}) = u^\top M u + u^\top r + c = 0 \qquad (23)$$

where $M = N^\top H N$, $r = N^\top(2Hu_0 + g)$, and $c = b(u_0, \hat{\beta})$. We can restate the problem in the free variable $u$:

$$\min_u \tfrac{1}{2}\,\|u\|^2 + \text{const.} \ \text{ s.t. } \ \tilde{b}(u,\hat{\beta}) = 0 \qquad (\mathcal{P}_S^{(u)})$$

A point $u$ is a *stationary point* of ($\mathcal{P}_S^{(u)}$) if it is feasible and satisfies

$$\nabla_u\big(\tfrac{1}{2}\|u\|^2 + \eta \cdot \tilde{b}(u,\hat{\beta})\big) = 0 \qquad (24)$$

for a multiplier $\eta \in \mathbb{R}$. Taking the derivative:

$$u + \eta(2Mu + r) = 0 \qquad (25)$$
$$(I + 2\eta M)\, u = -\eta r \qquad (26)$$

We call the support $S$ *degenerate* if all its pairwise balances $\beta_{kk'}$, $k, k' \in S$, coincide. We consider two scenarios:

**[Case 1: $S$ is degenerate]** Let $\bar{\beta}$ be the common value of the pairwise balances in $S$. Because $S$ is admissible, Theorem 3 forces $\hat{\beta} = \beta_{\min}(S) = \beta_{\max}(S) = \bar{\beta}$. For any pair $k, k' \in S$ we have $(a_k - a_{k'})^2 + (f_k - f_{k'})^2 > 0$, as no two systems share the same $(a_k, f_k)$; together with $\hat{\beta} = \beta_{kk'}$ and (12) this gives

$$(1-\hat{\beta})(a_k - a_{k'})^2 - \hat{\beta}(f_k - f_{k'})^2 = 0 \tag{27}$$

Substituting into (18)

$$\begin{aligned} &b(w, \hat{\beta}) = \\ &\sum_{k<k'} w_k w_{k'} \big((1-\hat{\beta})(a_k - a_{k'})^2 - \hat{\beta}(f_k - f_{k'})^2\big) \\ &= \sum_{k<k'} w_k w_{k'} \cdot 0 = 0 \end{aligned} \tag{28}$$

for every $w$. So the quadratic $\tilde{b}(\cdot, \hat{\beta})$ vanishes identically and $M = 0$, $r = 0$, $c = 0$ in (23). The stationarity condition (26) reads $u = 0$, so $S$ carries exactly one stationary point: the uniform weighting $u_0$. It is feasible, minimizes the strictly convex objective $\frac{1}{2}\|u\|^2$, and is the unique global optimum on $S$.

**[Case 2: $S$ is non-degenerate]** The pairwise balances in $S$ are not all equal. Let $\tilde{a}$ and $\tilde{f}$ be the score vectors restricted to $S$ and centered by their uniform means over $S$:

$$\tilde{a}_k = a_k - \mu(a; u_0) \tag{29}$$

$$\tilde{f}_k = f_k - \mu(f; u_0) \tag{30}$$

for $k \in S$. These are linearly independent: were $\tilde{f} = \kappa \tilde{a}$ for some $\kappa \in \mathbb{R}$, every pair would satisfy $(f_k - f_{k'}) = \kappa(a_k - a_{k'})$ and hence $\beta_{kk'} = (1+\kappa^2)^{-1}$, contradicting non-degeneracy; the same holds with the roles of $\tilde{a}$ and $\tilde{f}$ exchanged.

Within the zero-sum subspace defined by $N$, $M$ acts as the difference of two independent rank-1 outer products: $\hat{\beta}\tilde{f}\tilde{f}^\top$ and $(1-\hat{\beta})\tilde{a}\tilde{a}^\top$. By definition of $\beta$, we have $0 < \hat{\beta} < 1$. Therefore, this difference provides one strictly positive and one strictly negative direction. Consequently, $M$ is indefinite with rank two, possessing exactly two nonzero eigenvalues:

$$\theta_1 > 0 > \theta_2 \tag{31}$$

We use this structure to solve for the stationary candidates. Projecting (26) onto the eigen basis $\{v_j\}_{j=1}^{|S|-1}$ of $M$, and defining the coordinate components $u_j = v_j^\top u$ and $r_j = v_j^\top r$, splits it into independent scalar equations of the form

$$u_j(1 + 2\eta\theta_j) = -\eta r_j \tag{32}$$

The system is singular exactly at the two poles $\lambda_j = -1/(2\theta_j)$ for $j \in \{1, 2\}$. We categorize the candidates by resolving across three subcases for $\eta$:

**[Case 2.1: $\eta = \lambda_j$ and $r_j \neq 0$]** The $j$-th equation reads $u_j \cdot 0 = -\lambda_j r_j \neq 0$. The system is inconsistent, yielding zero candidates.

**[Case 2.2: $\eta = \lambda_j$ and $r_j = 0$]** The $j$-th equation is $0 = 0$, leaving the coordinate $u_j$ free. For every other coordinate $m \neq j$, the coefficient $(1 + 2\lambda_j\theta_m) = 1 - \frac{\theta_m}{\theta_j}$ is strictly non-zero: $\theta_m \neq 0$ for flat directions $m \geq 3$ and $\frac{\theta_{3-j}}{\theta_j} < 0$ by (31). Therefore, every $u_m : m \neq j$ is uniquely fixed to

$$u_m = \frac{-\lambda_j r_m}{1 + 2\lambda_j\theta_m} \tag{33}$$

Defining $u^\circ$ as this baseline vector with $u_j^\circ = 0$, the full quadratic constraint separates into:

$$\tilde{b}(u, \hat{\beta}) = \theta_j u_j^2 + r_j u_j + \tilde{b}(u^\circ, \hat{\beta}) = 0 \tag{34}$$

Because $r_j = 0$, the linear term vanishes, leaving $\theta_j u_j^2 = -\tilde{b}(u^\circ, \hat{\beta})$. This yields at most two candidates:

$$u_j = \pm\sqrt{-\tilde{b}(u^\circ, \hat{\beta})/\theta_j} \tag{35}$$

**[Case 2.3: $\eta \neq \lambda_j$]** In this case, $1 + 2\eta\theta_j \neq 0$, which gives

$$u_j(\eta) = \frac{-\eta r_j}{1 + 2\eta\theta_j} \tag{36}$$

which simplifies to $-\eta r_j$ for $j \geq 3$. We substitute these components into (23).

When $j \geq 3$, the quadratic terms vanish by $\theta_j = 0$, and the linear terms sum to:

$$\sum_{j \geq 3} r_j(-\eta r_j) = -\eta \sum_{j \geq 3} r_j^2 \tag{37}$$

For $j \in \{1, 2\}$, substituting $u_j(\eta)$ into its quadratic and linear terms yields:

$$\begin{aligned} &\theta_j u_j(\eta)^2 + r_j u_j(\eta) \\ &\quad = \theta_j \left(\frac{-\eta r_j}{1 + 2\eta\theta_j}\right)^2 + r_j \left(\frac{-\eta r_j}{1 + 2\eta\theta_j}\right) \qquad (38) \\ &\quad = -\eta r_j^2 \, \frac{(1 + \eta\theta_j)}{(1 + 2\eta\theta_j)^2} \qquad (39) \end{aligned}$$

Combining the constant $c$, (37), and (39) for the two $j$ values, (23) becomes:

$$c - \eta \left[ \sum_{j=1,2} \frac{r_j^2(1+\theta_j\eta)}{(1+2\eta\theta_j)^2} + \sum_{j\geq 3} r_j^2 \right] = 0 \quad (40)$$

Clearing denominators by multiplying through by the squared characteristic polynomial $(1+2\eta\theta_1)^2(1+2\eta\theta_2)^2$ yields a polynomial equation $\Phi_{S,\hat{\beta}}(\eta) = 0$, where

$$\begin{aligned}\Phi_{S,\hat{\beta}}(\eta) = c\,&(1+2\eta\theta_1)^2(1+2\eta\theta_2)^2 \\ &- \eta\, r_1^2\,(1+\theta_1\eta)(1+2\eta\theta_2)^2 \\ &- \eta\, r_2^2\,(1+\theta_2\eta)(1+2\eta\theta_1)^2 \\ &- \eta \sum_{j\geq 3} r_j^2\,(1+2\eta\theta_1)^2(1+2\eta\theta_2)^2\end{aligned} \quad (41)$$

has degree at most five.

It remains to bound the number of candidates. We proceed in three steps. First, we evaluate $\Phi_{S,\hat{\beta}}$ at $\lambda_1$ and $\lambda_2$. We show that $\lambda_j$ is a root only when $r_j = 0$ (Case 2.2), and that it is then a root of multiplicity two. Second, we count the candidates when $\Phi_{S,\hat{\beta}}$ is not the zero polynomial. A root $\eta \notin \{\lambda_1, \lambda_2\}$ gives one candidate (Case 2.3) and costs one of the five roots, while a root at $\lambda_j$ gives two candidates and costs two of them by the first step. Hence the bound of five holds. Third, we treat the case where $\Phi_{S,\hat{\beta}}$ is the zero polynomial. In this case, counting roots does not apply and we solve the stationarity condition (26) directly.

**[Poles of $\Phi_{S,\hat{\beta}}$]** At $\eta = \lambda_1$ the factor $(1+2\eta\theta_1)$ vanishes, killing every term of (41) except the second one, so

$$\begin{aligned}\Phi_{S,\hat{\beta}}(\lambda_1) &= -\lambda_1 r_1^2(1+\theta_1\lambda_1)(1+2\lambda_1\theta_2)^2 \\ &= -\frac{\lambda_1 r_1^2}{2}\left(1-\frac{\theta_2}{\theta_1}\right)^2\end{aligned} \quad (42)$$

using $\lambda_1 = -1/(2\theta_1)$, and symmetrically for $\lambda_2$ with the indices 1 and 2 exchanged. Because $\lambda_j \neq 0$ and $\theta_1\theta_2 < 0$ by (31), $\lambda_j$ is a root of $\Phi_{S,\hat{\beta}}$ if and only if $r_j = 0$, which is exactly Case 2.2; and when $r_j = 0$, every remaining term of (41) carries the factor $(1+2\eta\theta_j)^2$, making $\lambda_j$ a double root.

**[Counting when $\Phi_{S,\hat{\beta}} \not\equiv 0$]** The polynomial has at most five roots counted with multiplicity. Each root $\eta \notin \{\lambda_1, \lambda_2\}$ contributes exactly one candidate through Case 2.3. Each $\lambda_j$ that is a root uses two roots and contributes at most two candidates through (35). Summing over all configurations, the number of candidates is at most five.

**[Counting when $\Phi_{S,\hat{\beta}} \equiv 0$]** We have $c = \Phi_{S,\hat{\beta}}(0) = 0$ and $r_1 = r_2 = 0$ by (42). The remaining (last) term of (41) forces $\sum_{j\geq 3} r_j^2 = 0$ and hence $r = 0$. The stationarity condition (26) becomes $(I + 2\eta M)u = 0$, which in the eigen coordinates reads $u_j(1+2\eta\theta_j) = 0$ for every $j$. If $\eta \notin \{\lambda_1, \lambda_2\}$, all the coefficients $1+2\eta\theta_j$ are nonzero and $u = 0$. If $\eta = \lambda_j$ for some $j \in \{1, 2\}$, the $j$-th coefficient vanishes and leaves $u_j$ free, while every other coefficient is nonzero as shown in Case 2.2; the solution is thus $u = u_j v_j$, a multiple of the $j$-th eigenvector of $M$. Feasibility (23) then gives

$$\tilde{b}(u_j v_j, \hat{\beta}) = \theta_j u_j^2 + u_j\, r_j + c = \theta_j u_j^2 = 0 \quad (43)$$

using $r = 0$ and $c = 0$. $\theta_j \neq 0$ forces $u_j = 0$. So $u = 0$ in every case, and $S$ carries the single stationary point $u_0$.

In all scenarios $S$ carries at most five stationary points, each obtained in closed form from the roots of a polynomial of degree at most five.

**[Part (b)]** By assumption, $w^\star$ is a global optimum of ($\mathcal{P}$) with support $S = S(w^\star)$, and $S$ is admissible by Theorem 3. Because $w_k^\star > 0$ for all $k \in S$, the non-negativity constraints are inactive: $w^\star$ locally minimizes $\frac{1}{2}\|w\|^2$ subject to $\mathbf{1}^\top w = 1$ and $b(w, \hat{\beta}) = 0$ on $S$. Write $u^\star$ for its reduced coordinate, $w^\star = u_0 + N u^\star$. We consider two scenarios:

**[The constraint gradients are linearly independent]** The linear independence constraint qualification holds at $w^\star$, so $u^\star$ is a stationary point of ($\mathcal{P}_S^{(u)}$) and is enumerated by Part (a).

**[The constraint gradients are linearly dependent]** Dependence forces $\nabla_w b(w^\star, \hat{\beta}) = \mu\mathbf{1}$ for some $\mu \in \mathbb{R}$. The chain rule gives the reduced gradient

$$\begin{aligned}\nabla_u \tilde{b}(u^\star, \hat{\beta}) &= \nabla_u \big[b(u_0 + Nu, \hat{\beta})\big]\big|_{u=u^\star} \\ &= N^\top \nabla_w b(w^\star, \hat{\beta}) = \mu N^\top \mathbf{1}\end{aligned} \quad (44)$$

which is equal to zero since the columns of $N$ are orthogonal to $\mathbf{1}$. Together with feasibility $\tilde{b}(u^\star, \hat{\beta}) = 0$, expanding the quadratic (23) around

$u^\star$ along a direction $\delta$ with step size $t$ gives

$$\begin{aligned}&\tilde{b}(u^\star + t\delta, \hat{\beta})\\ &= \underbrace{\tilde{b}(u^\star, \hat{\beta})}_{=0} + \underbrace{t\,\nabla_u \tilde{b}(u^\star, \hat{\beta})^\top \delta}_{=0} + \tfrac{t^2}{2}\delta^\top \underbrace{\nabla_u^2 \tilde{b}(u^\star, \hat{\beta})}_{=2M}\delta\\ &= t^2 \delta^\top M \delta \end{aligned} \tag{45}$$

Call $\delta$ a null direction if $\delta^\top M \delta = 0$. Along such a direction the line $u(t) = u^\star + t\delta$ satisfies the constraint $\tilde{b}(\cdot, \hat{\beta}) = 0$ for every $t \in \mathbb{R}$. Because $w_k^\star > 0$ for all $k \in S$, the points of this line with $|t|$ small are feasible for ($\mathcal{P}$), so $t = 0$ is a local minimizer of

$$\varphi(t) = \|u^\star + t\delta\|^2 \tag{46}$$

$$= \|u^\star\|^2 + 2t\,(u^{\star\top}\delta) + t^2\|\delta\|^2 \tag{47}$$

This function is a convex quadratic, so $\varphi'(0) = 0$, which asserts

$$u^{\star\top}\delta = 0 \tag{48}$$

for every null direction $\delta$.

If $S$ is degenerate, then $M = 0$ and every direction is null, so (48) forces $u^\star = 0$. Otherwise, $M$ is indefinite of rank two by (31), and its null directions span the reduced space: they contain the kernel directions $\{v_j\}_{j\geq 3}$ together with $\sqrt{-\theta_2}\,v_1 \pm \sqrt{\theta_1}\,v_2$, whose span is all of $\mathbb{R}^{|S|-1}$. Orthogonality (48) to a spanning set again forces $u^\star = 0$. In both cases $w^\star$ is the uniform weighting on $S$. Moreover $r = -2Mu^\star = 0$ by (44) and $c = \tilde{b}(0, \hat{\beta}) = 0$ by feasibility, so every term of (41) vanishes and $\Phi_{S,\hat{\beta}} \equiv 0$. Part (a) enumerates $u^\star = 0$ as the single stationary point on $S$ in this situation, both when $S$ is degenerate and when $\Phi_{S,\hat{\beta}} \equiv 0$. The global optimum is therefore contained within the candidate set enumerated in Part (a). □

### A.3 Proof of Theorem 3

**Theorem 3** (Admissible supports)**.** *If $w_S$ with support $S$ is a feasible weighting for target $\hat{\beta}$, then $\beta_{\min}(S) \leq \hat{\beta} \leq \beta_{\max}(S)$.*

*Proof.* For any $w_S$ with at least two positive values, (*) gives

$$\hat{\beta} = \beta(w_S) = \frac{\sigma(a; w_S)^2}{\sigma(a; w_s)^2 + \sigma(f; w_s)^2} \tag{49}$$

Given $w_S = \{w_k\}_k$, by Proposition 1 we have

$$\hat{\beta} = \frac{\sum_{k<k'} w_k w_{k'} (a_k - a'_k)^2}{\sum_{k<k'} w_k w_{k'} \left[(a_k - a'_k)^2 + (f_k - f'_k)^2\right]} \tag{50}$$

Letting

$$p_{kk'} = \frac{w_k w_{k'} \left[(a_k - a'_k)^2 + (f_k - f'_k)^2\right]}{\sum_{l<l'} w_l w_{l'} \left[(a_l - a'_l)^2 + (f_l - f'_l)^2\right]} \tag{51}$$

with $p_{kk'} \geq 0$ and $\sum_{k<k'} p_{kk'} = 1$, we substitute (12):

$$\hat{\beta} = \sum_{k<k'} p_{kk'} \beta_{kk'} \tag{52}$$

Therefore, $\hat{\beta}$ is a strict convex combination of pairwise balances over non-zero weights $\{\beta_{kk'}\}_{w_k w_{k'} > 0}$, hence strictly between their smallest and their largest, unless they all coincide, in which case it equals their common value. We have

$$\{\beta_{kk'}\}_{w_k w_{k'} > 0} \subseteq \{\beta_{kk'}\}_{kk'} \in [\beta_{\min}(S), \beta_{\max}(S)] \tag{53}$$

thus $\beta_{\min}(S) \leq \hat{\beta} \leq \beta_{\max}(S)$. □

### A.4 Proof of Theorem 4

**Theorem 4** (Support size bound)**.** *For any weighting $w$ supported on $S$, $\mathrm{P}_{\mathrm{collis}}(w) \geq 1/|S|$, with equality iff $w$ is uniform on $S$.*

*Proof.* $S$ is the support of $w$, meaning $w_k = 0$ for $k \notin S$. The collision probability is defined as:

$$\mathrm{P}_{\mathrm{collis}}(w) = \sum_k w_k^2 = \sum_{k\in S} w_k^2 \tag{54}$$

By Cauchy–Schwarz inequality:

$$\underbrace{\Big(\sum_{k\in S} w_k \cdot 1\Big)^2}_{=1} \leq \underbrace{\Big(\sum_{k\in S} w_k^2\Big)}_{\mathrm{P}_{\mathrm{collis}}(w)} \underbrace{\Big(\sum_{k\in S} 1^2\Big)}_{|S|} \tag{55}$$

Equality holds in the Cauchy–Schwarz inequality iff the vectors $(w_k)_{k\in S}$ and $(1)_{k\in S}$ are proportional, meaning $w_k$ is a constant across all $k \in S$. Given $\sum_{k\in S} w_k = 1$, this forces $w_k = 1/|S|$ for all $k \in S$. Therefore, equality holds iff $w$ is uniform on $S$. Dividing both sides of (55) by $|S|$ yields the claim. □

### A.5 Proof of Theorem 5

**Theorem 5** (Exit certificate)**.** *Let $w$ be feasible for Problem ($\mathcal{P}$). Let $\tilde{a} = a - \mu(a)\mathbf{1}$, $\tilde{f} = f - \mu(f)\mathbf{1}$ be both nonzero, and $\rho = \frac{\tilde{a}^\top \tilde{f}}{\|\tilde{a}\|\,\|\tilde{f}\|}$ the adequacy–fluency Pearson correlation across systems. If there*

Table 2: Number of times each of Theorems 3–5 fires over a 50-point $\beta$-sweep.

*exist* $\eta, \lambda \in \mathbb{R}$ *such that*

$$k \in S(w): \quad w_k + \eta \frac{\partial b(w, \hat{\beta})}{\partial w_k} + \lambda = 0 \tag{i}$$

$$k \notin S(w): \quad \lambda + \eta \frac{\partial b(w, \hat{\beta})}{\partial w_k} \geq 0 \tag{ii}$$

$$I_2 + 2\eta \begin{pmatrix} \hat{\beta}\|\tilde{f}\|^2 - (1-\hat{\beta})\rho^2\|\tilde{a}\|^2, & -(1-\hat{\beta})\rho\sqrt{1-\rho^2}\|\tilde{a}\|^2 \\ -(1-\hat{\beta})\rho\sqrt{1-\rho^2}\|\tilde{a}\|^2, & -(1-\hat{\beta})(1-\rho^2)\|\tilde{a}\|^2 \end{pmatrix} \succeq 0 \tag{iii}$$

*where* $\succeq 0$ *means positive semidefinite, then* $w$ *is a global optimum of Problem* ($\mathcal{P}$).

*Proof.* The balance constraint $b(w, \hat{\beta}) = 0$ is governed by an indefinite quadratic matrix $H = \hat{\beta} f f^\top - (1 - \hat{\beta}) a a^\top$, according to (21) in the proof of Theorem 2. This makes the constraint domain non-convex. Therefore, we verify the Karush–Kuhn–Tucker (KKT; Wu, 2007) conditions, as well as the second-order sufficiency criteria adapted for non-convex quadratically constrained quadratic program (QCQPs; Park and Boyd, 2017).

**[KKT Conditions]** Consider the Lagrangian for Problem ($\mathcal{P}$):

$$\mathcal{L}(w, \eta, \lambda, \gamma) = \tag{$\mathcal{L}$}$$
$$\tfrac{1}{2}\|w\|^2 + \eta\, b(w, \hat{\beta}) + \lambda \mathbf{1}^\top w = 1 - \sum_{k=1}^{K} \gamma_k w_k$$

where $\eta, \lambda \in \mathbb{R}$, and $\gamma_k \geq 0$ are the dual variables for the non-negativity constraints $w_k \geq 0$ so that $\gamma_k w_k = 0$ for all $k$ (complementary slackness). Differentiating ($\mathcal{L}$) with respect to each weight $w_k$ yields the general stationarity condition

$$\frac{\partial \mathcal{L}}{\partial w_k} = w_k + \eta \frac{\partial b(w, \hat{\beta})}{\partial w_k} + \lambda - \gamma_k = 0 \tag{56}$$

for all $k$. To validate this, we split the analysis into two parts based on whether $k \in S(w)$:

**[Case $k \in S(w)$]** By definition, $w_k > 0$. Complementary slackness forces the corresponding dual variable $\gamma_k = 0$. Substituting this into (56):

$$w_k + \eta \frac{\partial b(w, \hat{\beta})}{\partial w_k} + \lambda = 0 \quad \text{for } k \in S(w) \tag{57}$$

which is given by condition (i).

**[Case $k \notin S(w)$]** By substituting $w_k = 0$ into (56) and keeping only $\gamma_k$ on one side:

$$\gamma_k = \lambda + \eta \frac{\partial b(w, \hat{\beta})}{\partial w_k} \geq 0 \quad \text{for } k \notin S(w) \tag{58}$$

which is given by condition (ii). Note that the inequality is given by $\gamma_k$'s definition.

Together, (57) and (58) satisfy all KKT conditions for Problem ($\mathcal{P}$), which are necessary but not sufficient. Next, we verify second-order sufficiency criteria.

**[Second-order sufficiency criteria]** We have the Hessian of ($\mathcal{L}$)

$$\nabla_w^2 \mathcal{L} = I + 2\eta H \tag{59}$$

where $H$ is the indefinite matrix $H = \hat{\beta} f f^\top - (1-\hat{\beta}) a a^\top$, following (21). For $w$ to be a global minimizer, the Lagrangian Hessian must be positive semi-definite along all directions $v$ that preserve the equality constraints $\mathbf{1}^\top v = 0$ and $\nabla b(w, \hat{\beta})^\top v = 0$ (Moré and Sorensen, 1983). Through standard null-space elimination (Nocedal and Wright, 2006), this requirement projects onto the zero-sum subspace, demanding

$$v^\top \big(I + 2\eta H\big) v \geq 0 \tag{60}$$

for all vector directions $v$ such that $\mathbf{1}^\top v = 0$.

To validate this condition without explicitly constructing high-dimensional sweeps, we invoke the structural reduction detailed in (22–23) in the proof of Theorem 2. As shown in that proof, eliminating the budget constraint via the affine transformation $w = u_0 + Nu$ restricts the quadratic form to the zero-sum subspace via the reduced matrix $M = N^\top H N$. According to Theorem 2's proof, Case 2, $M$ acts as the difference of two rank-1 outer products and has rank two on the relevant subspace with two non-zero eigenvalues $\theta_1 > 0 > \theta_2$. Projecting the quadratic form onto the orthonormal basis of this two-dimensional span $\{\tilde{a}, \tilde{f}\}$ transforms the test of (60) into the explicit $2 \times 2$ symmetric matrix test defined in condition (iii). That is, condition (iii) requires that $H(\eta, \hat{\beta}) \succeq 0$, and requiring $H(\eta, \hat{\beta}) \succeq 0$ is strictly equivalent to $v^\top (I + 2\eta H) v \geq 0$ for all $v$ with $\mathbf{1}^\top v = 0$, which satisfies the second-order sufficiency criteria.

Since $w$ satisfies KKT conditions across both active and inactive supports via (i) and (ii), and the second-order subspace sufficiency condition via (iii), $w$ is certified to be a global optimum of Problem ($\mathcal{P}$). □

## B Efficiency and Ablation Analysis

We evaluate the computational efficiency of Algorithm 1 and ablate its three pruning mechanisms using the ende24 dataset[11] ($K = 16$). We sweep

[11]The choice of this dataset is due to its large $K$. The trends and conclusions are similar across the datasets.

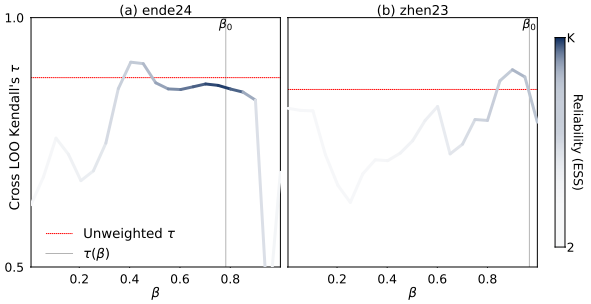

Figure 6: Leave-one-out stability with and without fixing $\beta$. The horizontal red line corresponds to the baseline values in Table 3. The blue curve shows the pooled pairwise Kendall's $\tau$ correlation of scorer rankings after reweighting each subset to the fixed $\beta$. Curve intensity represents ESS (reliability).

$\hat{\beta}$ across 50 values in two regimes: a narrow band around the natural balance $\beta_0$, and the full reachable range $[\beta_{\min}, \beta_{\max}]$. The former represents the practical use case, as performance is more reliable here (§4.3) and minor adjustments reflect realistic demands. The latter serves as an extreme regime to stress-test the algorithm. We compare against a numerical optimization baseline using varying grid resolutions $N$ and a fixed tolerance of $10^{-3}$. Tables 1 and 2 summarize the results.

**Near natural balance.** When the target $\hat{\beta}$ is close to $\beta_0$, the optimal weighting remains close to uniform. Table 2 shows that Theorem 5 (exit certificate) triggers immediately on the full support for all 50 targets. Consequently, the search evaluates exactly one support per target. Table 1 demonstrates the resulting efficiency: solving the narrow sweep requires only 1.3M FLOPs, substantially faster than the numerical baseline required to guarantee 100% success, while strictly guaranteeing global optimality. Without early exit, the algorithm exhaustively evaluates over 3.2M supports, increasing FLOPs by nearly five orders of magnitude.

**Full range.** Reaching extreme $\hat{\beta}$ targets requires sparse weight vectors. In this regime, Theorem 3 (admissible supports) drives the pruning, firing over 65.5K times (Table 2) to safely skip infeasible branches. The exact algorithm demands more computation than the numerical baseline across the full range, which is the cost of guaranteeing the global minimum. The ablation confirms that combining all pruning theorems reduces the full-range computational cost by more than $3\times$ compared to the unpruned exact search.

| Dataset | # Systems | Cross-LOO Kendall's $\tau$ |

| ende24 | 16 | 0.8797 |
| enes24 | 13 | 0.8815 |
| jazh24 | 13 | 0.7931 |

Table 3: Pooled pairwise Kendall's $\tau$ correlation of scorer rankings across leave-one-out (LOO) system subsets for each dataset. The sub-optimal correlation values indicate that meta-evaluation rankings are sensitive to system selection.

## C Does Controlling Adequacy–Fluency Balance Stabilize Meta-Evaluation?

Meta-evaluation rankings vary across datasets. While intrinsic differences partially explain this, instability also stems directly from system selection within a single dataset. We quantify this by computing the pooled pairwise Kendall's $\tau$ (Kendall et al., 1938) of scorer rankings across all leave-one-out (LOO) system subsets for each dataset. Table 3 reports these results. These values confirm that meta-evaluation outcomes are sensitive to the specific MT systems included in the pool.

A reasonable hypothesis is that this within-dataset instability is partly driven by varying adequacy–fluency balances across subsets. To test this, we evaluate whether fixing $\beta$ stabilizes the scorer rankings across the LOO subsets.[12] Our results reject this hypothesis. As illustrated for two representative datasets in Figure 6, precisely controlling $\beta$ does not resolve the ranking variance. While the adequacy–fluency balance may contribute to the instability of specific datasets, it is not the primary driver of the system-selection sensitivity observed in recent WMT evaluations. Identifying the root cause of this instability remains an open problem beyond the scope of this work.

## D Dataset Statistics

Tables 4–7 report descriptive statistics for the eleven datasets used throughout this work. Table 4 covers pool size and the balance parameter. Table 5 summarizes the distribution of pairwise balances $\beta_{kk'}$. Table 6 reports system-level Adequacy MQM and Fluency MQM statistics, together with their correlation and covariance across systems. Table 7 lists by name the base scorers augmented for each dataset.

## E Main Results for All Datasets

Figure 7 presents the main results across all datasets, reproducing the figures from the main text for completeness. The observed trends remain consistent throughout, demonstrating our method's generalizability.

## F Main Results for Pearson Correlation

Figure 8 mirrors the experiments from §4.3, using Pearson correlation as the meta-metric rather than SPA. Markers representing Shayegh et al. (2025) are omitted, as Pearson correlation falls outside the scope of their work. These findings align closely with our SPA evaluation, confirming the robustness of our approach.

## G Variance Analysis for All Datasets

Figure 9 presents the variance analysis heatmaps across all datasets, reproducing the figures from the main text for completeness. The observed trends remain consistent throughout, demonstrating the reliability of $\beta$ as a control parameter.

[12] In preliminary studies, we also controlled the adequacy-over-fluency preference directly (see §4) to account for different subsets possessing different balance–$\beta$ relations. This alternative control also failed to resolve the instability.

Table 6: System-level Adequacy and Fluency MQM. Every statistic is taken over the $K$ systems of a single dataset, at the uniform weighting $w = \frac{1}{K}\mathbf{1}$, on the system-level score vectors $a$ (Adequacy MQM) and $f$ (Fluency MQM). $\rho$ is the Pearson correlation between $a$ and $f$ across systems. $\Sigma(a, f)$: the covariance between $a$ and $f$ across those same systems. Means are negative because MQM is defined as a negated error weight.

# In-Context Learning for Upper Sorbian to German Translation: Comparing Lexical and Morpho-Syntactic Information

**Qimin Sheng**[1] **and Marion Di Marco**[1,2] **and Alexander Fraser**[1,2]

## Abstract

LLM-based translation remains challenging for low-resource languages, as LLMs often lack linguistic knowledge due to their limited representation in pre-training data. This is particularly problematic for morphologically rich languages where a large vocabulary can lead to further data sparsity.

Previous work has shown that providing external guidance on the source sentence in the form of language-specific information can help LLMs with tasks such as machine translation. In this study, we investigate zero-shot context augmentation for Upper Sorbian-to-German translation by enriching prompts with different types of contextual information: translation candidates in the form of bilingual dictionary entries, and morpho-syntactic analysis provided through morphological tagging. We first compare the effectiveness of these types of information in a zero-shot setting and then evaluate whether they generalize across additional experimental settings. We find that context-augmented prompting can improve Upper Sorbian-to-German translation. Contexts only containing translation candidates perform overall best, whereas morpho-syntactic analysis offers limited benefits, both on its own and in combination with lexical cues.

## 1 Introduction

Large Language Models (LLMs) have shown strong capabilities in machine translation (MT), especially for English and other high-resource languages (HRLs) (Brown et al., 2020; Chowdhery et al., 2023). However, a performance gap remains between high- and low-resource languages (LRLs) (Robinson et al., 2023; Hendy et al., 2023; Nicholas and Bhatia, 2023), as LRLs are underrepresented with only limited data available (Ponti et al., 2019; Joshi et al., 2020).

The absence of sufficient training data is particularly problematic for languages with complex morphology, because a large vocabulary can further increase data sparsity. When translating *out of* a morphologically rich language, words must be analyzed in the sentence context and their semantic content needs to be transported appropriately into the target language. With a large variety of inflected word forms, some forms might not be well attested in the LLM pre-training data, or are even entirely absent from it. At the same time, other word forms of the same lemma might be better attested, meaning that the LLM knows the words in principle but cannot necessarily access this knowledge optimally. For HRLs, large pre-training corpora can provide language competence. In contrast, for LRLs with only limited data available, focused *linguistic descriptions* can contribute structured and context-relevant information to compensate for data sparsity during pre-training, for example Tanzer et al. (2024) and Zhang et al. (2024b).

In-context learning (ICL) constitutes an interesting approach for LRL translation, as it reduces the reliance on large-scale training data (Cahyawijaya et al., 2024) by providing external linguistic information in prompts (Garg et al., 2023). Unlike fine-tuning, ICL does not require parameter updates and is therefore relatively cost-effective (Brown et al., 2020; Dong et al., 2024). Previous work has explored the use of additional linguistic resources in prompts, such as dictionaries, parallel examples, grammatical descriptions, morphological analysis, and glosses to support LLM-based MT for LRLs, with several studies reporting improvements on translation quality (Pei et al., 2025; Zhang et al., 2024b,a; Court and Elsner, 2024).

In this work, we explore context augmentation strategies for translation from Upper Sorbian, a low-resource morphologically rich Slavic language, into German, a high-resource language. We investigate two complementary sources of information: the morpho-syntactic information obtained from a morphological tagger, and the lexical information

*Proceedings of the Eleventh Conference on Machine Translation*, pages 698–710
October 28-29, 2026 ©2026 Association for Computational Linguistics

from a translation dictionary derived from parallel data. They are intended (i) to help the model understand morphologically complex input and (ii) to facilitate the transfer to German. To evaluate their individual and combined effects, we compare four context strategies.

We address the following research questions:

- RQ1: *How do different context strategies perform, and what is the optimal configuration for each?*
- RQ2: *Do they perform effectively and stably across different settings*?

We first evaluate all context strategies in zero-shot setting using our primary model (`llama3.3-70B-instruct`), and then further evaluate whether each strategy's optimal configuration in zero-shot generalizes to another model (`gpt-4o`) and also to few-shot prompting.

We find that providing contextual information in prompts can improve Upper Sorbian-German MT across different settings. Lexical context in the form of lemma-level dictionary entries performs best across most settings, whereas source-side morphology alone provides only limited benefit. Combining lexical and morphological information brings no additional stable gains, suggesting that direct source-to-target lexical mapping is the major contributor to translation performance.

## 2 Related Work

### 2.1 Low-Resource Scenarios in LLM Machine Translation

LLM-based MT formulates translation as a language modeling task (Ataman et al., 2025), as its multilingual pretraining (Lai et al., 2023) may enable cross-lingual transfer from HRLs to LRLs (Xu et al., 2025). LLMs achieve strong translation performance for HRLs such as English which are well represented in model training data (Brown et al., 2020; Chowdhery et al., 2023; Vilar et al., 2023). In contrast, LRLs with only limited available training data are underrepresented in multilingual models (Robinson et al., 2023; Hendy et al., 2023; Nicholas and Bhatia, 2023; Hasan et al., 2024). For morphologically rich languages, a large inventory of inflected forms further increases data sparsity (Samardzic et al., 2024). Consequently, LLMs lack sufficient linguistic knowledge of LRLs, making translating low-resource languages challenging.

### 2.2 In-Context Learning for Machine Translation

To improve source-side understanding for LRL translation, linguistic information can be incorporated into prompts via in-context learning (ICL) (Garg et al., 2023). Unlike fine-tuning, this approach gives LLMs the possibility to learn from externally provided knowledge without updating their parameters (Brown et al., 2020), while reducing reliance on large-scale annotated data (Cahyawijaya et al., 2024).

**Dictionary.** Previous work has explored dictionary-based prompting for translating low-resource languages. For example Ghazvininejad et al. (2023) and Zhang et al. (2024a) integrate bilingual dictionary information into translation prompts. Lu et al. (2024) explore Chain-of-Dictionary (CoD) Prompting, which uses multilingual dictionary chains. However, dictionary-only approaches can produce syntactically incoherent translation (Zhang et al., 2024b).

**Grammar.** Tanzer et al. (2024) showed that LLMs can learn to translate languages unseen during pre-training with in-context information obtained from grammar books and dictionaries. However, the effectiveness of grammatical information for LRL MT remains debated. Explicit grammar rules can help resolve lexical ambiguities and guide word-order transformations (Zhang et al., 2024b), while grammar explanations show limited or even negative effects (Court and Elsner, 2024; Pei et al., 2025). Zhang et al. (2025) argue that LLMs can apply explicitly provided grammar rules but may struggle to retrieve them on their own.

**Morphology & Gloss.** Morphological information can provide useful linguistic cues, for example number and case information (Zhang et al., 2024b), which is especially relevant for morphologically rich languages. Interlinear glosses, which combine lexical and morphological information, can improve prompting-based MT (Ramos et al., 2025).

**Parallel Examples.** Few-shot prompting can provide a model with a small number of source-target translation examples (Brown et al., 2020). Increasing the number of demonstrations generally improves translation performance, although gains tend to diminish after only a few examples (Vilar et al., 2023). Using similar and higher-quality

demonstrations also benefits MT (Sia and Duh, 2023; Agrawal et al., 2022; Vilar et al., 2023).

### 2.3 Machine Translation between Upper Sorbian and German

Upper Sorbian (HSB) is a West Slavic minority language spoken in eastern Germany, with an estimated fewer than 15,000 speakers (Howson, 2017). Its rich morphology (e.g. the seven-case nominal system and uncommon archaic dual number) is particularly challenging for MT.

Sorbian ↔ German MT has been studied in a series of WMT Shared Tasks since WMT20 (Fraser, 2020; Libovický and Fraser, 2021; Weller-Di Marco and Fraser, 2022; Okabe et al., 2025), for both Upper and Lower Sorbian.

**Summary.** This study explores the effectiveness of in-context learning (ICL) in this low-resource translation task. Previous studies on low-resource MT have shown that dictionaries, morphological analysis and parallel examples are generally beneficial, whereas grammatical information provides rather limited benefits (Pei et al., 2025; Zhang et al., 2024b; Court and Elsner, 2024). Motivated by these findings, this work mainly investigates the effects of dictionary and morphological contextual information for Sorbian–German MT.

## 3 Tagging and Dictionary Creation

Machine translation remains challenging for Upper Sorbian due to its low-resource nature and rich morphology. We explore context augmentation strategies to better support the model in translating a Sorbian input sentence by providing two complementary types of information: *morphological tags* and bilingual *dictionary entries*. The morphological analysis provides an abstract description of the input sentence in which inflectional features such as case, number and tense are directly accessible, as well as the respective lemma. Relying on a bilingual dictionary, translation options support the model with lexical mappings from the source to the target language.

### 3.1 Parallel Data

All datasets, a parallel HSB-DE training corpus, as well as our test set, are sourced from previous WMT Shared Tasks on the Sorbian languages, WMT 2022[1] and WMT2025[2].

The parallel training corpus used to create a HSB-DE dictionary contains 510,077 unique sentence pairs after deduplication. As test set, we use the TUM-NLP 2025 MT development set. After removing sentence pairs that overlap with the training corpus, we randomly sampled 2000 sentences for testing. The remaining 902 sentence pairs formed the candidate pool for few-shot example selection.

### 3.2 Pre-Processing: Tagging

We used RNNTagger[3] (Schmid, 2019) to obtain morphological information. The tagger is applied to both the training corpus used for dictionary construction and the test set. Each tagged token is represented by its surface form, morphological full tag (POS tag and inflectional features) and lemma. Table 1 shows an example of tagging output.

### 3.3 Dictionary Creation

The HSB-DE dictionary is derived from word-aligned parallel data, from which we extract 1-1 and 1-$n$ translation pairs.

**Alignment.** Word alignment was obtained with Eflomal[4,5] (Östling and Tiedemann, 2016)). For the alignment, each token is represented by its lemma and morphological full tag. We follow the standard procedure of computing alignments for both the forward and the reverse direction, and then apply symmetrization using *atools* from FastAlign[6].

**Dictionary at the `Lemma|CoreTag` Level.** To mitigate the data sparsity issue exacerbated by the rich morphology of Upper Sorbian, the HSB-DE dictionary is constructed at the `Lemma|CoreTag`-level according to the tagged training corpus and corresponding alignments. Each dictionary entry maps a source word to a frequency-ranked list of target-language translation candidates. The construction process consists of five steps:

[1] https://statmt.org/wmt22/unsup_and_very_low_res.html

[2] https://github.com/TUM-NLP/llms-limited-resources2025/tree/main/Sorbian/hsb/MT

[3] https://www.cis.uni-muenchen.de/~schmid/tools/RNNTagger/

[4] https://github.com/robertostling/eflomal

[5] We opted for statistical word alignment as opposed to a neural alignment tool like SimAlign (Jalili Sabet et al., 2020) where the alignment quality depends on the coverage of the language in the underlying model; for example, mBERT (Devlin et al., 2019) does not support Sorbian.

[6] https://github.com/clab/fast_align

1. Extracting source-target token pairs according to alignment indices.

2. Filtering noisy token types, e.g. PROPN, NUM.

3. Aggregating occurrence frequencies for associated target candidates.

4. Representing one-to-many alignments as a multi-word expression with a PHRASE tag.

5. Ranking target candidates by descending frequency.

The resulting HSB-DE dictionary contains 177,436 unique source entries with an average of 3.77 translation candidates per entry. Using the same token filtering criteria as in dictionary construction, the dictionary reaches 96.21% coverage at the Lemma level and 95.68% at the Lemma|CoreTag level on the test set. Most uncovered entries belong to the noun (NOUN/NN/NE) and adjective (ADJ/ADJA/ADJD) word types, and the majority of their lemmas are tagged as <unknown>.

**Dictionary Lookup.** When applying the dictionary to retrieve translation candidates for context construction, each token in the HSB test set is looked up using the following fallback order: (1) exact matching at the Lemma|CoreTag level, (2) matching at the Lemma level, and (3) matching using lowercased or title-cased lemma forms. The first successful match returns the ranked list of target translation candidates at the Lemma|CoreTag level used for subsequent context construction. Filtered or unmatched tokens receive no translation candidates.

## 4 Context Strategies

To compare the individual and combined effects of **lexical information** from the generated Lemma|CoreTag dictionary and **morphological information** from the source-side tagged output, we explore four context construction strategies: **Strategy A** combines the most frequent translation candidate with optional morphological information in a pseudo-gloss format; **Strategy B** provides multiple translation candidates; **Strategy C** uses morphological information only; **Strategy D** combines multiple translation candidates with complete morphological information. Throughout this section, we use the example in Table 1 to illustrate different context construction strategies.

**Source:** Zo bychu prózdnjeńcu před přistupom kunow abo wrónow škitali, zamurjuja pikotače zachod.

**Reference:** Um die Höhle vor dem Zugriff von Mardern oder Krähen zu schützen, mauern die Kleiber den Eingang zu.

*English for readability*: To protect the nest cavity from access by martens or crows, nuthatches wall up the entrance.

**Source-side tagged representation**

| Word | Morph | Lemma |

| pikotače | ADJ.Acc.Neut.Sing.Part.Pass | pikotači |
| zachod | NOUN.Inan.Acc.Masc.Sing | zachod |
| . | PUNCT | . |

Table 1: Example sentence with morphological analysis.

### 4.1 Context Strategy A: Pseudo-Gloss

We consider two variants of Context Strategy A, illustrated in Table 2.

Context Strategy A1 constructs a pseudo-gloss by replacing each matched source token with its most frequent target translation candidate, while unmatched tokens keep their original form. The resulting lexical sequence is interleaved with Upper Sorbian morphological tags to provide inflectional information. This context design provides an abstract target-language representation while preserving the original source token order.

While some Upper Sorbian-specific morphological features (e.g. dual number and grammatical gender and some cases) have no direct mapping in German, we assume that they still provide relevant linguistic signals to help form a complete translation into German. To assess the impact of the morphological information, we also evaluate a variant without source-side morphological tags (A2), resulting in a lexical-only sequence containing German lemmas for matched tokens and original forms for unmatched tokens, in Upper Sorbian word order.

### 4.2 Context Strategy B: Dictionary Entries

An obvious issue with Context A is that it relies solely on the highest-ranked translation option. Context B provides multiple translation candidates to better address lexical ambiguity and to offer a larger range of options. This is relevant not

**A1: Translation candidates with source morpho-tags.**

```
<gloss> dass ADP sein AUX.Cnd.Plur.3.Fin Höhle
NOUN.Acc.Fem.Sing vor ADP Beitritt NOUN.Ins.Neut.Sing Marder
NOUN.Gen.Fem.Plur oder CCONJ Krähe NOUN.Gen.Fem.Plur schützen
VERB.Inan.Masc.Plur.Past.Part.Act , PUNCT mauern
VERB.Ind.Sing.3.Pres.Fin Kleiber ADJ.Acc.Neut.Sing.Part.Pass
Eingang NOUN.Inan.Acc.Masc.Sing . PUNCT </gloss>
```

**A2: Translation candidates only.**

```
<pseudo_translation> dass sein Höhle vor Beitritt Marder oder
Krähe schützen , mauern Kleiber Eingang . </pseudo_translation>
```

*Note:* The representation uses a single line, wrapped here only because of space constraints.

Table 2: Example for Context Strategy A

only for words with clearly different meanings, but also for function words like conjunctions or prepositions that have a large variety of possible translations which strongly depend on the context. To select the translation candidates, we consider the following factors:

**Representation:** Keeping vs. not keeping the main tag of the translation candidates, as illustrated in the dictionary entry for `zamurjować` (EN: '*to wall up*'; DE: '*einmauern*') below:

- **With Tag & Raw** keeps `Lemma|CoreTag` format to provide shallow syntactic information. `zamurjować (VERB): mauern (VVFIN), einmauern (VVINF), einmauern (VVPP)`
- **No Tag & Unique** provides unique lemma-level target candidates ranked by aggregated frequency. `zamurjować: einmauern, mauern`

**Probability Threshold:** Only translation candidates with relative frequency above the threshold are kept. Table 9 summarizes the statistics for Context B across thresholds.

### 4.3 Context Strategy C: Morphological Analysis

To help the model capture the rich morphology of Upper Sorbian, Context Strategy C provides morphological information for each source token, including the surface form, morphological tags (POS tag and inflectional features) and lemma, cf. `<morph>...</morph>` in Table 3. This representation links each inflected form to its lemma to address data sparsity at the lexical level, and also provides a morpho-syntactic analysis in the sentence context.

*Configuration: Block-by-Block Order-BC*

```

</morph>
```

*Note:* The representation uses one token per line. Long lines wrap here only because of space constraints, with continuation lines indented to distinguish them from new token entries.

Table 3: Context Strategy D: lexical information (`<dict>`) and morphological information (`<morph>`).

### 4.4 Context Strategy D: Combined Dictionary Entries and Morphological Analysis

Context Strategy D combines lexical information from the best-performing configuration of Context Strategy B with morphological information from Context Strategy C. The combined representation varies along the following dimensions:

- **Structure:** *All-in-One*, where all information for each source token appears on a single line, or *Block-by-Block*, where the two information types are grouped into separate blocks.
- **Order:** *OrderBC*, where lexical information is presented first, or *OrderCB*, where morphological information is presented first.

## 5 Experiments

To address RQ1, we compare the context-free baseline (baseline prompt) with the four context-augmented strategies (extended prompts with described context) in a zero-shot setting using

```
Translate the following Upper Sorbian sentence
into German: <hsb> {sentence} </hsb>
The following context is provided to assist with
the translation:
[Context block]
Provide exactly one translation (no
alternatives, no explanations) in this format:
<de> {German translation} </de>
```

Table 4: Zero-shot Generic-Intro prompt template.

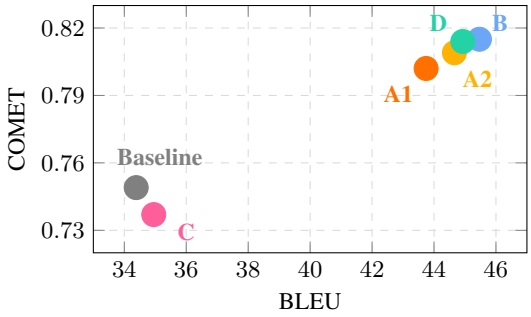

Figure 1: Cross-Strategy Performance Comparison measured by BLEU and COMET. See numerical results in Table 10 in Appendix B.

`Llama3.3-70B-Instruct` with the prompt template shown in Table 4[7]. For RQ2, we further investigate whether the observed effects in the LLaMA zero-shot setting generalize to another model (`GPT-4o`) as well as to the LLaMA few-shot setting.

### 5.1 Experimental Setup

Experiments were conducted on our test set of 2000 HSB source sentences; few-shot examples were drawn from an extra pool of 902 sentences.

We used `Meta:Llama 3.3 70B Instruct` (hereafter `LLaMA`) (Meta AI, 2024) as primary model, while `OpenAI: GPT-4o` (hereafter `GPT`) (OpenAI et al., 2024) was used only for the cross-model comparison. All requests were sent through OpenRouter API with the temperature set to 0.

### 5.2 Prompt Settings

The zero-shot baseline prompt contains only the translation instruction and the output format, whereas the context-augmented prompt additionally includes a context introduction and a strategy-specific context block.

In the few-shot setting, all prompts additionally include the same three demonstration pairs with source sentences of 10–15 tokens, randomly sampled with a fixed seed of 42 from a separate parallel HSB-DE sentence pool disjoint from the test set. The source and target sentences serve as demonstration inputs and outputs, respectively, while demonstration contexts for context-augmented variants are constructed according to the strategy being evaluated.

### 5.3 Evaluation Metrics

We evaluate translation quality using BLEU (Papineni et al., 2002) for lexical overlap via the implementation of SACREBLEU[8] (Post, 2018) and COMET (Rei et al., 2020) for semantic similarity. Model outputs were post-processed by removing configuration headers and formatting tags to ensure sentence alignment, without modifying the translation content.

### 5.4 RQ1 Experimental Results

Figure 1 shows an overview of all strategies, displaying each in its best-performing configuration.

**Lexical information is the primary contributor to translation performance.** All strategies providing source-to-target lexical mappings (Contexts A1, A2, B, and D) substantially outperform the baseline in both BLEU and COMET (Figure 1), with lexical-only Context B performing best overall. Strategies providing multiple translation candidates (Contexts B and D) consistently outperform those using only the top-ranked candidate (Contexts A1 and A2). In contrast, morphology-only Context C shows a marginal BLEU improvement and a slight COMET decline. Adding source-side morphology to lexical information also offers limited benefit, as Context D and A1 does not outperform the corresponding lexical-only strategies, B and A2, respectively.

**Compact sets of unique, tag-free translation candidates perform best.** The *No Tag & Unique* variant consistently outperforms *With Tag & Raw* across all thresholds in both BLEU and COMET (Figure 2), with a particularly large BLEU gain at the 20% threshold, indicating that removing tags and deduplicating translation candidates provides more effective lexical context. As thresholds increase, both variants improve and then decline,

[7] In preliminary experiments, we compared a *Generic-Intro* prompt with a *Described-Intro* variant that replaces the generic term `context` with a strategy-specific description (e.g. *token-aligned German gloss with morpho-syntactic features*), but found the generic prompt more effective.)

[8] `BLEU signature:nrefs:1|case:mixed|eff:no|tok:13a|smooth:exp|version:2.6.0`

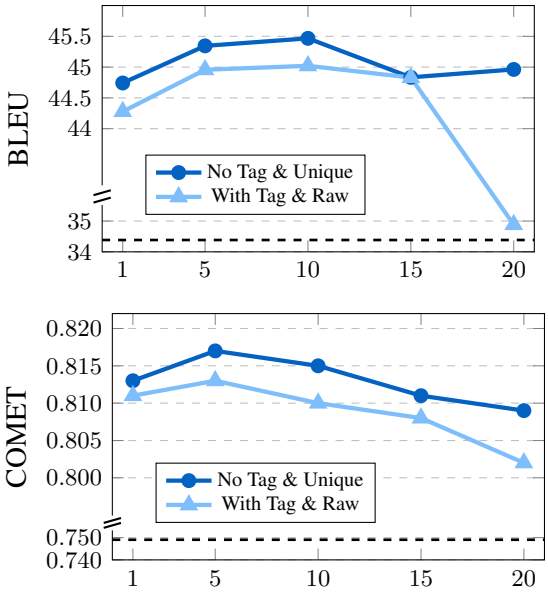

Figure 2: Comparison of Context B Variants across different frequency-filtering thresholds measured by BLEU and COMET. The dashed lines indicate context-free baseline. See numerical results in Table 11 in Appendix B.

with BLEU and COMET for *No Tag & Unique* peaking at 10% and 5%, respectively. The corresponding averages of 1.6307 and 2.3691 candidates per source token (Table 9 in Appendix A) suggest BLEU favors a more focused candidate set than COMET. We therefore select *No Tag & Unique* variant with a 10% threshold for subsequent Context B experiments, as it achieves the highest BLEU and near-peak COMET.

**A lexical block followed by a morphological block performs best in combining information.** *OrderBC* (lexical information first) generally outperforms *OrderCB* (morphological information first) in both BLEU and COMET (Figure 3), except for a slight COMET advantage for *Order-CB* in *All-In-One*. This suggests that presenting lexical information before morphology is generally more beneficial. While *All-In-One* remains relatively stable across orderings, *Block-By-Block* is more sensitive to information order, achieving the highest BLEU and COMET scores with its *OrderBC* variant. We therefore select *Block-By-Block OrderBC* for subsequent Context D experiments.

### 5.5 RQ2: Evaluating Additional Settings

For RQ2, we first evaluate whether the observed improvements also hold with another model (GPT). Then, we evaluate the four context strategies in a few-shot setting with our primary LLaMA model.

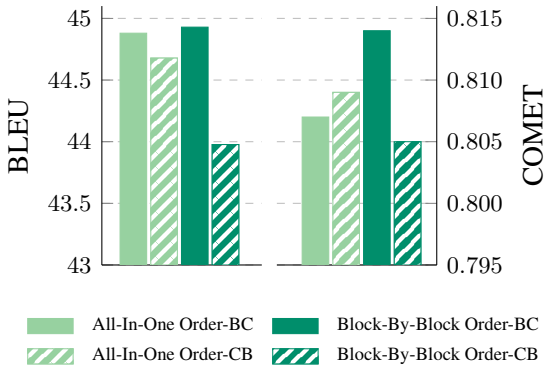

Figure 3: Comparison of Context D Variants across different representations measured by BLEU and COMET. See numerical results in Table 12 in Appendix B.

**Same trend for GPT.** Although GPT achieves higher translation quality overall, the effects of context augmentation follow the same general pattern as with LLaMA (cf. Figure 4): improvements over the baseline for context strategies providing source-target mappings, and the worst performance for the morphology-only context. Notably, the GPT baseline reaches a BLEU score comparable to several context-augmented LLaMA results.

**Few-shot consistently outperforms zero-shot for LLaMA.** Across all strategies, including the baseline, few-shot prompting improves both BLEU and COMET (Figure 5). Notably, Context A2 achieves the highest BLEU score in the few-shot setting, with Contexts B and D close behind.

**Summary.** The context strategies with their selected configurations show broadly similar performance patterns across LLaMA zero-shot, GPT zero-shot and LLaMA few-shot settings. Con-

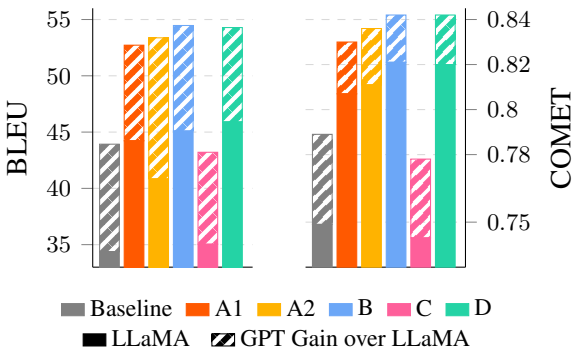

Figure 4: Comparison of LLaMA and GPT under zero-shot prompting measured by BLEU and COMET. See numerical results in Table 13 in Appendix B.

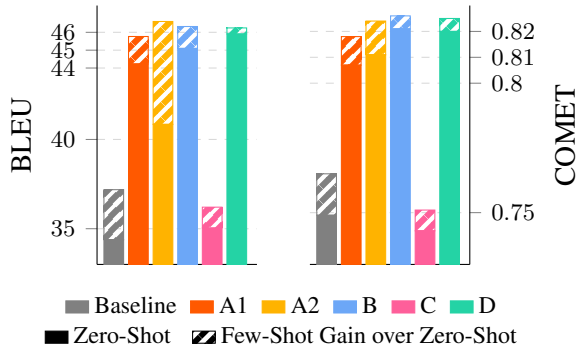

Figure 5: Zero-shot and few-shot performance of LLaMA measured by BLEU and COMET. See numerical results in Table 14 in Appendix B.

texts B and D consistently form the top-performing group, while A1 and A2 tend to rank in the middle. Context C remains the weakest context strategy in almost all evaluated settings, often performing below the baseline.

## 6 Discussion

The experimental findings of RQ1 (Section 5.4) are examined through sentence-level case studies[9], focusing on the benefits of multiple translation candidates and the conditional usefulness of source-side morphology. The full corresponding Context D examples are provided in Appendix C.

**Multiple translation candidates help context-dependent lexical selection.** This example (Table 5) contains two source words with multiple plausible translations: *wopismo*, with candidates *Urkunde* (*document*) and *Bescheinigung* (*certificate*), and *puć̀owanje*, with candidates *Wanderung* (*hike*) and *Reise* (*trip*) (see Table 15 in Appendix C). The reference translation uses *Bescheinigung* and *Reise*. Given only the most frequent candidate for each word in Context A1, the model produces *Urkunde* and *Wanderung*, which are plausible dictionary translations in isolation but less suitable in this context. By contrast, Contexts B and D provide multiple candidates, allowing the model to choose the contextually appropriate alternatives *Bescheinigung* and *Reise*.

**Reliable morphological tags can be beneficial.** In this example (Table 6), the morphological tags are largely accurate (see Table 16 in Appendix C). Contexts A1, B, and D correctly recover key lexical

[9]With the context configurations selected in Section 5.4; using *Zero-Shot Baseline* prompt for the baseline and *Zero-Shot Generic-Intro* prompt for context-augmented examples.

| **Context D** | **Verfasst** von einem Mönch des Mittelalters, **berichtet** der Brief über den **Schatz** des **Fürsten**. | 0,904 |

*Note:* English for readability: "**Written** by a medieval monk, the letter **recounted** the **prince's treasure**." See Context D in Table 16 in Appendix C.

Table 6: Reliable morphological tags

choices consistent with the reference, such as *verfasst* (*written*) and *Schatz* (*treasure*), while the baseline and Context C produce less appropriate lexical choices. The baseline correctly reproduces the first part of the sentence, but fails to translate the second part. Nevertheless, Context C outperforms the baseline and is the only variant that correctly reproduces the source tense, likely due to the explicit past-tense tag (`VERB.Ind.Sing.3.Past.Fin`). Context D achieves the highest COMET score, suggesting that reliable morphological tags can further improve translation quality when combined with lexical candidates.

**Incorrect morphological tags can cause error propagation.** This example (Table 7) illustrates how morphological ambiguity in Upper Sorbian can lead to contextually inappropriate tags, as illustrated in Table 8[10].

The dual verb *namołwitej* ('call upon') identifies *Koaliciskej frakciji* ('two coalition parliamentary groups') as the dual nominative subject and *knježerstwo* ('government') as the accusative ob-

|---|---|---|
| **Baseline** | Die Regierung **der Koalitionsfraktion** hat den Vorschlag der MSPI angenommen, der von der Europäischen Kommission verfolgt wird, um ihn zu überprüfen. | 0.660 |
| **Context B** | **Die Koalitionsfraktion** hat die Regierung aufgefordert, den Vorschlag des MSPI zu prüfen, soweit die Europäische Kommission ihm folgt, und zwar zunächst. | 0.728 |
| **Context C** | **Der Koalitionsfraktion**, die die Regierung gebildet hat, schlägt die MSPI vor, da die Europäische Kommission sie verfolgt, um sie besser zu prüfen. | 0.541 |

*Note:* English for readability: "**The two coalition parliamentary groups** called upon the government to promptly review MSPI's proposals, insofar as the European Commission adopts them." See Context D in Table 17 in Appendix C.

Table 7: Incorrect morphological tags

| HSB | Possible morphological analyses | Role |
|---|---|---|
| ADJ *Koaliciskej* | Sing.Dat/Ins/Loc **or** Dual.Nom/Acc | subject (Dual.Nom) |
| NOUN *frakciji* | Sing.Dat/Loc **or** Dual.Nom/Acc/Voc | |
| VERB *namołwitej* | Ind.Dual.3.Pres.Fin | verb (Dual) |
| NOUN *knježerstwo* | Sing.Nom/Acc/Voc | object (Acc) |

Table 8: Relevant Morphological Information.

ject. The baseline already misinterprets the subject-object relation, translating the first part into "*The government of the coalition parliamentary group* ...". While this translation is somewhat ambiguous due to case ambiguity in German, it does not correctly reproduce the relation between the two phrases.

Context C further amplifies this error by explicitly providing contextually inappropriate tags, where the actual subject *Koaliciskej frakciji* is labeled as locative and the non-subject element *MSPI* as nominative (see Table 17 in Appendix C). This appears to lead the model to treat *die MSPI* as the subject. In contrast, Context B avoids this subject-object confusion, suggesting that translation candidates presented in source-token order provide useful anchors for generation. All strategies fail to recover the dual feature from Upper Sorbian, translating *Koaliciskej frakciji* as singular rather than *Die beiden Koalitionsfraktionen* (*the two coalition parliamentary groups*) as shown in the reference. This suggests that the source-side dual feature is not reliably captured by neither the tagger nor the model.

Taken together, these case studies support the overall experimental findings. Providing multiple translation alternatives enables the model to select contextually appropriate lexical choices. In contrast, source-side morphology is conditionally useful: reliable tags can provide complementary structural cues, while incorrect tags can introduce noise and lead to error propagation.

## 7 Conclusion

This study investigates how lexical and morphological information provided in prompts affects LLM-based Upper Sorbian-to-German translation via ICL, using four representations: pseudo-gloss, lexical-only, morphology-only, and combined contexts. Context augmentation improves translation quality, with lexical-only context performing best overall. Morphological information shows limited benefit on its own and no consistent gains when combined with lexical guidance (RQ1). The relative ranking among context strategies remains largely stable across experimental settings (RQ2). These findings suggest that source-to-target lexical mapping is the major contributor to translation improvements. Case studies further show that the usefulness of source-side morphology can be limited by morphological ambiguity. Overall, the effectiveness of context augmentation depends on the type and reliability of the information provided.

## 8 Limitations

We briefly discuss some limitations of our study.

**Representation and reliability of source-side tags.** We used the morphological tags produced by RNNTagger without modification. However, the rich inflectional system of Upper Sorbian makes morphological analysis challenging, as reflected in the erroneous tags identified in our case studies which raises questions of the overall tagging quality. Furthermore, not all of the Sorbian features have a direct equivalent in German inflection, and thus might not provide a useful signal.

**Translation candidate selection and word sense disambiguation.** The most frequent translation candidates are not always contextually appropriate, but might put less frequent word senses at a disadvantage. Future work could consider the sentence-level context in candidate selection. Similarly, we only consider 1-1 and 1-many translation options, excluding longer $n$–$m$ phrase translations. Investigating more flexible translation units might help to preserve more contextual information, but is not trivial due to potential phrase overlap.

**Translation direction.** This study explores the translation from Upper Sorbian to German. Future work can investigate the reverse direction, shifting the focus from understanding low-resource input to generating low-resource text.

## Abstract

Neural machine translation attains high fluency on general-domain text but systematically fails on specialized terminology, where polysemous and low-frequency terms carry domain-specific meanings absent from general training data. We investigate two complementary interventions for English–Russian specialized translation across ten professional domains: (i) a four-stage retrieval-augmented pipeline of LLM-based term extraction, domain classification, lemma-based knowledge-base retrieval, and glossary-augmented translation; and (ii) a preference-based fine-tuning stage combining supervised fine-tuning (SFT) with Contrastive Preference Optimization (CPO) layered on top of retrieval. We release an open multi-domain English–Russian terminology knowledge base of 50,000 terms with 120,161 domain-tagged translations, a 200-item curated test set selected for terminology difficulty, and a 1,300-item Wikipedia-derived test set. Across four open base models, retrieval-augmented prompting alone delivers the bulk of the terminology gain and already exceeds the two commercial reference systems; the additional preference-tuning stage contributes only a small further gain at a measurable fluency cost. The pattern transfers to the WMT25 Terminology Translation Task, the most recent iteration of the shared task that included English–Russian as a language pair.

## 1 Introduction

Modern neural machine translation (NMT) is remarkably strong on general-domain text, but specialized text is where it breaks down: a drilling report's *Christmas tree* becomes a holiday tree rather than a wellhead valve assembly, and a legal *consideration* reverts to its everyday sense. NMT and LLM architectures do condition on local context, but a strong frequency bias in the general training data often overrides that signal, driving the model toward the higher-frequency general sense because specialized senses are under-represented in training data.

Retrieval-Augmented Generation (RAG) sidesteps retraining by querying an external knowledge base at inference time and inserting retrieved term translations into the prompt. The complementary route is fine-tuning the model itself, optionally with preference-based objectives such as the Contrastive Preference Optimization (CPO) stage of ALMA-R (Xu et al., 2024). Both directions have been studied separately; their combination – structured multi-domain glossary retrieval on top of CPO-style fine-tuning – has not been systematically evaluated for English–Russian. There is also a resource gap: openly available Russian termbases either spread coverage unevenly across domains or focus on a single specialization.

This paper asks two research questions.

**RQ1**: to what extent does domain-classified glossary retrieval improve EN–RU translation of specialized terminology across ten professional domains, compared to direct translation?

**RQ2**: does preference-based fine-tuning (SFT followed by CPO) complement retrieval?

**Contributions.** (1) An open multi-domain EN–RU terminology knowledge base of 50,000 terms with 120,161 domain-tagged translations across ten domains. (2) A 200-item test set whose items are specifically selected for terminology difficulty (polysemy, compositionality, rarity), plus a 1,300-item Wikipedia-derived test set for a larger distributional check. (3) A four-stage retrieval-augmented pipeline evaluated across four open-source base models and two commercial systems, with an SFT+CPO ablation on two of the open models. (4) External validation on the WMT25 Terminology Translation Task. All resources – code, knowledge base, both test sets, evaluation scripts, and verbatim prompts – are released at https://github.com/Maryleya/RAG_System_for_Specialized_Terms.

## 2 Related Work

**MT of specialized text.** Domain shift is a long-standing failure mode of NMT (Koehn and Knowles, 2017), and recent multi-domain studies confirm that terminology errors propagate to downstream quality (Oncevay et al., 2025). Domain-adaptation surveys (Chu and Wang, 2018; Saunders, 2022) address the domain as a whole rather than individual terms, which motivates term-level intervention.

**Terminology-constrained translation.** Constrained decoding (Hokamp and Liu, 2017; Hasler et al., 2018) enforces pre-specified lexical constraints but degrades fluency on morphologically rich targets. Training-time term injection (Dinu et al., 2019) avoids this at the cost of retraining. The WMT Terminology Shared Task (Semenov et al., 2025) has run in 2021, 2023, and 2025 and provides the closest evaluation precedent to the present work.

**Retrieval-augmented MT.** kNN-MT (Khandelwal et al., 2021) established inference-time retrieval for domain adaptation at the token level. RAG (Lewis et al., 2020) combines parametric and non-parametric knowledge; RAGtrans (Wang et al., 2024) applies this to MT with document-level retrieval. Dictionary-level prompting (Ghazvininejad et al., 2023; Moslem et al., 2023) injects bilingual entries directly into the LLM prompt, which we adopt. The closest prior system, DragFT (Zheng et al., 2024), combines dictionary prompting with SFT for EN–ZH but does not target Russian, omits a separate domain classifier, and does not extend to preference-based fine-tuning – the gap the present work addresses. WMT25 retrieval-augmented systems (Nieminen et al., 2025; Guttmann et al., 2025) assume the terminology dictionary is supplied as part of the task rather than retrieved end-to-end.

**Fine-tuning for translation.** Parameter-efficient adaptation of large translation models is now typically done with LoRA (Hu et al., 2022). On top of that, ALMA (Xu et al., 2023) and its preference-tuned successor ALMA-R (Xu et al., 2024) argue that CPO sidesteps the reward-margin collapse that plain DPO (Rafailov et al., 2023) runs into when the *chosen* side is a human reference translation.

**Evaluation.** chrF2++ (Popović, 2015), BLEU (Papineni et al., 2002), the COMET family (Rei et al., 2020, 2022), and MetricX (Juraska et al., 2023) provide the general quality signal. The WMT Terminology Shared Task (Semenov et al., 2025) and its prior editions score term compliance with a lemmatized exact-match criterion: a constraint counts as satisfied only if some surface form sharing the reference lemma appears in the output, which penalises a system that conveys the correct meaning through a valid same-domain synonym the reference happens not to use. We build our own Terminology Success Rate (TSR) as a two-stage extension of that same idea: pymorphy3 (Korobov, 2015) lemma matching first – equivalent to the WMT-style criterion – and then, only for the items the first stage rejects, an LLM-as-judge pass that additionally credits morphological variants and legitimate same-domain synonyms, following Semenov and Bojar (2022) and Zheng et al. (2023). We add the second stage because our KB itself routinely lists several valid Russian variants per English term (§3.1), so a strict single-reference match would undercount correct translations by construction; the two stages are kept separable so that the first-stage-only number remains directly comparable to the WMT-style criterion. For external validation against WMT25 itself (§5.7) we accordingly report the shared task's own official script rather than substituting our two-stage TSR, keeping that comparison on WMT's own terms. Freitag et al. (2021) document the miscalibration of general-domain neural quality metrics on out-of-distribution translations – a finding sharpened by Zouhar et al. (2024), who show that fine-tuned MT metrics specifically degrade in unseen, specialized domains – a concern we return to in §5.5.

## 3 Resources

### 3.1 Terminology Knowledge Base

The KB pulls entries from five sources, each covering a different gap in EN–RU terminological coverage. **Multitran**[1] is a large, crowd-sourced online dictionary that functions as the de facto standard reference tool for Russian professional translators; entries are contributed by volunteer translators, each tagged by its contributor with a subject field. It supplies the bulk of our material, with its editor-assigned domain tags mapped down to our ten canonical labels. We add three further sources to extend coverage beyond Multitran: **Wikipedia interlanguage titles**, i.e. pairs of article titles linked across language editions of Wikipedia, which yield

[1] https://www.multitran.com

a term pair whenever an encyclopedia entry exists in both English and Russian; **Wikidata label pairs**, the English and Russian labels attached to the same item in Wikidata (Wikipedia's structured companion knowledge base of entities); and **EngCom**[2], an open, community-maintained English–Russian dictionary of computing terminology, used only to extend the IT domain. Finally, **Wiktionary**[3], the collaboratively edited multilingual dictionary, contributes general-vocabulary pairs; since Wiktionary entries carry no subject-field tag of their own, they inherit the domain tag of whichever KB entry they align with. Polysemy is preserved at the entry level rather than collapsed: *draft* keeps both *осадка* for shipbuilding and *черновик* for general use, and *haircut* keeps the financial discount reading separately from the cosmetic one. The final KB has 50,000 unique English terms and 120,161 domain-tagged Russian translations (2.46 per term on average) across IT, aviation, medicine, oil and gas, agriculture, construction, shipbuilding, finance, energy, and law.

### 3.2 Test Sets

Two test sets serve complementary roles. The **curated set** has 200 items, 20 per domain. It was assembled semi-automatically from three specialized reference sources – **UNTERM**[4], the United Nations' own multilingual terminology database of terms used in UN documentation; **Linguee**[5], a bilingual search engine that pairs a conventional dictionary with real translated sentence pairs mined from the web; and **Gufo.me**[6], an online aggregator of Russian-language dictionaries and encyclopedias spanning many subject fields – topped up by hand through **ProZ.com**[7], the largest online community and job marketplace for professional translators, whose crowd-sourced KudoZ glossary lets translators propose and vote on translations for difficult terms. Every candidate was then checked manually item by item and kept only if it presented at least one of three concrete difficulties – polysemy, compositionality, or rarity – so that a strong general-purpose system is expected to get it wrong even though the intended translation is known. The **wiki set** is much larger (1,300 items), drawn from Wikipedia-aligned parallel data without any difficulty filter, and gives a broader distributional view. Because it lacks aligned reference sentences, it is scored with reference-free metrics and TSR only.

### 3.3 Fine-Tuning Pool

The fine-tuning pool holds 10,000 (source, chosen, rejected) triplets mined from WikiMatrix (Schwenk et al., 2021) and ParaCrawl (Bañón et al., 2020). Selection is lemma-aware: sentences are kept when they match a KB term pair. About 86% of the pool is an "other"-domain portion mixed in on purpose so the model does not drift away from general-domain text. Rejected candidates come from the very model being fine-tuned, run zero-shot without the glossary, which points the preference signal at that model's own failure modes rather than at some generic baseline. A three-stage filter runs before mining is complete: it drops proper nouns and short generic terms, transliteration cognates such as *router* – *роутер*, and any term Google Translate already handles correctly. Google Translate is used here purely as a difficulty proxy – an external, off-pipeline system that flags examples on which a strong general-purpose engine already succeeds, so the surviving pool concentrates on terminology cases where a fine-tuning gain is actually possible; the fine-tuned models themselves are never compared to or trained against Google Translate. Any sentence that overlaps with the curated or wiki test set – by source sentence or by target term – is excluded from the mining pool throughout, so that no fine-tuning example leaks into evaluation.

## 4 Methodology

### 4.1 Pipeline

The pipeline turns a single English source sentence into a Russian translation in four stages (Figure 1), each consuming the previous stage's output and producing one new artifact.

**Stage 1: Term Extraction.** A few-shot prompt to Qwen3-4B-Instruct-2507 (Appendix B) reads the source sentence and returns a newline-separated list of the noun phrases it judges to be specialized terminology, with no other output. We compared this LLM extractor against three lighter-weight alternatives – a supervised BERT-NER model trained on ACTER (Rigouts Terryn et al., 2020), and the unsupervised keyword extractors KeyBERT and YAKE – and adopted the LLM extractor for its recall–precision trade-off and, more importantly,

[5] https://www.linguee.com
[6] https://gufo.me
[7] https://www.proz.com

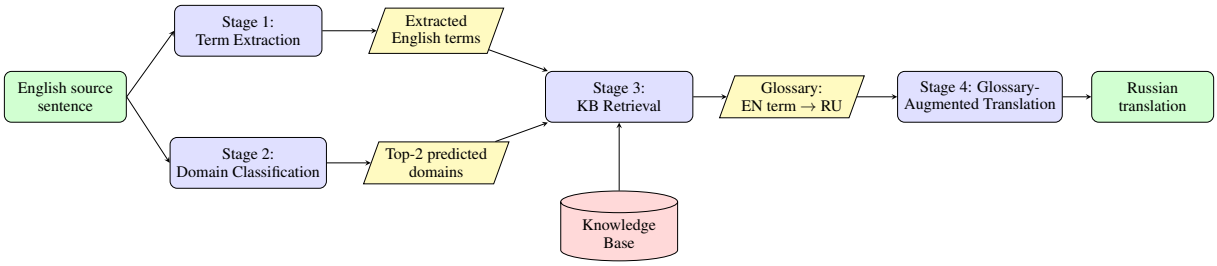

Figure 1: Overview of the four-stage retrieval-augmented translation pipeline. Blue rounded boxes are processing stages; yellow parallelograms are intermediate data artifacts passed between stages; the red cylinder is the external terminology knowledge base queried at Stage 3; green boxes are the source input and target output.

because it needs no domain-specific retraining to generalize across our ten target domains (Table 1). Its average of 4.04 extracted terms per sentence is in the same range as the unsupervised baselines (5.00 / 4.91), so some of what it extracts will not be genuine specialized terminology; this is tolerable because Stage 3 only ever inserts a glossary entry for a string that is actually present in the KB, so a spurious extraction simply fails to retrieve anything rather than propagating as a translation error.

**Stage 2: Domain Classification.** In parallel with extraction, the same source sentence is classified into one of the ten KB domains by a second Qwen3-4B-Instruct-2507 prompt (Appendix C). The classifier is primed with 30 synthetic (sentence, domain) examples – three per domain, themselves LLM-generated from a short keyword description of that domain (Appendix C.1) – so bootstrapping the classifier needs no manual per-domain annotation. Rather than commit to one label, the classifier outputs a `Primary` and an `Alternative` domain, and both are passed forward to filter Stage 3 retrieval; we found this top-2 handoff meaningfully more robust than using the top-1 label alone (Table 2), since some sentences are genuinely ambiguous between adjacent domains (e.g. energy vs. oil and gas). We chose this LLM classifier over an embedding-centroid alternative – paraphrase-multilingual-mpnet-base-v2 sentence embeddings, with class centroids computed from the same 30 synthetic examples – because it gave consistently higher top-1/top-2 accuracy.

**Stage 3: KB Retrieval.** The extracted terms and the predicted top-2 domains are jointly used to query the KB (§3.1): for each extracted term, its lemma is looked up, and only the Russian translations tagged with either predicted domain are kept, discarding translations tagged for other domains even when the lemma matches. This restricts a polysemous entry like *draft* to only its shipbuilding sense when Stage 2 predicts shipbuilding, rather than surfacing all 2.46 average translations regardless of context. We chose this lemma-based lookup over two dense-retrieval alternatives we also tried – embedding the single-word KB entries and matching by cosine similarity, and embedding whole sentences to match against single-word entries – because both degraded on exactly the polysemy cases the pipeline is meant to fix: a single embedding for a polysemous word collapses toward its dominant sense, and sentence-to-word matching compares the wrong granularity. The output is a compact glossary: English term → one or more domain-tagged Russian translations.

**Stage 4: Glossary-Augmented Translation.** The Stage 3 glossary is inserted into a translation prompt (Appendix D) that instructs the model to strongly prefer a glossary translation whenever the corresponding English term appears in the source, to pick among several domain-tagged variants by context when more than one survives filtering, and to inflect the chosen Russian lemma for the correct case, number, and gender rather than pasting it in unchanged. Terms absent from the glossary – because Stage 1 missed them or the KB has no entry – are left entirely to the model's own judgment. This is a soft preference rather than a hard decoding constraint, a deliberate choice: it lets the model fall back to a fluent translation when the glossary is empty, wrong, or grammatically awkward in context, at the cost of not guaranteeing that a supplied glossary term actually surfaces in the output – which is exactly what TSR measures downstream (§3.1, §5.5).

### 4.2 Pipeline Variants

The four-stage pipeline above is referred as `rag_clf` below. We compare it against six other

configurations, each isolating one design choice by changing exactly one stage relative to `rag_clf`.

**`baseline`.** No glossary at all: the source sentence is translated with a plain zero-shot translation prompt (Appendix D), so that the reported baseline is a standard ordinary-MT number, comparable to how the four base models are used off the shelf. This means the baseline and the `rag_*` variants differ both in retrieval content and in prompt template, so some fraction of the observed `rag_clf` lift may be attributable to the glossary prompt itself rather than to retrieved content. A prompt-only control (the glossary prompt run with an empty dictionary) would separate the two contributions and we flag its absence in Limitations.

**`rag_auto`.** Stages 1, 3, and 4 run as usual, but Stage 2 is skipped entirely: Stage 3 retrieves *every* domain-tagged translation for each extracted term regardless of predicted domain, so the model sees every sense of a polysemous term at once rather than a domain-filtered subset. Comparing `rag_auto` to `rag_clf` isolates the contribution of domain classification specifically, separately from the contribution of retrieval itself.

**`rag_clf`.** The full four-stage pipeline described above.

**`rag_clf_sft` and `rag_clf_sft_cpo`.** Identical to `rag_clf` at Stages 1–3; only the Stage 4 translation model changes, to the SFT checkpoint and the SFT+CPO checkpoint respectively (§4.3). Fine-tuning is applied only to Hy-MT and Qwen, so these two variants exist only for those two base models.

**`term_substitution`.** A non-retrieval-augmented alternative that never shows the model a glossary: Stage 1's extracted terms are instead substituted, in Russian, directly into the *source* sentence before translation (a code-switched source, cf. Dinu et al., 2019), and the model is prompted only to keep the inserted Russian words as-is while translating the rest of the sentence (Appendix D). This trades away Stage 4's soft preference for a much stronger guarantee that the term survives into the output, at a fluency cost we quantify in §5.5.

**`rag_oracle`.** Identical to `rag_clf` except that Stage 2's prediction is replaced by the ground-truth domain label. This is not a deployable configuration – it requires a human to specify the domain – but it serves two purposes: as an upper bound that isolates classifier error from every other source of pipeline error (§5.5), and as a description of a practical translator-in-the-loop workflow, where a human specifies the domain once per document and the pipeline automates term extraction and retrieval underneath it.

### 4.3 Base Models and Fine-Tuning

The open side of the comparison uses four models: Llama-3.2-3B-Instruct, Qwen3-4B-Instruct-2507, TranslateGemma-4B, and Hy-MT2-7B. Google Translate and Yandex Translate serve as commercial reference points. Fine-tuning is applied only to two of the four open models – Hy-MT (the strongest baseline) and Qwen (a general-purpose control) – via LoRA at rank 64, $\alpha = 128$. The training recipe is 2 epochs of SFT at $10^{-4}$ on the chosen translations, with the glossary already sitting in the training prompt exactly as at inference; then 1 epoch of CPO at $5 \times 10^{-6}$, $\beta = 0.1$. An early DPO attempt collapsed with the same reward-margin pattern reported for ALMA-R (Xu et al., 2024); switching to CPO, whose NLL anchor keeps the chosen side pinned, stabilised it.

### 4.4 Evaluation

Surface quality is measured with sacrebleu (Post, 2018) chrF2++ and BLEU. On the neural side we report COMET (`Unbabel/wmt22-comet-da`) and COMET-Kiwi (`Unbabel/wmt22-cometkiwi-da`) together with MetricX-23 XXL and its reference-free variant MetricX-23-QE XXL (`google/metricx-23-v2p0` and `google/metricx-23-qe-v2p0`). Terminology accuracy uses our two-stage TSR: a lemma-based first pass – equivalent to the exact-match criterion used by the WMT Terminology Shared Task – then a RuQwen-2.5-32B judge that decides whether the remaining misses are actually valid same-domain synonyms. We report the combined two-stage number throughout the main results because it better reflects whether the intended meaning was conveyed; the first stage alone recovers the WMT-style score whenever a strictly comparable number is needed. For the WMT25 numbers (§5.7) we run the shared task's official script rather than our own pipeline, so that comparison stays on WMT's own terms.

| Extractor | Recall | Terms/sent. |
|---|---|---|
| LLM (Qwen3-4B-Instruct-2507) | 95.2% | 4.04 |
| KeyBERT | 84.1% | 5.00 |
| YAKE | 74.5% | 4.91 |
| BERT-NER (ACTER) | 37.5% | 2.26 |

Table 1: Term extraction results on the curated test set.

| Classifier | Top-1 | Top-2 |
|---|---|---|
| Embedding centroid | 74% | 86% |
| LLM (Qwen3-4B-Instruct-2507) | 80% | 90% |

Table 2: Domain classification results on the curated test set. Embedding centroid was made using paraphrase-multilingual-mpnet-base-v2.

## 5 Results

### 5.1 Component Ablations

The LLM-based term extractor reaches 95.2% recall at 4.04 terms per sentence, clearly ahead of KeyBERT (84.1%) and YAKE (74.5%). A supervised BERT-NER model trained on ACTER (Rigouts Terryn et al., 2020) does not transfer across our ten domains and finishes at 37.5% recall. For domain classification the same pattern holds: the LLM classifier reaches 80%/90% top-1/top-2 accuracy, while an embedding-centroid baseline plateaus at 74%/86%.

### 5.2 Main Pipeline Comparison

On the curated test set, rag_clf alone lifts TSR by at least +0.15 absolute over baseline on every open model, with the largest absolute gain (+0.295) on the weakest baseline (Llama), consistent with retrieval helping most where parametric terminology knowledge is weakest (Zheng et al., 2024). rag_clf_sft_cpo reaches 0.845 on Hy-MT (+0.17, 25% relative) and 0.84 on Qwen (+0.26, 45% relative), as shown in Table 3. The pattern replicates on the 1,300-item wiki set (Hy-MT: 0.755→0.86; Qwen: 0.607→0.813), and the classifier-filtered variant alone already exceeds both commercial systems on TSR (Table 4: 0.852 vs. Yandex 0.764 / Google 0.769 on wiki).

### 5.3 Per-Domain Analysis

Table 6 breaks down Hy-MT TSR by domain (both test sets combined). The baseline varies substantially, from 0.53 (shipbuilding) to 0.91 (IT). The rag_clf stage yields its largest gains on shipbuilding (+0.21) and aviation (+0.23), followed by oil and gas (+0.12), while providing little or no benefit on domains where the baseline is already strong (IT decreases slightly; law gains only +0.03). rag_clf_sft_cpo adds a further small gain on some domains but reverses the rag_clf gain on shipbuilding, energy, and finance, indicating that fine-tuning does not benefit all domains equally.

### 5.4 Qualitative Analysis

Individual items illustrate the four main patterns behind the aggregate numbers.

**Polysemy resolved by domain filtering.** In sentence (1) the aviation term *canopy* refers to the transparent cockpit cover:

> (1) When he looked up through the *canopy*, Taylor could barely make out the distant black specks on the horizon.

All four models at baseline render it as *крона деревьев* (tree canopy), whereas the glossary-augmented pipeline substitutes the aviation-correct *фонарь (кабины)*. The same pattern holds for *bulkhead* in a shipbuilding context, rendered as generic *перегородки* at baseline but correctly as *переборки* under `rag_clf`.

**Classifier noise.** When the classifier misroutes a sentence, the glossary steers translation toward the wrong sense. In (2) the medical *vehicle* means *растворитель* (solvent):

> (2) Water is often used as a *vehicle* in pharmaceutics.

Hy-MT baseline is correct, but under `rag_clf` the misclassified domain injects a pharmacy-related gloss that shifts the output away from the solvent reading. This is the mechanism behind the classifier-noise fluency cost quantified in §5.5.

**Fine-tuning: targeted gains and false substitutions.** Adding SFT and CPO on top of `rag_clf` sometimes recovers terms that retrieval alone misses: aviation *wet leasing* is rendered as *аренда без экипажа* only after fine-tuning. But the CPO preference signal also amplifies unrelated glossary entries. On oil and gas *break-out torque* (*развинчивание*), `rag_clf` produces the acceptable *отвертывание*, whereas the fine-tuned variant produces *борьба с появлением прыщей на лице*, a completely different English sense of *breakout* that CPO has over-weighted. On construction *truss* (*ферма*), `rag_clf` correctly produces *ферм* but the fine-tuned variant replaces it with *кистей*.

| Variant | Qwen | Llama | Gemma | Hy-MT | Google | Yandex |
|---|---|---|---|---|---|---|
| baseline | 0.580 | 0.200 | 0.650 | 0.675 | 0.745 | 0.760 |
| rag_auto | 0.755 | 0.385 | 0.780 | 0.825 | — | — |
| rag_clf | 0.830 | 0.495 | 0.800 | 0.830 | — | — |
| rag_clf_sft | 0.830 | — | — | 0.825 | — | — |
| rag_clf_sft_cpo | 0.840 | — | — | 0.845 | — | — |
| term_substitute | 0.905 | 0.800 | 0.845 | 0.920 | — | — |
| rag_oracle | 0.950 | 0.745 | 0.895 | 0.975 | — | — |

Table 3: Terminology success rate on the curated test set (200 items). Column headers denote base model versions: Qwen = Qwen3-4B-Instruct-2507, Llama = Llama-3.2-3B-Instruct, Gemma = TranslateGemma-4B, Hy-MT = Hy-MT2-7B (§4.3); Google / Yandex = Google Translate / Yandex Translate via their public APIs (§A). Fine-tuning (SFT/CPO) is applied only to the two strongest open models (Qwen and Hy-MT). Commercial systems are evaluated at their default settings; `rag_*` variants are not applicable to them.

| Variant | Qwen | Llama | Gemma | Hy-MT | Google | Yandex |
|---|---|---|---|---|---|---|
| baseline | 0.607 | 0.280 | 0.674 | 0.755 | 0.769 | 0.764 |
| rag_auto | 0.809 | 0.470 | 0.809 | 0.847 | — | — |
| rag_clf | 0.810 | 0.476 | 0.812 | 0.852 | — | — |
| rag_clf_sft | 0.805 | — | — | 0.856 | — | — |
| rag_clf_sft_cpo | 0.813 | — | — | 0.860 | — | — |
| term_substitute | 0.901 | 0.841 | 0.913 | 0.919 | — | — |
| rag_oracle | 0.910 | 0.757 | 0.885 | 0.955 | — | — |

Table 4: Model versions as in Table 3. Terminology success rate on the 1,300-item wiki test set. The classifier-filtered retrieval variant alone (`rag_clf`) already exceeds both commercial reference systems on Hy-MT, indicating that the terminology gain is not specific to a difficulty-filtered distribution.

**Cross-model validation and a possible size effect.** The weakest model (Llama-3.2-3B) exhibits a qualitatively different failure mode: it frequently fails to translate specialized terms at all and instead transliterates or copies the English word. Shipbuilding *bilge* (*льяло*) is rendered as *билг*; *pig* (pipeline scraper, *скребок*) becomes *интеллектуальный свинья* ("intelligent pig"); and *bollard* (*кнехт*) is copied as *bOLLARD*. This failure mode is absent from the three stronger models, which is consistent with a lower capacity bound below which a model cannot integrate glossary terms into fluent Russian output even when the correct term is explicitly provided in the prompt. We stop short of calling this a confirmed size effect, however: Llama-3.2-3B is the only sub-4B model in our comparison, and it also differs from the other three base models in pretraining data and instruction-tuning recipe, none of which we control for. Isolating parameter count from these family-specific differences would require an ablation across multiple sizes within a single model family, which we did not run (see the Limitations section).

### 5.5 Fluency–Terminology Trade-off

Surface metrics (chrF2++, BLEU) move in the same direction as TSR, but reference-free QE metrics move the opposite way. On Hy-MT curated, COMET-Kiwi drops from 0.800 (baseline) to 0.729 (`rag_clf_sft_cpo`) and MetricX-QE rises from 1.285 to 2.091; the same effect appears on wiki (Table 7: 0.839 → 0.762 and 0.914 → 1.809). Both QE metric families and both surface- and reference-free evaluation agree on the sign of the effect, ruling out a single-metric artifact.

Decomposing the cost via `rag_oracle` isolates classifier noise from glossary content, with different metrics showing different amounts of recovery. The cleanest decomposition is Hy-MT MetricX on the curated set: under gold domain classification MetricX is 2.57, essentially the baseline value of 2.60, so the entire `rag_clf` MetricX cost of $+0.58$ is attributable to classifier noise rather than glossary content, and the subsequent SFT+CPO stages add a further $+0.31$ MetricX on top – making classifier noise the larger of the two additive components. On the reference-free QE side, the same oracle diagnostic recovers only part of the drop: on Hy-MT wiki COMET-Kiwi baseline is 0.839 and `rag_oracle` sits at 0.768, closer to `rag_clf` (0.780) than to baseline, so on this metric a substantial residual fluency cost survives perfect domain classification. We take the two decompositions together as evidence that

| Variant | Qwen | Llama | Gemma | Hy-MT | Google | Yandex |
|---|---|---|---|---|---|---|
| baseline | 0.594 / 0.603 | 0.240 / 0.269 | 0.662 / 0.671 | 0.715 / 0.745 | 0.757 / 0.766 | 0.762 / 0.763 |
| rag_auto | 0.782 / 0.763 | 0.428 / 0.459 | 0.795 / 0.805 | 0.836 / 0.844 | — | — |
| rag_clf | 0.820 / 0.813 | 0.486 / 0.479 | 0.806 / 0.811 | 0.841 / 0.849 | — | — |
| rag_clf_sft | 0.818 / 0.809 | — | — | 0.841 / 0.852 | — | — |
| rag_clf_sft_cpo | 0.827 / 0.817 | — | — | 0.853 / 0.858 | — | — |
| term_substitute | 0.903 / 0.901 | 0.820 / 0.835 | 0.879 / 0.904 | 0.920 / 0.919 | — | — |
| rag_oracle | 0.930 / 0.915 | 0.751 / 0.755 | 0.890 / 0.887 | 0.965 / 0.958 | — | — |

Table 5: Model versions as in Table 3. Overall TSR averaged across the curated (200 items) and wiki (1,300 items) test sets, reported as macro / micro. Macro treats the two sets equally; micro weights by item count.

| Domain | base | rag_clf | +sft_cpo |
|---|---|---|---|
| IT | 0.91 | 0.85 | 0.85 |
| Aviation | 0.63 | 0.86 | 0.96 |
| Medicine | 0.85 | 0.91 | 0.91 |
| Oil and gas | 0.63 | 0.75 | 0.76 |
| Agriculture | 0.73 | 0.85 | 0.86 |
| Construction | 0.71 | 0.83 | 0.83 |
| Shipbuilding | 0.53 | 0.74 | 0.72 |
| Finance | 0.86 | 0.92 | 0.89 |
| Energy | 0.81 | 0.89 | 0.86 |
| Law | 0.82 | 0.85 | 0.84 |

Table 6: Per-domain TSR on Hy-MT, both test sets combined.

classifier noise is the dominant but not the only contributor to the QE regression.

We consider two non-exclusive explanations for the residual gap that oracle cannot close. First, calibration: COMET-Kiwi and MetricX-QE are trained primarily on general-domain human judgments where naturalness is weighted more heavily than terminology fidelity, so they may under-reward the more constrained but terminology-correct output that any glossary-augmented pipeline produces – consistent with Zouhar et al. (2024)'s finding that fine-tuned MT metrics degrade sharply outside their training domain. Second, a genuine fluency cost: inserting a specialized Russian lemma from the glossary can produce awkward collocations even when it is the domain-correct translation, so at least some of the residual may reflect a real drop in naturalness rather than a metric artifact. Distinguishing the two cleanly would require a human evaluation we did not run (Limitations), and we do not claim to isolate them here. The counter-example that reinforces both readings is `term_substitute`, which attains the second-highest TSR on Hy-MT curated (0.92) but scores worst of all variants on both QE metrics – source-side substitution produces terminology-correct but noticeably less fluent Russian, and both explanations predict this direction.

### 5.6 Fine-Tuning Contribution (RQ2)

Table 5 decomposes the fine-tuning delta over `rag_clf` into its SFT and CPO components. SFT alone is essentially $\Delta = 0$ on both fine-tuned models and both test sets ($-0.005$ / $+0.005$ on Hy-MT curated / wiki; $0.0$ / $-0.005$ on Qwen). CPO adds $+0.02$ / $+0.004$ on Hy-MT and $+0.01$ / $+0.008$ on Qwen. Neither stage restores the QE-metric fluency cost introduced by `rag_clf`; MetricX on Hy-MT curated is unchanged from `rag_clf` 3.18 to `rag_clf_sft` 3.20 and rises further to 3.49 under `rag_clf_sft_cpo`. SFT therefore contributes neither the expected fluency recovery nor a terminology gain.

We attribute the muted CPO effect (relative to the gains reported for ALMA-R on general translation) to a bounded-headroom mechanism. With the gold-domain glossary already in the prompt under `rag_clf`, the residual headroom for fine-tuning is capped by cases where the base model fails to use a glossary entry already present in its context. The `rag_oracle` diagnostic sets this gap at $+0.13$ (curated) / $+0.10$ (wiki) above `rag_clf`, of which CPO recovers roughly one-sixth. SFT is retained not for its evaluation contribution but as a training-stability prerequisite: preliminary runs in which CPO was applied directly on top of the base model reproduced the reward-margin collapse pattern reported by Xu et al. (2024), and only the SFT warm-up on the chosen translations stabilised the CPO loss.

### 5.7 External Validation on WMT25

We validate on WMT25 because it is the most recent iteration of the WMT Terminology Translation Task that includes English–Russian; the current WMT26 edition covers Spanish–Basque, English–Polish, and Traditional Chinese–English, so no contemporaneous en–ru terminology benchmark exists. Using the official WMT25 dictionaries directly (bypassing our own extraction/classification/retrieval

| Variant | Qwen | Llama | Gemma | Hy-MT | Google | Yandex |
|---|---|---|---|---|---|---|
| baseline | 0.814 / 1.394 | 0.685 / 3.109 | 0.825 / 1.119 | 0.839 / 0.914 | 0.836 / 1.130 | 0.840 / 1.019 |
| rag_auto | 0.795 / 1.668 | 0.646 / 4.457 | 0.809 / 1.396 | 0.766 / 1.822 | — | — |
| rag_clf | 0.796 / 1.625 | 0.636 / 4.592 | 0.808 / 1.362 | 0.780 / 1.553 | — | — |
| rag_clf_sft | 0.789 / 1.721 | — | — | 0.807 / 1.447 | — | — |
| rag_clf_sft_cpo | 0.781 / 1.842 | — | — | 0.762 / 1.809 | — | — |
| term_substitute | 0.780 / 1.691 | 0.663 / 3.411 | 0.793 / 1.395 | 0.806 / 1.142 | — | — |
| rag_oracle | 0.792 / 1.605 | 0.606 / 5.995 | 0.811 / 1.333 | 0.768 / 1.610 | — | — |

Table 7: Model versions as in Table 3. Reference-free QE metrics on the wiki test set: COMET-Kiwi (↑) / MetricX-QE (↓). `rag_oracle` recovers only part of the COMET-Kiwi drop (Hy-MT baseline 0.839 vs. `rag_oracle` 0.768, closer to `rag_clf` 0.780 than to baseline); the cleaner oracle-vs-baseline recovery holds for MetricX on the curated set (§5.5). We read the two decompositions together as classifier noise being the dominant but not the only contributor to the QE regression.

| Condition | baseline | sft_cpo |
|---|---|---|
| noterm (chrF2++) | 53.11 | 52.85 |
| proper (chrF2++ / TSR) | 59.32 / 0.918 | 60.53 / 0.931 |
| random (chrF2++ / TSR) | 56.47 / 0.911 | 54.44 / 0.917 |

Table 8: WMT25 Terminology Translation Task, Hy-MT results (Hy-MT = Hy-MT2-7B, §4.3; `sft_cpo` is the released `maryleya/hymt2-7b-sft-cpo` checkpoint, §A).

stages, since gold terminology is supplied), the SFT+CPO Hy-MT checkpoint improves +1.21 chrF2++ and +0.014 TSR over baseline under the *proper* terminology condition (Table 8), confirming that the gains transfer to an external benchmark. Under *noterm*, the two configurations are within noise of each other, as expected, since there is no glossary signal for fine-tuning to express itself through. Under *random* terminology, TSR is essentially unchanged (0.911 vs. 0.917), indicating the model does not blindly substitute unrelated glossary entries, though chrF2++ drops by 2.03 – a mild distractor sensitivity consistent with known RAG failure modes (Barnett et al., 2024).

We reuse WMT25's released dictionaries and official scoring script to evaluate our own system offline, rather than through WMT's centralized, ranked evaluation – so we lack a like-for-like basis for placing our absolute chrF2++/TSR values on the official leaderboard. One qualitative comparison is worth flagging though: WMT25's own headline finding is that proper terminology helps more for already-strong participating systems (Semenov et al., 2025), our within-model results show that the gain is largest where the underlying model or domain is weakest (§5.4). The two findings operate on different axes (between-system comparison across a leaderboard vs. within-model comparison across domains) and are not strictly contradictory, but we do not claim a consistency we cannot verify.

## 6 Discussion

### 6.1 RQ1: Retrieval Improves Terminology

Domain-classified glossary retrieval substantially improves EN–RU terminology accuracy on all four open base models, with the largest gains where the base model's parametric terminology knowledge is weakest (Zheng et al., 2024) – both across models (largest gain on the weakest baseline, Llama) and, at a finer grain, across domains within a single model (largest gains on Hy-MT's weakest domains; no benefit on its strongest, IT). The pattern transfers to the WMT25 external benchmark under the *proper* glossary condition (§5.7).

### 6.2 RQ2: Preference Fine-Tuning is Bounded by the Prompt

SFT and CPO deliver far less than the ALMA-R precedent (Xu et al., 2024) would suggest, which we attribute to a bounded-headroom mechanism rather than a design flaw: ALMA-R was developed for a setting with no inference-time glossary access, so the entire burden of producing the correct term falls on the fine-tuned weights. Once `rag_clf` already supplies the correct glossary entry in the prompt, the only headroom left for fine-tuning is cases where the base model fails to apply an entry already in front of it – a gap the `rag_oracle` diagnostic quantifies, of which CPO recovers roughly one-sixth (§5.5). This also explains why the CPO fluency cost partly compounds rather than adds to the classifier-noise cost: CPO amplifies whatever the classifier routed to, correct or not.

### 6.3 Practical Implications

The fluency–terminology trade-off maps onto a simple configuration rule: default to `rag_clf` (optionally with SFT+CPO) on domains where the baseline is weak and terminology fidelity is high-stakes (legal, medical, oil and gas, shipbuilding, aviation), and default to the plain baseline where it is already strong (IT, law), since the modular design supports switching per domain without a separate model. Where a translator-in-the-loop workflow is feasible, `rag_oracle` is the stronger option: because the dominant fluency cost comes from classifier noise rather than glossary content (§5.5), supplying the domain manually recovers most of the lost fluency while keeping the terminology gain. Either configuration already outperforms both commercial systems on TSR while running on a single consumer GPU (§A), making the pipeline a practical option where data confidentiality or API cost rules out commercial cloud MT.

### 6.4 Position Relative to Related Work

The cross-model TSR improvement under `rag_clf` confirms the general principle established by DiPMT (Ghazvininejad et al., 2023), Moslem et al. (2023), and DragFT (Zheng et al., 2024) that prompt-level dictionary injection improves specialized translation, extending it to EN–RU across ten domains. Unlike WMT25 retrieval-augmented systems that assume the dictionary is supplied (Guttmann et al., 2025; Nieminen et al., 2025), our pipeline closes the loop with its own extraction and classification stages, at the cost of the classifier-noise component in §5.5; and unlike constrained decoding (Hokamp and Liu, 2017; Hasler et al., 2018), our prompt-level conditioning leaves the model free to fall back to a fluent translation where the glossary is absent or wrong.

The systematic divergence between surface metrics (which agree with TSR) and reference-free QE metrics (which penalise the same translations) admits two non-exclusive readings, as detailed in §5.5: a calibration mismatch on specialized-domain outputs, and a genuine but small fluency cost from inserting glossary lemmas into contexts that were not necessarily selected for them. We do not claim to isolate the two without a human evaluation (Limitations), only that the QE regression is bounded above by what the oracle diagnostic and the surface metrics jointly imply.

## Limitations

**Training pool size and source.** The fine-tuning pool contains approximately 10,000 items after the filtering cascade, small relative to the tens to hundreds of thousands of pairs used by ALMA and ALMA-R (Xu et al., 2023, 2024). At this scale SFT may have too few examples to reshape the output distribution of a 7B model and the CPO preference signal may be similarly undersupplied. A substantial share of the pool is mined from WikiMatrix (Schwenk et al., 2021), whose Russian sides can themselves be translations from English and may not carry fully natural Russian fluency – a plausible contributor to the QE-metric fluency regression.

**Curated test set size.** With 200 items, the curated set is small. TSR gains are large enough to stand well above evaluation noise, but the neural-metric deltas are close to it and should be read together with the 1,300-item wiki set and the WMT25 numbers, both of which show the same trade-off at a smaller magnitude.

**Knowledge-base quality and provenance.** Multitran, the main source behind the KB, has no editorial moderation – entries are added by volunteers. Individual glosses can be noisy or dated, and the classifier-filtering step will not catch these on domains where Multitran is the only supplier of candidates. The same volunteer sourcing shapes what is covered and which variants get treated as canonical; we did not audit these biases directly.

**Single language pair.** Our experiments cover only English–Russian. Nothing in the pipeline design assumes Russian specifically, but we have not tested it on other morphologically rich targets, on lower-resource languages, or on pairs that lack a Multitran-scale open termbase.

**Model-size confound.** The size-floor observation in §5.4 rests on a single small model, Llama-3.2-3B, compared against three larger models from three different model families. We cannot separate the effect of parameter count from other differences between Llama and the other base models – pre-training corpus, instruction-tuning recipe, tokenizer. A controlled ablation varying model size within a single model family would be needed to confirm whether the observed failure mode is a genuine capacity floor rather than a Llama-specific artifact; we leave this to future work.

## Ethics Statement

All source materials for the knowledge base and both test sets come from openly licensed or publicly accessible dictionaries and parallel corpora. Nothing in the data is personally identifiable or otherwise sensitive. Because Multitran is user-contributed, domain coverage and the choice of preferred variants inevitably reflect the editorial habits of its volunteer contributors, and some of that bias carries over into what we release. We publish everything to make the results reproducible and easier to build on.

## A Reproducibility

**Compute.** All SFT and CPO fine-tuning fits on a single A100 (40 GB). At inference, each of the four open models, along with the RuQwen-2.5-32B judge, runs on one 24 GB consumer GPU.

**Fine-tuning setup.** We use LoRA with $r$=64 and $\alpha$=128. SFT runs for 2 epochs, learning rate $10^{-4}$, on the chosen translations, with the same glossary block in the training prompt that is used at inference. CPO then runs for 1 epoch at $5 \times 10^{-6}$ with $\beta$=0.1. Decoding is greedy throughout.

**Commercial systems.** Outputs from Google Translate and Yandex Translate were pulled through their public APIs. The exact timestamps and API versions are logged in the repository.

**Randomness and reproducibility.** Open-model inference is deterministic (greedy decoding), so it repeats exactly. Fine-tuning uses a fixed seed. Everything needed to rerun the experiments – seed, full hyperparameters, KB, both test sets, evaluation scripts, verbatim prompts – is at https://github.com/Maryleya/RAG_System_for_Specialized_Terms.

**Model checkpoints.** The four fine-tuned LoRA adapters are released on the Hugging Face Hub as `maryleya/hymt2-7b-sft`, `maryleya/hymt2-7b-sft-cpo`, `maryleya/qwen3-4b-sft`, and `maryleya/qwen3-4b-sft-cpo`. Each adapter loads on top of its declared base model (`tencent/Hy-MT2-7B` or `Qwen/Qwen3-4B-Instruct-2507`) via the `peft` library.

## B Term Extractor Prompt

The term extractor is a few-shot prompt to Qwen3-4B-Instruct-2507, structured as a system instruction, three in-context examples from heterogeneous domains, and the source sentence.

```
System: You are a domain
terminology specialist.
Extract specialized
technical/professional terms
from the given English sentence.
A specialized term is a noun
or noun phrase from a specific
field that has a domain-specific
meaning, not a common word.
Output terms one per line.
Output ONLY the terms - no
explanations, no numbering.

Example 1:
Input: The patient was
diagnosed with chronic
obstructive pulmonary disease
and prescribed long-acting
bronchodilators.
Output:
chronic obstructive pulmonary
disease
long-acting bronchodilators

Example 2:
Input: The contract included
a force majeure clause and was
governed by the law of England
and Wales.
Output:
force majeure clause
law of England and Wales

Example 3:
Input: The wellhead Christmas
tree is rated for 10,000
psi working pressure during
production testing.
Output:
wellhead Christmas tree
working pressure
production testing

Input: {SOURCE_SENTENCE}
Output:
```

## C Domain Classifier Prompt

The classifier is a two-step synthetic few-shot prompt. Before the first classification pass, Qwen3-4B-Instruct-2507 generates three example English sentences per domain from a keyword description (Appendix C.1). The resulting 30 (sentence, domain) pairs are reused as in-context labelled examples in the classifier prompt for every test sentence (Appendix C.2). Domain names are kept in their mixed English–Russian form to match the KB labels. Output is parsed as a fixed `Primary/Alternative` pair; an alias map and a difflib fuzzy match recover misspellings, transliterations, and Latin–Cyrillic confusables at parse time.

### C.1 Synthetic Example Generation

```
System: You are an expert
technical writer. Given
a domain and its keywords,
generate authentic example
English sentences that would
appear in real specialized texts.
Output EXACTLY 3 sentences as a
numbered list.

User:
Domain: {DOMAIN}
Keywords/topics:
{DOMAIN_DESCRIPTION}

Generate 3 distinct English
sentences.
```

The ten keyword descriptions are: *IT* (software, programming, computers, networks, code); *авиация* (aircraft, aviation, flight, runway, fuselage); *медицина* (medical, anatomy, diseases, symptoms, treatment, surgery); *нефтегаз* (oil and gas extraction, drilling, wells, reservoirs, pipelines); *сельское хозяйство* (agriculture, crops, livestock, soil, fertilizer, irrigation); *строительство* (construction, buildings, concrete, walls, beams); *судостроение* (shipbuilding, naval, hulls, navigation, ports); *финансы* (fi-

nance, banking, investments, securities, accounting); *энергетика* (energy, electricity, grids, turbines, transformers); *юриспруденция* (law, contracts, courts, regulations, liability).

### C.2 Classifier Prompt

```
System: You are a domain
classifier. You will be given
a list of allowed domain names,
descriptions, a few labeled
example sentences per domain,
and a target English sentence.
Output EXACTLY two lines:
Primary: <domain>
Alternative: <domain>
where both <domain> values are
copied verbatim from the allowed
list (including Cyrillic).
Primary is your best guess;
Alternative is the second-best
guess (must differ from Primary).
Do NOT translate, transliterate,
abbreviate, or rephrase domain
names. No explanations.

User:
Allowed domain names:
{TEN_DOMAIN_NAMES}
Descriptions:
{TEN_KEYWORD_DESCRIPTIONS}
Labeled examples:
{30_SYNTHETIC_PAIRS}
Target sentence:
{SOURCE_SENTENCE}
Output:
```

## D Translation Prompts

Three prompt variants are used across all open-source translation models; only the glossary contents differ across models and conditions.

### D.1 Baseline

```
Translate the following text
to Russian. Provide only
the translation, without any
explanations or comments.

{SOURCE_SENTENCE}
```

### D.2 Term Substitution

```
System: You are a professional
English-to-Russian translator.
The source sentence may already
contain some Russian words -
keep them as-is and adapt their
grammatical form (case, number,
gender) to fit the Russian
sentence naturally. Translate
the rest of the sentence to
fluent Russian. Output ONLY the
Russian translation.

User: {SOURCE_WITH_
  RU_TERM_SUBSTITUTED}
```

### D.3 Glossary-Augmented Translation

```
System: You are a professional
English-to-Russian translator
specializing in technical
texts. You will be given a
source English sentence and a
dictionary of specialized terms
with their Russian translations.

RULES:
1. Strongly prefer the Russian
translation from the dictionary
when an English term appears in
the source.
2. When several variants under
different domains - choose the
one whose domain best fits the
context.
3. Adapt the translation to
the correct grammatical case,
number, gender - keep the lemma.
4. For words NOT in the
dictionary, translate naturally.
5. Output ONLY the Russian
translation - no explanations.

User:
Dictionary:
{ENGLISH_TERM_1}:
- {RU_TRANSLATION_1A}
 [{DOMAINS}]
- {RU_TRANSLATION_1B}
 [{DOMAINS}]
...
Source sentence:
{SOURCE_SENTENCE}
Translation:
```

### D.4 LLM-as-Judge Prompt for TSR

The second-stage verifier (RuQwen-2.5-32B, temperature 0) is invoked only on terms that the first-stage lemma matcher classified as not-matched, to recover valid synonyms and paraphrases. The prompt is in Russian and is structured around an explicit FAIL-only criterion list with seven worked PASS/FAIL examples across IT, medicine, shipbuilding, and aviation.

```
System: You are evaluating
whether the translator correctly
conveyed the meaning of a
specialized term.
Given: domain, English
sentence, gold Russian term,
candidate translation.
Rule: PASS if the candidate
correctly expresses the term
from the source - this may
be the gold term (in any
grammatical form) OR ANY valid
Russian synonym with the same
meaning in this domain. Be
LENIENT toward synonyms.
FAIL only if:
- a word from a DIFFERENT domain
is used ("partition" for the
aviation term bulkhead);
```

```
    - transliteration without
    translation ("pig" instead of
    "scraper");
    - a generic word that loses the
    domain-specific meaning ("empty"
    for the medical term void);
    - the term is missing or
    rendered with the opposite
    meaning.
Seven worked PASS/FAIL examples covering
IT, medicine, shipbuilding, aviation,
and oil & gas omitted for brevity;
released in full at the repository URL
above.

    Answer with STRICTLY one word:
    PASS or FAIL.
    User:
    Domain: {DOMAIN}; source
    (EN): {SOURCE_EN}; specialized
    term: {TERM_EN} → gold
    Russian: {TERM_RU}; candidate:
    {CAND_RU}.
    Answer:
```

## E Strict Lemma-Match TSR

Tables 9 and 10 report the first-stage (pymorphy3 lemma-match) TSR alone, without the LLM-as-judge second stage. This is exactly the criterion used by the WMT Terminology Shared Task and is reproducible without any LLM call. The direction of every claim in the main text – retrieval improves over baseline, oracle sets the upper bound, fine-tuning adds a small residual, commercial systems trail retrieval-augmented open models – holds under this stricter criterion as well; the absolute numbers are correspondingly lower because same-domain synonyms that the KB and the judge both accept do not count here.

## F Reference-Based Surface Metrics on the Curated Set

Table 11 reports chrF2++ and BLEU on the 200-item curated set, aligned to the pipeline variants used elsewhere. These are the reference-based counterparts to the reference-free QE metrics in Table 7. On Hy-MT the strongest retrieval-augmented variant `rag_clf_sft_cpo` lifts chrF2++ from 45.69 (baseline) to 50.52 and BLEU from 19.81 to 22.75, moving in the same direction as TSR.

| Variant | Qwen | Llama | Gemma | Hy-MT | Google | Yandex |
|---|---|---|---|---|---|---|
| baseline | 0.190 | 0.070 | 0.245 | 0.240 | 0.410 | 0.385 |
| rag_auto | 0.555 | 0.280 | 0.540 | 0.650 | — | — |
| rag_clf | 0.655 | 0.395 | 0.565 | 0.665 | — | — |

## Abstract

When the target language must mark a distinction the source does not, a translation system must still pick a value. English *they came* becomes one Tamil verb if those who came are people and another if they are not; English does not say which. We ask what automatic evaluation charges when the choice is wrong, or never made. We release TamilLingBench,[1] an English→Tamil challenge set for three verb-agreement distinctions, checked by a morphological analyser: rationality (திணை *tiṇai*), gender, and number as a control. We pre-registered a prediction that neural metrics would not notice a single wrong morpheme. It is wrong for the neural reference-based metrics: COMET-22 charges 8.52× the score difference that human raters reliably notice. On the systems' own errors, both reference-free metrics rank the wrong form first more often than not, and a legitimate Tamil form that leaves the distinction out is not charged at all. **Under reference-free evaluation, dropping the distinction is free**; reference-based metrics do charge for it. xCOMET finds the error's region but not the morpheme. Inside one model, activation patching finds the same asymmetry: a distinction English marks is settled by the middle of the network, one it leaves unmarked only near the output.

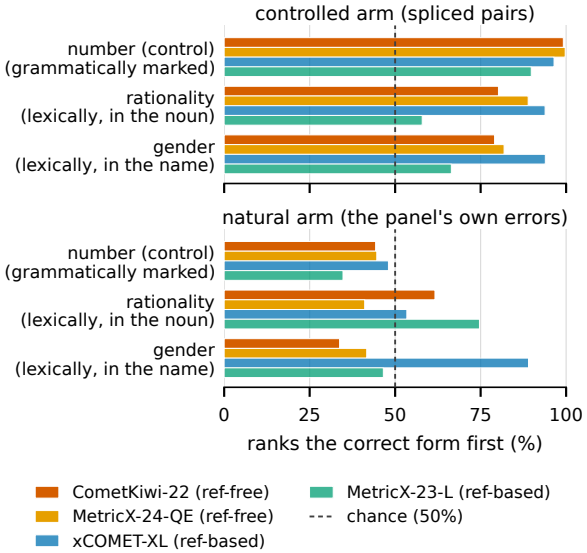

Figure 1: **What each metric can rank, ordered by what the English source makes recoverable.** Each bar is the share of pairs on which a metric ranks the correct member first; 50% is chance. Pairs differ in one grapheme-cluster span, the analyser confirming the rejected member carries the wrong value. **Top:** constructed pairs. The two reference-based metrics with headroom disagree with each other here, so this ordering is **not** a reference-free phenomenon. **Bottom:** the panel's own errors, where the reference-free/reference-based split *is* clean, the result §5 defends. COMET-22 and chrF2 are omitted: they sit at 100.0% everywhere, partly definitionally, since here the correct variant *is* the reference.

## 1 Introduction

English *they came* has two Tamil translations. If the referents are people, the verb is வந்தார்கள் *vantārkaḷ*; if they are not, it is வந்தன *vantaṉa*. The English sentence never chose, and Tamil cannot avoid choosing, because the finite verb agrees with its subject in rationality (திணை *tiṇai*), gender and number. We call such a slot *obligatory*: every well-formed target realisation commits to a value the source does not determine. The stake is not stylistic. அஃறிணை *aḵṟiṇai* agreement, the class Tamil uses for everything that is not a person or a deity, on a human referent is a dehumanising error. This paper asks what automatic evaluation charges when the value is wrong, and when the system quietly declines to pick one at all. The answer, on a morphologically checked English→Tamil benchmark we release, splits by metric type. Reference-based metrics charge a large penalty, falsifying our own pre-registered prediction. Reference-free metrics do not: on the er-

rors the systems themselves make both rank the wrong output first more often than not, and the legitimate Tamil form that drops the distinction costs nothing they can distinguish from zero.

Tamil marks several such distinctions on the finite verb, and a purpose-built, morphologically checked benchmark is necessary rather than nice-to-have because the standard annotation infrastructure cannot express most of them. UD_Tamil-TTB contains 0 `Gender=Fem` tokens and 0 -ஆன் *-āṉ*/-ஆள் *-āḷ* finite verbs, so a tagger trained on it cannot express the masculine/feminine contrast at all; Tamil is absent from UniMorph entirely; and in total the annotation cannot express 7 categories a reference grammar treats as central (aspect, causation, clusivity, deixis, evidentiality, honorific contrast, modality). Appendix D and Table 11 give every count, each a direct count over the released treebanks. These are reproducible counts, not arguments about anyone's competence.

**Where this sits.** Challenge sets in the contrastive tradition, from ContraPro (Müller et al., 2018) to Morpheval (Burlot et al., 2018), test whether a system *propagates* a feature present in the source. CoCoA-MT and the IWSLT formality tasks (Nadejde et al., 2022; Anastasopoulos et al., 2022) meet the unmarked case but run it as an uncontrolled baseline row, and GENDER1PERSON (Popović and Lapshinova-Koltunski, 2025) measures the resulting skew for one slot without asking what evaluation charges for it. The question here is what happens when there is nothing to propagate and a value must still appear, and what a metric can see when it does; §9 draws the full comparison.

**The metric question.** An obligatory-slot error is one morpheme in an otherwise fluent, adequate sentence, and whether automatic evaluation can see it decides whether the error type is actionable at all. We pre-registered the prediction that neural metrics would not charge a human-noticeable penalty for it. **That prediction is falsified for the reference-based metrics**, and we report the falsification rather than narrowing the claim after the fact: 3 of the 4 neural metrics with a published calibration charge well above the 75%-agreement threshold (Kocmi et al., 2024), and so does chrF2, a character $n$-gram metric the prediction never covered.

**Design, and one thing it got wrong.** Every item appears in four conditions that vary only where the disambiguating cue sits. To be plain about what is new: **only the cue-free condition has no answer in the source**. The other three carry a gold value, supplied by the instruction, by the sentence itself, or by the sentence before, and on those the benchmark is contrastive evaluation in the usual sense. The cue-free condition is the one the contrastive tradition runs, at most, as an unscored baseline row (§9), and it is where the forced choice this paper is about actually happens. Our first release had three independent construction defects in one slot, which inverted a headline we had already drawn; §8 reports what broke and how the audit caught it, because the failure mode generalises to any benchmark of this shape.

**Contributions.** (i) A measurement of what automatic metrics charge for obligatory-slot errors. Our own prediction is falsified for the neural reference-based metrics. The finding that survives, that dropping the distinction is free under reference-free evaluation, is established on the outputs the systems actually produce, with positive controls on the same sentences. (ii) **TamilLingBench**, a generator and an FST-based checker for a linguistically controlled Tamil challenge set, released with per-item judgments and 12 construction guards, verified by two native speakers of Tamil. (iii) Three construction confounds in one slot, with the audit that found them. (iv) A pre-registered causal dissociation inside one model, reported with the pre-registered probe failure from the same frozen document. (v) Provisional model measurements, including the withdrawal of our own first headline, and the annotation negative results above.

## 2 Obligatory Slots in Tamil

The scored slots are rationality, gender and number as a control; Table 5 in Appendix A gives each one's Tamil realisation and prior MT coverage. The contrast with source ambiguity separates an obligatory slot from contrastive conditioning (Vamvas and Sennrich, 2021b): there the source admits two readings and the question is which the system selects; here it admits one and is silent on a distinction the target must realise. A system cannot hedge: except where the language supplies a neutral exponent, which is what makes the gender slot a cautionary tale (§8). All three are realised on the finite verb, which makes this one system rather than a checklist. **Rationality** (திணை *tiṇai*)

splits referents into உயர்திணை *uyartiṇai*, people and deities, against அஃறிணை *aḵriṇai*, everything else, and agreement follows: வந்தார்கள் *vantārkaḷ* against வந்தன *vantaṉa*. English has no exponent of it, though the subject noun usually makes it lexically recoverable, *the dogs* against *the students* — a different thing from marking it, and what §5 turns on. On a plural அஃறிணை subject the licit exponent is -அன *-aṉa*, not the singular -அது *-atu*, on the ruling of a native speaker among the authors. **Gender** in the verb is வந்தான் *vantāṉ* / வந்தாள் *vantāḷ* / வந்தார் *vantār* — masculine, feminine, and an *epicene* form, a licit Tamil word committing to neither. English marks it on a name or a pronoun, so it too is lexically recoverable. **Number** is the control: both languages mark it, so a competent system should be at ceiling.

**What is not here, and why.** Second-person honorificity and first-person-plural clusivity were scored in earlier releases and are withdrawn as construction defects rather than findings (Appendix A); §5 states what withdrawing them costs its recoverability result. Second-person address in the indicative is **binary** — நீ *nī*/நீர் *nīr* against நீங்கள் *nīṅkaḷ*/தாங்கள் *tāṅkaḷ*, on the ruling of a native speaker among the authors, and the shipped items pooled it with a differently sized imperative paradigm under one chance rate. A fourth slot, deictic proximity, is under construction and is not reported. All items are standard written Tamil, and Literary/Spoken diglossia is *orthogonal* to the choices tested here (Prasanna and Arora, 2024).

## 3 TamilLingBench

**Four conditions over one frame.** With the slot inventory fixed, the benchmark varies one thing. Every item is a minimal set over a single frame, and the conditions differ only in where the value can be found. **Instructed**: the instruction names the target Tamil form outright. This is a capability ceiling rather than a translation task: a system that fails here cannot be read as *defaulting* anywhere else. **In-sentence cue**: the English source itself determines the value, and gold exists. **Prior-sentence cue**: the value is recoverable only from the sentence before; gold exists, and following Bawden et al. (2018) the gold values are balanced so a system that ignores context scores exactly chance. **Cue-free**: the source is genuinely silent, **there is no gold and no answer is wrong**, so we report the distribution of emitted values against a Tamil corpus prior, never against a notion of the correct default, which does not exist. **The comparison we report is in-sentence against cue-free**, which holds the frame and the cue type fixed and deletes the cue. **In-sentence against prior-sentence is not reported for gender**, because there the two conditions cue the value through different channels (§8); §6 reports it for rationality only. Table 1 shows one released item per slot and cue.

**Construction.** The release contains 2873 items generated from a template grammar with a fixed seed (20260807), split into a public portion and a blind holdout at the *template* level: holding out items is worthless once the generator ships. Validation is at that level too, plus a stratified item audit, because templates decide whether the contrast is real and fillers only vary lexical content. The source↔gold audit of §8 is run on every release of the set. Vamvas and Sennrich (2021b) show that contrastive results generalise only when the hypothesised contrast is independently motivated; ours is a typological obligation. The distributional gap to natural Tamil they also ask for is not computed (Limitations).

**Automatic checking.** Outputs are scored by a finite-state analyser built on the ThamizhiMorph transducer union (Sarveswaran et al., 2021) plus a hand-written fallback layer, with an ISO 15919 canonical scoring key (Rajan, 2018). We report the ablation rather than one number (Table 10): coverage on the UD_Tamil-TTB test verb forms is 38.6% lexicon-only and 69.3% with fallback rules. **The checker is not 100% accurate and we do not claim it is**; items it cannot analyse are UNPARSED, reported separately, never dropped. Scoring is universal after context filtering, since வந்தார்கள் *vantārkaḷ* is ambiguous between honorific-singular and rational-plural, and the tooling needed four documented repairs at the scoring layer first (Appendix C).

**Outcome taxonomy, and what *commitment* means.** Each judgment is CORRECT, WRONG, UNDECIDABLE, one of three AVOIDANT outcomes (no carrier, a value-neutral form, or a negated clause, which in Tamil can strip the agreement), or UNPARSED. A system *commits* on an item when it emits a form that takes a value in the slot — CORRECT or WRONG, but not AVOIDANT and not UNPARSED; the *commitment rate* is the share of items on which it does so, and accuracy is always com-

| Slot | Cue | English source | Tamil gold (ISO 15919) | Value |
|---|---|---|---|---|
| rationality | in-sentence | The dogs came at dawn. | நாய்கள் வந்தன. *nāykaḷ vantaṉa.* | அஃறிணை *aḵriṇai* |
| | in-sentence | The students came at dawn. | மாணவர்கள் வந்தார்கள். *māṇavarkaḷ vantārkaḷ.* | உயர்திணை *uyartiṇai* |
| | cue-free | *The sky had been overcast since dawn.* They came at dawn. | *no gold: any value is licit* | none |
| gender | in-sentence | Akanakai came at noon. | அகநகை வந்தாள். *akanakai vantāḷ.* | feminine |
| | in-sentence | Akaran came at noon. | அகரன் வந்தான். *akaraṉ vantāṉ.* | masculine |
| | cue-free | *Aram, our new neighbour, had been waiting at the station since noon.* Aram came at noon. | *no gold: any value is licit* | none |
| number (ctrl.) | in-sentence | The students spoke outside the hall. | மாணவர்கள் பேசினார்கள். *māṇavarkaḷ pēciṉārkaḷ.* | plural |
| | in-sentence | The student spoke outside the hall. | மாணவன் பேசினான். *māṇavaṉ pēciṉāṉ.* | singular |
| | cue-free | *A short notice about the theft had gone up.* The accused spoke outside the hall. | *no gold: any value is licit* | none |

Table 1: **One released item per slot and cue.** In-sentence items come in minimal pairs whose English differs only in the cue (for gender, the name itself) and whose Tamil verb differs in the agreement morpheme; the cue-free item keeps the frame and deletes the cue, so nothing in the source determines the value and no gold exists. In the cue-free gender item the systems' dominant output is the epicene வந்தார் *vantār*, a well-formed form that commits to neither gender; §3 scores it as AVOIDANT, never as an error. Cue-free items carry a preceding context sentence (italic) that says nothing about the value. The prior-sentence and instructed conditions use the same frames (§3).

puted among committed items only. **AVOIDANT is never folded into "incorrect"** — the decision that makes §5's main result visible at all, since a benchmark scoring the epicene form as an error would report an accuracy collapse where there is a refusal. A cell with fewer than 30 committed items or below 30% commitment prints *n/a*.

## 4 Experimental Setup

The panel is 13 systems, chosen to make three contrasts available rather than to rank anything: Gemma 3 at 4 sizes for a scale series inside one family; Qwen3 at three sizes and Llama-3.1 for family variation at roughly fixed scale; NLLB-200-3.3B and IndicTrans2 as dedicated encoder–decoder systems; and Sarvam-Translate, a Gemma-3-4B derivative fine-tuned for Indic translation, which against Gemma 3 4B varies the fine-tuning objective alone. 11 are prompted and 2 dedicated MT systems, read off the data rather than declared; there is no frontier commercial system, by decision. Scoring is on generated output, not forced choice: $\log P(\text{ref}) > \log P(\text{contrast})$ is unusable on systems that do not expose likelihoods. Decoding is greedy for the prompted systems and beam search at the deployed defaults for the dedicated MT systems, on seed 20260807, over 37 runs on `transformers` 5.12.1; each run records its resolved model revision, config hashes and decoding block. The dedicated MT systems take no prompt at all (Appendix A).

**Prompt choice moves these numbers.** Across the 73 cells where more than one prompt yields a reportable accuracy, the median spread is 7.5 points and the worst is 82.5. **Every headline cell is therefore a single-prompt measurement**, held fixed across systems so that between-system comparisons are clean, and no absolute accuracy here should be read as a property of a system independent of its prompt. The prior-sentence condition uses the prompt that marks the target sentence and tells the system not to translate the preceding one (P4_context in the released prompt set). Unreadable outputs are UNPARSED with their own denominator, mean 6.5% and worst cell 45.8%.

The cue-free condition has no gold, so we report the emitted distribution against a Tamil corpus prior pooled over 3 corpora, always a range because every slot is fragile: which corpus one picks moves the prior more than how many tokens one counts. We therefore say an output rate *deviates from general Tamil text frequency* and no more; the stronger claim, that it matches a system's *own* training rate, is unavailable because no evaluated system's training mixture was measured.

| Metric | ref. | scale | win | ×agr. | $\Delta_{av}$% | CI∋0 |
|---|---|---|---|---|---|---|
| COMET-22 | yes | 0–1 | 100.0 | 8.52 | 3.96 | no |
| xCOMET-XL | yes | 0–1 | 62.3 | 6.55 | 2.23 | no |
| MetricX-24 | yes | 0–25 | 90.2 | *n/a* | 7.56 | no |
| MetricX-23 | yes | 0–25 | 51.3 | 2.16 | 0.11 | yes |
| chrF2 | yes | 0–100 | 100.0 | 9.78 | 8.96 | no |
| chrF++ | yes | 0–100 | 100.0 | *n/a* | 13.91 | no |
| **CometKiwi-22** | no | 0–1 | 42.3 | 0.35 | -0.10 | yes |
| **MetricX-24-QE** | no | 0–25 | 38.5 | *n/a* | -0.42 | yes |

Table 2: **What each metric charges for an obligatory-slot error.** *ref.*: does the metric see a reference? *no* is reference-free (quality estimation). *win*: share of the panel's own slot errors on which the metric ranks the correct form first (%); below 50 it prefers the wrong-valued output. ×*agr.*: de-confounded slot signal as a signed multiple of the 75%-agreement threshold (Kocmi et al., 2024), negative meaning the metric prefers the wrong value; *n/a* where no threshold has been published for the metric. *scale*: the metric's native score range. $\Delta_{av}$ %: mean penalty for the epicene form the systems emit, over 1252 items, as a percentage of that native range so that rows on different scales can be read against each other; the last column marks whether the 95% bootstrap CI on the raw penalty includes zero. **Read the last two columns by reference type.** The 2 reference-free metrics are below the rule: both win on under half the panel's own errors and both have an avoidance interval containing zero, which is the paper's claim. Most reference-based metrics above the rule *do* charge for avoidance, and their intervals exclude zero.

## 5 What Metrics Charge for an Obligatory-Slot Error

**The scoring set, and the three arms.** The metric study is scored on in-sentence-cue items only, over 6231 records drawn from the ten-system panel run on the superseded release (§8). We group them into three kinds of evidence, which we call *arms*. The *controlled* arm is constructed: a minimal pair differing in exactly one grapheme-cluster span, with the analyser confirming that the rejected member carries the wrong value. The *natural* arm is not constructed: the pair is an error the panel actually made and its repair, with nothing spliced. The *avoidance* arm is neither. Its emitted member is the epicene -ஆர் *-ār* form, which is not an error in the usual sense. **The three do not agree, so every per-slot number below names the arm it comes from.**

One benchmark limitation shapes the design. The released gold field is the *slot-bearing core*, a median of two words against five- to nine-word sources, so **the benchmark ships no full-sentence reference**. We therefore use the DEMETR/ACES construction (Karpinska et al., 2022; Moghe et al., 2025). Because the good variant is then the reference itself, we also re-score against another system's independent output, which takes COMET-22 from 100.0% to 92.1%. **Direction and magnitude are reported separately.** Magnitude is calibrated against Kocmi et al. (2024): the score difference at which human raters agree three times in four, which we call the **75%-agreement threshold**. 3 metrics have no published calibration and are left uncalibrated rather than given another checkpoint's thresholds. Direction is Holm–Bonferroni corrected within family, one family per (cell × comparison), 257 families in total.

**Our prediction was falsified for the neural reference-based metrics.** We pre-registered that neural metrics would not charge a human-noticeable penalty for a single obligatory morpheme. That prediction is false for 3 of the 4 neural metrics that have a published calibration (Table 2): against that threshold, COMET-22 charges 8.52×, xCOMET-XL 6.55× and MetricX-23 2.16×; it holds for CometKiwi-22, and 2 neural metrics have no calibration key. chrF2 is a character $n$-gram metric, not a neural one, and the prediction never covered it; it charges 9.78× as well, so the reference-based penalty is not a property of learned metrics. The signal we test it on is de-confounded: each metric also prefers unspliced text over spliced, so we difference the controlled and natural arms over the items they share, which removes that preference and leaves the slot signal. **"Neural metrics are blind to morpheme errors" is not true as a blanket claim.** The raw controlled-arm ratios before de-confounding are larger and are not the ones we defend.

**On real errors, both reference-free metrics prefer the wrong output.** This needs no splicing and no control slot. The *natural* arm is the 1479 errors the panel itself makes, each paired with its repair. Both members are well-formed Tamil; *wrong* means only that the slot carries the wrong value. On these pairs CometKiwi-22 ranks the correct form first 42.3% of the time and MetricX-24-QE 38.5%, so each *prefers the wrong output more often than not*. Every reference-based metric stays above chance on the same pairs; the closest is MetricX-23-large at 51.3%. Two checkpoints from different labs failing the same way makes this a property of the reference-free setting rather than of one model.

**Avoidance is free, under reference-free evaluation.** The panel's dominant behaviour in the gender slot is not a wrong choice but the epicene -ஆர் *-ār*, a legitimate Tamil form that silently drops information the grammar requires. There are 1252 such outputs, all real panel outputs rather than constructed pairs. Over them CometKiwi's mean penalty is -0.000965, with a 95% bootstrap interval from -0.00426 to 0.00275 that **includes zero**; that is 0.23 of the agreement threshold. MetricX-24-QE's interval includes zero as well. **Under reference-free evaluation, a system that never marks the distinction loses nothing.** The qualifier is load-bearing and Table 2 carries it: the reference-based metrics do charge for avoidance, and their intervals exclude zero. The title is a claim about what reference-free evaluation can see, which is the setting most system-level monitoring runs in. Within that setting the result holds in both arms and does not depend on the control slot.

**What a metric can rank tracks recoverability, and it is not exclusive to reference-free metrics.** Figure 1 orders the slots by what an English source makes recoverable rather than by what it grammatically marks, because that is what the data order on. In the *controlled* arm CometKiwi-22 scores 99.2% on number, which English marks grammatically, against 80.2% on rationality and 79.1% on gender, which English leaves to the noun and the name. MetricX-24-QE gives 99.7% against 88.9% and 81.9%. **Three qualifications, and they are not small.** First, the ordering is a *controlled*-arm result and is gone in the natural arm, where CometKiwi scores 44.3% on number against 61.6% on rationality. Second, it is not exclusive to reference-free metrics: the reference-based MetricX-23-large separates the slots further (89.8% against 57.9%), while the equally reference-based xCOMET-XL is nearly flat (96.5% against 93.9%). Third, the two slots for which English has no grammatical exponent at all were the floor of this curve (CometKiwi 67.9% and 20.7%). Both are withdrawn for construction defects, and **their loss removes the strongest part of it**.

**xCOMET detects the region and does not localise it.** xCOMET advertises identification of "localized critical errors" (Guerreiro et al., 2024), which makes it the sharp target. Against the gold morpheme span, with numeral and named-entity perturbations of the *same* sentences as positive controls, the verdict is detects but does not localise. It flags the morpheme's region on 91.1% of items, but that region covers 71.2% of the sentence against a gold span of 3.3 characters, so the hit rate at the conventional half-overlap threshold is 9.4%. It also flags 72.9% of *unperturbed* correct sentences. **The finding is severity.** When it flags the obligatory morpheme it calls it `critical` 6.3% of the time; on a named-entity swap in the same sentences, 67.7%; on a *duplicated word*, DEMETR's canonical *minor* error, 52.4%. The control is what makes this specific: a metric merely weak on Tamil would not rate a duplicated word critical far more often than a violation that changes who the sentence is about, so DEMETR's minor-versus-critical finding reproduces on Tamil. The obvious remedy, augmenting a metric's training data, is bounded by Amrhein and Sennrich (2022) and Singh et al. (2024) (§9).

## 6 Model Behaviour, Provisionally

**A prior-sentence cue suppresses avoidance without supplying the answer.** If a reference-free metric cannot see the distinction, the next question is what the systems do with it. One result here is solid, and §3's taxonomy is what makes it visible: because AVOIDANT is a first-class outcome rather than an error, commitment and accuracy move independently. In rationality, moving the cue out of the sentence and into the sentence before makes systems *more* willing to commit, not less: commitment rises on 12 of 13 systems, from 73.7–90.3% with an in-sentence cue to 66.2–100.0% with a prior-sentence one. Accuracy on the items they do commit to moves the other way, from 88.4–100.0% down to 49.6–95.1%. It holds across four prompted families and both dedicated MT systems, so no architecture story explains it. The context does not make these systems right; it stops them avoiding and makes them commit anyway (per-system rates: Table 6, Figure 2, Appendix B).

**What does not hold, stated so it is not read into the table.** That is the only cue-position claim the data support. Every model number here is measured on the corrected release, on 13 systems, and by the repaired checker: the -இன் past-class repair (Appendix C) landed after this panel was first scored, so the panel was re-scored with it; every rationality number here is post-repair, and the re-score moved no cell of any other slot. **The number rows carry no cue-position reading**: systems of-

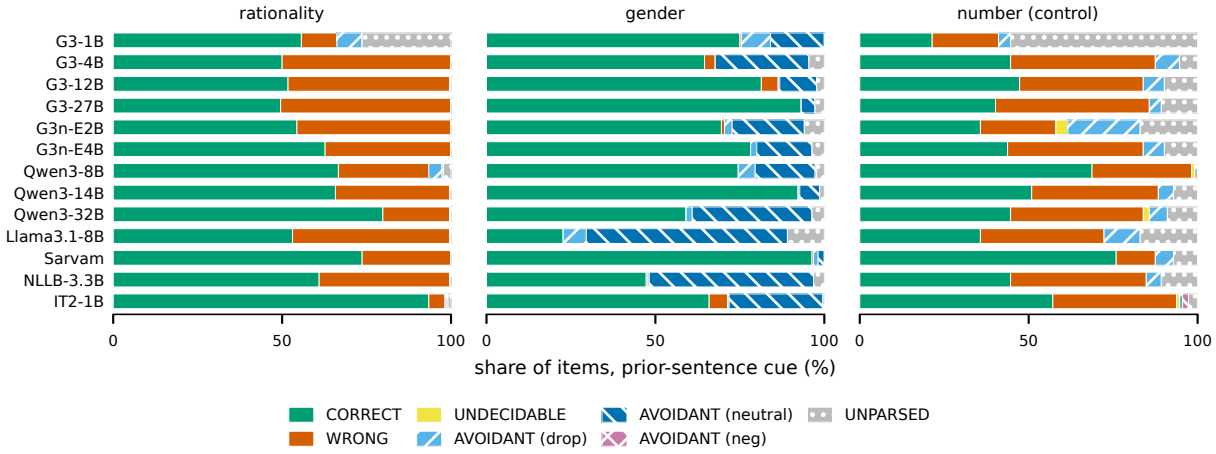

Figure 2: **Outcome composition with a prior-sentence cue.** Each bar is one system's outcomes on one slot, as shares of its items: correct, wrong, avoidant, undecidable, unparsed. Avoidance is hatched and in its own hue family because it is a different event from an error: a system that declines to specify and a system that specifies wrongly are doing different things, and folding the two together would report an accuracy collapse where there is a refusal. Labels are ISO 15919.

ten answer with -ஆர் *-ār*, which is either honorific singular or plural, so the same output is scored wrong on one item and right on another and the instrument can move the difference by itself; **the number control does not function on these items** either, with accuracy among committed items under a prior-sentence cue between 46.9% and 86.7% against chance 50%, so **no between-slot comparison is drawn anywhere in this paper**; and **gender shows no reliable direction** between the two cue positions. One caveat bounds even the result above: the prior-sentence condition runs a single context prompt, so template interaction cannot be separated from cue position.

**Deleting the cue is a different manipulation.** Commitment falls from the in-sentence condition to the cue-free one on 13 of 13 systems in gender and on 0 in rationality (Table 9, Figure 5). What fills the gap is not the corpus: every system emits the same rationality value on nearly every item (100.0% for Gemma 3 27B) against a prior range of 34.5–69.6% (Table 7, Figure 4), so the defaults are real and system-specific but unexplained. Finally, the capability ceiling does not clear uniformly, and **the instruction that measured it was itself defective**: it named the benchmark's internal label codes rather than the Tamil form the system was meant to produce, moving accuracy by up to 75.0 points (Table 8, both verdicts reported). Even under the corrected wording only 6 of 11 systems clear chance by a margin on gender and 0 of 11 on rationality, so a low rationality score cannot be distinguished from incapacity.

## 7 Where the Decision Is Fixed

If a reference-free metric cannot see a distinction the source does not encode, the next question is whether the *model* settles it any earlier. We answer it causally on `gemma-3-4b-pt`, against a preregistration frozen before the first result file (checked by file modification time rather than asserted), by symmetric activation patching of the residual stream at the decision token in both directions (Zhang and Nanda, 2024). The statistic is the *onset*: the normalised depth at which patching first restores 0.50 of the clean logit difference and stays above it, bootstrapped over templates. **Number is the control** because Ferrando and Costa-jussà (2024) report a language-independent subject-number direction in a Gemma base model, so a null there would mean a broken instrument.

**The marked distinction is fixed halfway; the unmarked one is not.** Table 3 gives the onsets. Number, which English marks, reaches onset at 0.561 of normalised depth; rationality, which English leaves unmarked, not until 0.888. The gap that matters is rationality minus number: 0.327, with a 95% CI of 0.301–0.339. It excludes zero and clears the pre-registered floor of 0.200, and both patching directions agree. **The control reproduces**: peak restored effect on number is 0.992, which is Ferrando and Costa-jussà's positive result on our items and makes this a *dissociation* rather than a bare null. In this checkpoint, a distinction

| Slot | marked in English | onset (95% CI) |
|---|---|---|
| number *(control)* | yes | 0.561 (0.550–0.585) |
| gender | no | 0.731 (0.710–0.863) |
| rationality | no | 0.888 (0.878–0.891) |
| difference | | 0.327 (0.301–0.339) |

Table 3: **Where each decision is causally fixed in `gemma-3-4b-pt`.** Onset is the normalised depth at which activation patching first restores 0.50 of the clean logit difference and stays above it, bootstrapped over templates. The last row is rationality minus number, the pre-registered contrast; its interval excludes zero and clears the pre-registered floor of 0.200. Number is the control: Ferrando and Costa-jussà (2024) report a subject-number direction in a Gemma base model, and it reproduces here.

English marks is causally settled around the middle of the network; one English leaves unmarked is not settled until close to the output.

**The probe study failed its own pre-registered bar, and we report that.** The same frozen document specified a layerwise linear probe that had to add 0.75 AUC over surface-token controls. It does not: the peak excess is 0.29 for rationality, 0.18 for number and 0.02 for gender, so the kill criterion fires, and we drop the probe rather than override it. That same document made patching the primary instrument and the probe the secondary one, which is why the headline result survives the failure: patching locates where the decision is causally fixed, a probe only where a classifier finds a correlate. What the failure costs is real. We make no decodability claim, and the tuned lens that would separate "not represented" from "represented and not yet decoded" was not run, so that alternative is untested rather than excluded.

## 8 Three Confounds in One Slot

All of the above is measured on the corrected release; this section is how it came to need correcting. The first release produced a clean, quotable result on the gender slot: the language models almost never committed to a value, while the dedicated MT systems did. **We retract it.** It was a property of how the items were built, and the three defects behind it are independent.

**The claim does not weaken, it inverts.** On the corrected items the ordering is the other way round. The 11 prompted systems commit at a median of 75.4% on prior-sentence gender against 47.7–71.4% for the 2 dedicated MT systems, and 7 of the 11 exceed every one of them: Sarvam-Translate 96.8% and Gemma 3 27B 93.2% against NLLB-200 47.7% and IndicTrans2 71.4% (Table 4 is the per-system difference). We state the inversion rather than softening the claim: its sign is wrong, not merely its support.

| | superseded | corrected | |
|---|---|---|---|
| System | commit | commit | acc. |
| Gemma 3 1B | 51.8 | **75.4** | 99.4 |
| Gemma 3 4B | 2.3 | **67.7** | 95.3 |
| Gemma 3 12B | 0.0 | **86.4** | 94.2 |
| Gemma 3 27B | 0.0 | **93.2** | 100.0 |
| Gemma 3n E2B | *n/a* | **70.5** | 98.7 |
| Gemma 3n E4B | *n/a* | **78.2** | 100.0 |
| Qwen3 8B | 2.3 | **74.6** | 100.0 |
| Qwen3 14B | 0.4 | **92.3** | 100.0 |
| Qwen3 32B | *n/a* | **59.1** | 100.0 |
| Llama 3.1 8B | 0.0 | **22.7** | *n/a* |
| Sarvam-Translate | 0.0 | **96.8** | 99.5 |
| NLLB-200 3.3B | 22.7 | **47.7** | 99.1 |
| IndicTrans2 1B | 44.1 | **71.4** | 92.4 |

Table 4: **The gender result was a property of the items, not of the systems.** Prior-sentence gender commitment (%) on the superseded release, whose prior-sentence source is singular *they*, and on the corrected one, whose prior-sentence source is a singular animate name. The same systems move by up to 96.8 points; every other slot moves by at most 26.8. A commitment cell prints *n/a* where that system was not run on the superseded release; the accuracy cell prints *n/a* below the reporting floor ($<30$ committed items or $<30\%$ commitment). **The original claim does not merely weaken, it inverts**: the 11 prompted systems reach a median of 75.4% against 47.7–71.4% for the 2 dedicated MT systems, and 7 of the 11 exceed every one of them (§8).

**The three defects, each independent of the others.** A neutral anaphor: singular *they* against a singular-feminine gold, in the one slot whose Tamil target has a neutral exponent, so a *correct* translation scored as avoidance. Two cued conditions that differ in cue *type* rather than distance, the prior-sentence one being the *easier* on 11 of 13 systems: **no comparison between them may be read off this benchmark, in either release**, which is why §6 compares in-sentence against cue-free instead. And a leak detector keyed on output length, blind to a system that translates the context *instead of* the marked sentence: the dangerous shape, since it is in the context that a prior-sentence cue lives. Appendix F gives each in full.

**The audit, and why the defective release is kept.** All three were found by an automated check that asks, per slot × condition, whether the source carries *any* exponent of the feature the gold commits to — deliberately lexical rather than clever, since the weakest question that would have caught them is the one worth running on every release. It returns 1141 unanswerable items in the first release across 12 (slot, condition, check) categories and 0 in the second, where it is a hard check. **The defective release is retained as a positive control**, so every guard is verified against a real defect.

## 9 Related Work

**The nearest neighbour.** GENDER1PERSON (Popović and Lapshinova-Koltunski, 2025) shares the experimental logic exactly: English leaves first-person gender unmarked, the target obligates it, and the skew is measured on system output. Three things separate this paper from it. Scope: gender in two Indo-European targets there, a Dravidian agreement system here, where one slot (rationality) has no prior MT treatment we could find. The informed conditions: both cued conditions carry gold, so a skew that survives when the answer is available is a prior overriding evidence rather than a gap being filled. And, the contribution we would defend first, it does not ask what *evaluation* charges for the error, which is §5's question. GRAPE (Menis Mastromichalakis et al., 2025), Staliunaite et al. (2026), Dawkins et al. (2025) and Prates et al. (2020) develop the same programme with external social statistics, entropy, ambiguity preservation and output proportions.

DEMETR (Karpinska et al., 2022) licenses the question and explains why it cannot answer it here: all its examples are into English. ACES (Moghe et al., 2025) is the largest challenge set for MT metrics and its taxonomy is the MQM *accuracy* branch, so morphology is absent by construction and English→Tamil is 1 of its 36476 rows; IndicMT Eval (Sai B et al., 2023) supplies the Tamil half, where metrics fail on the fluency branch that obligatory-slot errors land on. Amrhein and Sennrich (2022) and Singh et al. (2024) bound how far retraining closes a metric's blind spot, and both targeted a phenomenon that *is* marked in the source, so supervision could be derived automatically: which an unmarked distinction does not allow. Kocmi et al. (2024) supplies the calibration, Guerreiro et al. (2024) is the localisation claim §5 tests, and Robinson et al. (2023) make resource level the dominant predictor of translation *quality*, an axis we argue is orthogonal to obligatory-slot correctness.

The paradigm runs from LingEval97 (Sennrich, 2017) through Bawden et al. (2018), whose balance constraint our prior-sentence condition adopts directly, and ContraPro (Müller et al., 2018), to the DFKI WMT suites (Avramidis et al., 2020). Morpheval (Burlot and Yvon, 2017; Burlot et al., 2018) is the sharpest contrast: it perturbs a distinction that *is* marked in the source and checks whether it propagates, though its hyponym-substitution family is the nearest precedent for our cue-free condition. Contrastive conditioning (Vamvas and Sennrich, 2021a) detects which reading a system defaults to under *source ambiguity*; our slots have none. CoCoA-MT (Nadejde et al., 2022) and the IWSLT formality tasks (Anastasopoulos et al., 2022; Agarwal et al., 2023) run "unspecified" as an uncontrolled baseline row rather than a condition, and Měchura (2022) named the category without measuring any system's defaults. The reference grammars, treebanks and analyser papers behind our Tamil facts are listed in Appendix A.

## 10 Conclusion

Our pre-registered prediction that neural metrics cannot see a single obligatory morpheme is false for the neural reference-based metrics, and we report the falsification. What survives is narrower and harder to explain away: on the errors these systems actually make, both reference-free metrics rank the wrong output first more often than not, and under both, the epicene form that drops the distinction carries a penalty whose interval includes zero. Reference-based metrics do charge for it, so the claim is about what reference-free evaluation can see.

## Limitations

This is one language in one register: written Tamil, and a Dravidian agreement system whose particular shape may not generalise to other target languages that obligate distinctions English leaves unmarked. The panel is open-weight models of at most 32B parameters, so we cannot say whether a frontier system behaves differently. Three measurement limits bound what we claim rather than qualifying it. First, the number slot is withheld

from every cue-position result: systems often answer with -ஆர் *-ār*, which is either honorific singular or plural, so the same output string is scored wrong on a singular item and right on a plural one, and any effect there would be measuring the instrument. Second, one prompt supplies the prior-sentence condition, so template interaction cannot be separated from cue position; the direction is consistent across systems, but the magnitude is not attributable to cue position alone. Third, the rationality analyser was repaired after the panel was first scored and the panel was re-scored with the repair; the repair alone moved in-sentence rationality commitment by up to 21.1 points on one system (Appendix C), which is a measure of how far one analyser defect can move a headline cell, and a defect not yet found could move it again. The pre-repair scoring is released with the repaired one. The probe study reports a pre-registered failure alongside its causal result: the layerwise probe never cleared its frozen threshold, so we establish *where* a distinction is causally fixed without establishing that it is linearly decodable earlier, and the tuned lens that would separate "not represented" from "represented but not decoded" was not run. The benchmark was verified by two native speakers of Tamil, whose rulings corrected shipped data in two respects (second-person address is binary, and the neuter singular is ungrammatical on a plural subject). Verification is described throughout as human-led with finite-state support, never as verified by the transducer alone: round-tripping a form through the analyser that generated it establishes internal consistency, not correctness, and two forms that round-tripped cleanly proved to have no corpus attestation at all.

## Ethics and Broader Impact

Choosing the wrong value in an obligatory slot is not a style error. Assigning அஃறிணை *akṟiṇai* (the agreement class Tamil uses for animals, plants and objects) to a human referent is a dehumanising error in a way a fluency slip is not, and the finite verb forces the choice in every clause. The harm is asymmetric: it lands on the reader in the target community, who cannot see the source, cannot tell that the source was silent, and has no way to attribute the offence to the system rather than the speaker. A translation that is fluent, adequate and highly scored by every automatic metric can be socially unusable for its entire length. The gender slot is a site of misgendering harm and is present for commensurability with the gender-bias literature rather than as a claimed contribution; we retract the behavioural claim our first release made about it (§8). A system emitting the epicene form commits no misgendering and also destroys information the source did supply, and whether that is preferable is a judgment about deployment context rather than a fact about the model, which is why avoidance is a separate outcome here and not an error, and why we publish gold only where the source determines the answer.

**Annotators, data and provenance.** The two native speakers who verified the benchmark were informed of the use of their judgments and are credited or anonymised at their choice. Released data are CC BY-SA 4.0, forced by the ShareAlike term on UD_Tamil-MWTT rather than chosen; code is Apache-2.0. UD_Tamil-TTB is CC BY-NC-SA 3.0, so it is excluded from the release path and only aggregate counts derived from it appear here.

## A Reproducibility

We release the template generator, the 2873-item benchmark with its gold targets, the FST-based checker with the five analyser repairs of Appendix C, the prompt set, and the raw outputs and scored records of all 13 systems, under the licences given in the ethics statement. Both the pre-repair and the repaired scoring are included, so the re-score reported in Appendix C can be checked record by record. Every run records its resolved model revision, decoding configuration and seed (20260807), so any panel system can be re-run and re-scored against the same gold; the withdrawn slots and the superseded first release of the set are retained alongside the corrected one rather than deleted (§8).

**Scoring policy.** Determinism is why the checker is an FST rather than a neural model: the best published neural Tamil grammatical-error system reports F1 73.4 (Murugesapillai et al., 2021). Scoring is universal-after-context-filtering: only analyser readings compatible with the item's declared referent number are retained, and the form counts as correct only if *all* surviving readings match the target. The existential policy is computed as a robustness column and the residual undecidable rate carries its own denominator. Of the 3980 items built, 3040 carry gold; 4 are marked undecidable and are emitted with the marker rather than dropped. The released gold field is the column `gold_targets`. Direction tests in §5 are Holm–Bonferroni corrected within family across 257 families; magnitude intervals are cluster bootstraps over `template_id`, so items sharing a template are not counted as independent.

**Sources for the Tamil facts.** The grammatical descriptions this paper relies on come from Lehmann (1993); Schiffman (1999); Arden (1942); Perumalsamy (1991); Annamalai and Steever (1998); Suseendirarajah (1993); Krishnamurti (2003); Prasanna and Arora (2024); Dorr (1994), the annotation facts of §1 from Ramasamy and Žabokrtský (2012); Krishnamurthy and Sarveswaran (2021a,b); Batsuren et al. (2022), the analyser from Sarveswaran et al. (2021); Sarveswaran (2024); Murugesapillai et al. (2021) and the positive control §7 reproduces from Ferrando and Costa-jussà (2024).

**Figures.** Every series carries colour, line style and marker redundantly, so the figures survive greyscale printing. Figure labels are ISO 15919 romanisation because the plotting library has no complex-text shaper for Tamil; Tamil script appears in tables and body prose only.

**One methods result worth reusing.** We first cached the residual stream in `float16`. **On Gemma-3 that overflows**: the residual passes the `float16` maximum of 65504 in the upper third of the network: exactly the depths this result is about. On 200 real Tamil chat-formatted prompts `float32` matches the reference implementation on 200 top-1 predictions at a maximum logit-difference error of 4.67e-05, while `bfloat16` matches 197 at 0.25 larger than several of the effects above. The study runs `float32` throughout.

**The two withdrawn slots.** §2 gives the honorificity mechanism. The imperative sub-family's optative targets also carry no exponent the analyser will license. Clusivity has no valid in-sentence condition at all: only 0 of 196 unique in-sentence sources contain a first-person-plural English pronoun.

## B Full Per-System Results

Table 6 is the per-system commitment rate §6 reports and Figure 3 the same rates against model scale; the outcome composition behind them is Figure 2 in §6, and the per-system superseded-against-corrected difference on which the retraction rests is Table 4 in §8.

**Where the systems fall back to.** Table 7 and Figure 4 give the emitted distribution on cue-free items against the between-corpus prior, per system and per slot.

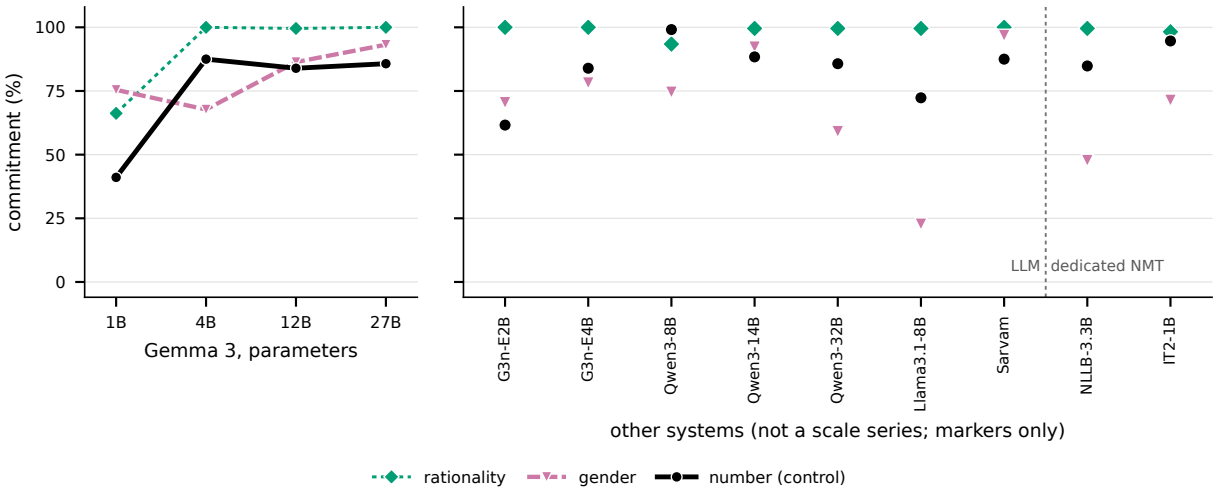

Figure 3: **Commitment rate by slot with a prior-sentence cue, on the corrected release.** Commitment is the share of items on which a system emits a form that takes a value in the slot. The four Gemma 3 sizes on the left are a scale series and are joined; the right-hand systems are markers only, are not a scale series, and are not joined by a line. Labels are ISO 15919; `matplotlib` cannot shape Tamil.

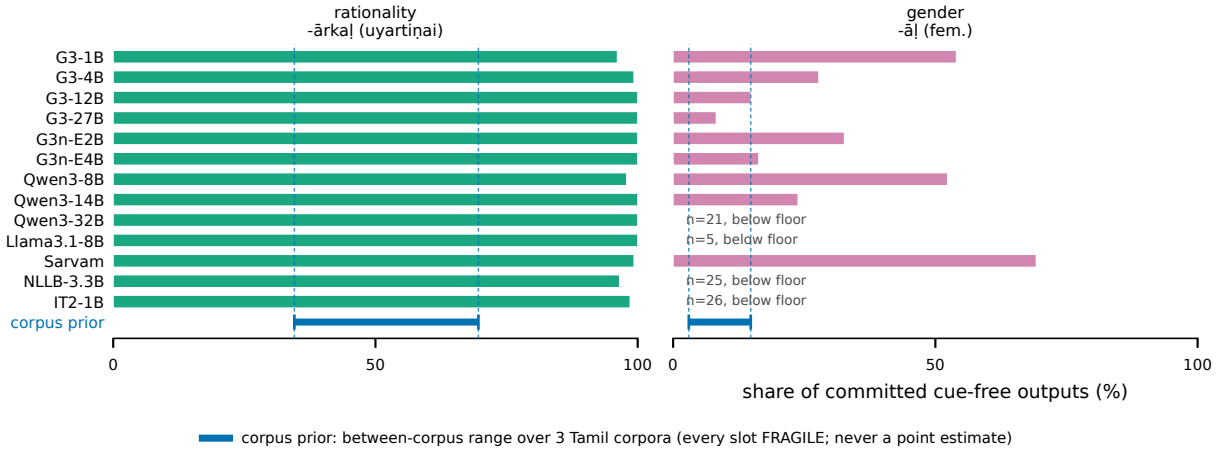

Figure 4: **Cue-free output against the corpus prior, drawn as a range.** Every slot is fragile by a criterion fixed in advance — which corpus is chosen moves the prior more than how many tokens are counted, so the prior is a band and never a line. In rationality every system's rate falls outside the band, some above its top and some below its bottom.

**The capability ceiling.** The instructed condition names the target value in the instruction, so a system failing it cannot be read as defaulting in any of the other three. The shipped instruction was defective — it named the benchmark's internal label codes rather than the Tamil morpheme, and naming the actual target form moves accuracy by up to 75.0 points. Both verdicts are reported side by side across all 55 cells rather than one replacing the other (Table 8). Even under the corrected wording the ceiling is not cleared everywhere, and §6 states which slots it fails for.

**Deleting the cue.** Table 9 and Figure 5 are the in-sentence-against-cue-free comparison §6 reports, per system and per slot.

## C Analyser Repairs

Off-the-shelf Tamil morphological tooling required four documented repairs before it could score obligatory-slot agreement, and a fifth landed after the panel reported here was first scored; the panel was re-scored with it, and the paragraph after the list reports what that moved. Each is at the scoring layer; the validated transducer is untouched, and both ablations are published (Table 10).

1. ***-ஆர் -ār* syncretism.** The suffix is honorific-singular or rational-plural and the transducer is inconsistent about which. Resolved by the

Figure 5: **From an in-sentence cue to no cue: commitment when the cue is deleted.** Each line is one system; commitment is the share of items on which it emits a form that takes a value in the slot. The cue-free condition carries no gold, so the quantity is commitment, not accuracy. The two cued conditions are not compared: they cue the value through different channels and the prior-sentence one is the easier on 11 of 13 systems (§8). Gender is the only slot in which deleting the cue reduces commitment across the panel: it falls on 13 of 13 systems there, against 0 in rationality and 5 in number.

| Slot and Tamil realisation | Prior MT |
|---|---|
| Rationality (திணை) | **none** |
| வந்தார்கள் / வந்தன | *prov.* |
| *vantārkaḷ* / *vantaṉa* | |
| Gender in the verb | heavily covered |
| வந்தான் / வந்தாள் / வந்தார் | *calib.* |
| *vantāṉ* / *vantāḷ* / *vantār* | |
| Number *(control)* | marked in both |
| வந்தது / வந்தன | *control* |
| *vantatu* / *vantaṉa* | |

Table 5: The scored slots, with the ISO 15919 scoring key under each Tamil form: the agreement features Tamil realises on the finite verb. Tamil is typeset by XeTeX with the Tamil shaper engaged; the romanisation is what appears in every figure, because `matplotlib` runs no complex-text shaper. **Rationality has no prior MT coverage at all** and is marked *provisional* (see Limitations); gender is a *calibration* axis, not a claimed contribution, and is the slot whose first measurement we retract (§8); number is the control, marked in both languages.

context filter, with the residual undecidable rate reported.

2. **-ஈர்கள் *-īrkaḷ* and -உங்கள் *-uṅkaḷ*.** Second-person plural suffixes are syncretic between plain-plural and honorific-singular, exactly as -ஆர்/-ஆர்கள் are in the third person, but are tagged bare. This is a grammatical claim we make and the transducer does not; it is in the native-check queue for that reason.
3. **-அனர் *-aṉar*.** Tagged singular although it is unambiguously plural.
4. **Word-final sandhi.** A sandhi consonant hides an overt pronoun, so எங்களைப் *eṅkaḷaip* returns a spurious verb reading and inflates the AVOIDANT_DROP rate.
5. **-இன் *-iṉ* past, finite reading.** ஓடின *ōṭiṉa* is a finite verb and நாய்கள் ஓடின *nāykaḷ ōṭiṉa* is a complete sentence, but the transducer admits only `+nonfin+adjpart`, so the checker scored correct Tamil as wrong. The repair adds the finite reading and keeps the participial one, since the form is genuinely ambiguous. It landed after the reported panel was first scored.

**What the fifth repair moved.** The panel was re-scored from the same raw outputs with the repair on, every rationality number in this paper is from that re-score, and the pre-repair scoring is released beside it. Of 54443 scored records, 728 changed outcome, 725 of them in the rationality slot and 3 elsewhere; no headline cell of any other slot moved. 717 rationality outcomes became CORRECT (512 from UNPARSED, 139 from WRONG), every one of them on அஃறிணை gold, where the -இன plural is the target form; 8 UNPARSED outputs on உயர்திணை gold became WRONG. 568 of the changes are in the in-sentence condition, and all 13 systems are affected: in-sentence rationality commitment moved from 58.3–75.0% to 73.7–90.3%, a rise of up to 21.1 points on one system. The old analyser was *under*-reporting commitment, not

| System | rat. | gen. | num. |
|---|---|---|---|
| Gemma 3 1B | 66.2 | 75.4 | 41.1 |
| Gemma 3 4B | 100.0 | 67.7 | 87.5 |
| Gemma 3 12B | 99.6 | 86.4 | 83.9 |
| Gemma 3 27B | 100.0 | 93.2 | 85.7 |
| Gemma 3n E2B | 100.0 | 70.5 | 61.6 |
| Gemma 3n E4B | 100.0 | 78.2 | 83.9 |
| Qwen3 8B | 93.4 | 74.6 | 99.1 |
| Qwen3 14B | 99.6 | 92.3 | 88.4 |
| Qwen3 32B | 99.6 | 59.1 | 85.7 |
| Llama 3.1 8B | 99.6 | 22.7 | 72.3 |
| Sarvam-Translate | 100.0 | 96.8 | 87.5 |
| NLLB-200 3.3B *(NMT)* | 99.6 | 47.7 | 84.8 |
| IndicTrans2 1B *(NMT)* | 98.2 | 71.4 | 94.6 |

Table 6: **Commitment rate with a prior-sentence cue (%): does the system make the obligatory choice at all?** A system *commits* when it emits a form that takes a value in the slot. Measured on the **corrected** release, on which every system in the original panel has been re-run; the superseded release appears only in Table 4, where differencing the two is the point. All cells are the same context prompt for prompted systems; dedicated MT systems take no prompt, and they are below the rule. Cells remain *provisional* for the reasons §6 gives — the number control does not function on these items, the capability ceiling is not cleared for rationality, and the checker has a known defect in the rationality slot — not because any system is unmeasured. **Commitment, not accuracy**: accuracy is undefined at zero commitment and is reported separately in Table 9.

over-reporting error. The metric study is unaffected: re-judged with the repaired analyser, all 73 natural-arm and all 1415 controlled-arm rationality errors remain errors, and every gold-bearing variant remains correct.

## D Annotation Facts

Table 11 is the full version of the counts §1 opens with. Each row is a direct query over the released treebanks and can be re-run against a later treebank release, so a release that changed any of them would change the table rather than the prose.

## E Open Native-Speaker Queue

The queue of open native-speaker questions is generated from the released data rather than maintained by hand, and its size is reported rather than summarised. 134 rows are open in total: 26 design questions, 45 verb lemmas, 35 noun lemmas and 36 personal names, the last of which no Tamil transducer covers at all. 156 items are scored against a reading the analyser does not license, all of them in the withdrawn imperative honorificity family.

| System | emitted (%) | corpus prior range (%) | obs. / prior range |
|---|---|---|---|
| *rationality* | | | |
| Gemma 3 1B | 96.1 | 34.5–69.6 | 0.38–1.78 |
| Gemma 3 4B | 99.3 | 34.5–69.6 | 0.43–1.87 |
| Gemma 3 12B | 100.0 | 34.5–69.6 | 0.44–1.9 |
| Gemma 3 27B | 100.0 | 34.5–69.6 | 0.44–1.9 |
| Gemma 3n E2B | 100.0 | 34.5–69.6 | 0.44–1.9 |
| Gemma 3n E4B | 100.0 | 34.5–69.6 | 0.44–1.9 |
| Qwen3 8B | 97.9 | 34.5–69.6 | 0.41–1.83 |
| Qwen3 14B | 100.0 | 34.5–69.6 | 0.44–1.9 |
| Qwen3 32B | 100.0 | 34.5–69.6 | 0.44–1.9 |
| Llama 3.1 8B | 100.0 | 34.5–69.6 | 0.44–1.9 |
| Sarvam-Translate | 99.3 | 34.5–69.6 | 0.43–1.88 |
| NLLB-200 3.3B | 96.5 | 34.5–69.6 | 0.39–1.79 |
| IndicTrans2 1B | 98.6 | 34.5–69.6 | 0.42–1.85 |
| *gender* | | | |
| Gemma 3 1B | 54.0 | 3.0–14.8 | 2.65–17.07 |
| Gemma 3 4B | 72.2 | 7.0–22.3 | 2.24–9.28 |
| Gemma 3 12B | 85.1 | 7.0–22.3 | 2.82–11.12 |
| Gemma 3 27B | 91.8 | 7.0–22.3 | 3.12–12.06 |
| Gemma 3n E2B | 67.3 | 7.0–22.3 | 2.02–8.59 |
| Gemma 3n E4B | 83.7 | 7.0–22.3 | 2.75–10.91 |
| Qwen3 8B | 52.3 | 3.0–14.8 | 2.53–16.5 |
| Qwen3 14B | 76.2 | 7.0–22.3 | 2.42–9.85 |
| Sarvam-Translate | 69.2 | 3.0–14.8 | 3.68–22.16 |

A slot appears here only where a system's cue-free cell clears the reporting floor *and* the slot has a reportable corpus prior; **number** has no prior of its own.

Table 7: **Emitted share on cue-free items**: the share of the modal value against the **between-corpus range** of the prior over 3 Tamil corpora. Every slot is fragile by the pre-registered criterion — which corpus one picks moves the prior more than how many tokens one counts — so the prior is a range and never a point estimate, and the observed-to-prior ratio is computed at both ends of that range. This licenses the statement that the output rate *deviates from general Tamil text frequency*; it does *not* license 'deviates from its own training frequency', because no evaluated system's training mixture was measured. In rationality every system's rate falls outside the corpus range, some above its top and some below its bottom.

Every lemma has its own row because round-tripping through the transducer is not evidence of correctness. A form the transducer over-generates round-trips perfectly, and at least one such form survived all four automatic screens and was still wrong: the -இன் *-iṉ* past plural the transducer builds by concatenation, ஓடினன *ōṭiṉaṉa*, which has zero occurrences in 105 million tokens of Tamil while the real form ஓடின *ōṭiṉa* is frequent. This is why the validation protocol is described as human-validated with FST support throughout, and why the surviving slots stay provisional. It also bounds the attestation gate in the other direction: the optatives இறங்குக *iṟaṅkuka*, ஏறுக

*ēṟuka*, கழுவுக *kaḻuvuka* and நீந்துக *nīntuka* are ordinary written Tamil with zero occurrences in the same corpora, so a zero count is evidence about our corpora and not about the language. The frequent optative வருக *varuka* is attested there and is not one of them.

## F The Construction Audit

The audit behind §8 asks one question per (slot, condition): does the English source carry *any* exponent of the feature the Tamil gold commits to? It parses no English and inspects word inventories, which is deliberate — the weakest question that would have caught the defects is the one that can be run on every release and disputed word by word. It is advisory on the superseded release, which is retained as its positive control, and a hard check from the corrected release on: a change to the audit that stopped it detecting the original defect would be caught rather than pass quietly.

**The three gender confounds in full. 1. The anaphor was neutral in the one slot with a neutral target form.** 100.0% of prior-sentence gender sources used singular *they* against a singular-feminine gold, and gender is the one slot whose Tamil target admits the epicene -ஆர் *-ār*, so a neutral rendering was a *correct translation* that the scorer recorded as avoidance. On corrected items, whose prior-sentence source is a singular animate name, the same systems commit at 22.7–96.8% with 92.4–100.0% accuracy; nothing about the models changed. **2. The two cued conditions differ in cue *type*, not cue distance.** The in-sentence condition cues gender through the onomastics of the Tamil name, which is world knowledge; the prior-sentence condition cues it through an explicit English appositive, which is reading comprehension. If the two differed only in where the cue sits, the in-sentence condition could not be the harder one. It is: the prior-sentence condition scores higher on 11 of 13 systems, and the per-system gap runs from -18.2 to 43.6 points. **3. The leak detector was watching the wrong signal.** The shipped detector keyed on output length, so it was blind to a system that translates the context *instead of* the marked sentence — the dangerous shape, since it is in the context that a prior-sentence cue lives. Its replacement differences the rate at which the marked sentence's own gold verb stem appears in the output, within a system so that paraphrase cancels against that system's own baseline. It exposes the failure at once: gemma3-1b misses that stem on 98.2% of prior-sentence gender items against 38.6% with an in-sentence cue, while every other system stays above 55.0% in both. On the superseded release, only 3 of the 5 slots the audit covers have an interpretable comparison between the two cued conditions; which do not is computed from the sources (clusivity, gender).

**Three further defects.** Besides the three gender confounds of §8, the audit found three defects nobody had reported: a condition whose English sources were built by deleting the cue string out of another condition's frame, and which were therefore malformed; items whose Tamil reference named a person the English source never mentions, so the reference is not a translation of its source; and personal names used as gendered cues that appear in both gender sections of the name lexicon.

| System | Slot | shipped (%) | corrected (%) |
|---|---|---|---|
| Gemma 3 12B | gender | 70.0 | 95.0 |
| | number | 25.0 | 100.0 |
| | rationality | 50.0 | 50.0 |
| Gemma 3 1B | gender | 12.5 | 25.0 |
| | number | 0.0 | 25.0 |
| | rationality | 42.5 | 45.0 |
| Gemma 3 27B | gender | 80.0 | 100.0 |
| | number | 50.0 | 100.0 |
| | rationality | 50.0 | 55.0 |
| Gemma 3 4B | gender | 40.0 | 35.0 |
| | number | 0.0 | 25.0 |
| | rationality | 50.0 | 50.0 |
| Gemma 3n E2B | gender | 47.5 | 42.5 |
| | number | 50.0 | 75.0 |
| | rationality | 50.0 | 50.0 |
| Gemma 3n E4B | gender | 47.5 | 45.0 |
| | number | 50.0 | 50.0 |
| | rationality | 50.0 | 52.5 |
| Llama 3.1 8B | gender | 40.0 | 67.5 |
| | number | 25.0 | 50.0 |
| | rationality | 55.0 | 45.0 |
| Qwen3 14B | gender | 80.0 | 85.0 |
| | number | 25.0 | 75.0 |
| | rationality | 50.0 | 50.0 |
| Qwen3 32B | gender | 65.0 | 100.0 |
| | number | 50.0 | 50.0 |
| | rationality | 50.0 | 52.5 |
| Qwen3 8B | gender | 50.0 | 92.5 |
| | number | 35.0 | 100.0 |
| | rationality | 50.0 | 52.5 |
| Sarvam-Translate | gender | 47.5 | 37.5 |
| | number | 25.0 | 25.0 |
| | rationality | 50.0 | 50.0 |

Table 8: **The capability ceiling was measured with a defective instruction, and both verdicts are reported.** The shipped instruction named the benchmark's internal label codes rather than the target Tamil morpheme. With an instruction that names the actual form, accuracy moves by up to 75.0 points. The instructed condition gates the interpretation of every other one, so the uncorrected column is retained rather than replaced: the models can perform these mappings when actually told what to produce, and the original ceiling was failing for the wrong reason.

| | | cue in the sentence | | | no cue, no gold | | | |

Table 9: **An in-sentence cue against no cue: the comparison the construction licenses.** The two conditions share a frame and a cue type and differ in whether the cue is present at all, so the pair isolates cue presence. **In gender the two cued conditions do not**: they cue the value through different channels, the prior-sentence condition scores higher on 11 of 13 systems, and no gender comparison between them is drawn (§8). The cue-free condition carries no gold by construction, so it has no accuracy; the emitted distribution is reported instead, as the modal value and the share of committed items taking it. A cell prints *n/a* below the reporting floor ($< 30$ committed items or $< 30\%$ commitment), because a ratio over a handful of items is not a rate. In gender, commitment falls when the cue is deleted on 13 of 13 systems, by 4.1–42.4 points. In rationality it falls on 0, and the systems answer a cue-free item as confidently as a cued one; in number it falls on 5, a slot whose results are not interpreted (§6).

| Verb-form set | lexicon only (%) | +guesser (%) | +fallback (%) |
|---|---|---|---|
| UD_Tamil-TTB test (264 forms) | 38.6 | 64 | 69.3 |
| UD_Tamil-MWTT test (295 forms) | 62 | 75.3 | 89.8 |
| *Precision / recall, -ஆன் masculine slice on MWTT* | | | |
| precision (audited) | | | 100 |
| recall (audited) | | | 98.7 |
| recall, universal-after-context-filter | | | 94.9 |
| recall, existential (robustness) | | | 94.9 |
| *Slot-value extractor, benchmark gold* | | | |
| clusivity / gender / number / rationality recall | | | 100.0 / 100.0 / 100.0 / 100.0 |
| honorificity recall | | | 79.0 |
| contrast false positives | | | 0 |

Table 10: Analyser coverage as an ablation, and precision/recall on held-out UD_Tamil-MWTT. The fallback layer is reported because it was necessary, not because it flatters the number. The checker is *not* 100% accurate and we do not claim it is. Scoring follows the universal-after-context-filtering policy, with existential as a robustness column. Recall is reported for the withdrawn honorificity slot as well, because it is the measurement that withdrew it: 79.0% reflects the imperative sub-family, whose optative targets carry no exponent ThamizhiMorph will license (Appendix E).

| Direct FEATS count | tokens | Consequence |
|---|---|---|
| `Gender=Fem` in UD_Tamil-TTB | 0 | no masc./fem. contrast is expressible |
| -ஆன்/-ஆள் finite verbs in TTB | 0 | the exponents themselves never occur |
| `Clusivity` across both treebanks | 0 | நாம்/நாங்கள் are not distinguished |
| -வில்லை/இல்லை tagged `Polarity=Pos` | 41 / 41 | the most frequent negation strategy is mislabelled |
| `Aspect` across both treebanks | 0 | unannotated |
| `Deixis` across both treebanks | 0 | documented as Tamil-specific, never used |
| `Polite` distinct values | 1 | one value only; the binary contrast is not annotated |
| `Voice=Cau` | 0 | causation unannotated |
| `Mood` ∈ {`Pot`,`Nec`,`Des`} | 0 | modality unannotated |
| `Evident` | 0 | evidentiality unannotated |

Table 11: **Reproducible annotation facts**, counted directly from UD_Tamil-TTB (train/dev/test) and UD_Tamil-MWTT (test) by `scripts/ud_negative_facts.py`. Taken together, the standard Tamil annotation cannot express 7 categories a reference grammar treats as central: aspect, causation, clusivity, deixis, evidentiality, honorific contrast, modality. Tamil is also absent from UniMorph entirely. These are counts rather than arguments, which is why they open the paper. TTB is CC BY-NC-SA 3.0 and only counts are reproduced.

# AmanaMT: Translation Direction Predicts Automatic Metric Reliability

**Isaac Thompson**
Brigham Young University
it238@byu.edu

## Abstract

When machine translation (MT) metrics fail in low-resource settings, the field typically blames data scarcity. We show this diagnosis is often wrong using AmanaMT, a unified benchmark spanning 730,748 segments, 33 languages, three annotation tiers, and 10 metrics: the dominant predictor of metric unreliability is not resource level but *domain mismatch* and *translation direction*. Direction is the single largest predictor of between-language variance in metric reliability ($\eta^2_{\text{dir}} = 0.309$, nearly a third of between-language variance); morphological type is a substantially smaller main effect ($\eta^2_{\text{morph}} = 0.073$), though the joint direction×morphology cells account for $\eta^2_{\text{cell}} = 0.618$, capturing direction-specific morphological variation. Ukrainian's near-zero COMET correlation is fully explained by a domain label (`other`, not news): a genre confound, not a language problem. Russian's weak aggregate dissolves into clean per-year signals once stratified by WMT year, a textbook Simpson's Paradox from pooling heterogeneous system generations. Neural metrics (MetricX-24, xCOMET, COMET) substantially outperform $n$-gram baselines at every tier; the gap is largest in morphologically complex and non-news settings where surface overlap is an especially poor proxy for adequacy.

## 1 Introduction

Automated MT metrics are the connective tissue of modern MT research: they drive model selection, benchmark comparisons, and shared-task rankings across hundreds of language pairs. Yet the conditions under which these metrics are trustworthy remain poorly understood. A practitioner evaluating a new Hindi or Swahili translation system reaches for BLEU or COMET without knowing whether those metrics bear any reliable relationship to human judgment for that language, domain, or translation direction.

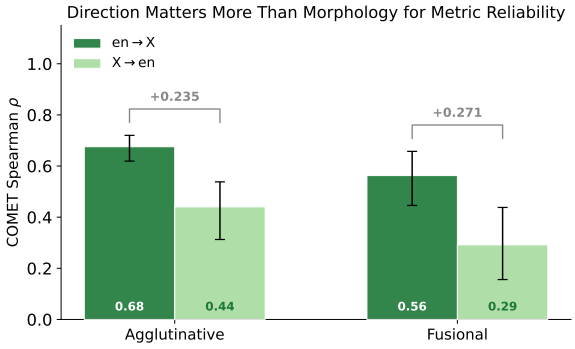

Figure 1: Translation direction matters more than morphological type for COMET reliability: en→X (dark green) consistently outperforms X→en (light green) within both morphological types with Tier-1 data in both directions (§3.3). Isolating is omitted: there are no Tier-1 en→X isolating observations (Limitations), so it cannot show a direction contrast.

The WMT Metrics Shared Task (Freitag et al., 2023) has produced annual meta-evaluations for over a decade, but each edition covers only the language pairs in that year's shared task, typically 5–15 pairs, nearly always news-domain, and never with a systematic typological framing. Efforts to extend coverage to low-resource languages (Yari et al., 2025) remain limited in scope. No prior work has unified professional Multidimensional Quality Metrics (MQM) annotations, crowd-sourced Direct Assessment (DA), and synthetic annotations across a common evaluation framework spanning the full range of typological diversity.

We fill this gap with AmanaMT[1], a unified three-tier benchmark across 33 languages, 10 metrics, and 730,748 segments. Our design enables the first direct comparison of metric reliability across resource tiers, translation directions, and morpholog-

[1]*Amana* (Hausa, borrowed from Arabic *amāna*): trust, reliability, honesty. Named for the benchmark's purpose: determining when and where automatic MT metrics can be trusted. Code and data: https://github.com/byu-matrix-lab/amana-mt.

ical types in a single controlled study. The results reveal that the field's go-to explanation for metric failure, "this language is low-resource," is often wrong in a correctable way: domain mismatch and the joint configuration of translation direction and morphological type predict failure far better than resource level alone.

### 1.1 Contributions

**Direction dominates over morphological type.** We quantify metric reliability across a 2×3 grid of translation direction (en→X, X→en, X↔Y) and morphological type (isolating, agglutinative, fusional). Translation direction is the dominant predictor ($\eta^2_{\text{dir}} = 0.309$, nearly a third of between-language variance); morphological type is a much smaller main effect ($\eta^2_{\text{morph}} = 0.073$). The joint direction×morphology cells account for $\eta^2_{\text{cell}} = 0.618$, capturing direction-specific morphological variation (particularly within X→en) absent from prior MT meta-evaluation work.

**Domain as the primary confound.** Ukrainian's near-zero correlation ($\rho = .001$) is fully explained by a domain label mismatch (`uk-en_2022_other`): every Ukrainian segment is conversational-register text evaluated against a news-trained metric. Controlled comparison with direction-matched X→en languages confirms a 0.143 absolute gap to the next-lowest language (ja-en), attributable to domain shift, not language difficulty.

**Simpson's Paradox in multi-year evaluation.** Russian's anomalously low aggregate correlation ($\rho = .157$) conceals clean per-year signals ($\rho = .383$ in 2021, .501 in 2022). Pooling WMT system generations across years creates aggregation bias that should be treated as a methodological artefact, not a linguistic finding.

**Neural metrics dominate across typological cells and resource tiers.** MetricX-24, xCOMET, and COMET outperform surface metrics in every typological cell and at every resource tier. The gap is largest for the hardest cases: morphologically complex languages and non-news domains.

## 2 Related Work

**WMT Metrics Shared Task.** The primary venue for systematic MT metric evaluation is the annual WMT Metrics Shared Task, which has evolved from BLEU-focused comparisons (Bojar et al., 2017) to MQM-based meta-evaluation (Freitag et al., 2023). Each edition covers 5–15 language pairs with professional MQM annotations, generating yearly rankings. Our work differs in three ways: (1) we aggregate across years rather than evaluating a single shared-task snapshot; (2) we include 22 additional language pairs via DA and synthetic annotations; (3) we frame results typologically rather than as a ranking exercise.

**MQM and annotation quality.** Freitag et al. (2021) establish that expert MQM annotation substantially outperforms crowd-sourced DA for high-quality MT evaluation. Deutsch et al. (2023) show that tie handling in pairwise accuracy (PA) materially affects rankings, motivating our adoption of soft pairwise accuracy (SPA) (Thompson et al., 2024). Reference quality as a confound is studied by Freitag et al. (2023), who argue that "metrics might be guilty but references are not innocent."

**Metric reliability under domain and resource shift.** Zouhar et al. (2024) demonstrate that learned metrics fine-tuned on WMT news data degrade substantially when applied to out-of-domain text, directly predicting the Ukrainian result we observe. Yari et al. (2025) find that metric reliability varies significantly across Indian languages, with low-resource languages showing systematically weaker correlations, a finding our broader typological framing partially confirms and partially complicates (Khmer is low-resource but correlates well due to domain homogeneity).

**Morphology and MT evaluation.** Mondshine et al. (2025) study metric reliability across morphological types in summarization and find that COMET correlates better for fusional languages, the inverse of the sign we observe within X→en. In MT, morphological type is not an independent main driver of metric reliability ($\eta^2_{\text{morph}} = 0.073$); the direction axis, absent from monolingual summarization, dominates instead, and morphology's residual effect only surfaces as a within-direction interaction rather than a standalone predictor. Bugliarello et al. (2020) show that MT difficulty (cross-mutual information) is asymmetric across translation direction; we show the same asymmetry holds for metric reliability, extending their finding from difficulty to evaluability.

**Typological diversity in NLP.** The broader context for this work is the recognition that NLP systems, including evaluation metrics, are not language-agnostic (NLLB Team and Costa-jussà, 2022). The morphological and directional effects

we quantify are one instance of a general pattern: models trained predominantly on English-centric data inherit English-centric assumptions about what good translation looks like.

## 3 Methodology

### 3.1 Three-Tier Annotation Design

A core contribution is the unified three-tier data pipeline that brings together human and synthetic annotations under a shared evaluation framework:

**Tier 1a, WMT MQM** (*high-resource*): Professional Multidimensional Quality Metrics span-level annotations from the WMT shared task (Freitag et al., 2021), covering de, zh, ru, he (WMT20–23). Segment-level MQM penalty scores are converted to sentence-level quality scores via the standard weighted formula. WMT24 en-es also uses MQM annotation but is tiered as Medium, not High (see §4.2), since it is single-year with a more recent system generation and annotation cohort than de/zh/ru/he.

**Tier 1b, WMT Direct Assessment** (*medium/low-resource*): Sentence-level DA scores from the WMT direct assessment protocol (Graham et al., 2017) covering cs, tr, uk (medium) and ha, km, ps (low-resource), drawn from the corresponding per-year WMT shared task releases. DA scores are normalized to $[0, 1]$.

**Tier 2, Synthetic MQM** (*very-low-resource*): For 7 languages with no human MT annotations (sw, ht, lo, th, my, am, ka), we generate hypotheses using NLLB-200 (NLLB Team and Costa-jussà, 2022) over FLORES+ (Goyal et al., 2022; NLLB Team and Costa-jussà, 2022) source sentences (`openlanguagedata/flores_plus`, the community-maintained successor to FLORES-101 that also incorporates the FLORES-200 expansion introduced alongside NLLB-200), then prompt the large language model (LLM) Llama-3.1-8B-Instruct (Dubey et al., 2024) with a GEMBA-MQM-style few-shot template (Kocmi and Federmann, 2023a) to produce synthetic span-level quality judgments. **Circular-evaluation caveat**: the same Llama-3.1-8B backbone is also evaluated as the GEMBA metric. GEMBA correlations are therefore excluded from all Tier 2 analyses; only reference-based and kiwi metrics are reported for this tier. Validation against human annotation (even 200 Error Span Annotation (ESA)-annotated segments per language) would be required to confirm that Tier 2 synthetic scores reflect real translation quality rather than LLM self-consistency.

### 3.2 Metrics Evaluated

**Lexical surface metrics.** **BLEU** (Papineni et al., 2002): $n$-gram precision with brevity penalty. **ChrF++** (Popović, 2015): Character $n$-gram F-score with added word-unigram/bigram terms (`sacrebleu word_order=2`, the chrF++ configuration); more morphology-sensitive than BLEU.

**Embedding-based.** **BERTScore** (Zhang et al., 2020): Contextual embedding cosine similarity (mDeBERTa-v3-base). **BLEURT** (Sellam et al., 2020): Fine-tuned BERT regression on human ratings.

**Learned regression (reference-based).** **COMET** (Rei et al., 2022a): Regression over source+hypothesis+reference (wmt22-comet-da). **xCOMET** (Guerreiro et al., 2024): COMET with MQM error-span detection (XCOMET-XL). **MetricX-24** (Juraska et al., 2024): Google's WMT 2024 winning hybrid metric (metricx-24-hybrid-large-v2p6-bfloat16).

**Reference-free quality estimation.** **COMET-Kiwi** (Rei et al., 2022b) (Kiwi-22): Reference-free QE using source+hypothesis only (wmt22-cometkiwi-da). **COMET-Kiwi-23** (Rei et al., 2023) (CK23): Larger 2023 variant (wmt23-cometkiwi-da-xl).

**LLM-based.** **GEMBA-MQM** (Kocmi and Federmann, 2023b,a): Llama-3.1-8B-Instruct (Dubey et al., 2024) prompted with a GEMBA-MQM few-shot template to predict MQM error spans; excluded from Tier 2 analysis (see §3.1).

**Ensemble**: Min-max normalized score average over the five neural metrics (COMET, xCOMET, MetricX-24, Kiwi-22, Kiwi-23), excluded from Tier 2.

### 3.3 Translation Direction and Morphological Type Analysis

A central novel contribution is a 2×3 cell analysis of *translation direction* crossed with *morphological type*, defined at the language level as follows.

**Translation direction:**

**X→en** non-English source, English target (e.g. zh, he, uk)

**en→X** English source, non-English target (e.g. de, tr, sw)

**X↔Y** neither source nor target is English; each pair is labeled by its target language (e.g. fr for de→fr, bn for hi→bn, hi for bn→hi)

**Morphological type** (standard linguistic taxonomy):

**isolating** minimal inflection, meaning via word order (zh, th, lo, km, my)

**agglutinative** transparent suffix/prefix stacking (tr, fi, et, ka, kk, sw, ja, ta, am)

**fusional** multiple grammatical features fused per morpheme (de, ru, es, cs, fr, pl, uk, he, ps, bn, hi, gu, and others)

Khmer (km) is Austroasiatic/Mon-Khmer and isolating, not agglutinative as sometimes assumed; Burmese (my) is predominantly analytic. Hausa (ha) is classified fusional here: although it has real agglutinative affixation, its Afroasiatic verbal-grade system fuses aspect, transitivity, and direction via tone and vowel apophony rather than discrete morphemes, and its typology is genuinely mixed rather than a clean fit to either category.

For each language we compute Spearman $\rho$ between each metric and human scores, yielding a $2\times3$ matrix of mean $\rho$ per (direction, morphology) cell. Effect sizes are reported as $\eta^2$ (proportion of variance explained), with 95% bootstrap CIs over the languages in each cell. $\eta^2_{\text{dir}}$ and $\eta^2_{\text{morph}}$ are computed via one-way ANOVA on the per-language $\rho$ values with direction and morphological type as the respective factors. $\eta^2_{\text{cell}}$ is computed via one-way ANOVA over the six direction$\times$morphology cells and therefore measures total between-cell variance rather than a formally partitioned interaction term; it is bounded below by each main effect by construction. The informative comparison is therefore how direction dominates the main-effect decomposition ($\eta^2_{\text{dir}}$ much larger than $\eta^2_{\text{morph}}$), while the cell structure ($\eta^2_{\text{cell}}$) captures additional direction-specific morphological variation not visible in either main effect alone.

This analysis is motivated by and extends Mondshine et al. (2025), who study metric reliability across morphological types in summarization (not MT) and find that COMET correlates *better* for fusional languages in their setting, treating morphology as an independent main driver. Our result does not simply reverse their sign under an added direction confound: morphology is a substantially weaker independent main driver of metric reliability in MT than direction is ($\eta^2_{\text{morph}} = 0.073$, versus $\eta^2_{\text{dir}} = 0.309$ for direction). Their morphology-driven story does not replicate as a standalone effect in our MT setting; what residual morphological signal exists is direction-dependent (§3.3), a structurally different claim from theirs. The direction axis is independently motivated by Bugliarello et al. (2020), who show that translation *difficulty* (measured via cross-mutual information) is asymmetric across direction; our contribution is showing the same asymmetry holds for metric *reliability*.

### 3.4 Evaluation Protocol

For each (language, metric) pair, we compute: (1) Spearman $\rho$ with 95% bootstrap confidence intervals (1000 resamples, percentile method); (2) Kendall $\tau$; (3) Pairwise accuracy (PA), fraction of concordant segment pairs, excluding metric-tied and human-tied pairs (Freitag et al., 2023); (4) Soft pairwise accuracy (SPA), the WMT 2024 standard (Thompson et al., 2024), which credits metric-tied pairs as 0.5 rather than excluding them, providing a tie-calibrated alternative to PA (Deutsch et al., 2023); (5) Williams (1959) test for significance of the difference between two correlations sharing a common criterion.

Segments where the human quality score is tied are excluded from both PA and SPA denominators, following Deutsch et al. (2023).

All main analysis runs over 723,664 professionally annotated segments across Tier 1a and Tier 1b; the 730,748 total segment count includes Tier 2 synthetic annotations, which are reported separately and flagged as exploratory.

## 4 Results and Analysis

### 4.1 Main Correlation Results

Table 1 reports per-tier Spearman $\rho$ and soft pairwise accuracy (SPA) averaged across all languages in each tier. Neural regression metrics dominate at every resource level; surface metrics degrade more sharply on Tier 1a (MQM) where human judges penalize subtle errors that $n$-gram overlap misses. Williams tests (COMET vs. BLEU and vs. chrF, per language) confirm COMET's advantage over surface metrics is statistically significant at every Tier 1 language (Tier 1a and Tier 1b) except uk, zu: Ukrainian is the domain-confound outlier discussed below, where COMET's own correlation collapses toward zero so it cannot significantly exceed anything; Zulu's COMET advantage is significant against BLEU ($p = 7.5 \times 10^{-9}$) but not

against chrF ($p = 3.6 \times 10^{-1}$).

Tier 2 synthetic correlations are near-zero across all metrics, most consistent with the local LLM judge (Llama-3.1-8B) failing to produce reliable quality judgments for these low-resource, largely non-Latin-script languages, rather than with the MT metrics themselves failing. This uniform near-zero pattern does not itself distinguish which metric is more reliable for these languages, and we draw no such conclusion from it; without human validation of the synthetic judgments, we cannot separate this LLM-judge-unreliability explanation from a genuine ceiling on metric reliability at this resource level.

We explicitly ruled out a data-pipeline explanation: Tier 2's segment identifiers are shared across all seven languages (each keyed only by FLORES+ sentence index, with no per-language disambiguator), a structurally identical risk to the reference/segment-ID pipeline error affecting the he-en and en-es span-fallback pairs, discussed below (§4.2) and in Limitations. Independently rebuilding each language's quality scores from the raw synthetic-annotation cache and rejoining by language and segment confirms the reported Tier 2 correlations are correctly aligned, not an artifact of cross-language score bleed. We report Tier 2 for completeness, not as evidence for any typological claim.

| Family | Metric | High | Med | Low |
|---|---|---|---|---|
| | | *Spearman ρ / SPA* | | |
| Lexical | BLEU | .186 / .582 | .293 / .636 | .230 / .576 |
| | ChrF | .201 / .588 | .295 / .632 | .267 / .590 |
| Embed. | BERTScore | .265 / .617 | .404 / .688 | .283 / .595 |
| | BLEURT | .349 / .654 | .423 / .702 | .291 / .600 |
| Regr. | COMET | .436 / .690 | .526 / .747 | .331 / .613 |
| | xCOMET | **.485 / .709** | .496 / .730 | .315 / .607 |
| | MetricX-24 | .465 / .698 | **.588 / .773** | **.383 / .632** |
| QE | Kiwi-22 | .380 / .661 | .445 / .701 | .289 / .598 |
| | Kiwi-23 | .380 / .660 | .474 / .714 | .368 / .626 |
| LLM | GEMBA | .035 / .501 | – | – |
| – | Ensemble | .485 / .709 | .557 / .759 | .363 / .624 |

Table 1: Average Spearman $\rho$ / soft pairwise accuracy (SPA) by resource tier. High = Tier 1a MQM (de, ru, zh, he); Med = Tier 1b DA plus en-es WMT24 MQM; Low = Tier 1b DA. Values are averaged across annotation tiers within each resource tier. **Bold**: best single metric per tier. GEMBA shown for MQM tier only; excluded from Tier 1b (Med, Low) because its backbone was not fine-tuned on DA-style human judgments, and from Tier 2 to avoid circular evaluation with the Llama-3.1-8B-generated hypotheses. GEMBA's High-tier value averages only de/ru/zh, not all four Tier 1a languages: he-en's GEMBA score predates a segment-identifier correction applied to every other metric (§4.2) and could not be realigned, so it is excluded pending recomputation (see Limitations). en-es's GEMBA score has the same problem and is excluded from all reported statistics, but this does not affect the High-tier average shown here, since en-es is tiered Medium, not High (§4.2).

### 4.2 Per-Language Analysis

Figure 2 shows per-language Spearman $\rho$ for COMET. Notable patterns:

**Top performers**: Latvian achieves the highest individual COMET correlation ($\rho = .746$), followed by Lithuanian (0.742), Finnish (0.739), Turkish (0.724), and Estonian (0.721) – all en→X-specific values for the languages with data in both directions (Table 8), not the direction-pooled averages, which would understate them – spanning two morphological types. The unifying feature is not morphological type but data quality: all five use single-year WMT DA news data with high inter-annotator agreement, suppressing the multi-year pooling variance that depresses Russian and German.

**Ukrainian** collapses to near-zero correlation for all metrics ($\rho_{\text{COMET}} = .001$, pairwise acc. $= 0.499$). A uniform near-zero result across unrelated metric families (surface overlap and learned regression alike) is also the signature of a broken human-score join, so before accepting a domain explanation we independently rebuilt Ukrainian's quality scores from the raw WMT DA data and rejoined them to every metric checkpoint by segment ID: the alignment is correct, and the near-zero result is not a pipeline artifact. Investigation confirmed the cause: all 16,470 Ukrainian segments in the WMT DA dataset carry the domain label `other` (segment IDs: `uk-en_2022_other`), indicating non-news text, whereas every other language in our pipeline uses news-domain test sets. The short average sentence length (≈12 words) is consistent with a conversational or social-media register (Kocmi et al., 2024). A single-reference metric evaluated against conversational MT cannot discriminate quality adequately. Ukrainian should be treated as a domain outlier, not a language/script effect, consistent with Zouhar et al. (2024), who show that fine-tuned metrics degrade substantially under domain shift. We applied the same segment-ID rebuild-and-rejoin check to is-en and ha-en, the two other languages with weak aggregate correla-

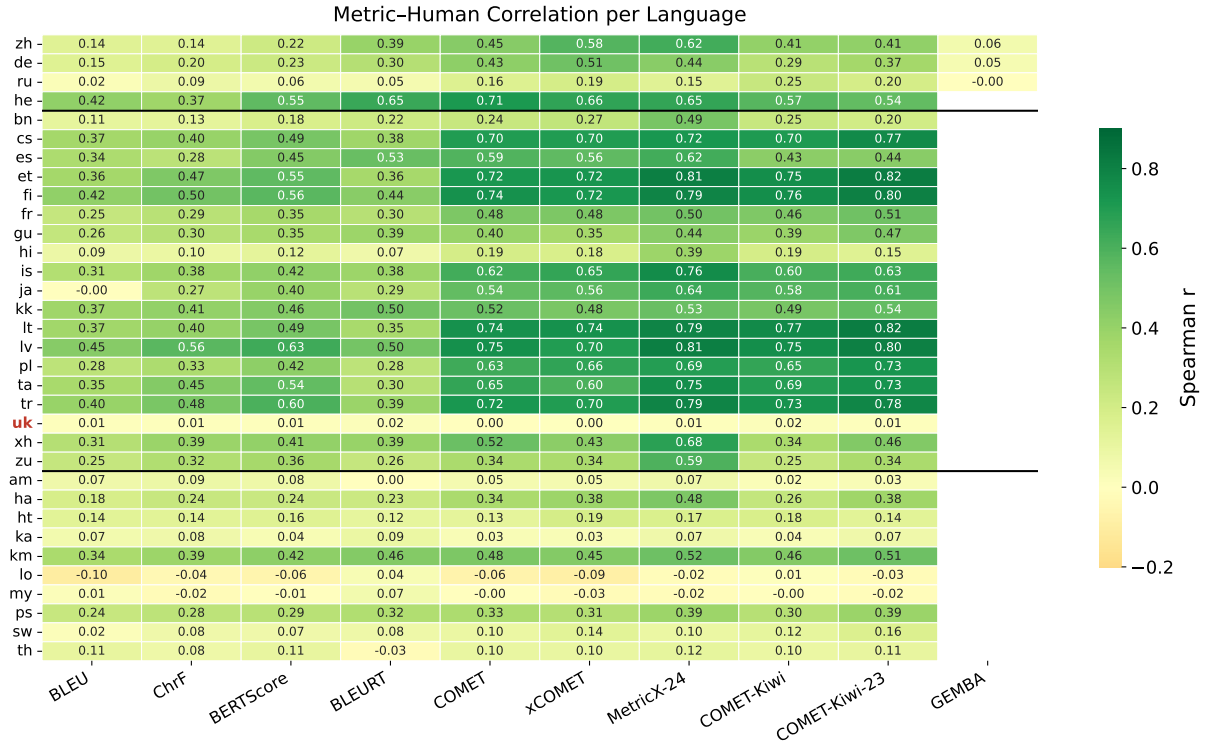

Figure 2: Per-language Spearman $\rho$ heatmap for all evaluated metrics. Languages sorted by resource tier. Black horizontal lines divide tiers. Ukrainian (**uk**) is a domain outlier (non-news register; see §4.2). *Tier 2 languages* (am, ht, ka, lo, my, sw, th) use synthetic MQM annotations generated by Llama-3.1-8B; their correlations are exploratory and unvalidated against human judgments. GEMBA's column is sparse by design: it is reported only for the high-resource MQM languages (§3.1), excluded from Tier 1b because its backbone was not fine-tuned on DA-style judgments, and excluded from Tier 2 to avoid circular evaluation with the Llama-3.1-8B-generated hypotheses. he-en is additionally blank for GEMBA specifically: its scores predate a segment-identifier correction applied to every other metric (§4.2) and could not be realigned (see Limitations).

tions (Table 8); both alignments are correct, and their weakness is annotation noise rather than a domain or pipeline effect.

**Medium > High**: Averaged across metrics, medium-resource languages outperform high-resource (COMET: $\rho = .526$ vs. .436; MetricX: .588 vs. .465; Figure 4 plots this for all ten metrics). This reverses the intuitive ordering and mirrors the Hindi anomaly reported by Yari et al. (2025) in Indian-language MT evaluation. The mechanistic explanation is that high-resource MQM languages span multiple WMT years (2020–23) and MT systems, introducing inter-year domain and system variance that suppresses aggregate correlation, a source of noise absent from the medium-tier DA languages.

Spanish (en-es WMT24) is classified in the medium tier despite using MQM annotation because it comes from a single year with a more recent system generation and annotation cohort. Had it been grouped with High, the medium>high gap would be smaller, not larger: High would rise from .436 to approximately .466, and removing Spanish from Medium would lower the medium-tier mean; the ordering survives but with a narrower margin.

**Russian anomaly, Simpson's Paradox**: Russian achieves the lowest MQM correlation of any non-domain-outlier language (aggregate COMET $\rho = .157$). Year-stratified analysis reveals the mechanism: WMT21-only yields $\rho = .383$ ($n = 15{,}600$) and WMT22-only yields $\rho = .501$ ($n = 19{,}725$), but pooling both years collapses to .157. This is a textbook aggregation bias: the two WMT system pools have different quality distributions, so across-year pooling creates a between-year confound that suppresses the within-year metric–human relationship. German shows the same pattern but less severely (2020: $\rho = .497$; 2021: .323; 2022: .456; aggregate: .425). The Russian aggregate is extreme because its two yearly pools are more divergent. This is not a property of Russian as a language, it is an artefact of pooling heteroge-

neous MT system generations.

**Khmer**: Despite being classified as low-resource, Khmer achieves COMET $\rho = .476$ and MetricX $\rho = .516$, higher than several medium-tier languages (e.g., Japanese .279, Hindi .194). Khmer is Austroasiatic (Mon-Khmer) and typologically *isolating* (not agglutinative as sometimes assumed), sharing that property with Chinese and Thai. Its strong performance here reflects single-year Wikipedia-domain data, which produces cleaner and more consistently-structured reference translations than news. This suggests that annotation consistency and domain homogeneity can compensate for low absolute resource level.

**Hebrew** shows no metric-family anomaly: COMET (reference-based) achieves the strongest correlation of any metric reported for this language ($\rho = .713$), ahead of xCOMET ($\rho = .660$), MetricX ($\rho = .653$), CK23 ($\rho = .540$), COMET-Kiwi-22 ($\rho = .569$), and BERTScore ($\rho = .552$), despite Hebrew having 12,441 professionally annotated segments. Figure 3 shows this COMET-over-CK23 gap is the largest deviation from the reference-free/reference-based equal-performance diagonal across all evaluated languages. An earlier version of this analysis reported the reverse pattern (reference-based COMET substantially underperforming reference-free QE) and attributed it to Hebrew being out-of-distribution for COMET-22's training window. That result traced to a reference-omission error in the data-loading pipeline for the he-en span-fallback pair (see Limitations), not to a property of the metric or the language; correcting it reverses the finding. We validated the correction externally, not just internally, and at segment level rather than system level: aggregating to one mean per system before correlating (as an earlier draft did) is a weak check, since averaging cancels exactly the kind of per-segment misalignment this correction fixes. For both affected language pairs (he-en, en-es) and all four affected metrics (COMET, BLEURT, xCOMET, MetricX), we paired our corrected per-segment scores directly against the official `mt-metrics-eval-v2` (Freitag et al., 2023) per-(system, segment) baseline releases for WMT23 he-en and WMT24 en-es, across all 8 (language, metric) checks ($n \approx$8,700–8,900 segment pairs each). COMET and xCOMET, whose checkpoints match the official baseline exactly (`wmt22-comet-da`, `XCOMET-XL`), agree closely with the official scores (Pearson/Spearman $r \geq 0.867/0.837$). BLEURT and MetricX agree more weakly overall (Pearson/Spearman $r \geq 0.572/0.623$), which traces to a genuine checkpoint-version mismatch rather than a residual alignment error: we score BLEURT with an unofficial HF port (`Elron/bleurt-large-512`) rather than Google's official `BLEURT-20` checkpoint, and for he-en specifically the official WMT23 baseline is `MetricX-23` while our pipeline scores every language with the newer `MetricX-24`.

**Spanish** (WMT24 en-es) achieves the strongest correlations of any MQM language: MetricX $\rho = .625$, COMET $\rho = .586$. Classified in the medium tier (single-year, recent system generation), it is consistent with en→es being the most resource-rich, morphologically regular fusional en→X pair in the benchmark: alphabetic script, abundant training data, and single-year WMT24 annotations with high inter-annotator agreement. Spanish confirms the upper bound of what learned metrics can achieve on well-matched conditions.

### 4.3 Statistical Robustness

Bootstrap 95% CIs are narrow for large-corpus languages (de COMET: $[.418, .433]$, $n = 49{,}741$) and wider for small ones (ps COMET: $[.307, .360]$, $n = 4{,}611$), confirming that high-confidence claims require $n \gtrsim 10{,}000$ segments. All Tier 1a and Tier 1b COMET correlations except Ukrainian are significant at $p < 10^{-10}$ or better. Ukrainian COMET $p = 0.90$ (domain outlier). Russian despite $n = 35{,}325$ achieves $p \ll 10^{-10}$, but $\rho = .157$, statistically significant but practically weak, highlighting that statistical significance and practical reliability are distinct in large-$n$ meta-evaluation.

### 4.4 Translation Direction × Morphological Type

Table 2 reports the 2×3 cell means for COMET (full results across all ten metrics are in the released code and data repository). 12 languages contribute data in both translation directions; we separate them by segment-id prefix before computing cell means (per-language breakdowns in Table 8). The dominant pattern is directional: en→X languages score substantially above X→en across both morphological types.

- **Agglutinative:** en→X $\rho = 0.675$ vs. X→en $\rho = 0.440$, a gap of $+0.235$.
- **Fusional:** en→X $\rho = 0.563$ vs. X→en $\rho = 0.292$ (depressed by the Ukrainian domain

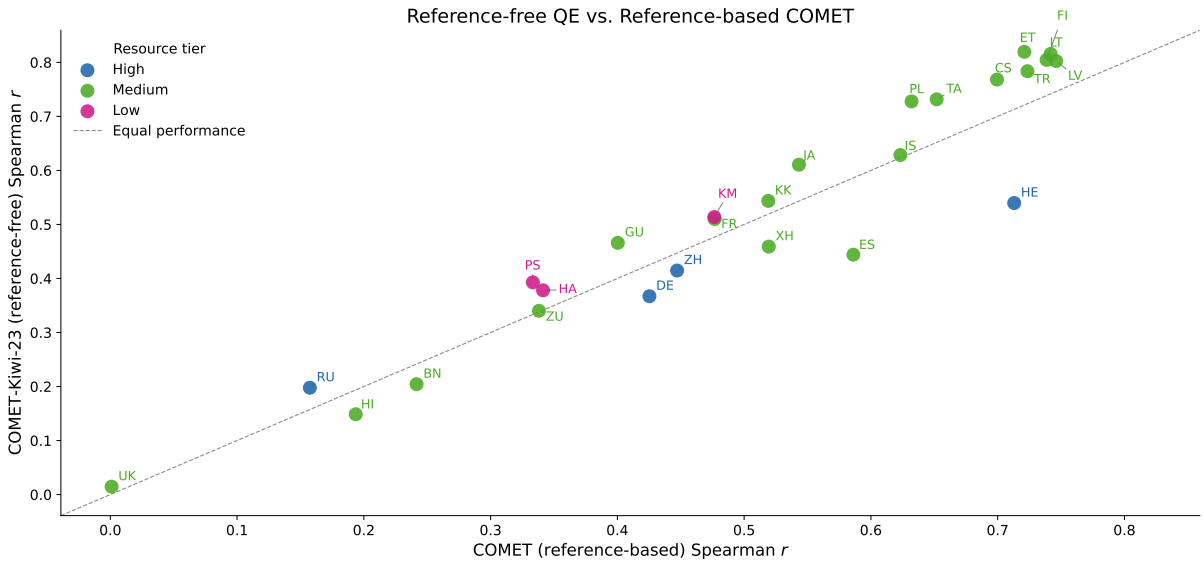

Figure 3: CK23 (reference-free) vs. COMET (reference-based) Spearman $\rho$ for all 26 languages with human annotations. Most languages cluster near the equal-performance diagonal, with reference-free QE holding a modest overall edge. Hebrew and Spanish are the two largest deviations from the diagonal in the dataset, both in COMET's favor ($-0.173$ and $-0.142$ Spearman points, CK23 minus COMET); we have no validated explanation for either and do not speculate one. uk sits below the diagonal for both metrics due to domain mismatch (see §4.2); ru reflects a Simpson's Paradox aggregate.

outlier, included here for transparency rather than excluded), a gap of $+0.271$.

The difference-in-differences between the fusional direction gap and the agglutinative direction gap is $0.036$ (Table 2), indicating the direction effect is largely constant across morphological types with only a modest interaction. The best metric varies by direction: CK23 leads X→en while MetricX leads en→X in 4 of 6 agglutinative languages.

**Robustness: mixed-effects model.** The one-way ANOVAs above treat every (language, direction) row as independent, but 12 languages contribute two correlated rows each (one per direction). To check whether this affects the conclusions, we fit a linear mixed-effects model via restricted maximum likelihood (REML): $\rho \sim$ direction + morphology, random intercept per language, $n = 38$ observations, 26 languages. Direction remains highly significant (X→en coefficient $-0.286$, $p = 7.5 \times 10^{-17}$); the fusional-vs-agglutinative morphology coefficient does not reach significance ($-0.136$, $p = 0.118$). The language random intercept absorbs $0.79$ of total variance (the intraclass correlation, ICC), confirming the non-independence this model was designed to check for. The mixed-effects model agrees with the ANOVA: morphological type is not an independently detectable main effect once repeated-measures structure is modeled explicitly, and direction remains the dominant, robustly significant predictor.

**Robustness: year stratification.** Only de, ru, zh, and cs are multi-year in this cell analysis; every other contributing language is single-year. de and ru enter the en→X×fusional cell via their pooled (not year-stratified) rho, and §5.2 already shows ru's pooled value is Simpson's-Paradox-suppressed. Substituting each language's mean-of-per-year rho for its pooled value moves that cell's mean from $0.563$ to $0.591$, a small increase, meaning year-stratification if anything slightly strengthens the en→X advantage rather than explaining it away. A fully rigorous per-metric training-coverage control (checking whether each metric's training-data volume differs by direction) is not attempted here: none of the 10 metrics publish per-language-pair-and-direction training coverage at the granularity this would require, and we flag it as future work.

Contrast with Mondshine et al. (2025): in their summarization setting, COMET correlates *better* for fusional languages (coherence Pearson $\approx 0.35$ for high-fusional vs. $0.07$ for isolating). In the MT setting the dominant factor is direction, not morphological type: fusional X→en languages score only $\rho = 0.292$ (depressed by the Ukrainian outlier),

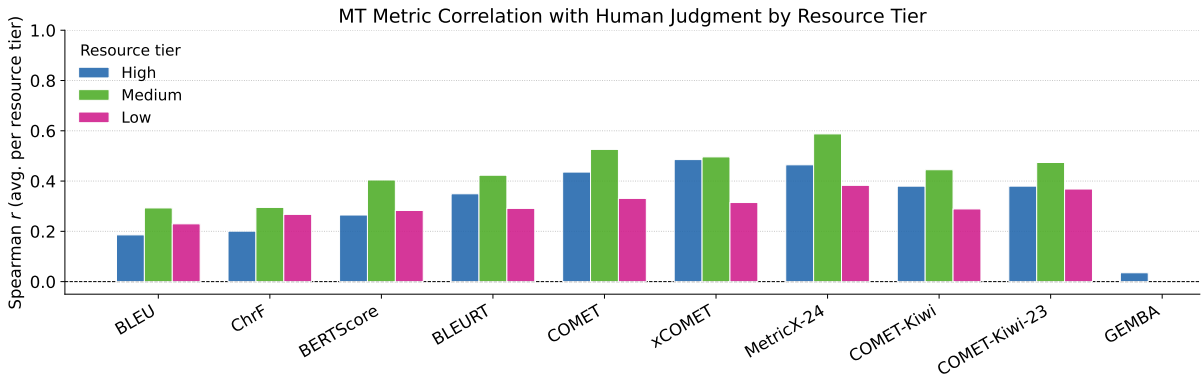

Figure 4: Average Spearman $\rho$ by metric and resource tier. The medium > high anomaly holds for all ten metrics with a Medium-tier value (GEMBA has none, excluded from Tier 1b by design: Table 1); it is explained by cross-year pooling variance in the high-resource MQM tier (see §4.2).

| Dir. | Isol. | Agglutin. | Fusional |
|---|---|---|---|
| | | *Mean COMET $\rho$ [95% CI]* | |
| X→en | 0.462 [—] | **0.440**[0.313,0.538] | 0.292[0.156,0.438] |
| en→X | – | 0.675[0.619,0.720] | 0.563[0.446,0.657] |
| X↔Y | – | – | 0.354[0.242,0.466] |
| $\eta^2_{\text{dir}}$ | | 0.309 | |
| $\eta^2_{\text{morph}}$ | | 0.073 | |
| $\eta^2_{\text{cell}}$ | | 0.618 | |

Table 2: Mean COMET Spearman $\rho$ by translation direction and morphological type. Cells with $n \leq 2$ languages have no CI (marked [—]). Empty (–) = no Tier-1 languages in that cell. $\eta^2$ via one-way ANOVA on per-language $\rho$. Russian ($\rho = .157$, en→X+fusional) and Ukrainian ($\rho = .001$, X→en+fusional) are included in their cells; see §4.2. **Bold** marks the X→en agglutinative cell specifically because it is where the reference-free metric CK23 (not shown in this COMET-only table) wins all 6/6 direction-separated pairs (Table 8); no other cell in this table carries that meaning, and $\eta^2$ values below are never bolded.

| Direction | BLEU | ChrF++ | COMET | xCOMET | MetricX |
|---|---|---|---|---|---|
| en→X | 0.303 | 0.380 | 0.605 | 0.602 | **0.671** |
| X→en | 0.230 | 0.253 | 0.364 | 0.350 | **0.392** |
| X↔Y | 0.202 | 0.247 | 0.354 | 0.340 | **0.530** |

Table 3: Mean Spearman $\rho$ by translation direction for five representative metrics (averaged across all languages in each direction group). MetricX-24 leads across all three directions among these five metrics, including X→en, where it now edges out CK23 (not shown) by a narrow margin ($\rho$=0.392 vs. $\rho$=0.387); this pooled ranking is not the same question as which metric wins the most individual X→en language pairs (Table 4), where CK23 remains the more frequent winner. X↔Y pairs show the lowest surface-metric scores but near-parity on MetricX.

while fusional en→X languages score $\rho = 0.563$, a gap of $+0.271$ attributable to translation direction. Agglutinative languages show the same directional pattern ($\rho = 0.440$ X→en vs. $\rho = 0.675$ en→X, a gap of $+0.235$), confirming that direction dominates in the MT setting: within this design we cannot detect an independent morphological main effect (the empty en→X isolating cell limits what the data can rule out; see Limitations). $\eta^2_{\text{cell}} = 0.618$ quantifies the combined effect; $\eta^2_{\text{dir}} = 0.309$ isolates direction as the dominant contributor.

### 4.5 Typological Predictors of Metric Choice

Translation direction is the dominant predictor of metric reliability ($\eta^2_{\text{dir}} = 0.309$; §3.3); we now ask whether that directional signal extends to metric *choice*, that is, which metric a practitioner should prefer for an unseen language.

For each of the 26 languages with human annotations, we rank all metrics by Spearman $\rho$ and record the best-performing metric. Table 4 summarizes these 35 direction-language pair observations (34 in the main pipeline; de-en held out as a blind validation), with leave-one-out (LOO) cross-validation for cells with $n \geq 6$ (overall 19/26 = 73%). Isolating X→en ($n$=2) and X↔Y ($n$=5) fall below this threshold and are marked '–' in the LOO column rather than validated. The most robust pattern in the table needs no morphological breakdown at all: CK23 beats COMET in all 6 of 6 agglutinative and 7 of 7 fusional en→X pairs (13/13 overall), both cells with bootstrap CI $[1.00, 1.00]$ on the win fraction. Table 4 is organized first by direction, the dominant factor, and then by morphological type within each direction as a secondary refinement: even though morphology explains substantially less

of the aggregate variance in reliability than direction does ($\eta^2_{\text{morph}} = 0.073$ vs. $\eta^2_{\text{dir}} = 0.309$), the within-direction agglutinative-vs-fusional splits are large enough to flip which specific metric wins the discrete argmax comparison (§3.3), so morphology remains a useful secondary key for the practitioner-facing recommendation even though it is not the primary driver of reliability. Three patterns emerge:

1. **X→en: CK23 wins consistently across morphological types.** CK23 is the best metric for agglutinative X→en (6/6, LOO 6/6; bootstrap CI on CK23>COMET: $[1.00, 1.00]$) and fusional X→en (6/9 including Hebrew and de-en held-out, LOO 5/7 over the smaller DA-pipeline-only subset; see Table 4's note). De-en (German→English, $n$=134,792) is genuinely unseen, German enters the pipeline via WMT MQM en→de only; CK23 achieves $\rho$=.414 vs. COMET $\rho$=.383 and MetricX $\rho$=.389, confirming the prediction. The reference-free design sidesteps the $n$-gram overlap problem that BLEU and ChrF++ face when rich morphology produces sparse token matches.

2. **en→X: MetricX competitive for agglutinative; CK23 leads for fusional.** For agglutinative en→X (6 languages), MetricX wins 4/6 (LOO 4/6), though margins are often small (kk: MetricX 0.770 vs. CK23 0.766; tr: 0.787 vs. 0.784). CK23 still beats COMET in 6/6 agglutinative en→X pairs (bootstrap CI $[1.00, 1.00]$), so the CK23-vs-COMET choice is unambiguous; the MetricX advantage only matters when choosing between all three neural metrics. For fusional en→X (7 languages), CK23 wins 4/7 and beats COMET in 7/7 (CI $[1.00, 1.00]$).

3. **Isolating X→en and X↔Y: MetricX.** MetricX-24 wins both isolating X→en cases (zh: +0.478 over BLEU; km: +0.174; average +0.326) and dominates X↔Y pairs (4/5), where neither source nor target is English and reference-free QE encoders are off-domain.

Across all profiles, the gain over BLEU from choosing the recommended metric ranges from +0.130 to +0.432 Spearman $\rho$ (Table 4), the "always use a neural metric" message is robust even where the *choice* among neural metrics is uncertain.

As a post-hoc check, we trained a Ridge regression predictor (World Atlas of Language Structures (WALS; Dryer and Haspelmath, 2013) typological features + morphological type + direction, leave-one-language-out cross-validation (LOLO-CV), $n$=26 Tier-1 languages). Pearson $r = 0.47$ for CK23 and $r = 0.56$ for Kiwi-22; recommendation accuracy is 5/26, too low to treat the predictor as deployable. The moderate $r$ for the CK family confirms that direction and CK advantage are partially co-predictable from typological features, but the low recommendation accuracy is a negative result on the stronger claim that typological features alone suffice to select among neural metrics.

## 5 Discussion

### 5.1 The Neural-Surface Gap Scales With Morphological Complexity

This is a claim about a different quantity than §3.3: $\eta^2_{\text{morph}} = 0.073$ measures how much morphological type explains variance in absolute metric–human correlation, and it is small. The finding here concerns the *gap* between neural and surface metrics, a derived quantity that morphology predicts much more strongly than it predicts either metric's raw reliability. COMET, xCOMET, and MetricX-24 dominate at every tier and in every typological cell (Tables 1–3), but that gap over surface metrics is not uniform: it is largest for morphologically complex languages and non-news domains, precisely the conditions where evaluation is most needed and most difficult.

For fusional X→en languages (excluding the Ukrainian outlier), the COMET–BLEU gap averages 0.119 Spearman points; holding direction fixed, agglutinative X→en languages show a larger gap still, 0.151 (the same pattern holds en→X, where the gap is 0.351 for agglutinative languages). This is not simply a ceiling artifact of agglutinative X→en being an easier cell overall: within X→en, BLEU's own reliability is nearly flat across morphological type ($\rho \approx 0.230$ pooled; agglutinative and fusional differ by only a few points), while COMET's reliability rises substantially from fusional to agglutinative. The widening gap comes from COMET tracking something morphology-related that BLEU does not, not from BLEU degrading uniformly.

This is consistent with $n$-gram overlap systematically underestimating adequacy when target morphology is rich: a correct translation of a Finnish verb may share zero surface $n$-grams with the reference if a different but equally valid inflected form was chosen. Neural metrics are comparatively insensitive to this effect, which is exactly why mor-

| Direction | Morphological type | $n$ pairs | Recommended metric | LOO accuracy | Avg $\Delta\rho$ vs. BLEU |
|---|---|---|---|---|---|
| X→en | Agglutinative | 6 | CometKiwi-23 (6/6) | 6/6 | +0.196 |
| X→en | Isolating | 2 | MetricX-24 (2/2) | – | +0.326 |
| X→en | Fusional | 9[†] | CometKiwi-23 (6/9) | 5/7 | +0.130 |
| en→X | Agglutinative | 6 | MetricX-24 (4/6)[‡] | 4/6 | +0.432 |
| en→X | Fusional | 7 | CometKiwi-23 (4/7) | 4/7 | +0.356 |
| X↔Y | Fusional | 5 | MetricX-24 (4/5) | – | +0.327 |

Table 4: **Typological metric selection guide**: empirically observed best metric per profile across 35 direction-language pair observations (de-en held out). $n$ = number of direction-separated pairs; LOO accuracy = leave-one-out cross-validation (– = cell too small to validate); Avg $\Delta\rho$ = mean Spearman gain over BLEU. [†]Fusional X→en's $n$=9 includes Hebrew and the held-out de-en pair, neither scored by the DA direction-separated pipeline the LOO cross-validation runs over; its LOO column (5/7) therefore validates only the 7 DA-pipeline languages, a smaller denominator than the win count. Held-out de-en ($n$=134,792, absent from main pipeline): CometKiwi-23 $\rho$=.414 vs. COMET $\rho$=.383, confirming prediction. [‡]Agglutinative en→X: MetricX-24 wins 4/6, but CometKiwi-23 beats COMET in 6/6 (bootstrap CI $[1.00, 1.00]$); advantage often $< 0.004$ $\rho$ (kk, tr).

phology moves their reliability much less than it moves direction ($\eta^2_{\text{morph}} = 0.073$ vs. $\eta^2_{\text{dir}} = 0.309$) while still moving the size of their advantage over BLEU. We note this pattern rests on two X→en cells without bootstrap CIs on the gap itself, and should be read as a documented pattern in the available data rather than a strongly powered general law.

### 5.2 Domain Is the Confounding Variable, Not Resource Level

The Ukrainian domain confound provides a clean natural experiment: among X→en direction-controlled languages using news or Wikipedia domains (excluding ha-en and is-en, whose near-zero correlations across all metrics are attributed to annotation noise rather than domain effects (see Table 8)), COMET $\rho$ ranges from approximately .144 (ja-en) to .613; Ukrainian (domain `other`) sits at $\rho = .001$, 0.143 below the next-lowest X→en language (ja-en, $\rho \approx .144$). Kocmi et al. (2024) note WMT24 comprised "news data and four other separate domains", precisely the inconsistency creating the Ukrainian outlier. Zouhar et al. (2024) confirm that fine-tuned metrics degrade substantially under domain shift. The practical implication is that the diagnosis "our language is low-resource, so metrics are unreliable" is often wrong in a correctable way: resource level and domain mismatch require different remedies.

This fits the broader pattern established in §3.3: translation direction is the dominant predictor of metric reliability ($\eta^2_{\text{dir}} = 0.309$; Table 2), accounting for nearly a third of between-language variance, while morphological type is a substantially smaller main effect ($\eta^2_{\text{morph}} = 0.073$); the joint direction×morphology cells ($\eta^2_{\text{cell}} = 0.618$) capture additional within-direction morphological variation, particularly the agglutinative vs. fusional split within X→en ($\rho = 0.440$ vs. $\rho = 0.292$). Domain mismatch and translation direction, not resource level, are the two factors that actually predict where metrics fail.

**Always stratify by year.** Table 5 documents two failure modes from multi-year pooling: *suppression* (Russian pooled $\rho = .157$ hides within-year $[0.38,\ 0.50]$, $\Delta = +0.285$, from heterogeneous WMT21/22 system generations) and *masking of heterogeneity* (Czech cs-en pooled $\rho = .288$ masks a per-year range of $[-0.01,\ 0.69]$, including complete metric failure in 2021 and strong correlation in 2017). Both are correctable by year-stratification.

| Lang | Tier | Years | Pooled $\rho$ | Year $\rho$ range | $\Delta$ |
|---|---|---|---|---|---|
| ru | MQM | 2021–22 | .157 | $[0.38,\ 0.50]$ | +0.285 |
| zh | MQM | 2020–22 | .447 | $[0.47,\ 0.57]$ | +0.054 |
| de | MQM | 2020–22 | .425 | $[0.32,\ 0.50]$ | +0.000 |
| cs-en | DA | 2017–22 | .288 | $[-0.01,\ 0.69]$ | +0.012 |

Table 5: Year-stratified vs. pooled COMET Spearman $\rho$ for languages with multiple WMT years. $\Delta$ = stratified mean − pooled. Year $\rho$ range = $[\min, \max]$ per-year $\rho$. Russian (suppression: $\Delta = +0.285$) and Czech cs-en (masking: pooled$\approx$.288, but year range $[-0.01,\ 0.69]$) show two distinct aggregation failure modes.

## 6 Conclusion

We presented a unified meta-evaluation of ten MT metrics across 33 languages, three annotation tiers, and 730,748 segments, with the goal of understanding *when* metrics can be trusted and *why* they fail.

The central finding is that metric failure correlates with domain mismatch and the joint configuration of translation direction and morphological type far more strongly than with resource level. Ukrainian's catastrophic failure is entirely explained by a genre confound; Russian's weak aggregate correlation is a Simpson's Paradox artefact from multi-year pooling. Neither finding is about language difficulty, both are correctable evaluation design choices.

Translation direction is the largest quantified predictor of metric reliability in our study ($\eta^2_{\text{dir}} = 0.309$; Table 2): en→X is reliably better-evaluated than X→en regardless of morphological type. Morphological type is a substantially smaller main effect ($\eta^2_{\text{morph}} = 0.073$), though within X→en, agglutinative languages ($\rho \approx 0.440$) outperform fusional ones ($\rho \approx 0.292$). The practical implication is concrete: deploying COMET or MetricX to evaluate en→X translation into agglutinative targets should be expected to be reliable ($\rho \approx 0.675$); deploying the same metrics for X→en fusional targets with mixed-year data should not ($\rho \approx 0.292$, and even lower when pooling artefacts are present).

Neural metrics (MetricX-24, xCOMET, COMET) are substantially better than surface metrics in exactly the settings where surface metrics are most relied upon: the en→X gap between MetricX-24 ($\rho \approx 0.671$) and BLEU ($\rho \approx 0.303$) is large enough that any low-resource evaluation still using BLEU as its primary metric should be revisited.

**A practical decision procedure.** Table 4 reduces to a short recipe for choosing a metric on an unseen language pair:

1. **Always prefer a neural metric over BLEU/ChrF++.** The gap ranges from $+0.130$ to $+0.432$ Spearman points and only widens for morphologically complex or non-news-domain languages (§5).

2. **X→en, agglutinative or fusional target: use CometKiwi-23.** It wins these two X→en cells and beats COMET specifically in 6/6 agglutinative and 6/9 fusional pairs. (Isolating X→en is a separate case: see below.)

3. **en→X, fusional target: use CometKiwi-23. en→X, agglutinative target: MetricX-24 usually edges it out**, but the choice barely matters for the reference-free-vs-reference-based question: CometKiwi-23 beats COMET in 13/13 en→X pairs regardless of morphological type.

4. **Isolating X→en or X↔Y pairs: use MetricX-24.**

5. **Typological features alone will not pick the metric for you**: our Ridge predictor over WALS (Dryer and Haspelmath, 2013) features reaches only 5/26 recommendation accuracy. Direction and morphology as defined here are the operative signal, not abstract typology.

Future work should validate Tier 2 synthetic annotations against human judgments, extend the direction×morphology analysis to polysynthetic languages, and determine *why* direction predicts reliability rather than only that it does. Our claim throughout is predictive/associational (direction is the dominant term in an ANOVA and a mixed-effects model), not causal. Distinguishing candidate mechanisms (asymmetric training-data coverage by direction, source-side complexity, or reference-generation artefacts specific to translating into vs. out of English) would require controlled intervention on training data or synthetic directional pairs, not further observational analysis of existing WMT releases.

Broader coverage is the most direct extension: the analysis pipeline is language-agnostic and will incorporate new WMT DA pairs as they are released. The key open question is whether the direction×morphology cell structure holds for polysynthetic languages (e.g. Inuktitut) and for the currently empty abjad×agglutinative cell, which Arabic would fill.

A within-language, within-year MQM-versus-DA comparison on en-de, zh-en, and en-ru would isolate the annotation-protocol effect from resource level and training-data coverage; if the medium-tier advantage collapses under matched protocol, §4 requires reinterpretation.

## Limitations

Tier 2 synthetic annotations have not been validated against human judgments; Tier 2 results are exploratory. The Ukrainian result is a domain confound (`uk-en_2022_other`), not a linguistic finding. Russian and German aggregate correlations are depressed by multi-year system-pool heterogeneity (Simpson's Paradox) and should not be interpreted as language-level metric failure. We evaluate he-en and en-es against a single reference

(refA) throughout; WMT23 he-en additionally provides a second official reference (refB), not used in this analysis, so a multi-reference sensitivity check remains future work. GEMBA's he-en and en-es scores are excluded from all reported statistics: they were computed before the segment-identifier fix described above and cannot be safely realigned to the corrected data (a positional remapping was attempted and rejected after it produced an implausible near-zero correlation against COMET, versus $\rho \geq 0.77$ segment-level agreement between two independently-correct metrics, COMET and xCOMET, on the same languages). Of these, only he-en is a Tier 1a (High-resource) language, so Table 1's High-tier GEMBA value averages only de/ru/zh, not all four Tier 1a languages; en-es is tiered Medium and GEMBA is not reported for Medium/Low at all (Table 1's caption), so its exclusion has no separate effect on any reported average.

Four directional variants present in the WMT DA dataset were not included in the main pipeline (`de-en`, `ru-en`, `de-cs`, `fr-de`); incorporating these would add fusional X→en and X↔Y observations to the direction×morphology analysis.

**Empty en→X isolating cell.** All isolating languages in the benchmark (zh, km, th, lo, my) are X→en or Tier 2; there are no Tier-1 en→X isolating observations. The relatively small $\eta^2_{\text{morph}} = 0.073$ may partly reflect this structural gap: if en→X isolating languages had been available, the morphological main effect might have been larger.

**Language non-independence in the direction×morphology analysis.** 12 languages contribute per-language $\rho$ values in both translation directions; these observations are not independent, and the correct specification is a mixed-effects ANOVA with language as a random factor. We report this model in §3.3: direction remains significant, morphology does not. The one-way ANOVA is retained alongside it because it is what the direction×morphology cell means and their bootstrap confidence intervals are computed from.

**Annotation protocol and resource tier are perfectly confounded.** Every Tier 1a (high-resource) language uses MQM annotation; every Tier 1b (medium/low-resource) language uses DA. This means the "medium > high" pattern and all tier-level metric differences have an alternative explanation: annotation protocol, not resource level. MQM annotators are trained to flag subtle adequacy and fluency errors that DA crowd-workers routinely smooth over, which compresses metric–human correlation independently of anything typological. We cannot separate these effects with the current data, and a dedicated study comparing MQM-annotated and DA-annotated pairs for the *same language* would be required to attribute the effect causally. Readers should treat tier-level comparisons as confounded on this axis.

A partial, protocol-controlled check is possible within Tier 1b alone, where medium and low resource levels are both DA-annotated: the raw gap (medium 0.441 vs. low 0.312) narrows once Hausa, the same X→en outlier already flagged as likely annotation noise in Table 8, is excluded (medium 0.441 vs. low 0.388), leaving only two low-resource languages and no reliable residual gap. This does not resolve the Tier 1a-vs-Tier 1b confound, which remains unfixable without a language annotated under both protocols, but it is evidence against resource level driving the pattern in the one place protocol can be held constant.

## Ethics Statement

This work is a meta-evaluation of existing MT metrics using publicly available datasets (WMT MQM, WMT DA, FLORES+) and does not collect new human annotations or deploy systems in production. The Tier 2 synthetic annotations are generated by prompting Llama-3.1-8B-Instruct, a publicly released model, and are used only for exploratory correlation analysis clearly labelled as unvalidated. We explicitly flag synthetic Tier 2 results as exploratory throughout and exclude GEMBA from that tier to avoid circular evaluation.

No personally identifiable information is used or generated. The benchmark languages include several low-resource and endangered languages (Hausa, Khmer, Pashto, Swahili, and others); we make no claims about translation quality in those languages beyond the statistical patterns observable in the available test sets, and we caution that metrics should not be used for high-stakes decisions in settings where they have not been separately validated on domain- and script-appropriate data.

## Acknowledgments

Compute resources were provided by the BYU Office of Research Computing. This work was supported by the BYU Computer Science Graduate Fellowship and generous donations to the BYU MAchine Translation Research and Interlingual

eXperimentation (MATRIX) Lab, run by Dr. Steve Richardson and Dr. Eric Ringger. Thanks to my advisor, Dr. Eric Ringger, for his guidance and for proofreading this paper. This project grew out of a course taught by Dr. Nancy Fulda and Jay Orten. We also thank the anonymous WMT reviewers for their valuable feedback.

## Abstract

Text-in-image translation aims to translate all textual content embedded in an image. In Text Image Translation (TIT), the output is translated text; In-Image Machine Translation (IIMT) additionally renders the translation back into the image. We introduce IMGMT, a massively multilingual dataset and benchmark mined from localized SVG illustrations on Wikimedia Commons, focusing on diagrams, maps, and infographics. IMGMT contains 35,612 aligned image pairs grouped into 1,855 image sets, spanning 129 languages, 20+ writing systems, and 4,886 language pairs.

We propose a multi-level evaluation protocol that measures source-side text-region detection and OCR accuracy alongside target-side translation quality. We benchmark several multimodal large language models and a dedicated TIT system in English→X and X→English settings, and find that the source language and writing system substantially affect TIT quality. Finally, we show that IMGMT is not well suited for isolating the contribution of visual information in multimodal translation.

## 1 Introduction

Modern multimodal models can translate from text, images, or both. A family of *text-in-image translation* tasks takes an image as input and aims to translate all textual elements appearing within it. This setting includes Text Image Translation (TIT), which outputs translated text (optionally with bounding boxes), and In-Image Machine Translation (IIMT), which further renders the translated text back into the image. By contrast, in Multimodal Machine Translation (MMT), the source is text and the image is used only as auxiliary context.

Several datasets for text-in-image translation already exist (Ma et al., 2022; Lan et al., 2023; Qian et al., 2024; Lyu et al., 2025; Vaidya et al., 2025; Wu et al., 2026), but they share a key limitation:

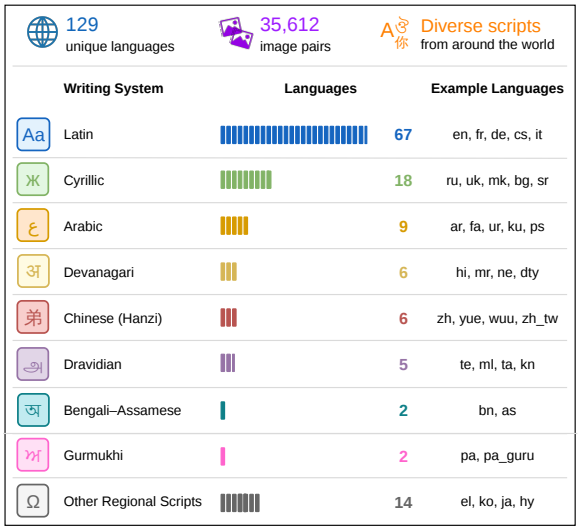

Figure 1: IMGMT languages across different scripts.

limited language coverage. Even the most multilingual resources typically include only 14–16 languages (Li et al., 2025, 2026). Consequently, existing benchmarks do not sufficiently stress-test systems' multilingual capabilities, either in translating across a wide range of languages or in recognizing text written in diverse scripts.

Wikipedia has served as a rich source of multilingual supervision for multimodal tasks (e.g., Srinivasan et al., 2021). For vision-language tasks, a particularly appealing property is that many Wikipedia illustrations are localized: the same visual is available with labels translated into dozens of languages. Since these illustrations are often stored as SVGs, where text is encoded separately from the graphical elements, they can be mined to create aligned multilingual resources for text-in-image translation.

In this paper, we introduce IMGMT, a dataset and evaluation framework for assessing methods for text-in-image translation. IMGMT contains 35,612 aligned image pairs grouped into 1,855 sets of visually distinct SVG images extracted from Wikimedia Commons. The embedded text spans

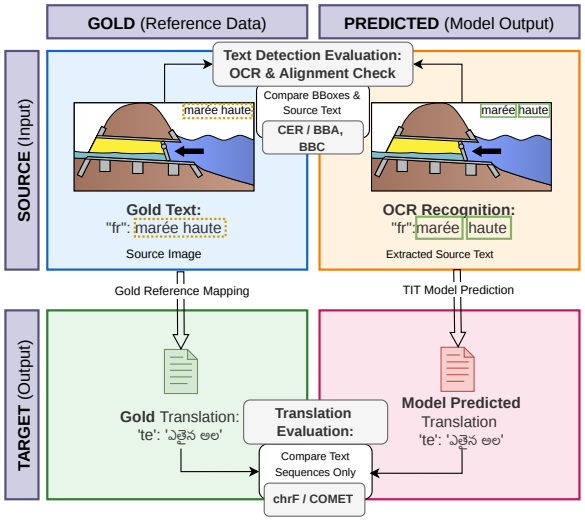

Figure 2: Text Image Translation evaluation diagram.

129 languages, covering more than 20 writing systems (as illustrated in Figure 1), and yields 4,886 distinct language pairs.

IMGMT targets diagrams, maps, and infographics—content typically created as vector graphics. In contrast to scene text translation (Lan et al., 2023; Qian et al., 2024; Vaidya et al., 2025), where robustness to distorted or occluded text is often the primary challenge, our setting is dominated by translation-specific difficulties. Unlike document image translation (Liang et al., 2024), where translated passages can be substantially longer, the text snippets in IMGMT are often short and information-dense, and they frequently include specialized terminology and named entities from scientific and educational domains.

Along with the dataset, we release an evaluation framework. As shown in Figure 2, it evaluates system outputs on both the source and target sides: on the source side, it measures text-region detection and OCR accuracy; on the target side, it scores translations using standard MT metrics.

To demonstrate our evaluation framework in practice, we use it to benchmark multiple TIT systems, most of which are general-purpose vision–language models (VLMs).[1] We evaluate their ability to translate from English into a wide range of target languages. In addition, we benchmark one system on translation into English to study how different source-side writing systems affect performance.

[1]The framework also supports IIMT evaluation, but we leave it for future work.

Beyond evaluating TIT systems, we ask whether IMGMT is also useful for evaluating multimodal machine translation, specifically for quantifying the contribution of the visual modality to translation quality. In many infographics, the extracted text is sufficiently self-contained to translate correctly on its own, especially when the system is given all text at once. Therefore, any improvement from providing the image may reflect either genuine visual grounding (e.g. resolving polysemy, units, or abbreviations using surrounding graphics) or incidental cues such as layout and line segmentation. To tease these factors apart, we compare translations produced with (i) the full source image, (ii) a text-only rendering that preserves layout while removing graphical content, and (iii) plain text input without any image.

The IMGMT dataset and evaluation framework are publicly available.[2] We also provide a development repository[3] with supplementary scripts and intermediate artifacts produced during this work.

The remainder of the paper is organized as follows. We first situate IMGMT in the context of related work (Section 2). We then introduce the dataset (Section 3) and describe our evaluation protocol (Section 4). Next, we detail our experimental setup and how we use IMGMT to benchmark TIT approaches (Section 5), followed by the benchmarking results (Section 6). Finally, we conclude in Section 7.

## 2 Related Work

### 2.1 Datasets for text-in-image translation

Existing datasets for TIT and IIMT vary widely in realism (synthetic vs. authentic), supervision (text-only vs. image-to-image), and domain. Synthetic resources such as E2E_TIT_With_MT (Ma et al., 2022), the Multilingual IIMT dataset (Lan et al., 2024), IIMT30k (Tian et al., 2025), and VT-Syn (Vaidya et al., 2025) scale by rendering parallel text onto background images, producing large corpora with controllable variation; their synthetic nature makes it straightforward to provide both source- and target-language texts and images.

Authentic datasets instead curate real images with natural typography and visual clutter, typi-

[2]Released simultaneously on Hugging Face (https://huggingface.co/datasets/sarkau/ImgMT-Dataset-For-Evaluating-Text-Image-Translation) and in the LINDAT/CLARIAH-CZ repository (http://hdl.handle.net/11234/1-6251).

[3]https://github.com/ufal/imgmt-devel

cally relying on OCR and MT during construction. They often omit target-language images, which limits their direct applicability to IIMT and prevents evaluation in the reverse translation direction. OCRMT30K (Lan et al., 2023), MTIT6 (Qian et al., 2024), and VT-Real (Vaidya et al., 2025) collect human-translated scene text from multiple OCR datasets, with OCRMT30K and MTIT6 additionally providing bounding boxes. Although MTIT6 does not include target images, it supports IIMT evaluation by applying OCR to system-generated target images to recover the translated text.

ECOIT (Zhu et al., 2023) and MIT-10M (Li et al., 2025) target e-commerce imagery crawled from the web, pairing OCR-extracted text with MT; ECOIT uses human post-editing, while MIT-10M applies a secondary MT system and embedding-based semantic similarity to filter likely translation errors. Following a similar pipeline, IMTBench/IMT-1M (Lyu et al., 2025) and MMTIT-Bench (Li et al., 2026) combine scene images, web-crawled images, and document images. DoTA (Liang et al., 2024) focuses on document-page translation, using images of scientific-paper pages and providing outputs in Markdown.

Vectra-Bench (Wu et al., 2026) is one of the few benchmarks with authentic source images that also provides target-language images (generated by vision–language models), enabling direct IIMT evaluation; it further emphasizes evaluation beyond text accuracy, including multilingual generalization and visual quality.

Most existing datasets cover only a small set of languages, with the broadest coverage (14–16 languages) reported by Li et al. (2025, 2026). In addition, because target-side images are often missing, these datasets are generally unsuitable for reverse-direction translation.

IMGMT differs from prior datasets along three axes. First, it targets vector-graphic diagrams, maps, and infographics rather than natural scene photos, e-commerce images, or document pages, shifting the challenge toward translating short, information-dense labels with specialized terminology and named entities. Second, it is built from Wikipedia SVG variants that preserve the underlying visual content while changing only the text, yielding aligned multilingual image pairs with consistent layouts and text positions, and directly supporting IIMT. Third, it substantially expands multilingual breadth: IMGMT spans 129 languages and over 20 writing systems, enabling evaluation across 4,886 language pairs in both directions and stress-testing multilingual and multi-script text-in-image translation beyond the coverage of prior benchmarks.

### 2.2 Effect of Image in Multimodal Translation

The question of whether visual context improves translation quality has been studied extensively in the general MMT literature, most prominently in the context of the Multi30K dataset (Elliott et al., 2016) and the associated WMT Multimodal Translation shared tasks (Parida et al., 2024). CoMMuTE (Futeral et al., 2023) is an evaluation dataset for resolving textual ambiguity with visual context: 155 ambiguous English sentences, each paired with two images and two meaning-specific translations into French, German, and Czech by native speakers, with images sourced from Google Images or the authors.

Early architectures such as multi-encoder, double-attention or gated fusion models reported only marginal improvements from incorporating image features over strong text-only baselines, and subsequent adversarial evaluations (Elliott, 2018) showed that many multimodal systems are largely insensitive to the visual input, achieving similar scores even when paired with unrelated or shuffled images. Caglayan et al. (2019) revisited this question and found that visual grounding becomes useful mainly when the textual signal is degraded or ambiguous, rather than in standard, fully legible text conditions. More recently, Wu et al. (2021) argued that much of the previously reported benefit of visual context in prior work stemmed from erroneous evaluation protocols rather than from genuine multimodal grounding.

Recent work with large vision-language models suggests that visual context is useful mainly when it resolves information that is missing or ambiguous in the text. DeDiT (Liu et al., 2025), for example, first detects textual ambiguity and then, optionally, uses the visual modality. Similarly, Yu et al. (2025) argue for adaptive fusion because images can help with ambiguity but may also introduce redundant or noisy information. Most recently, Guerra and Khrapunova (2026) show that the benefits of visual context are strongly task-dependent: relevant images help on CoMMuTE, but gains do not transfer consistently to other domains, including technical documentation with accompanying figures.

This distinction is especially relevant for diagrams, maps, and infographics. Visual structure

may be important for locating text, recovering reading order, or linking labels to graphical elements, but once the text is correctly extracted and semantically self-contained, the surrounding image may add little to the translation itself. We therefore expect visual context to matter mainly for ambiguous labels, abbreviations, or domain-specific terms whose meaning depends on the graphic, while having little effect on ordinary text. Section 6 tests this hypothesis directly.

## 3 Dataset

The primary source of data for this project is Wikimedia Commons,[4] a repository of freely usable images and other multimedia content related to Wikipedia topics. Our objective was to create a multilingual dataset consisting of image pairs that differ only in their textual content, where texts at identical positions represent mutual translations.

At the top level, the dataset is split into the directories `train`, `dev` and `test`. Within each split, files are organized into numbered folders representing image groups. Each group directory corresponds to one Wikimedia image with all its variants.[5] It contains SVG source files, their PNG exports, and alignment annotations stored in JSON format. Each JSON file represents a directed translation pair between a source and a target language,[6] specifying image metadata, bounding box coordinates and aligned texts. For detailed overview of the repository directory and JSON schema, see Appendix A.

### 3.1 Basic Statistics

The dataset contains 35,612 aligned image pairs across 1,855 image groups (i.e., visually distinct images), comprising 235,637 text strings in total. The number of language variants per group ranges from 2 to 77, with an average of 4.95 variants per group.

Overall the dataset includes 129 unique languages in over 20 writing systems (such as Latin, Cyrillic, Arabic, Devanagari, etc.; see more in Figure 1). Of 8,256 possible language pairs,[7] the dataset includes 4,886 that can be used in both translation directions.

[4] https://commons.wikimedia.org/

[5] We prefer to talk about image *groups* rather than simply images because the image files belonging to the same group can and do differ. Conceptually, they should be the same image, differing at least in the text translation variant.

[6] It can also be used for translation in the reverse direction.

[7] Corresponding to $\binom{129}{2}$.

| Category | Count | Share |
|---|---|---|
| Proper name | 126,835 | 60.2% |
| Common noun phrase | 79,175 | 37.6% |
| Statement without finite verb | 1,964 | 0.9% |
| List of common noun phrases | 1,003 | 0.5% |
| Single clause | 943 | 0.4% |
| List of proper names | 493 | 0.2% |
| List mixing common and proper | 127 | 0.1% |
| Multiple clauses | 78 | 0.0% |
| List of statements without finite verb | 26 | 0.0% |
| **Consensus total** | **210,644** | **100.0%** |
| No consensus (disagreed labels) | 24,993 | – |
| **All strings** | **235,637** | – |

Table 1: Distribution of string types (LLM-based categorization). Shares are computed over the consensus subset.

**Theoretical vs. actual image pairs** During the initial crawling (see Section 3.2), we collected raw URLs for all available image language variants in each group. Theoretically, taking any language as the source and any language as the target, this could lead up to 118k image pairs. However, web-scraped SVG files are often noisy or unsuitable for our purpose. After applying our pipeline, the final dataset contains 35k pairs (about 30% of the theoretical maximum). The drop is intentional: many pairs could not be created because of issues in the SVG files, such as (1) invalid SVGs or SVGs with zero height or width, (2) font rendering errors, (3) failing the spatial overlap check, and (4) text saved as paths (`<path>`) instead of text elements (`<text>`) – unlike normal text elements, outlined paths do not store characters or words; they are saved only as drawing curves (shapes). While we could use OCR to read these shapes, we decided not to do so to avoid introducing recognition errors into the gold ground-truth data.

**Language distribution** The dataset contains a wide variety of languages, but they are not evenly distributed. The most common languages are English (appearing in 5k image pairs across the entire dataset), Spanish (with 3.5k image pairs) and French (appearing in 3.3k pairs). In contrast, some languages are very rare, for example, Northern Sami language and Venetian language appear in only 4 pairs within the whole dataset. The complete distribution is detailed in Appendix B.

The test split is similar: 3,575 image pairs in total and 548 of them (15%) involve English. This allows us to reliably test translations to and from English while still keeping other diverse languages

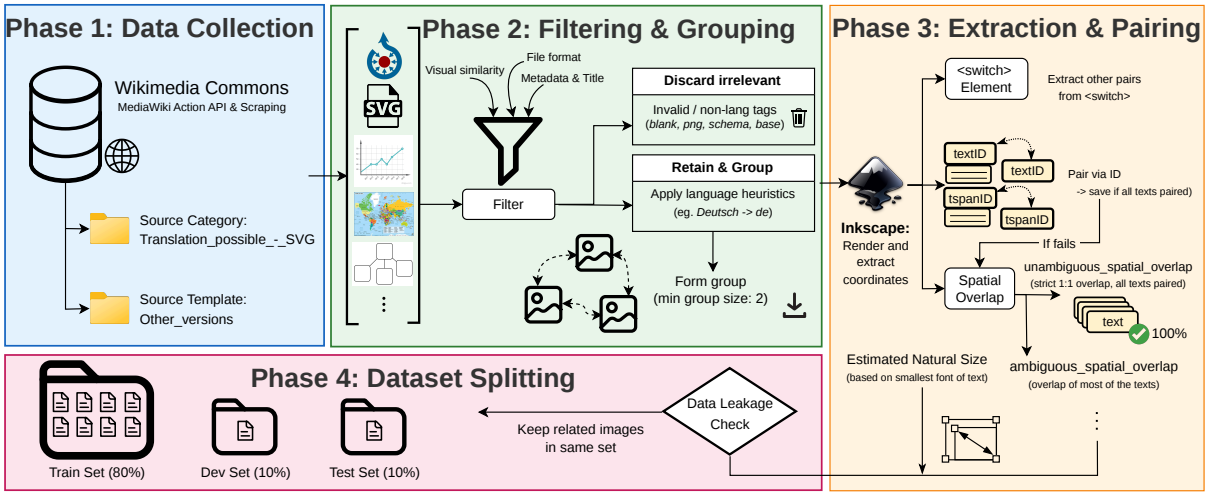

Figure 3: Pipeline overview for generating the multilingual IMGMT dataset

in the test set.

**String type distribution.** Because IMGMT consists primarily of diagrams, maps, and infographics, we expect most extracted strings to be short and rarely to form full sentences. Across all 235,637 strings, the average length is 9.29 characters. To characterize the strings more deeply, we performed a multilingual analysis using an ensemble of three LLMs (Gemma 4, GPT-OSS-120B, Qwen3.8-27b). The models agreed on a label for 210,644 strings (89.4%; see Table 1), while the remaining 24,993 strings had no unanimous label. Across the full set of strings, about 60% are proper names, about 33–38% are common noun phrases, and 1–3% are statements without a finite verb; well-formed sentences account for only about 0.5%. Overall, this distribution indicates that IMGMT is dominated by short, label-like text, with a high share of proper names rather than sentence-level discourse.

### 3.2 Processing Pipeline

As shown in Figure 3, the pipeline consists of the four following steps: (1) data collection, (2) filtering and grouping, (3) extraction and pairing and (4) dataset splitting.

**Data collection** In this stage, raw multimodal data is sourced from Wikimedia Commons. We primarily crawl files from the category *Translation_possible_-_SVG*,[8] which is a rich source of multilingual diagrams, maps, graphs etc. Additionally, we extract explicitly linked language variants by parsing the *Other versions* templates often found on file description pages. This combined approach allows us to get a large initial pool of potential image translations.

**Filtering and grouping** The crawled data goes through a filtering process. Non-SVG formats or SVG files which cannot be parsed and images that render with zero width or height are immediately discarded. Then we parse the file descriptions to extract valid language codes using a custom heuristic mapped to ISO language codes. While images from the *Translation_possible_-_SVG* category often label their variants by language, this is not always the case (some labels describe file types or visual changes rather than languages). Next, to accurately group the translated variants, we evaluate visual similarity across the images. Candidate files found within the same translation table on the image Wikimedia page are grouped together only if their visual layout is similar, evaluated using the *Structural Similarity Index Measure (SSIM)* (Wang et al., 2004). If a visually consistent cluster contains two or more valid language variants, we keep it as a separate group.

**Extraction and pairing** To accurately extract textual elements and their spatial coordinates, we utilize Inkscape (Inkscape Project, 2023) which renders the SVGs to provide precise absolute bounding boxes. The extracted text elements are then paired across languages using three prioritized strategies. First, if the SVG file contains `<switch>` elements, texts are paired purely based on predefined `systemLanguage` tags (the `svg_switch` method). Second, if standard switches are absent, the pipeline attempts to align texts using

[8] https://commons.wikimedia.org/wiki/Category:Translation_possible_-_SVG

| Alignment Method | Train | Dev | Test |
|---|---|---|---|
| 1. `svg_switch` | 6,514 | 238 | 328 |
| 2. `svg_id_match` | 366 | 41 | 28 |
| 3. `unamb_spatial_overlap` | 8,842 | 1,223 | 1,065 |
| 4. `amb_spatial_overlap` | 12,771 | 2,042 | 2,154 |
| *Theoretically achievable image pairs* | | | 118,000 |
| Total JSON metadata files | | | 35,612 |
| Total PNG images | | | 9,191 |

Table 2: Success of text alignment methods across dataset splits. The methods are carried out in the specified order and an image pair is counted with the method which succeeds first.

structural identifiers (eg. `tspanID` or `textID`; the `svg_id_match` strategy). However, as internal IDs are frequently mismatched, missing or incomplete across translated images, we mostly rely on the third method: spatial overlap, which pairs text elements based on their intersection over union (IoU score). The image pairs are then categorized as *unambiguous* (strict 1:1 match between the boxes with zero unmapped ones; denoted `unamb_spatial_overlap`) and *ambiguous* mapping (the rest; labeled `amb_spatial_overlap`). Table 2 reports detailed statistics on the number of image pairs obtained by each alignment method in the cascade. Finally, the image dimensions and corresponding bounding boxes are normalized: we identify the minimum font size within an image group and proportionally scale the image dimensions and spatial coordinates by a calculated ratio, ensuring that the smallest text remains clearly legible.

**Dataset splitting** In the final stage, the processed data is distributed into `train`, `dev` and `test` sets using an 80:10:10 ratio.[9] Importantly, this stage implements a data leakage prevention mechanism. Image groups that share identical visual content but differ slightly in layout or metadata — such as a standard historical map versus a visually impaired version, which might have been initially parsed as a separate groups — are identified and put into the same dataset split. This constraint guarantees that no language variant or minor visual modification of a specific image seen during training can appear in the development or test sets. The splitting algorithm also balances the distribution of the three alignment methods across all sets, as detailed in Table 2. However, to strictly prevent cross-split visual leakage, we did not enforce explicit balancing of individual languages or writing systems across the sets.

**Producing the PNG images** To convert the processed SVG files into raster PNG images, we use Inkscape via command-line interface. To maintain identical resolution and scale across all language variants within a single group, the target export height is extracted from the alignment JSON metadata (which was pre-calculated based on the smallest font size, as described above) and passed to Inkscape using the `export-height` flag.

### 3.3 Manual Evaluation of the Dataset Collection Method

The dataset construction pipeline comprises multiple stages, each of which can introduce errors. For example, paired images can diverge beyond acceptable text differences, some text may be missed when it is encoded as vector paths rather than text objects, and our position-based heuristics can fail. To quantify the impact of these issues, we compare the automatically collected dataset against manual annotations.

We randomly sample 100 image pairs from the test set and annotate them using a purpose-built tool implemented for this study (a screenshot is shown in Appendix C).[10] First, annotators judge whether the images in the pair are identical (still regardless the texts). They may decide to skip an example if they consider the images too different. Second, annotators manually correct the bounding boxes and their cross-image correspondences. All bounding-box edits are permitted (addition, deletion, and resizing). Annotators do not edit the text content associated with each box, as this is often impractical, particularly when the text uses an unfamiliar script. Finally, the annotators correct the cross-lingual correspondences. These are required to be one-to-one, which may require splitting or merging bounding boxes. In addition to visual cues, annotators can use automatic English translations of the extracted text fields provided by the annotation tool. Two annotators split the batch evenly, each correcting half of the pairs.

[9] Due to the leakage-prevention clustering constraint, the resulting dev and test splits each comprise slightly more than 10% of the total data.

[10] Due to a display bug affecting SVGs paired using the `svg_switch` method, we had to omit 10 such examples from the evaluation. Since this alignment method is, by design, the most precise, this omission should not negatively affect the reported statistics.

| Bounding boxes | Count | | | Area | | |
|---|---|---|---|---|---|---|
| | P | R | F1 | P | R | F1 |
| All boxes | 96.2% | 90.6% | 91.5% | 94.9% | 86.8% | 89.0% |
| Matched boxes | 96.2% | 90.2% | 91.3% | 94.9% | 86.6% | 88.9% |
| Correctly matched | 92.7% | 86.9% | 88.3% | 91.6% | 83.3% | 86.0% |

Table 3: Manual evaluation of dataset quality. Rows correspond to (i) all detected text-field boxes (*All boxes*), (ii) boxes for which a one-to-one cross-image correspondence exists (*Matched boxes*), and (iii) boxes whose correspondence is the correct cross-lingual match (*Correctly matched*). Columns report precision/recall/F1 for box *count* (BBC) and *area overlap* (BBA).

In 13% cases the paired images were too different for text-in-image translation evaluation. In 16% cases the images were identical except for minor graphical differences. These images are usable for IIMT with a grain of salt but they are perfectly suitable for TIT evaluation. The remaining pairs of images were visually completely identical.

We measure bounding-box localization accuracy with two precision/recall metrics that quantify alignment between the manually annotated boxes and those in the original data. *Bounding Box Count* (BBC) measures agreement in the number of boxes, while *Bounding Box Area* (BBA) measures agreement by the area of overlap between boxes.

Table 3 reports bounding-box quality for all boxes (text-field detection), matched boxes (a one-to-one match exists across the pair), and correctly matched boxes (the match is the correct cross-lingual correspondence).

After all steps, BBA precision remains above 91%, while recall is around 83%; most of the gap is due to text-field detection. BBC exhibits similar performance. Although this recall drop should not affect comparing multiple systems on the same dataset, it should be considered when interpreting the absolute results.

## 4 Evaluation Method

In our work, we focus on evaluating Text-in-Image Translation (TIT). As shown in Figure 2, our evaluation system compares gold reference data with model predictions (machine output).

**Text detection and OCR evaluation** The first phase evaluates the model's ability to accurately detect and read text from the source image. We compare the extracted predicted text with the source gold text using the *Character Error Rate (CER)*.

If predicted bounding boxes are available – which may not be the case for models that only output raw text – we use them to pair the predicted texts with the reference texts. At the same time, we evaluate the bounding boxes localization accuracy by two metrics already introduced in Section 3.3: (1) *BBA* (*Bounding Box Area*), which measures spatial overlap by calculating the harmonic mean of area-based precision and recall across intersecting bounding boxes, and (2) *BBC* (*Bounding Box Count*), which measures discrete block-level retrieval based on paired True Positives. If not stated otherwise, we mean the F1 score by referring to these measures.

To handle cases where an OCR model splits a single line or paragraph into multiple smaller boxes, we use a text merging mechanism. If several predicted boxes overlap with the same reference box, we sort their text horizontally from left to right and join it into one string. We also merge their coordinates into a single bounding box before calculating the CER and BBA metrics.

**Translation evaluation** The second phase measures the quality of translated text. We evaluate the output using a traditional lexical metric *chrF* (Popović, 2015) and an advanced semantic metric *COMET*, specifically the `wmt22-comet-da` model (Rei et al., 2022).

**Text-based alignment** In scenarios where the prediction does not provide bounding box coordinates, the system aligns text blocks using the Hungarian algorithm for matching in bipartite graphs. Alignment is driven by a composite cost matrix combining text dissimilarity with a spatial reading-order penalty. Dissimilarity is calculated using CER for OCR or inverted quality score (one minus the metric score) for translation evaluation via chrF or COMET, with low-quality candidate pairs filtered out by task-specific thresholds. To maintain spatial consistency, we add a position penalty calculated as the absolute difference between the relative positions of predicted and reference texts, assuming a top-to-bottom, left-to-right reading order. The algorithm then selects one-to-one pairs that minimize the total cost and rejects any pairs that exceed the threshold.

## 5 Experimental Setup

To demonstrate the practical utility of the proposed framework, we evaluate several multimodal systems on both the TIT and MMT tasks. All ex-

periments are conducted on the dataset's test split. For TIT, we use the PNG versions of the images at their native resolution as the input, without any additional preprocessing or visual transformations.

**Evaluation of TIT systems** The first experiment evaluates the performance of several multimodal large language models (MLLMs) and one dedicated pipelined system on the TIT task with English as the source language.

The evaluated MLLMs are **Qwen3.5** (MoE of 122B parameters, 10B active), **Claude Haiku 4.5**, **Kimi K3** (MoE of 2.8T parameters, 104B active), and **GPT-5.6 Luna**. To ensure a fair comparison, all models are evaluated using the same zero-shot prompt. The prompt instructs the model to detect all text present in the bitmap image, estimate the corresponding source text bounding boxes, transcribe the detected text, and translate it into the target language. The expected output consists of a structured representation containing the predicted source text bounding boxes, the recognized source texts, and the translated target texts.

We also evaluate AnyTrans (Qian et al., 2024), a pipelined IIMT system that we slightly adapt to our benchmark. While **AnyTrans** can render translations back into the image, we do not use this capability in our TIT experiments. Given an input image and the source and target languages, the system performs translation in three stages. First, an OCR engine detects and recognizes the text in the image, producing transcriptions together with their bounding boxes. Our adaptation supports multiple OCR backends; in the experiments reported here, we use *PaddleOCR* (Cui et al., 2025) only. The recognized text is then passed to a large language model for translation; we use *DeepSeek-V4-Flash-Thinking*. Finally, in the rendering stage (not used in our TIT setup), the original text regions are removed and replaced with the translated text using the detected bounding boxes.

In these experiments, an image is scored only when the model returns a well-formed output that matches the required structured format. If the model fails to produce a valid result, that image is skipped and excluded from all metrics. Reported scores therefore reflect performance on the subset of English-source test images with valid model outputs, not on the full test set.

**Effect of source script on TIT performance** The second experiment aims to test the influence of writing systems on TIT performance. It evaluates **GPT-5.6 Luna** on language pairs with English as the target language, allowing for comparison of translation quality across different source scripts. GPT-5.6 Luna is selected for this experiment because it combines relatively strong overall performance with a low rate of invalid outputs as demonstrated in the previous experiment, resulting in a more complete and reliable evaluation across the diverse set of source languages. Results are reported separately for each script group using the same OCR and translation metrics.

**Effects of visual modality on translation quality** To isolate the contribution of visual context in our MMT analysis (beyond translating the extracted text alone) we compare three input conditions on the English-source test set. Because this experiment targets MMT, we evaluate only the four MLLMs and exclude AnyTrans. The extracted source text—pulled directly from the SVGs (i.e., without OCR)—is held constant across conditions: (1) *Image*, where the fully rendered source image is provided alongside the text input; (2) *Text-only image*, where we render the same image after removing all non-text graphical elements (e.g., backgrounds, icons, shapes) and retaining only the black text layer, preserving line breaks and spatial layout but discarding graphical content (see Section 3.2); and (3) *No image*, where the model receives only the extracted source text segments with no visual input.

## 6 Experiments and Results

**TIT from English** Table 4 reports end-to-end TIT scores for all evaluated systems, covering translation quality, OCR accuracy, and bounding-box localization. Kimi K3 performs best overall, achieving the highest chrF (61.3) and COMET (0.834). GPT-5.6 Luna attains slightly higher localization scores (BBA and BBC) while delivering comparable translation quality. Claude Haiku 4.5 lags behind on all metrics, with a CER of 0.822 and markedly lower translation and localization scores.

Qwen3.5 shows worse OCR quality and text localization, but almost the same translation quality. This suggests that end-to-end translation quality is not determined solely by exact source-side transcription and bounding-box prediction. Nevertheless, the large performance gap of Claude Haiku 4.5 across both source- and target-side metrics indicates that errors in text detection and recognition can become a major bottleneck when sufficiently

| Model | chrF | COMET | CER | BBA | BBC |
|---|---|---|---|---|---|
| Qwen3.5 | 59.86 | 0.827 | 0.313 | 0.453 | 0.746 |
| Kimi K3 | 61.30 | 0.834 | 0.174 | 0.620 | 0.829 |
| GPT-5.6 Luna | 59.72 | 0.826 | 0.224 | 0.655 | 0.838 |
| Claude Haiku 4.5 | 39.78 | 0.681 | 0.822 | 0.203 | 0.542 |
| AnyTrans | 57.50 | 0.803 | 0.161 | 0.620 | 0.813 |

Table 4: Translation and OCR performance of multimodal LLMs on English-source language pairs.

| Source Script | $N$ | CER (Δ) | BBA (Δ) | BBC (Δ) | chrF (Δ) | COMET (Δ) |
|---|---|---|---|---|---|---|
| Latin | 255 | -0.106 | +0.028 | +0.011 | +7.38 | +0.035 |
| Dravidian | 49 | +0.359 | -0.076 | +0.005 | -26.07 | -0.129 |
| Cyrillic | 48 | +0.094 | +0.015 | +0.002 | +8.90 | +0.073 |
| Devanagari | 25 | -0.002 | -0.006 | +0.027 | -3.12 | -0.001 |
| Bengali-Assamese | 22 | -0.025 | -0.035 | -0.068 | -15.80 | -0.098 |
| Arabic | 13 | -0.129 | -0.253 | -0.229 | -21.78 | -0.132 |
| Gurmukhi | 11 | +0.178 | +0.032 | +0.084 | -16.21 | -0.110 |
| Gujarati | 9 | +0.174 | -0.024 | +0.062 | -10.04 | -0.070 |

| Ol Chiki | 5 | +1.001 | +0.055 | +0.153 | -49.50 | -0.225 |
| Georgian | 5 | +0.079 | +0.187 | +0.140 | +9.68 | +0.087 |
| Japanese | 3 | -0.255 | +0.099 | -0.033 | +19.37 | +0.104 |
| Korean | 3 | -0.232 | -0.098 | -0.012 | +31.58 | +0.197 |
| Hebrew | 3 | -0.124 | -0.205 | -0.298 | +21.12 | +0.156 |
| Burmese | 2 | - | -0.590 | -0.774 | -57.71 | -0.754 |
| Thai | 1 | +0.165 | +0.144 | +0.226 | -0.36 | -0.028 |
| Armenian | 1 | +0.154 | -0.050 | -0.679 | -24.18 | +0.130 |
| **Overall** | **462** | **0.255** | **0.590** | **0.774** | **57.71** | **0.754** |

Table 5: Overall absolute scores, with per-script deltas shown in parentheses (row minus overall). Green indicates improvement (for CER: lower is better), red indicates degradation.

severe. This is further evidenced by results on the gold source texts extracted from the SVGs in Table 6 – Claude has a similar translation performance to the other three models in that setting.

The AnyTrans pipeline achieves the lowest CER (0.161) and competitive localization. Its translation quality is slightly lower than Kimi K3, Qwen3.5, and GPT-5.6 Luna, though it remains well above Claude Haiku 4.5.

**Effect of source script** We next examine GPT-5.6 Luna on language pairs with English as the target language, grouped by the source writing system. Table 5 reports per-script *deltas* relative to the overall mean. Latin (the largest group) improves over the mean across all metrics. Cyrillic shows consistent gains in translation quality despite slightly worse OCR. Cyrillic and Latin patterns are also observed for Georgian and Chinese, respectively, albeit with much smaller $N$.

In contrast, Dravidian and Bengali-Assamese degrade across most metrics, indicating that these scripts remain challenging for both transcription and translation. Arabic further illustrates that the metrics do not necessarily move together: it exhibits better CER but worse localization and downstream translation, so accurate transcription alone is not sufficient. Overall, OCR accuracy, localization accuracy, and translation quality are only weakly coupled across scripts; results for very small groups should be interpreted cautiously.

| Model | Image | No image | Text-only image |
|---|---|---|---|
| Claude Haiku 4.5 | 57.94 | 58.04 | 57.60 |
| GPT-5.6 Luna | 62.30 | 62.29 | 62.46 |
| Kimi K3 | 62.95 | 62.76 | 63.08 |
| Qwen3.5 | 57.43 | 60.18* | 57.84 |

Table 6: chrF scores on the test split, computed with unaligned (line-order) matching, with paired bootstrap significance testing against the baseline condition. * means significant at $\alpha = 0.05$. All of the conditions use the gold, extracted texts from the SVGs, *Image* additionally uses the source image, *Text-only image* additionally uses only the text layer of the input image, and *No image* translates the extracted text without ever seeing the image.

**Effects of visual modality on translation quality** Table 6 reports chrF scores under three input conditions: *Image* (full image), *Text-only image* (text layer only), and *No image*. As apparent from the table, differences across conditions are small. Overall, providing the image does not materially change performance: either the extracted texts are already unambiguous, or these models are not reliably using the visual signal for disambiguation.

If we nevertheless treat the small differences as meaningful, the *Image* condition is never best for any of the four models and is worst (or tied-worst) for Claude Haiku 4.5, Kimi K3, and Qwen3.5. The strongest condition depends on the model: *No image* is best for Claude Haiku 4.5 and Qwen3.5, while *Text-only image* is best for GPT-5.6 Luna and Kimi K3.

For Claude Haiku 4.5, GPT-5.6 Luna, and Kimi K3, the spread between the best and worst condition is at most 0.49 chrF, plausibly within run-to-run noise.

Overall, these results run counter to our hypothesis in Section 2.2: conditioning on the source image is neutral-to-harmful for chrF across all four models. This may reflect competition for attention/-context budget or OCR/reading errors from visual clutter; since infographic text is typically unambiguous, images offer little disambiguation benefit. We conclude that adding the source image is not a reliable way to improve translation quality on this benchmark.

## 7 Conclusion

In this paper, we introduced IMGMT, a massively multilingual dataset for evaluating text-in-image translation (image-only inputs), such as Text Image Translation (text-only output). We also proposed a multi-level evaluation protocol that combines complementary metrics at different granularities. We demonstrated the framework on several MLLMs and one dedicated system in both English→X and X→English settings, showing that the source language and writing system matter for TIT quality. Finally, we used IMGMT to probe the role of visual context in multimodal translation (text+image input). In our setup, adding the source image yields little benefit over text-only inputs and can even degrade performance, suggesting that IMGMT is not well suited for isolating the contribution of visual information in MMT.

Our experiments focused mainly on TIT; however, IMGMT can also be used to benchmark In-image Machine Translation (image-only output), which we leave for future work.

## Limitations

**Data and evaluation.** The dataset is derived from Wikimedia Commons SVGs, which introduces limitations for both data quality and evaluation. First, the annotations do not capture all text present in the source images. To reduce noise, we extract only text represented as SVG text spans and do not apply OCR; as a result, text rendered as vector paths is missing. Moreover, we rely on Inkscape's spatial query tool, which requires text elements to have explicit `id` attributes; elements without an `id` (or embedded in complex paths/groups) cannot be queried for exact bounding boxes and are omitted to avoid alignment errors. These choices may bias evaluation (e.g., by overestimating recall). Second, the language-pair distribution is imbalanced: because the source images come from Wikimedia Commons, high-resource languages (e.g., English, Spanish, French, German, and Russian) dominate, while some low-resource or regional languages occur in fewer than 10 pairs. Finally, because IMGMT is built from publicly available Wikimedia data, there is a risk of data contamination: some tested MLLMs may have encountered parts of the benchmark during pre-training.

**Experiments.** Due to budget and computational constraints, we restricted our evaluation to translation directions that include English (English→X and X→English) in a zero-shot setting, and we evaluated only the test split. This means our results cover only a subset of the available benchmark pairs; the remaining roughly 30,000 pairs in the training and development splits were prepared primarily to enable future training or fine-tuning studies, but we did not evaluate all bidirectional pairs across the full dataset in this paper. In addition, while IMGMT is suitable for evaluating text-in-image translation approaches beyond TIT, including IIMT (image-only output), we did not benchmark the IIMT setup here.

## Acknowledgments

This work was supported by the project TQ01000458 (EdUKate) financed by the Technology Agency of the Czech Republic (www.tacr.cz) within the Sigma 3 Programme. It has been also partially supported by the grant TQ28000003 (NCUI, Národní centrum umělé inteligence), and the grants CZ.02.01.01/00/23_020/0008518 ("Jazykověda, umělá inteligence a jazykové a řečové technologie: od výzkumu k aplikacím") and LM2023062 LINDAT/CLARIAH-CZ, both financed by the Ministry of Education, Youth and Sports of the Czech Republic.

We also thank the three anonymous reviewers for their helpful comments and suggestions.

## Abstract

Advanced large language models (LLMs) with long context windows can substantially reduce input truncation in document-level machine translation (DocMT). However, direct *Doc2Doc* translation remains prone to n-gram repetition and progressive quality degradation. A common remedy is to segment the document into finer-grained chunks. Nonetheless, conventional rule-based chunking approaches fail to handle the length distribution mismatch between training and inference. To address this, we introduce **F**ixed-**R**ange **C**hunking (**FRC**), utilizing dynamic programming to partition documents into chunks within a predefined length interval. By consistently applying FRC during training and inference, the input documents of any length are mapped to the same length distribution, substantially reducing train-test length mismatch. Centered on FRC, we propose a lightweight dual-boundary matching algorithm for chunk alignment, alongside four distinct training strategies. Experimental results show that FRC-based fine-tuning substantially improves 7B LLMs over direct *Doc2Doc* fine-tuning and outperforms existing DocMT methods on IWSLT2017. We further construct GLOBVDOC, a 10-language test set independent of mainstream DocMT training sources, and show that FRC improves out-of-distribution document translation.[1]

## 1 Introduction

Document-level machine translation (DocMT) has been continuously investigated for a long time (Miculicich et al., 2018; Voita et al., 2018; Maruf and Haffari, 2018; Lyu et al., 2021). Current large language models (LLMs) with long context windows have greatly alleviated the challenge of input length constraints for DocMT. However, direct *Doc2Doc* translation is still plagued by various issues, such as susceptibility to n-gram repetition during decoding (Jin et al., 2024; Peng et al., 2025a), and progressive quality degradation as sequence lengths increase (Yang et al., 2025). Accordingly, dominant strategies such as *Doc2Sent* and *Doc2Chunk* emerged, which translate documents sequentially at the level of sentences or chunks. While these methods can also mitigate the challenges associated with variable document input lengths, the design of optimal training paradigms based on them is still under active exploration.

Regarding the *Doc2Sent* strategy, early studies (Wu et al., 2024a; Li et al., 2024) utilized a fixed number of sentence pairs as contexts to facilitate training. While this approach can ensure input length alignment between training and inference, it remains rooted in sentence-level processing and thus lacks sufficient in-context information. More recently, Ramos et al. (2025) introduced a chunk-level training paradigm that partitions documents into a fixed number of sub-documents, and employs a hybrid training strategy incorporating both context-free and context-aware settings, emphasizing length-agnostic generalization. However, it cannot guarantee length distributional alignment between training and inference, which has been empirically observed to potentially lead to performance degradation (Varis and Bojar, 2021; Wan et al., 2022; Pitorro et al., 2024). While Peng et al. (2025a) proposed a solution using varying position embeddings to improve length extrapolation during training, they also prioritized enhancing translation capabilities across diverse lengths.

Driven by similar concerns regarding length distribution matching, instead of improving generalization across diverse lengths, we focus on achieving chunk-level alignment by mapping both training and inference documents into a unified length interval, thereby training exclusively on these consistent distributions. Nonetheless, conventional strategies, such as fixed-number and fixed-length

[1]The code, dataset, and fine-tuned models are publicly available at: https://github.com/ynklab/Doc2FRC.

*Proceedings of the Eleventh Conference on Machine Translation*, pages 782–817
October 28-29, 2026 ©2026 Association for Computational Linguistics

chunking, cannot fully reconcile length discrepancies, frequently leaving short residual fragments at the end of a document. To address this limitation, we propose **F**ixed-**R**ange **C**hunking (**FRC**), which employs a dynamic programming algorithm for document chunking, ensuring all document segments fall within a target length interval. Consequently, the length distribution of the training and inference data maintains consistently well-aligned.

In addition to introducing the method of FRC for DocMT, during the training data curation stage, we propose a lightweight chunk alignment algorithm based on dual-boundary matching, which can be applied to all document-level parallel corpora that are not fully sentence-aligned. Then, we use FRC pairs to construct five different data formats to train four types of models (as shown in Figure 1), enabling a systematic model-wise investigation.

Furthermore, aiming to probe out-of-distribution generalization and mitigate the scarcity of long-form evaluation data in the news and social domains, we manually curate a high-quality, 10-language test set named GLOBVDOC, based on the Global Voices[2]. This dataset is guaranteed to be strictly sentence-aligned and is designed to remain independent of the data distributions used in current mainstream DocMT training sets.

Our main contributions are as follows:

- We propose Fixed-Range Chunking and Dual-Boundary Matching-based Chunk Alignment algorithms to ensure length distribution consistency across training and inference with efficient chunk synchronization.
- We train four types of models across five training data formats. Our results show that FRC-based training strategies outperform the *Doc2Doc* baseline. On IWSLT2017 test data, our method achieves a d-BLEU improvement that exceeds the existing DocMT methods.
- We present GlobVDoc, a high-quality multilingual test dataset specifically designed for document translation, and establish a multilingual long-form DocMT benchmark.
- We introduce a variant of the Lexical Translation Consistency Ratio (LTCR) that estimates translation consistency based on the word alignments between the reference and the translation hypothesis.

## 2 Related Work

**Training-based DocMT** Following the emergence of various LLM-based sentence-level translation paradigms (Xu et al., 2024; Alves et al., 2024; Guo et al., 2024), research focus has increasingly pivoted toward LLM-based DocMT. Early investigations primarily focused on *Doc2Sent* methodologies. Wu et al. (2024a) leveraged historical context from previous translations, whereas Li et al. (2024) introduced retrieval-based sentence pairs to provide auxiliary contextual information. Subsequent research focused on dataset development, utilizing training to establish performance benchmarks (Wicks et al., 2024; Alabi et al., 2025). Jin et al. (2024) extended the translation object to the chapter level for literary translation, employing direct chapter-to-chapter fine-tuning using only inter-chapter context. Compared to training exclusively on long document pairs, Ramos et al. (2025) introduced a training paradigm that segments documents into {1,2,4} parts and fine-tuned the model with MRD2D (Sun et al., 2022) and CAPT (Wang et al., 2023a) techniques, achieving performance comparable to large-scale LLMs while ensuring generalized translation ability across diverse input lengths. In contrast, our FRC approach focuses on specializing within a targeted length range.

**Training-free DocMT** Early DocMT works explored prompting formats (Hendy et al., 2023; Wang et al., 2023a; Karpinska and Iyyer, 2023; Wu et al., 2024a). Subsequent studies enriched prompts with document-derived signals: Liu et al. (2025) extracted summarization and entity translation knowledge from documents to construct diverse prompts and reranked candidate translations. Hu et al. (2025) investigated DocMT within a multi-turn conversation framework and showed that providing the entire source document as prior context can improve iterative refinement.

Beyond prompting, agentic systems explicitly separate roles to support DocMT: TransAgent (Wu et al., 2024b) assigns specialized agents (e.g., translator and reviewer) to achieve iterative refinement. Sent2Sent++ (Guo et al., 2025), GRAFT (Dutta et al., 2025), and DELTA (Wang et al., 2025b) utilize translation memory to retrieve contextual cues and perform step-by-step translation without debate. Finally, TransGraph (Pham et al., 2025) constructs a discourse-based knowledge graph from document chunks to guide the translation.

Since this work focuses on FRC as a solution for

ensuring distributional consistency between training and inference, we do not discuss its application to training-free DocMT in detail.

**Analysis** Peng et al. (2025a) showed that translation quality degrades when inference-time inputs follow length distributions unseen during training, and mitigated this shift by modifying positional embeddings. Our proposed FRC approach addresses the same length-mismatch issue by directly synchronizing the length distributions between the training and inference phases. Moreover, while many studies incorporate partial translations as context (Wang et al., 2023a; Wu et al., 2024a; Pham et al., 2025; Ramos et al., 2025), Choudhary et al. (2025) demonstrate that source-only context can also effectively capture discourse phenomena. Therefore, to ensure length regulation in FRC and efficient decoding, we use source-only context by default (see Appendix G for further discussion).

## 3 Training Data Curation

### 3.1 Fixed-Range Chunking

We propose a Two-Stage Dynamic Programming Algorithm (see Algorithm 2 in the Appendix for details) designed to optimize the partitioning of a set of pre-segmented basic units $U = \{u_i\}_{i=1}^{n}$ into chunks that strictly fall within a fixed range $[m, M]$, where $m$ and $M$ denote the minimum and maximum token limits, respectively.

We also design a piecewise cost function $C(l)$. It encourages lengths to cluster within $[m, M]$ when valid, and minimizes the magnitude of deviation when boundary violations are inevitable.

**Pre-processing** Any single unit $u_i$ exceeding $M$ tokens is isolated prior to the DP process.

**Stage 1: Constraint Optimization** We search for a segmentation in which every chunk's length $l$ strictly satisfies $m \leq l \leq M$. Let $f[i]$ denote the minimum cost to pack the first $i$ units. If $f[n] < \infty$, the result is returned.

**Stage 2: Relaxed Optimization** If strict segmentation is infeasible, we relax the constraints. We allow at most $K$ chunks to violate the boundary $[m, M]$ and extend the DP state to $f[v][i]$, representing the minimum cost for the first $i$ units using exactly $v$ violations. The final solution is chosen by minimizing the cost over all $v \in [1, K]$.

### 3.2 Chunk Alignment

While existing sentence alignment methods (Sennrich and Volk, 2011; Thompson and Koehn, 2019) can provide precise correspondences and achieve global optimality for chunk alignment, the intensive preprocessing required for large-scale corpora is often computationally prohibitive. Additionally, perfect sentence alignment is often unattainable in real-world scenarios (O'Brien et al., 2025).

Therefore, we obviate strict sentence alignment by proposing a lightweight Dual-Boundary Matching based Chunk Alignment method that leverages the two boundary units of a source chunk to match high-scoring target units located in proximal relative positions within the target document; the span delimited by these two target units is designated as the corresponding target chunk. Although this heuristic may lead to marginal data loss due to algorithmic constraints (see Table 9 in the Appendix for details), it offers a highly scalable and efficient alternative for processing massive datasets.

Algorithm 1 details the proposed chunk alignment strategy. We first define SIMWRP, a hybrid scoring function that aggregates similarity and relative position information with hyperparameters $\lambda$ and $\sigma$. For each source chunk $c_i$, we calculate an initial match score against all target units $t_j \in \mathcal{T}$ based on the chunk's end boundary $c_i^{end}$ and identify the top-$k$ candidates. To reduce matching ambiguity, we perform dual verification, which refines their scores by incorporating the corresponding match of the subsequent chunk's start boundary unit $c_{i+1}^{first}$. Finally, a DP approach searches for the optimal path that maximizes the total score. If the boundary constraints remain unsatisfied, the candidate window size $k$ is incrementally expanded until a feasible alignment is identified or the search space is exhausted.

### 3.3 FRC-based Training Formats

Source documents are partitioned into fixed-range chunks using the method outlined in Section 3.1, and aligned via the algorithm described in Section 3.2 to generate FRC pairs. Utilizing these pairs, we develop various training strategies. As shown in Figure 1, we define five distinct data formats: (1) **Doc**: The original, full-length document; (2) **0c1t**: A standalone chunk pair without additional context; (3) **1c1t**: Uses the preceding chunk as context (the 1st chunk serves exclusively as the contextual input); (4) **2c1t**: Uses the two preceding chunks as context (the 1st and 2nd chunks serve exclusively as contextual inputs); (5) **FS4** (Fixed-Size 4): Chunks are merged into four segments, utilizing all previous chunks as context in an incremental

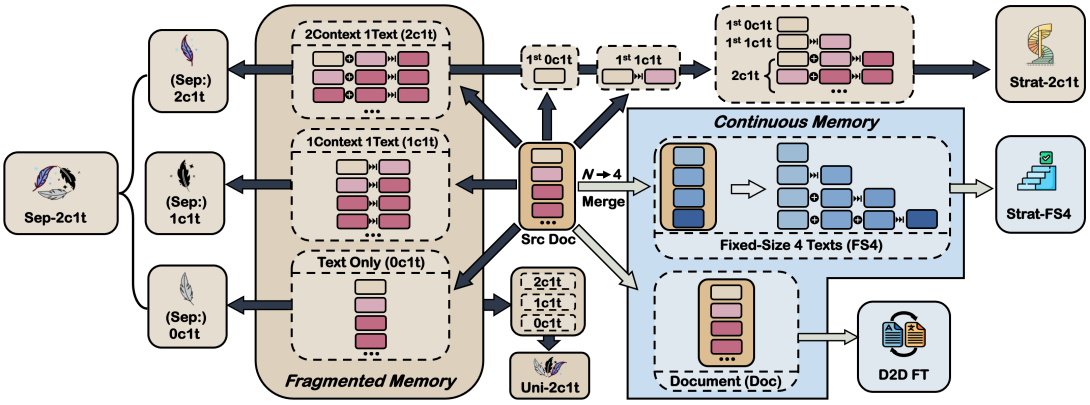

Figure 1: Construction scheme of training data for four model configurations derived from a single document.

manner. Leveraging these training data formats, we train four different types of models:

**D2DFT** A baseline model fine-tuned directly on document pairs.

**SEP** Independent models trained separately using 0c1t, 1c1t, and 2c1t formats. Their combined implementation is referred to as the SEP-2c1t.

**STAIR** This category includes STAIR-FS4, which utilizes the incrementally stratified data, and STAIR-2c1t, which employs a "spiral" staircase approach that begins with 0c1t and 1c1t samples before maintaining the 2c1t training format.

**UNI** A single model trained on a comprehensive mixture of 0c1t, 1c1t, and 2c1t data, where the three formats exhibit a clustered distribution, collectively forming three phases during training.

Regarding data formats, we categorize the training data into *Fragmented Memory* and *Continuous Memory* types: While ∗c1t formats utilize only partial contextual information, both Doc and FS4 provide access to the full document contexts. Regarding training methods, while chunks typically serve as a translation target once, the UNI model may target a single chunk up to three times. Moreover, while STAIR and UNI models undergo joint training on mixed formats, SEP models focus on "expert" training specialized for individual formats.

## 4 GlobVDoc Dataset

Existing test sets for DocMT in the news and social domains typically consist of relatively short documents (e.g., WMT2022 (Kocmi et al., 2022) and News Commentary). To address the scarcity of long-form document pairs within this domain, we introduce GLOBVDOC, a 10-language document-level test set sourced from Global Voices, a multilingual news site previously included in OPUS (Tiedemann, 2012). This dataset is designed to be independent of mainstream DocMT training sources, including ***IWSLT*** (Cettolo et al., 2012, 2017), ***BWB*** (Jiang et al., 2022), ***GuoFeng*** (Xu et al., 2022), ***News Commentary***, ***OpenSubtitles*** (Lison and Tiedemann, 2016; Lison et al., 2018), and ***Europarl*** (Koehn, 2005), thereby enabling the evaluation of out-of-distribution translation performance.

GLOBVDOC was constructed by a team of eight individuals, comprising several authors and additional volunteers. We manually selected 10 document pairs for each en → {de, es, fr, it, ko, nl, pt, ru, zh}. Considering document translation methods derived from a sentence-level translation system, the test data was required to be strictly sentence-aligned. To ensure consistency and quality, the construction process adhered to standardized guidelines, including Source Selection and Diversity, Temporal Relevance, Alignment Quality, Structural Consistency, Manual Segmentation, Minimal Adjustments, and Mapping Priority (see Appendix C for details). The documents comprise various formats, including interviews, biographies, real-time news reports, and podcasts. Appendix C provides detailed statistics for all language pairs in the GlobVDoc dataset (Table 7), together with a comparison against other commonly used datasets in Table 8.

In addition, we introduce a quality estimation function in Appendix D to evaluate the autocorrelation within each test dataset.

## 5 Experiment

### 5.1 Datasets

We utilize the ***DocBlocks*** dataset[3] (Ramos et al., 2025) as our training data, which is composed

[3] https://huggingface.co/datasets/sardinelab/DocBlocks

of five distinct corpora: IWSLT, BWB, GuoFeng, News Commentary, and Europarl.

For evaluation[4], we use IWSLT2017 (Cettolo et al., 2017) and BWB test data, as well as our self-established GlobVDoc dataset. Initially, we utilize the IWSLT2017 test data (TED talk documents), consistent with Ramos et al. (2025), to conduct experiments on the six language pairs en $\leftrightarrow$ {de, fr, it, ko, nl, zh}. The BWB test data was derived from continuous chapters extracted from six web novels. Due to the relatively short length of individual chapters, we concatenate two adjacent chapters from the same book for zh $\rightarrow$ en evaluation.

#### 5.1.1 Experimental Setups

We employ QWEN2.5-7B-INSTRUCT (Qwen Team, 2024) and TOWERINSTRUCT-MISTRAL-7B (Alves et al., 2024) (hereinafter referred to as TOWER-7B-INSTRUCT) as our backbone models to facilitate a comparison of fine-tuning performance on the shared DocBlocks dataset with Ramos et al. (2025). Both models support 32k-token contexts, with TOWER-7B-INSTRUCT model having been post-trained for sentence-level MT. Due to the significant discrepancy between their tokenizers, we construct two distinct sets of fixed-range $[256, 512]$ chunk pairs by utilizing the respective tokenizer of each model for length measurement, while the Stanza tokenizer (Qi et al., 2020) is jointly used to delineate the basic units, and cosine similarity based on LaBSE (Feng et al., 2022) embeddings is used for chunk alignment.

For reference, we also include results of some widely used commercial LLMs, GPT-4.1 (OpenAI Team, 2024), DeepSeek-v3.2 (DeepSeek-AI et al., 2025), and Gemini-2.5-Pro (Gemini Team, 2025).

We provide a comparison of the train-test length distributions across all the training formats in Appendix E.2. The training data curation procedure, sample statistics, and setups for both training and decoding are detailed in Appendix E.

#### 5.1.2 Evaluation Methods

**d-BLEU, ds-BLEU** Classical document-level BLEU (d-BLEU; Papineni et al., 2002; Liu et al., 2020) and ds-BLEU defined by Peng et al. (2025a), calculating the equivalent of sentence-level BLEU scores (Lin and Och, 2004).

[4]In the Limitations Section, we present the reasons for not incorporating the GuoFeng test data into our study.

**d-COMET** We compute d-COMET[5] at the chunk-level using SLIDE (Raunak et al., 2024) in the same manner as Ramos et al. (2025). However, we introduce variations to the chunking procedure (see Appendix A for details).

**LTCR** The Lexical Translation Consistency Ratio (LTCR; Lyu et al., 2021) measures terminology consistency in DocMT. The conventional implementation relies on cross-lingual word alignment between the source and hypothesis, making the metric sensitive to alignment errors. We propose a LTCR variant that performs monolingual alignment between the hypothesis and reference using the Needleman–Wunsch algorithm (Needleman and Wunsch, 1970).

Specifically, for each interest word $w$ in the reference (see Appendix B), we collect its aligned translations in the hypothesis across all sentence pairs. The word-level consistency is:

$$C(w) = \frac{\max_v \text{count}_w(v)}{K_w}, \quad K_w \geq 2 \qquad (1)$$

where $K_w$ is the number of aligned translations and $\text{count}_w(v)$ denotes the frequency of the translation form $v$. The document-level score is the occurrence-weighted average:

$$\text{LTCR} = \frac{\sum_{w \in W'} C(w) \cdot K_w}{\sum_{w \in W'} K_w} \qquad (2)$$

where $W' = \{w \mid K_w \geq 2\}$.

**GEMBA-DA** While GEMBA-MQM (Kocmi and Federmann, 2023a) has demonstrated efficacy in detecting error spans at the sentence or segment level, its applicability to document-level evaluation remains under-explored. Therefore, following Mrozinski et al. (2025) and Wu et al. (2024b), we utilize GEMBA-DA[6] for our evaluation.

### 5.2 Results on IWSLT2017 and BWB

**Overview** The performance of models trained with two different backbone architectures is reported in Table 1. First, chunking generally outperforms the d2d strategy for both original models, a benefit especially pronounced for TOWER due to its prior sentence-level fine-tuning. While all fine-tuned models naturally exceed the baselines on in-domain data, TOWER-based models show more substantial gains than QWEN2.5.

Table 1: Translation results of different models under various decoding formats. Decoding formats that are consistent with the model training setup are highlighted in **bold**. For the four evaluation metrics, the best performance achieved under the same backbone model is also shown in **bold**. For each individual model, comparisons across different decoding formats are indicated by underlining the better-performing results.

Since our evaluated d-BLEU scores for the original models differ from those reported by Ramos et al. (2025), we compare the relative gains over the original model in the d2d mode. On IWSLT2017, their best results via chunking reported improvements of approximately 6/26 d-BLEU points on en-xx and 13.5/47 on xx-en for QWEN2.5 / TOWER, whereas our SEP-2c1t model achieves gains of 12.44 (+6.44), 32.24 (+6.24), 11.26 (-2.24), and 56.84 (+9.84), respectively. Consequently, our approach outperforms theirs in most instances, except for the QWEN2.5-based IWSLT xx–en case.

**Model-Wise Analysis** From here on, we will describe the model-wise analysis.

**D2DFT**: Although the d2d decoding strategy consistently yields higher ds-BLEU scores than 0c1t, its d-BLEU scores on IWSLT2017 are markedly lower. Given that d-BLEU assigns greater weight to longer documents than ds-BLEU, this indicates that while the overall translation quality of the D2DFT model under d2d decoding is higher than 0c1t, chunking remains more effective for translating longer documents.

**STAIR-FS4**: Instead of rigidly dividing into four equal-sized chunks, this approach applies FRC followed by merging, which results in a highly discretized chunk-length distribution, increasing the coverage of test-time sequence lengths during training. Across all evaluation metrics, STAIR-FS4 outperforms D2DFT on IWSLT2017 and achieves comparable results on BWB. However, a latent issue remains regarding the mismatch between the FS4 training data format and the optimal decoding format, particularly in the QWEN2.5 variant.

**STAIR-1c1t / 2c1t**: As 1c1t and 2c1t samples dominate training, using their corresponding formats during decoding naturally yields optimal performance. Moreover, in terms of d(s)-BLEU, both models consistently exceed STAIR-FS4 on IWSLT2017, despite marginal differences

Table 2: Translation Benchmark on GlobVDoc. For the two evaluation metrics, the best performance achieved under the same backbone model is shown in **bold**. Large-scale LLMs utilize d2d decoding, while original model follows a 0c1t format. Other fine-tuned models utilize decoding format corresponds to the training configuration. {GRAFT, DELTA}-{Q,G} denote using QWEN3-30B-A3B-INSTRUCT and GPT-4.1-mini as backbone models, respectively.

on BWB. A direct comparison between STAIR-1c1t and STAIR-2c1t reveals a narrow performance gap, with the former maintaining a slight advantage.

**SEP / UNI-2c1t**: Leveraging three independently trained sub-models, the SEP strategy achieves superior performance across all ∗c1t decoding modes and yields the best overall results on IWSLT2017, attaining d(s)-BLEU and d-COMET parity with large-scale LLMs. Conversely, joint training with mixed formats (UNI-2c1t) significantly degrades accuracy. This decline likely stems from training confusion, as the same target chunk is mapped to three source texts with varying contextual depth (see Appendix F for further discussion).

### 5.3 Benchmark on GlobVDoc

Based on the proposed GlobVDoc test data, we establish a translation benchmark in Table 2. In the benchmark, we include two agent-based methods, GRAFT (Dutta et al., 2025) and DELTA (Wang et al., 2025b), with QWEN3-30B-A3B-INSTRUCT and GPT-4.1-mini as the underlying models.

For the QWEN2.5-based models, performance differences are mainly seen in en → {es, ko, zh}. Notably, STAIR-FS4 underperforms on es and ko, while SEP-2c1t lags on ko and zh. Therefore, STAIR-2c1t achieves the highest overall accuracy. While most TOWER-based models demonstrate consistent performance across various language pairs, the D2DFT model exhibits an obvious degradation in quality for en → {de, nl, ru} translations.

Unlike results on IWSLT2017 and BWB, performance on the out-of-distribution GlobVDoc dataset exhibits a gap compared to large LLMs, despite achieving parity in certain language pairs. This deficiency is most pronounced for pt, nl, and ko, likely due to limited samples in the DocBlocks dataset. Furthermore, while most of our models outperform {GRAFT,DELTA}-Q, they still trail GPT-4.1-mini.

In addition, Figure 2 reports the LTCR results for different models. The D2DFT and STAIR-FS4 models, leveraged by *Continuous Memory* training (Section 3.3), yield superior LTCR results, with the latter matching or surpassing large-scale LLMs. In contrast, while other models may achieve high accuracy scores, their limited contextual scope results in diminished terminology consistency.

## 6 Analysis

Beyond the experiments discussed in this section, Appendix G compares Source-Only and Source + MT context strategies, and Appendix H reports results of length-centric analysis and FRC unit selection during test time.

### 6.1 Extrapolating Position Embedding

Prior work has extensively explored Position Embedding (PE) to mitigate the discrepancy between sequence length distributions during training and inference. In this paper, we evaluate two primary strategies for comparison: (1) Position Offset Augmentation, which enhances model generalization across diverse length distributions by introducing an offset to position indices. Specifically, we implement two variants: SHAPE (Kiyono et al., 2021; Ruoss et al., 2023), which samples offsets uni-

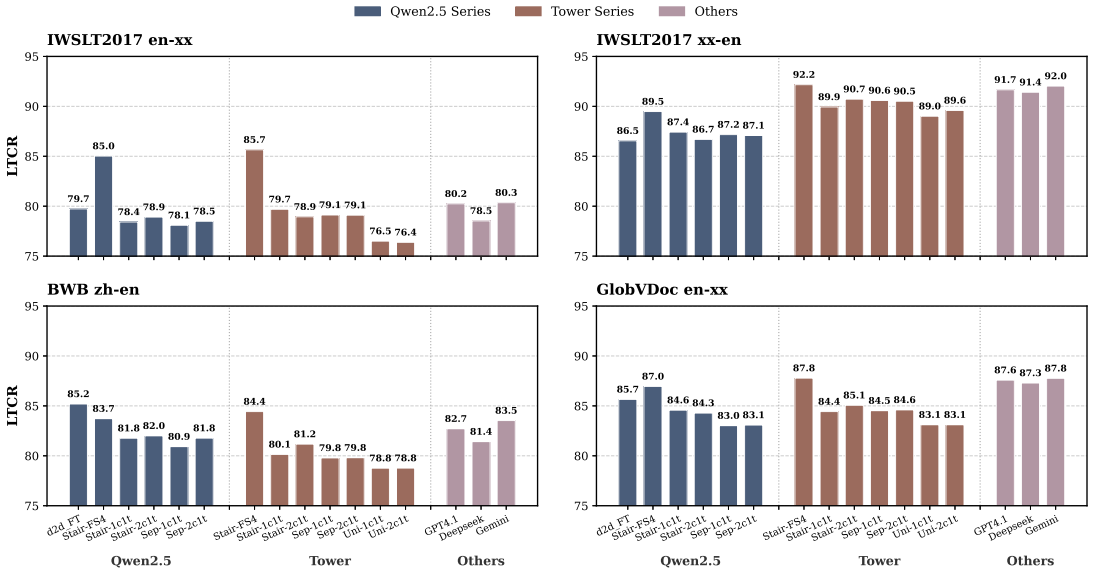

Figure 2: LTCR scores of various models on each dataset.

formly from the gap between the sample length and the model's maximum window size $M$; and Uniform SHAPE (UnifPE; Peng et al., 2025a), which makes each position within $[0, M-1]$ equally likely during training. (2) Position Interpolation (PI; Chen et al., 2023), which compresses or interpolates the position indices of long sequences into a pre-defined range. We implement Linear PI, which downscales position indices in both training and test data by a factor of 4 into $[0, 8192]$.

The results[7] are summarized in Table 3. All evaluated PE-based strategies successfully enhance the D2DFT baseline. This improvement is especially evident on the longer sequences of the IWSLT test set, where d-BLEU scores increased by 5.22, 9.25, and 10.58 across the backbone models. Because standard d2d decoding is prone to instability and n-gram repetition (Jin et al., 2024; Hiraoka and Inui, 2025), PE-based interventions effectively alleviate these hallucinations and stabilize text generation (Peng et al., 2025a). SEP-1c1t model achieves the best performance compared with these baselines, showing clear improvements in both accuracy and n-gram repetition rate. This advantage is particularly pronounced on the IWSLT dataset.

## 6.2 Chunking Strategy

In addition to our proposed FRC strategy and the FS4 strategy followed Ramos et al. (2025), we further compare our method with two conventional chunking strategies in this section:

[7]Since TOWER uses Sliding Window Attention, applying Linear PI would not remove the local-attention constraint. We therefore evaluate Linear PI on QWEN2.5 with full attention.

| Models | PE | FT | d-BLEU↑ (NRR↓) | | |
|---|---|---|---|---|---|
| | | | IWSLT | BWB | GlobVDoc |
| QWEN | R. | D2D | 25.82 (5.75%) | 26.27 (0.00%) | **40.39 (0.00%)** |
| | R.+L. | D2D | 36.40 (1.34%) | 26.12 (0.00%) | 39.76 (1.11%) |
| | R. | SEP | **42.79 (1.07%)** | **26.58** (0.00%) | 39.16 (2.22%) |
| TOWER | R. | D2D | 25.78 (13.64%) | 25.14 (0.00%) | 37.70 (3.33%) |
| | R.+S. | D2D | 31.00 (8.83%) | 26.51 (0.00%) | 41.11 (2.22%) |
| | R.+U. | D2D | 35.03 (7.36%) | 26.31 (0.00%) | 41.52 (**0.00%**) |
| | R. | SEP | **53.18 (1.07%)** | **27.16** (0.00%) | **41.87 (0.00%)** |

Table 3: SEP-1c1t v.s. PE-based methods. IWSLT values denote the average of en-xx and xx-en. Abbreviations: R. (RoPE), S. (SHAPE), U. (UnifPE) and L. (Linear PI). NRR denotes the n-gram repetition rate.

**Fixed Window Chunking (FW).** This method greedily traverses the document with a fixed-length sliding window, concatenating consecutive sentences into a chunk (aka., a *blob*; Finkelstein et al., 2024; Wang et al., 2025a) as long as their combined length does not exceed the window size. Since most chunks are close to the window size, FW is the baseline most similar to FRC. However, it suffers from the short-tail problem, where the final chunk of each document can have an arbitrary length ranging from one sentence up to the window size. FRC can be viewed as an enhanced version of FW by additionally enforcing a lower bound on chunk length, resulting in a narrower chunk-length distribution. We set the window size to 512 tokens.

**Fixed Number Chunking (FN).** This method greedily concatenates a fixed number of consecutive sentences into each chunk. Similar to FW, the final chunk of a document may contain fewer sentences than the predefined number. Moreover, unlike FW, the resulting chunk length is not directly controlled, as it depends on the lengths of

the sentences. Following Alabi et al. (2025), we set the fixed number to 10 for our experiments.

For both chunking strategies, we employed the same training data generation pipeline as used for FRC. All models were trained on TOWER-7B under the SEP-2c1t format.

As shown in Table 4, the proposed FRC strategy consistently outperforms the conventional FW and FN chunking strategies across almost evaluation settings. The exception is the OOD GlobVDoc dataset, where all chunking strategies achieve similar performance. In terms of d-BLEU, FW and FN remain competitive with FRC on IWSLT2017 en-xx and BWB, although a noticeable gap persists on the IWSLT2017 xx-en. In contrast, GEMBA-DA reveals a clearer advantage for FRC, which surpasses other chunking methods by approximately 1.0 point or more on IWSLT2017 and BWB.

| Models | Decode | d-BLEU / Gemba-DA | | | |
|---|---|---|---|---|---|

Table 4: Comparison of various chunking strategies. **Bold** denotes the highest score achieved on each dataset, while underline indicates the best performance for each SEP model on each dataset.

### 6.3 Fixed Range

Following the same data curation pipeline, we constructed two additional datasets based on fixed ranges of $[0, 256]$ and $[512, 768]$ (see Appendix E.2 for data statistics). We fine-tuned the TOWER model using the SEP-1c1t strategy, with the results shown in Table 5. Across the three fixed ranges, the performance discrepancies in the en-xx direction are relatively marginal, with the $[0, 256]$ interval performing slightly worse than the other two. Conversely, in the xx-en direction, the $[256, 512]$ range shows a clear advantage. Furthermore, the results consistently substantiate a strong dependency on contextual information for IWSLT xx-en.

### 6.4 Model Scale

We further examined the SEP-1c1t training strategy, which achieved the best performance on most test datasets, across different model scales using the QWEN2.5 series. The results are presented in Figure 3. As the model size increases from 3B to 14B, both d-BLEU and d-COMET exhibit a strictly increasing trend, indicating that our training strategy is broadly applicable to models of various sizes.

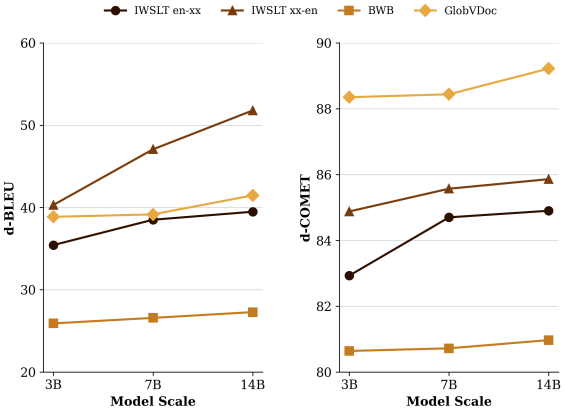

Figure 3: Performance of the SEP-1c1t training strategy under the $[256, 512]$ FRC setting across different model scales in the QWEN2.5 series.

| Models | en-xx | | xx-en | |
|---|---|---|---|---|
| | IWSLT | GlobVDoc | IWSLT | BWB |
| **S-0** | 39.37 / 78.6 | 41.79 / 84.2 | 59.12 / 88.3 | 26.83 / 80.1 |
| **S-1** | 39.50 / 78.7 | 41.66 / 83.9 | 62.83 / 89.4 | 26.76 / 78.7 |
| **M-0** | 39.61 / 79.2 | 41.92 / **85.5** | 61.75 / 89.9 | **27.38** / 80.8 |
| **M-1** | 39.51 / 79.1 | 41.87 / 84.5 | **66.84** / **90.6** | 27.16 / 79.8 |
| **L-0** | **39.66** / **79.4** | **42.15** / 85.1 | 61.70 / 89.0 | 26.61 / **81.7** |
| **L-1** | 39.61 / 79.1 | 41.67 / 84.8 | 63.62 / 89.5 | 27.03 / 80.9 |

Table 5: Results of TOWER-based SEP models trained on fixed ranges S, M, and L, corresponding to $[0, 256]$, $[256, 512]$, and $[512, 768]$, respectively. Results are reported as d-BLEU / LTCR. $*$-0 / $*$-1 denote 0c1t / 1c1t.

### 6.5 Trade-off: Accuracy, Training Cost and Deployment Efficiency

Although SEP-2c1t achieves the best overall accuracy (Section 5), it requires three times of full-parameter fine-tuning and the deployment of three separate models, resulting in substantial training and deployment overhead. To investigate a more efficient alternative, we replace full-parameter fine-tuning with LoRA (Hu et al., 2022) and analyze the trade-offs among translation quality, training efficiency, and deployment cost.

We adopt LoRA[8] with $r = 16$, $\alpha = 32$, and a dropout rate of 0.05 on the TOWER-7B model. The results are shown in Table 6. While LoRA performs slightly worse than full-parameter fine-

[8]We additionally evaluate a higher-rank configuration $r = 64$. Although a larger rank slightly improves in-distribution performance, it leads to degradation on the OOD GlobVDoc benchmark. Detailed results are provided in Appendix I.

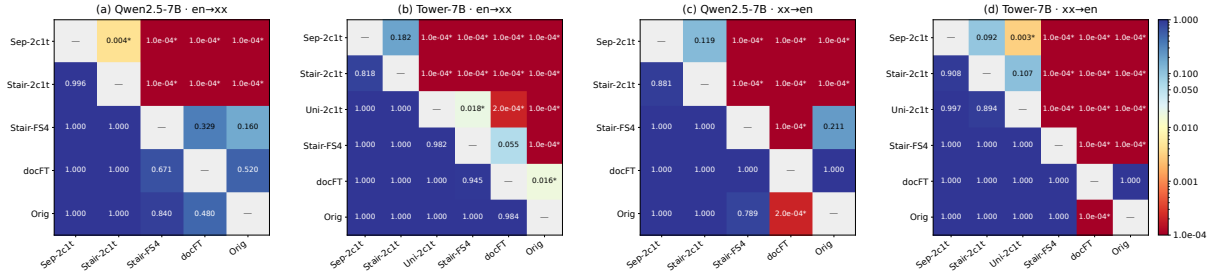

Figure 4: Pairwise one-sided significance tests on IWSLT2017 for QWEN2.5-7B and TOWER-7B. Each cell reports the paired document-bootstrap p-value for the hypothesis that the row system outperforms the column system in d-BLEU. Asterisks indicate $p < 0.05$.

| Models | SEP-2c1t (LoRA) | | | STAIR-2c1t (Full) | | | SEP-2c1t (Full) | | |
|---|---|---|---|---|---|---|---|---|---|

| **IWSLT en-xx** | 38.61 / 84.04 | 38.65 / 84.25 | 37.85 / 84.26 | 33.45 / 79.39 | 38.26 / 84.13 | 38.29 / 84.14 | **39.61** /84.69 | 39.51 / **84.83** | 38.78 / 84.80 |
| **IWSLT xx-en** | 43.04 / 85.06 | 43.56 / 86.15 | 43.88 / 86.30 | 60.46 / 85.37 | 65.32 / 86.17 | 66.51 / 86.26 | 63.05 / 86.09 | 66.84 / 86.49 | **67.20 /86.53** |
| **BWB** | 25.99 / 80.42 | 25.96 / 80.52 | 25.74 / 80.51 | 27.32 / 80.96 | **27.55** / 81.06 | 27.53 / 81.10 | 27.38 / **81.11** | 27.16 / 81.03 | 26.82 / 81.03 |
| **GlobVDoc** | 42.78 / 89.02 | **43.28 / 89.52** | 42.76 / 89.39 | 41.57 / 88.98 | 42.16 / 89.34 | 42.06 / 89.35 | 41.92 / 89.11 | 41.87 / 89.25 | 41.98 / 89.26 |

Table 6: Comparison of different training and deployment configurations. The values $*$ / $*$ denote d-BLEU and d-COMET, respectively. Within each dataset, the highest score is highlighted in **bold**.

tuning overall, the performance gap remains small. In particular, it yields substantially lower d-BLEU scores on IWSLT xx-en while maintaining competitive d-COMET, suggesting comparable translation quality despite reduced lexical overlap. Furthermore, LoRA surpasses full-parameter fine-tuning on the OOD GlobVDoc benchmark, indicating improved robustness under distribution shifts.

Overall, the three configurations represent different points on the efficiency–performance trade-off. SEP-2c1t (LoRA) offers the best balance between effectiveness and efficiency, STAIR-2c1t (Full) minimizes deployment complexity while maintaining strong performance, and SEP-2c1t (Full) achieves the highest accuracy at the cost of increased training and deployment overhead.

### 6.6 Statistical Significance Analysis

We assess the reliability of the d-BLEU differences using one-sided paired bootstrap resampling (Koehn, 2004), with documents as the sampling unit and 10,000 bootstrap samples. For each system pair, the alternative hypothesis is that the row system outperforms the column system. We adopt a significance threshold of $p < 0.05$.

The results on IWSLT2017 are shown in Figure 4. SEP-2c1t and STAIR-2c1t significantly outperform STAIR-FS4, DOCFT, and original model across both backbones and translation directions ($p \leq 10^{-4}$) on IWSLT2017. The difference between SEP-2c1t and STAIR-2c1t is significant only for QWEN2.5-7B on en-xx ($p = 0.004$), indicating that their relative advantage is not consistent across settings. For TOWER-7B, UNI-2c1t also significantly outperforms STAIR-FS4 in both directions. Overall, the results suggest the advantage of the 2c1t training strategies over the document-level and fixed-sized systems. The results of the statistical significance tests on BWB and GlobVDoc are provided in Figure 14 in the Appendix.

## 7 Conclusion

In this study, to handle training-inference length discrepancies caused by document length variability, we introduced FRC, a DP-based strategy that unifies length intervals across training and testing. Building upon FRC, we conducted a systematic analysis of various training paradigms across diverse data formats, finding that separate training exhibited superior stability on in-domain test data, while offering a trade-off analysis among translation quality, training efficiency, and deployment cost. Furthermore, we benchmarked our fine-tuned models against commercial LLMs and agent-based methods on our self-established GlobVDoc dataset. The results showed that our models surpassed QWEN3-30B-A3B-INSTRUCT based agent methods in out-of-distribution performance.

## Limitations

Although the GuoFeng dataset is widely used in the current DocMT task, we discovered only upon completing all training tasks that the DocBlocks dataset included GuoFeng's Test 1, Test 2, Valid 1, and Valid 2 data (Xu et al., 2022). However, some chapters of them overlap entirely with Test 3, which was used in the WMT23 and WMT24 Discourse-Level Literary Translation shared tasks (Wang et al., 2023b, 2024b). While this overlap constitutes only a small portion, we elected to exclude the GuoFeng test data from our evaluation to ensure the integrity and stringency of our results.

Since Ramos et al. (2025) did not release the parameters of their trained model, faithfully reproducing their method is challenging. Consequently, in Section 5.2, we compare our approach with theirs only in terms of the relative performance improvement over the corresponding baseline. However, we cannot guarantee that this comparison is fully equivalent.

In Section 6.2, we compare FRC with both FW and FN under the SEP-2c1t setting. Although we controlled the experimental variables as much as possible by using an identical data construction pipeline that differed only in the chunking method, and by training all models with the same hyperparameters and random seed, the resulting training information may still differ because intermediate processing steps, such as chunk alignment and filtering. Furthermore, the SEP-2c1t setting may encourage homogeneous representations, thereby reducing the observable performance differences among the compared methods.

Prior research (Kim et al., 2019; Peng et al., 2025b; O'Brien et al., 2025; Li et al., 2026) suggests that context selection can significantly influence model precision. Consequently, we leave the analysis of how to leverage FRC for optimized context selection as a subject for future work.

To ensure a fair comparison with existing methods, all the models undergo full-parameter fine-tuning, which incurs substantial computational costs. Consequently, most of our analysis and comparative experiments are conducted on a single backbone model under a specific training setting (e.g., TOWER under D2DFT, SEP-1c1t).

## Ethical Statement

All models, datasets, and tools utilized in this study are publicly accessible and intended for research purposes.

We ensure that all source material for the GlobVDoc Dataset, sourced from Global Voices, carries a Creative Commons (CC) license. Comprehensive metadata, including titles, authors, and translators, is recorded in Table 20 in the Appendix.

Regarding agent-based methods, we employed GRAFT[9] (Dutta et al., 2025) and DELTA[10] (Wang et al., 2025b) in their original states without modification to the source code.

Furthermore, while the formulation of our proposed reference-based LTCR metric is informed by Lyu et al. (2021), the software implementation was developed independently by the authors.

## Acknowledgements

We would like to thank all of our co-authors and the team members who voluntarily contributed to the construction of the GlobVDoc dataset.

We are grateful to all the anonymous reviewers for their constructive feedback, which greatly improved this paper. We also sincerely thank Adam Nohejl, Daiki Matsuoka, Koki Ryu, Ryoma Kumon, Rongzhi Li, Taisei Yamamoto, and Tomoki Doi for their valuable discussions, suggestions, and insightful comments.

## A Evaluation Procedures

**d-BLEU** The computation of the d-BLEU score is contingent upon the translation direction. For the "xx-en" direction, the sacreBLEU (Post, 2018) "13a" tokenization scheme is uniformly applied across the entire corpus. In contrast, for the "en-xx" direction, d-BLEU scores are first computed individually for each target language and subsequently averaged. The tokenization method for the target language is specified as "zh" for Chinese, "ko-mecab" for Korean, and "13a" for all other languages.

**d-COMET** Although many studies on DocMT use the contextual-embedding COMET (Rei et al., 2022; Vernikos et al., 2022) as their evaluation method, the metric essentially remains sentence-level and incorporates additional contextual information. Therefore, we follow Ramos et al. (2025) and compute d-COMET[11] at the chunk-level using SLIDE (Raunak et al., 2024). Since Ramos et al. (2025) relied solely on overlapping 512-token chunks to compute chunk-level scores independently, which may result in misalignment among the source, hypothesis, and reference, we construct three types of alignment-oriented chunk triplets $(src, hyp, ref)$, and across all strategies, we maintain a 50% overlap between consecutive chunks:

- **Src–Ref Aligned Stacking**: Source segments and their corresponding reference segments are concatenated until one sequence approaches the 512-token limit. Subsequently, the hypothesis is segmented and stacked to approximate the reference length, ensuring that the total count remains under 512 tokens.
- **Segment Independent Stacking**: Source, hypothesis, and reference segments are concatenated independently until each sequence

Table 7: Statistics of GlobVDoc Dataset. |D| represents the document count, |S| represents the total sentence count, and |W| indicates the total number of words in both the source language (English) and the corresponding target language (the second language listed in the Language Pair).

reaches its maximum capacity of 512 tokens, disregarding cross-sequence alignment.

- **Token Independent Stacking**: A 512-token sliding window is applied separately to the source, hypothesis, and reference sequences, ignoring segment boundaries and alignment.

The final d-COMET score is computed as the average of the scores derived from these three distinct segmentation methods.

**GEMBA-DA** GEMBA-DA (Kocmi and Federmann, 2023b) is an LLM-as-a-judge method (Zhu et al., 2024; Gu et al., 2025). We use GPT-4.1 as the judge model and set the temperature to 0 for deterministic evaluation. By conditioning on the source, hypothesis, and reference, the model conducts a direct assessment of translation quality at the document level, and the final score is obtained by averaging scores over the test set. The prompt used for GEMBA-DA evaluation is provided in Appendix K.

## B Interest Word Selection for LTCR

Interest words are defined as named entities extracted from the reference text using spaCy[12]. We retain entities corresponding to the following labels: PERSON, PER, PS, ORG, OG, GPE, NORP, FAC, LOC, LC, MISC, PRODUCT, EVENT, WORK_OF_ART, LAW, and LANGUAGE. Only entities appearing at least twice in the reference document are considered for consistency evaluation.

## C Details of GlobVDoc

All contributors hold at least a Master's degree and are engaged in research related to natural language processing, specializing in areas such as machine translation, linguistics, and interpretability. The team consisted of native speakers of English, Chinese, Spanish, and Dutch. For sentence alignment involving non-native languages, we conducted cross-verification using multiple high-precision translation tools and multilingual dictionaries. The team members are instructed to follow a standardized formatting protocol: the article title is placed in the first row, the introduction in the second, and the main body from the third row. Moreover, Global Voices articles that relied heavily on multimedia elements, such as videos, images, or audio, are excluded during the document compilation process to ensure textual consistency. In addition, while Global Voices features interview-based articles that may contain personal details, such information is publicly available and does not constitute sensitive or privacy-infringing data. Each document pair is checked by at least two volunteers, and disagreements are discussed and resolved collectively.

The detailed guidelines for data construction are provided below:

1. **Source Selection and Diversity**: English was designated as the source language. To ensure the diversity of the test data and avoid redundancy, each unique English document was utilized only once.

2. **Temporal Relevance**: Priority was given to the most recent documents to ensure the timeliness and contemporary relevance of the data.

3. **Alignment Quality**: We selected documents where sentence-level alignment was as complete as possible. Texts exhibiting significant alignment gaps or structural discrepan-

Table 8: Statistics of commonly used document-level test datasets. |D| denotes the number of documents, |S| denotes the number of sentences, |W| denotes the total number of words in English, and |W|/|D| denotes the average number of words per document. For IWSLT2017, the statistics reported in the table only include en ↔ {de, fr, it, ko, nl, zh} language pairs used in this work.

cies were excluded in favor of more consistent alternatives.

4. **Structural Consistency**: Preference was given to translations that maintained a structural sequence consistent with the source text. This avoided the alignment complexities often introduced by translations that radically reorder sentences within a paragraph.

5. **Manual Segmentation**: Sentence segmentation was performed manually. Rather than strictly decomposing texts into the smallest possible fragments, we merged related short segments to preserve discourse integrity.

6. **Minimal Adjustments**: In cases of minor content misalignment (e.g., where a translator added brief explanatory notes), slight adjustments were made while strictly respecting the original intent. No other modifications to the content were permitted.

7. **Mapping Priority**: In instances of many-to-many or many-to-one sentence mappings, priority was given to establishing complete semantic correspondence.

Detailed counts of documents, sentences, and words in the GlobVDoc dataset are summarized across different language pairs in Table 7. The specifications of the data utilized to construct the dataset, including document IDs, source and translated titles, source and target languages, and the names of authors and translators, are presented in Table 20.

Table 8 compares the statistics of GlobVDoc with those of other commonly used document-level machine translation test datasets. We compute the statistics for the IWSLT2017 and BWB datasets used in this work, while the statistics for the remaining datasets refer to Wang et al. (2023a, 2024b). We do not include GuoFeng Test 3, which was used in the WMT23 and WMT24 Discourse-Level Literary Translation shared tasks, because its reference translations are not publicly available at the time of this work. As shown in the table, the scale of GlobVDoc is comparable to existing commonly used document-level evaluation datasets.

## D Quality Estimation of Test Data

The intrinsic quality of the test data warrants careful examination. Following the word-level definition of autocorrelations using distributional semantics proposed by Mikhaylovskiy and Churilov (2023), we define a document-level non-centered autocorrelation function and further extend it to the corpus level.

Given a document $d \in \mathcal{D}$ consisting of units $\{u_1, \ldots, u_{T_d}\}$, the corpus autocorrelation function at lag $k$, denoted as $R[k]$, is defined as:

$$R[k] = \frac{\sum_{\mathrm{d}} \sum_{t=k}^{T_d} \mathrm{sim}(u_t, u_{t-k}) \cdot \left(1 - \frac{k}{T_d}\right)}{\sum_{\mathrm{d}} (T_d - k) \cdot \left(1 - \frac{k}{T_d}\right)} \tag{3}$$

where the term $(1 - k/T_d)$ serves as a length-penalty weight to mitigate the impact of large variations in document length within the corpus (e.g., in some documents, $u_1$ and $u_4$ are still located near

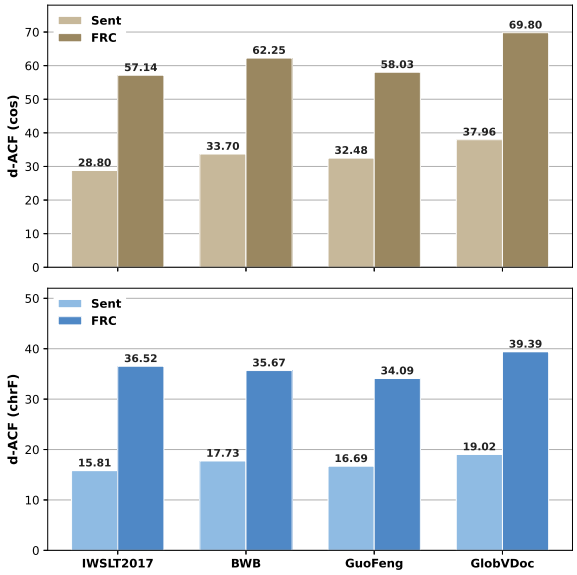

Figure 5: The results of d-ACF ($\times 100$) on four datasets.

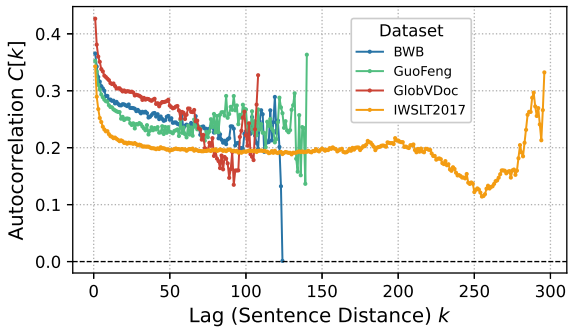

Figure 6: Autocorrelation distributions of all datasets across all lag values $k$.

the beginning of the document, whereas in others $u_4$ already appears at the end). We then take a weighted average of the first four lags as the autocorrelation coefficient of the data, referred to as d-ACF:

$$\text{d-ACF} = \sum_{k=1}^{K} w_k R[k] \tag{4}$$

Here, we simply adopt $K = 4$ and uniform weights. The similarity $\text{sim}(u_t, u_{t-k})$ is computed using two approaches: cosine similarity based on sentence embeddings and sentence-level chrF (Popović, 2015). For the former, we employ the jina-embeddings-v3 model (Sturua et al., 2024) for encoding. Our analysis is conducted on the English side[13] of IWSLT2017, BWB, GuoFeng, and GlobVDoc, considering two types of units: sentences and FRC pairs.

As shown in Figure 5, on the cosine-based d-ACF metric, GlobVDoc outperforms all other datasets at both the sentence level and the chunk level, indicating stronger semantic autocorrelation and greater document-level topical coherence. From a lexical perspective, the d-ACF value gap between GlobVDoc and the other datasets is smaller than that observed under the cosine-based setting, but GlobVDoc still maintains a slight advantage.

Due to the above discussion, which considers only autocorrelation values at relatively close intra-document positions (with the lag $k$ limited to 4), we further examine the overall document-level behavior by analyzing the autocorrelation distributions of all datasets across all lag values $k$. As presented in Figure 6, these distributions are computed at the sentence level using cosine similarity.

We observe that, at the initial stage of the curves, all datasets exhibit a sharp decline followed by a more gradual decrease, indicating that strong semantic relatedness is primarily concentrated among sentences that are close to each other. Furthermore, both GlobVDoc and IWSLT2017 show another significant drop followed by an increase toward the end of the curves, resulting in an overall U-shaped pattern. In particular, for IWSLT2017, the notable rise after around lag $k = 290$ suggests that certain documents in the corpus may exhibit strong correspondences between their beginnings and endings. In contrast, BWB and GuoFeng do not display a clear U-shaped trend in the later stages. Instead, after the steady decline, their curves gradually increase. This indicates that although semantic correlation at medium distances continues to weaken, these datasets still demonstrate meaningful long-range coherence at larger sentence separations.

## E Experimental Setups

### E.1 Hyperparameters for FRC and Chunk Alignment

For Fixed-Range Chunking, we set the maximum number of chunks allowed to fall outside the predefined range during the relaxed optimization stage to $K = 8$. This setting is intended to improve the robustness of the algorithm. Under this configuration, no invalid samples were encountered during either training data construction or test-time chunk generation.

[13] Although the original languages of some datasets are not English, both the chrF metric and the performance of the jina-embedding-v3 model exhibit obvious variation across different languages. Therefore, to maintain relative fairness, we conduct the evaluation on the common English side.

Table 9: Outlier sample statistics across different similarity approaches and tokenizers. **L** denotes chunk alignment methods using the QWEN2.5-7B-INSTRUCT tokenizer paired with either LaBSE embedding cosine similarity. And **B** denotes nllb-200-distilled-600M translation based sentence-BLEU as the similarity score, respectively. **Q** and **T** represent the use of QWEN2.5-7B-INSTRUCT and TOWER-7B-INSTRUCT tokenizers while maintaining LaBSE-based cosine similarity as the alignment criterion. "en↔xx" encompasses bidirectional data, the length ratio is uniformly calculated for all pairs as the length of the non-English language relative to the English text.

For the Dual-Boundary Matching-based Chunk Alignment algorithm, we set $\lambda = 0.5$ and $\sigma = 0.05$. In addition, the number $k$ of target-unit candidates considered for each source boundary is set to 256.

### E.2 Training Data Filtering and Statistics

Given that the DocBlocks dataset comprises high-quality data filtered via quality-aware methods (Rei et al., 2023; Ramírez-Sánchez et al., 2020), we adopt a simple strategy to process chunk pairs:

1. Exclude chunk pairs where the source chunk length exceeds the upper threshold of the predefined range.

2. Determine the median length ratio for each language pair, and then filter the parallel chunk pairs by retaining only those within the interval $[\text{median}/1.5, \text{median} \times 1.5]$.

We utilize these outlier samples as breakpoints to further segment documents into subdocuments. Table 9 presents the statistics for outlier samples, which can also characterize the data attrition rate of our proposed Dual-Boundary Matching-based Chunk Alignment Algorithm.

In addition to the LaBSE-based cosine similarity utilized for chunk alignment in Section 5.1.1, we introduce a comparative strategy using sentence-BLEU scores derived from the nllb-200-distilled-600M model[14] (NLLB Team et al., 2022) translations. Both methods employ the QWEN2.5-7B-INSTRUCT tokenizer for length measurement during the initial FRC phase. Our results indicate that while both approaches yield nearly identical median ratios due to the shared tokenizer, the translation-based method leads to a substantial increase in the outlier rate, particularly for zh. This discrepancy likely stems from the high proportion of GuoFeng and BWB data within the DocBlocks dataset. As these materials belong to the web novel domain, they pose relative translation challenges.

To quantitatively assess the difference in alignment quality between chunk alignment based on SentenceBLEU scores and that based on LaBSE-based cosine similarity, we also trained QWEN2.5-7B-INSTRUCT model using the SEP-1c1t strategy on samples obtained with the former method. A simple comparison of the results is shown in Figure 7. After data filtering, the LaBSE-based method, which retained a larger number of samples, unsurprisingly achieves consistently better performance on the test datasets than the SentenceBLEU-based approach. Notably, although the SentenceBLEU-based approach discarded a substantial number of outlier Chinese data points, its performance on the BWB dataset is not far behind that of the LaBSE-based approach. This suggests that the performance gains brought by large-scale Chinese training data exhibit a clear pattern of diminishing marginal returns.

Provided that LaBSE cosine similarity is used consistently, the sample attrition rates for FRC using either the QWEN2.5-7B-INSTRUCT or TOWER-7B-INSTRUCT tokenizers do not differ significantly. However, inherent discrepancies between these tokenizers lead to substantial variations in cross-lingual length ratios, a phenomenon particularly prominent in ko and zh.

Subsequently, based on these subdocuments and their corresponding FRCs, we construct training samples tailored to the formatting requirements of the D2DFT, STAIR, SEP, and UNI models. Ta-

| UNI-2c1t | – | 6,185,540 |

Table 11: The number of training data utilized for each model configuration.

ble 11 reports the number of final training samples under the fixed range of $[256, 512]$, while Table 10 presents the statistics for the three fixed-range datasets. In addition, Table 10 reports only the number of samples for en↔xx language pairs. However, there are also a very small number of samples corresponding to language pairs that do not include English. For example, under the fixed-range setting of $[256, 512]$, there are 63,403 such samples. These samples were also included in the final training dataset.

To further illustrate the effect of FRC on length control, Figure 8 visualizes the training- and test-time source-side input length distributions of different training formats under the TOWER backbone with the fixed range $[256, 512]$. Overall, D2DFT and STAIR-FS4 exhibit broader or less-aligned train-test length distributions, whereas SEP-2c1t, STAIR-2c1t, and UNI-2c1t, show more compact and better-aligned distributions. Notably, the three sub-models of SEP-2c1t exhibit particularly sharp and narrowly bounded length distributions.

### E.3 Training and Decoding Setups

We employ supervised fine-tuning (SFT) to train our models, where the loss is computed only on the target-side tokens. Given a document pair $d = (d^s, d^t) \in \mathcal{D}$ after FRC-based chunk alignment, we denote the aligned chunk pairs as $\{(c^s_{d,i}, c^t_{d,i})\}_{i=1}^{|d|}$. $C^*_{d,i}$ is the set of contextual source chunks used for predicting the $i$-th target chunk.

**D2DFT**

$$\mathcal{L}_{\text{D2DFT}} = -\sum_{d \in \mathcal{D}} \log p_\theta\big(d^t \mid d^s\big) \tag{5}$$

$$\theta_{\text{D2DFT}} = \arg\min_\theta \mathcal{L}_{\text{D2DFT}}(\theta) \tag{6}$$

**STAIR-2c1t**

$$C^{\text{STAIR-2c1t}}_{d,i} = \begin{cases} \varnothing, & i = 1, \\ \{c^s_{d,1}\}, & i = 2, \\ \{c^s_{d,i-2}, c^s_{d,i-1}\}, & i \geq 3. \end{cases} \tag{7}$$

$$\mathcal{L}_{\text{STAIR-2c1t}} = -\sum_{d \in \mathcal{D}} \sum_{i=1}^{|d|} \log p_\theta\big(c^t_{d,i} \mid c^s_{d,i}, C^{\text{STAIR-2c1t}}_{d,i}\big) \tag{8}$$

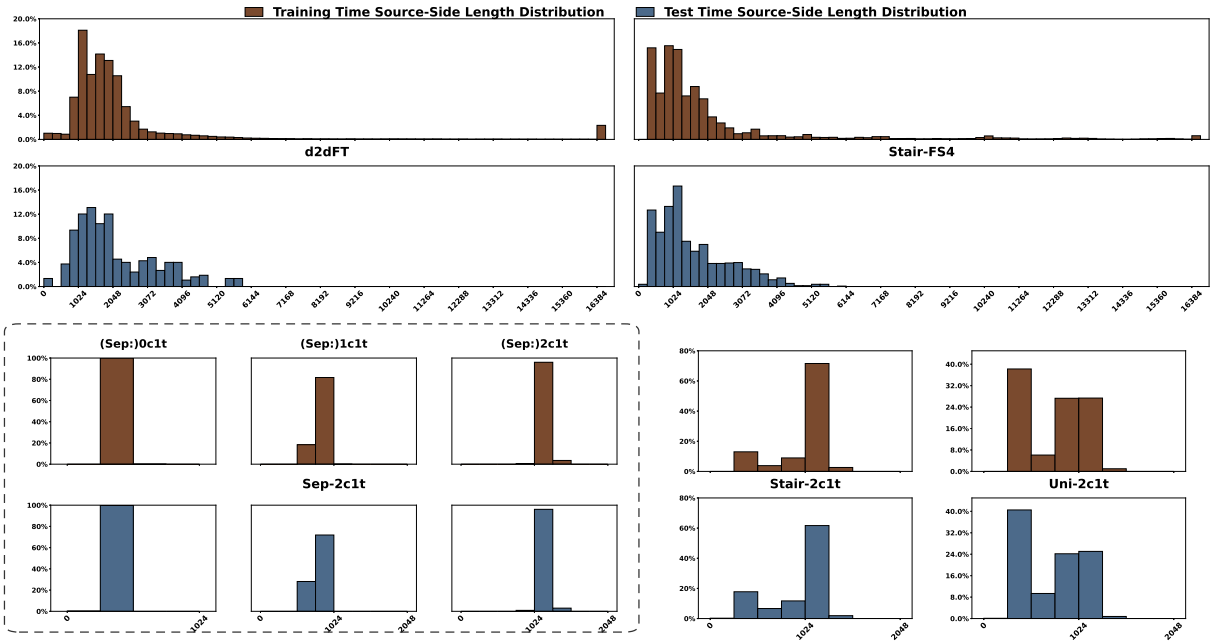

Figure 8: Training- and test-time (source-side) input length distributions. The x-axis denotes input length, and the y-axis denotes the proportion of documents or chunks in each length bin. Lengths are measured using the TOWER's tokenizer. Training statistics are computed on DocBlocks, and test statistics are computed on IWSLT2017 en-xx.

$$\theta_{\text{STAIR-2c1t}} = \arg\min_{\theta} \mathcal{L}_{\text{STAIR-2c1t}}(\theta) \quad (9)$$

**STAIR-FS4** We merge the aligned chunk pairs into four consecutive chunks within one document, defined as $\{(z^s_{d,i}, z^t_{d,i})\}_{i=1}^4$.

$$C^{\text{STAIR-FS4}}_{d,i} = \begin{cases} \varnothing, & i = 1, \\ \{z^s_{d,1}\}, & i = 2, \\ \{z^s_{d,1}, z^s_{d,2}\}, & i = 3 \\ \{z^s_{d,1}, z^s_{d,2}, z^s_{d,3}\}, & i = 4. \end{cases} \quad (10)$$

$$\mathcal{L}_{\text{STAIR-FS4}} = -\sum_{d\in\mathcal{D}} \sum_{i=1}^{4} \log p_\theta\left(z^t_{d,i} \mid z^s_{d,i}, C^{\text{STAIR-FS4}}_{d,i}\right) \quad (11)$$

$$\theta_{\text{STAIR-FS4}} = \arg\min_{\theta} \mathcal{L}_{\text{STAIR-FS4}}(\theta) \quad (12)$$

**SEP / UNI-2c1t**

$$C^{(k)}_{d,i} = \begin{cases} \varnothing, & k = \text{0c1t}, \\ \{c^s_{d,i-1}\}, & k = \text{1c1t}, \\ \{c^s_{d,i-2}, c^s_{d,i-1}\}, & k = \text{2c1t}. \end{cases} \quad (13)$$

$$\mathcal{L}^{(k)} = -\sum_{d\in\mathcal{D}} \sum_{i=1}^{|d|} \log p_\theta\left(c^t_{d,i} \mid c^s_{d,i}, C^{(k)}_{d,i}\right) \quad (14)$$

$$\theta^{(k)}_{\text{SEP-2c1t}} = \arg\min_{\theta} \mathcal{L}^{(k)}(\theta), k \in \{\text{0c1t}, \text{1c1t}, \text{2c1t}\} \quad (15)$$

$$\theta_{\text{UNI-2c1t}} = \arg\min_{\theta} \sum_{k} \mathcal{L}^{(k)}(\theta) \quad (16)$$

The training and inference prompts are presented in the Appendix K.

The training hyperparameters almost follow the configurations established by Ramos et al. (2025). However, we adjust the batch size to 16 for *Doc2Doc* fine-tuning while setting it to 64 for all other models. All training processes were conducted using 8 NVIDIA H100 GPUs, optimized by AdamW (Loshchilov and Hutter, 2019). Table 12 contains the detailed hyperparameter configuration for the training step.

| | |
|---|---|
| Batch size | 16 (D2DFT) / 64 (others) |
| Number of Epochs | 2 |
| Learning rate | $7 \times 10^{-6}$ |
| LR Scheduler | cosine |
| Warmup Steps | 125 |
| Weight Decay | 0.01 |
| Optimizer | AdamW |
| Adam $\beta_1$ | 0.9 |
| Adam $\beta_2$ | 0.999 |
| Adam $\epsilon$ | $1 \times 10^{-8}$ |
| Maximum Sequence Length | 32,768 |

Table 12: Hyperparameter configuration to fine-tune models.

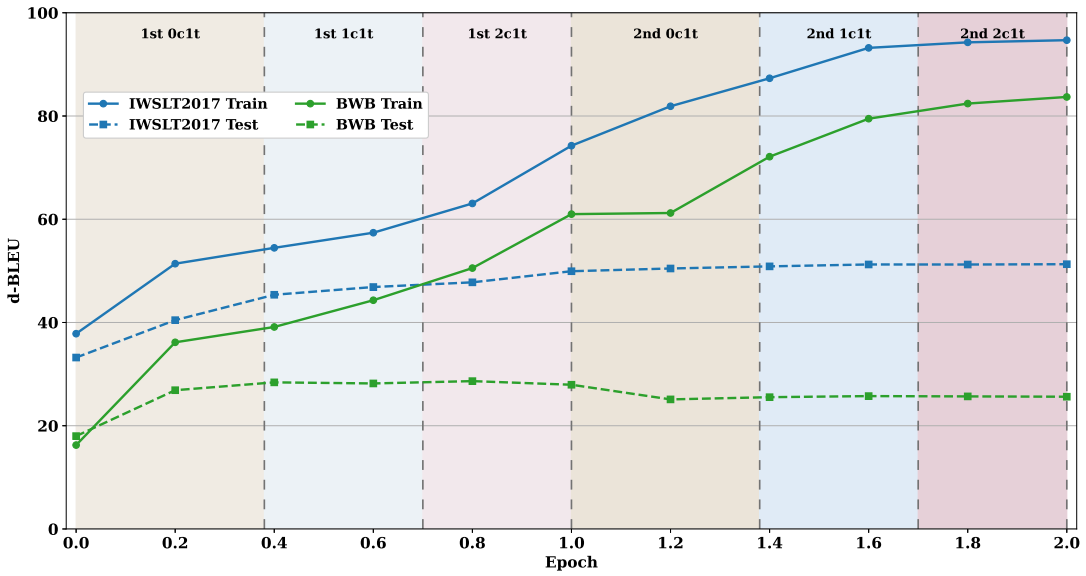

Figure 9: Training Process of TOWER-based UNI-2c1t model.

Both inference and evaluation were conducted on a single H100 GPU. For the decoding process, we utilized vLLM (Kwon et al., 2023) and employed a greedy decoding strategy.

During inference, d2d refers to direct document-to-document translation. The ∗c1t models utilize a staged decoding approach: 0c1t translates all fixed-range chunks without context; 1c1t initiates the first chunk of each document in 0c1t mode, while subsequent chunks follow the 1c1t format; 2c1t decoding begins with 0c1t for the first chunk and 1c1t for the second, with all remaining chunks processed using 2c1t context. FS4 follows a similar staged procedure. All inference prompts are kept consistent with the training prompts shown in Appendix K.

# F Analysis of Joint Training

## F.1 Training Process of UNI-2c1t

Given that the training data for UNI-2c1t reaches 6M samples (see Table 11) and that the model repeatedly encounters each source chunk three times through the 0c1t, 1c1t, and 2c1t formats, we sought to investigate the potential risk of overfitting. We monitored the performance of the UNI-2c1t model on both the test set and a subset of the training data throughout the training process. The training subset was constructed via random sampling, consisting of 12 document pairs selected from each of the IWSLT2017 and BWB datasets.

The results are illustrated in Figure 9. Since the IWSLT2017 training data is essentially bi-directional (xx-xx), we report the averaged performance across en-xx and xx-en directions on the test set. During the training process, model checkpoints were saved every 0.2 epochs. Since the training data is in a fixed sequence of 0c1t, 1c1t, and 2c1t formats within each epoch, we have explicitly marked the specific time points at which the learning phase for each data format concludes.

Regarding the training data, both the IWSLT2017 and BWB subsets exhibit a natural and consistent improvement in fitting as training progresses. For the test data, the performance on IWSLT2017 demonstrates a gradual increase before eventually plateauing, with no discernible signs of overfitting. However, a distinct trend emerges for the BWB data during the transition from epoch 1.0 to 1.2: we observe a marginal gain on the training set accompanied by a performance dip on the test set. This suggests that the transition in data format, reverting from 2c1t back to 0c1t at the start of a new epoch, may introduce temporary optimization confusion for the BWB domain. In the subsequent phased learning stages, while the model continues to fit the training data rapidly, its generalization performance on the test data eventually stabilizes. However, given the model's exceptionally high degree of fitting to the training data, its generalization performance may already have been limited.

## F.2 Analysis of Context Sensitivity

To better understand the behavior of UNI-2c1t under joint training, we conduct additional analyses

| Model | Decoding | IWSLT en-xx | | IWSLT xx-en | | BWB xx-en | |
|---|---|---|---|---|---|---|---|
| | | Orig-C | RDM-C | Orig-C | RDM-C | Orig-C | RDM-C |
| SEP-2c1t | 1c1t | 39.26 | 37.86 (-1.40) | 67.04 | 59.85 (-7.19) | 26.55 | 23.37 (-3.18) |
| | 2c1t | 38.40 | 37.02 (-1.38) | 67.26 | 57.70 (-9.56) | 26.15 | 21.96 (-4.19) |
| STAIR-2c1t | 1c1t | 39.12 | 37.43 (-1.69) | 65.79 | 57.72 (-8.07) | 27.18 | 23.12 (-4.06) |
| | 2c1t | 39.16 | 37.60 (-1.56) | 66.97 | 56.33 (-10.64) | 27.18 | 22.16 (-5.02) |

| | 2c1t | 36.55 | 35.84 (**-0.71**) | 66.43 | 63.66 (**-2.77**) | 25.28 | 24.28 (**-1.00**) |

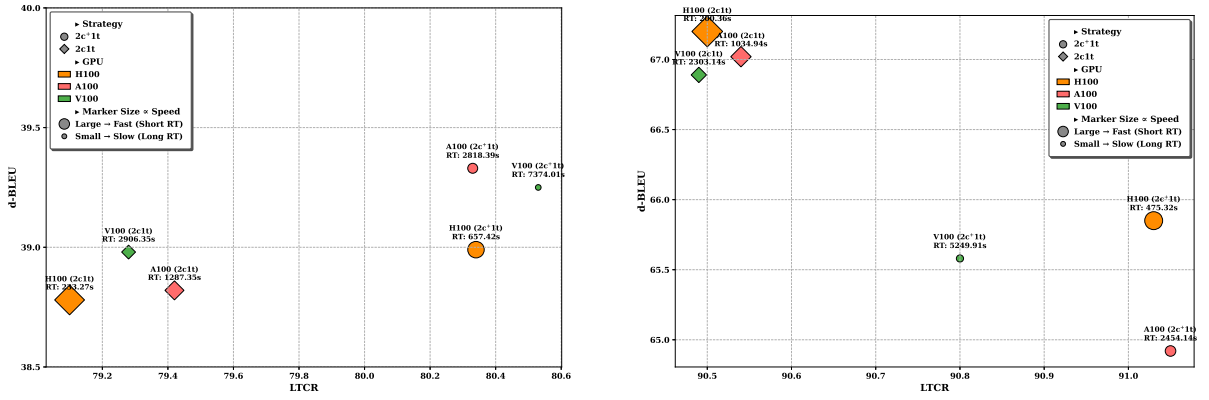
Table 13: d-BLEU scores under original context (Orig-C) and randomly replaced context (RDM-C). Numbers in parentheses denote the absolute performance drop after context replacement. Results are averaged over five runs.

| Model | Original | | | RDM1 | | RDM2 | | RDM3 | |
|---|---|---|---|---|---|---|---|---|---|
| | 0c1t | 1c1t | 2c1t | 1c1t | 2c1t | 1c1t | 2c1t | 1c1t | 2c1t |
| STAIR-2c1t | 49.29 | 52.36 | 56.99 | 47.95 | 46.63 | 47.08 | 45.29 | 46.52 | 44.56 |
| | – | – | – | -8.42% | -18.18% | -10.08% | -20.53% | -11.15% | -21.81% |
| UNI-2c1t | 97.35 | 97.50 | 97.35 | 95.40 | 95.27 | 96.62 | 95.78 | 96.14 | 95.22 |
| | – | – | – | **-2.15%** | **-2.14%** | **-0.90%** | **-1.61%** | **-1.39%** | **-2.19%** |

Table 14: d-BLEU on sampled training instances under different decoding formats and after random context replacement. Percentages denote the relative performance drop compared with the corresponding original score.

to investigate whether the model effectively utilizes contextual information or instead primarily relies on the source chunk itself.

**Context replacement: Test.** We randomly replace the context associated with each source chunk in the in-distribution test set while keeping the source chunk and target chunk unchanged. To maximize the perturbation, the replacement context is sampled from a different document written in a different language. During evaluation, we remove the first chunk of each document since it has no preceding context. We denote the original context as Orig-C and the replaced context as RDM-C. All results are averaged over five independent runs.



As shown in Table 13, replacing the context causes substantial performance degradation for both SEP-2c1t and STAIR-2c1t across all test sets. In contrast, UNI-2c1t exhibits only marginal performance drops under the same perturbation. This observation suggests that UNI-2c1t is considerably less sensitive to contextual information, even when the original context is replaced with unrelated content.

**Context replacement: Train.** To further investigate this phenomenon, we sample 320 source chunks from the training set. These chunks appear only in the 2c1t format for STAIR-2c1t, while they appear in all three formats (0c1t, 1c1t, and 2c1t) for UNI-2c1t. We first evaluate how well each model fits these training instances under different decoding formats and then perform the same context replacement experiment.

Table 14 reveals two notable observations. First, STAIR-2c1t achieves its highest fitting accuracy under the 2c1t decoding format, whereas UNI-2c1t attains nearly perfect d-BLEU scores across all three decoding formats, indicating that it fits the training data well regardless of the decoding format. Second, replacing the context results in approximately a 20% performance drop for STAIR-2c1t, while UNI-2c1t shows only negligible degradation. These results suggest that, although UNI-2c1t is trained with contextual information, the learned representations become largely insensitive to context. Instead, the model appears to rely primarily on the source chunk itself when generating translations. This behavior may partially explain why jointly training all three data formats does not perform as well as other models.

### F.3 Training Cost

Regarding computational efficiency, the (SEP:) 0c1t, 1c1t, and 2c1t sub-models required 39h 48m, 37h 21m, and 36h 42m respectively on 8× H100 GPUs, totaling 113h 51m. In contrast, the UNI-2c1t model required 119h 35m under the same hardware configuration. Given its shorter total training time and the capacity for simultaneous parallel training of its sub-models, the SEP approach

(a) Results on IWSLT2017 en-xx.

(b) Results on IWSLT2017 xx-en.

Figure 10: Results of Source-Only Context v.s. Source-MT Context on the IWSLT2017 dataset. "RT" denotes runtime. The marker size is directly proportional to the decoding speed and inversely proportional to the runtime.

can offer a higher degree of training efficiency.

## G Source-Only v.s. Source-MT Context

### G.1 Translation Quality–Efficiency Trade-off

We employ the same FRC dataset that was constructed previously. However, we introduce reference translations into the context parts of the 1c1t and 2c1t data, naming these augmented formats as $1c^{+}1t$ and $2c^{+}1t$. Notably, due to cross-lingual differences in lexical representation, appending target-language text to the context precludes a unified input-side length distribution. As a result, the length distribution transitions to a language-wise paradigm.

The results are presented in Figure 10. Utilizing the TOWER-based model, we evaluated the two strategies in terms of accuracy, term consistency, and efficiency across various hardware configurations on the IWSLT2017 dataset. However, it is worth noting that, although the hyperparameter configurations remained strictly consistent for the comparative experiments conducted across different GPUs, we cannot guarantee completely identical execution environments. Specifically, the H100 trials were deployed on an AArch64 architecture, whereas the A100 and V100 experiments were executed on an x86-64 architecture. We utilize the total runtime (RT) required to execute the complete decoding script as the primary metric for evaluating decoding efficiency.

As a consistent trend across all three hardware environments, under the $2c^{(+)}$ configuration, incorporating previous translations naturally yields superior terminological consistency (Choudhary et al., 2025), alongside marginally higher d-BLEU scores in the IWSLT2017 en-xx direction compared to the Source-Only method. Conversely, the Source-Only approach exhibits a highly significant edge in decoding efficiency, paired with a distinct accuracy advantage in the xx-en direction. Specifically, the decoding latency under the Source-MT context is, on average, approximately 2.5 that of the Source-Only baseline. This efficiency gap is readily apparent even on high-speed GPUs such as the H100, and becomes especially pronounced on comparatively slower hardware like the V100. This is because leveraging previous translations as context inherently requires strictly sequential decoding, in contrast to the Source-Only approach, which permits all chunks to be preprocessed and decoded in parallel. Given that document-level machine translation is fundamentally a long-sequence generation task, decoding efficiency remains an indispensable consideration for practical, real-world deployment.

To further evaluate the translation quality of both approaches, we conducted comprehensive experiments across all datasets using a single H100 GPU for inference. The results are summarized in Table 15. In terms of LTCR metric, the $1c^{+}1t$ configuration demonstrates comprehensive superiority. This advantage is particularly pronounced on the BWB dataset, where it approaches the peak performance of the STAIR-FS4 method (achieved under the Source-Only setting) and surpasses large-scale LLMs (see Figure 2). Given the characteristics of the BWB dataset's web novel domain, domain-specific terminology (e.g., character names) likely appears at a higher frequency than in other evaluated domains. Consequently, incorporating the previous translation as context yields the most sub-

| Dataset | Lang | d-BLEU ↑ | | | | | | LTCR ↑ | | | | | | NRR (%) ↓ | | | | | |

Table 15: Comparison among 1c1t, $1c^+1t$, 2c1t, and $2c^+1t$ across datasets. "Base" and "$c^+$" represent 1c1t and $1c^+1t$, respectively. $\Delta_1$ denotes $1c^+1t - 1c1t$, and $\Delta_2$ denotes $2c^+1t - 2c1t$. The better result for each metric on each dataset in the comparison is highlighted in bold.

stantial improvement in terminological consistency. However, regarding translation accuracy measured by d-BLEU, the Source-Only approach maintains the advantage in the majority of cases. This performance is strongly negatively correlated with the NRR; a lower NRR indicates a more stable generation output.

### G.2 Exposure Bias: A Case Study

Furthermore, for the $c^+$ strategy, conditioning on previous translations is vulnerable to exposure bias and error propagation (Wu et al., 2018; Arora et al., 2022): a suboptimal translation used as context can lead to cascading deterioration in the quality of subsequent chunk translations within the same document (Mino et al., 2020; Zhang et al., 2021). To illustrate this point, we provide a concise analytical overview alongside a qualitative case study. We define "broken chunks" as outputs with log probabilities (lp) below $-5$, and "repetition chunks" that contain n-gram repetitions. The distribution of these broken chunks across various languages under the $1c^+1t$ setting on the IWSLT2017 en-xx data is presented in Table 16. Notably, the number of repetition chunks exceeds that of broken chunks. This discrepancy arises because, in some instances, the repetition initiates near the tail end of the chunk. Consequently, the overall log probabilities for the chunk may not drop below the $-5$ threshold (typically hovering between $-3$ and $-5$). Importantly, these specific chunks frequently act as the initial trigger for cascading deterioration, as illustrated in Figure 11.

We categorize the model's capacity to return to standard output following a generation collapse into three distinct groups: Full Recovery indicates complete restoration after a brief degradation; Partial Recovery denotes a return to normal generation but with a sustained drop in output quality; and Failed to Recover signifies a continuous collapse until the end. In our analysis, we identified a total of 22 repetition chunks. Excluding those

| Lang | Chunks | Broken | Repetition | Mean Log-Prob |
|---|---|---|---|---|
| ko | 519 | 8 | 13 | -3.496 |
| zh | 520 | 9 | 7 | -3.354 |
| de | 460 | 1 | 2 | -0.349 |
| fr | 521 | 0 | 0 | -0.234 |
| it | 92 | 0 | 0 | -0.238 |
| nl | 94 | 0 | 0 | -0.285 |

Table 16: Distribution of broken and repetition chunks across languages on the IWSLT en-xx dataset (TOWER-based SEP-$1c^+1t$ model.

situated at the end of a document, 19 chunks remained. Strikingly, only two of them (the specific instances detailed in our case study) managed to recover when conditioned on a degraded translation context. This yields an error propagation rate of 89% (17/19), demonstrating that a mid-translation quality collapse is highly likely to trigger a subsequent cascading failure. In contrast to the independent decoding mechanism of the Source-Only context approach, this susceptibility to error propagation represents a critical latent issue that must be addressed when utilizing previous target translations as context.

## H Test-Time Chunking

### H.1 Length Analysis at Test Time

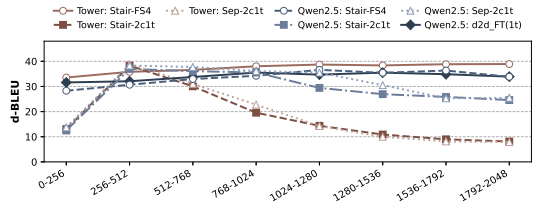
As shown in Figure 12, we perform a two-type length-centric analysis. First, we investigate test-time performance across varying FRC length intervals. Second, we increase test data lengths by concatenating adjacent chapters from the same book in the BWB dataset until full books are formed. Evaluation is conducted at the book level by concatenating all translated chapters for each of the six books.

For the STAIR-FS4 and D2DFT, d-BLEU scales positively as the FRC increases. However, when the length of the test data itself exceeds a certain threshold, performance begins to degrade. This indicates that while both models generalize effectively within their operational range, their capacity

**Error Propagation and Recovery Across Chunks**

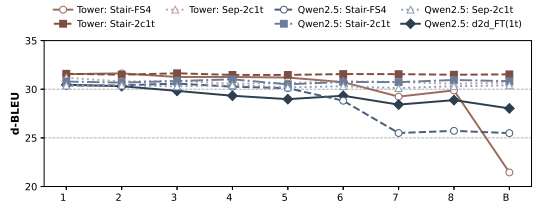
**En → Ko ($n = 6$ chunks)** *Status: Partial Recovery*

| Chunk No. | Log-Prob | State | Description |
|---|---|---|---|
| 0, 1 | $\approx -0.71$ | Normal | Standard Korean output. |
| 2 | $-3.43$ | Trigger | **[REP]** Initial repetition trigger. |
| 3 | $-368.97$ | Broken | Severely collapsed: "의 의 의 의 …" |
| 4, 5 | $-1.08 \pm 0.3$ | Recovered | Returns to normal flow. |



**En → Zh ($n = 11$ chunks)** *Status: Failed to Recover*

| Chunk No. | Log-Prob | State | Description |
|---|---|---|---|
| 0, 1 | $\approx -1.00$ | Normal | Standard Chinese output. |
| 2 | $-6.63$ | Trigger | **[REP]** Initial repetition trigger. |
| 3 | $-518.00$ | Broken | Deep failure: "计 计 计 计 …" |
| $4 \sim 10$ | $-32 \sim -212$ | Persistent | Never recovers; remains in error state. |



**En → De ($n = 7$ chunks)** *Status: Full Recovery*

| Chunk No. | Log-Prob | State | Description |
|---|---|---|---|
| 0 | $-1.48$ | Trigger | **[REP]** Early trigger. |
| 1 | $-36.54$ | Broken | Broken; inherits errors from No.0 Chunk. |
| $2 \sim 6$ | $\approx -0.25$ | Full Rec. | Rapid and stable recovery. |

Figure 11: A Case Study: Potential Exposure issues in the Source-MT Context Setting.

(a) d-BLEU results on IWSLT2017 en–xx with increasing FRC length intervals.

(b) d-BLEU results on BWB zh–en under progressive connection of adjacent chapters.

Figure 12: Test-time analysis of length variation.

is strictly bounded by the training data distribution.

Both the STAIR-2c1t and SEP-2c1t models achieve peak accuracy only when the test FRC aligns with the training range ($[256, 512]$). Meanwhile, TOWER-based models exhibit higher sensitivity to FRC than QWEN2.5-based models. In summary, as long as the FRC is set to match the training configuration, variations in test data length have little impact on their performance.

## H.2 Impact of Unit Selection on FRC

Beyond the baseline approach based on line breaks, we also adopt embedding-based semantic chunking and Meta-chunking (Zhao et al., 2025). For the former, we use the mE5-large model (Wang et al., 2024a) to compute embeddings for all sentences, measure the similarity between each pair of adjacent sentences, and retain only the top 20% of connection points with the highest similarity. For the latter, we directly employ the Meta-chunking method, which identifies appropriate breakpoints based on perplexity, using the original TOWER-7B-INSTRUCT-MISTRAL model for perplexity (PPL) computation. These generated units are subsequently used to construct fixed-range chunks. The experimental results are summarized in Table 17.

Compared to the BWB and GlobVDoc datasets, unit selection induces significantly greater perturbations on IWSLT en-xx. This effect is predominantly detrimental to both STAIR models, whereas SEP-2c1t exhibits a slight improvement in d-BLEU. To elucidate the underlying causes, we further calculated the ds-BLEU scores, n-gram repetition rate (NRR), and the proportion of problematic document lengths within the inference results for these three models on IWSLT2017 en-xx, as shown in Table 18.

A comparison of the three models reveals that

| Method | Unit | IWSLT2017 | | BWB | | GlobVDoc | |
|---|---|---|---|---|---|---|---|
| | | d-B. | d-C. | d-B. | d-C. | d-B. | d-C. |
| STAIR-FS4 | line-break | 35.81 | 82.29 | 27.61 | 80.56 | 41.96 | 88.31 |
| | emb-sim | -0.08 | **-0.33** | -0.13 | -0.05 | -0.07 | +0.01 |
| | meta-ppl | **-0.65** | **-0.35** | -0.17 | -0.13 | **+0.31** | +0.01 |
| STAIR-2c1t | line-break | 38.29 | 84.14 | 27.53 | 81.10 | 42.06 | 89.35 |
| | emb-sim | -0.09 | **-0.85** | **+0.30** | +0.11 | +0.07 | -0.01 |
| | meta-ppl | **+0.33** | **-0.59** | -0.12 | +0.09 | -0.08 | +0.02 |
| SEP-2c1t | line-break | 38.78 | 84.80 | 26.82 | 81.03 | 41.98 | 89.26 |
| | emb-sim | **+0.44** | -0.02 | +0.14 | -0.08 | +0.05 | +0.01 |
| | meta-ppl | **+0.56** | +0.04 | +0.01 | -0.10 | -0.10 | +0.06 |

Table 17: The results obtained with different compositions of FRC units. The translation directions for the three datasets are IWSLT2017 en-xx, BWB zh-en, and GlobVDoc en-xx. Increases and decreases are calculated relative to the "line-break" within each respective model. Significant changes in performance are emphasized in **bold**. All the three models are TOWER-based.

| Method | Unit | IWSLT2017 | | |
|---|---|---|---|---|
| | | ds-B. | NRR↓ | Prop.↓ |
| STAIR-FS4 | line-break | 35.32 | 9.89% | 28.25 % |
| | emb-sim | 35.22 | 10.70% | 28.62 % |
| | meta-ppl | 34.41 | 14.17% | 36.94 % |
| STAIR-2c1t | line-break | 36.40 | 9.09% | 16.37% |
| | emb-sim | 36.33 | 10.43% | 18.79% |
| | meta-ppl | 36.67 | 8.02% | 14.16% |
| SEP-2c1t | line-break | 37.54 | 1.87% | 4.56% |
| | emb-sim | 37.53 | 1.60% | 3.45% |
| | meta-ppl | 37.57 | 1.87% | 4.03% |

Table 18: Further investigation and analysis of unit selecetion results for IWSLT en-xx. NRR denotes the n-gram repetition rate, and Prop. represents the proportion of problematic document lengths.

SEP-2c1t exhibits the most stable decoding performance, characterized by the lowest NRR. In addition, this stability remains largely invariant to the FRC unit selection strategy. In contrast, both STAIR models demonstrate clear volatility in decoding results when unit configurations are varied. According to the findings of Jin et al. (2024), n-gram repetition tends to emerge when the input sequence length exceeds 1k tokens. However, while the inputs for SEP-2c1t (including context) typically surpass this 1k threshold, they exhibit a relatively low NRR. In contrast, STAIR-2c1t shows obviously higher NRR levels. This discrepancy can likely be attributed to the training phase: (SEP)-2c1t was trained on a single length distribution, whereas STAIR-2c1t was exposed to three. In addition, STAIR-FS4 incorporated even greater distributional diversity, with input lengths substantially exceeding those of the other two models.

Comparing the results in Table 17 and Table 18

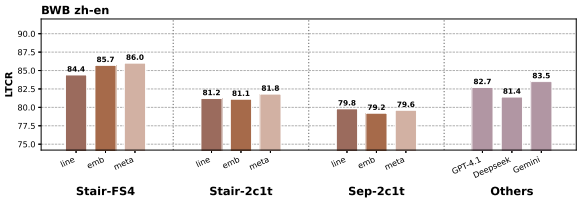


Figure 13: LTCR results of different unit selections across three models on BWB zh-en.

indicates that increases in NRR and the proportion of problematic document lengths correlate strongly with declines in d-BLEU and vise versa. While the NRR for SEP-2c1t remains relatively consistent across configurations, its d-BLEU improvements appear more salient because the other two strategies yield a smaller proportion of problematic document lengths compared to the line-break baseline. However, this trend is less pronounced in ds-BLEU, which utilizes averaged weights. The negligible variations in d-BLEU observed for the three models on the BWB and GlobVDoc datasets can be attributed to the fact that their NRR remains consistently at zero across all three unit selection settings.

In summary, utilizing various unit configurations for FRC fails to provide a stable boost in global accuracy. One explanation is that the structural significance of the units becomes generalized during the formation of fixed-range chunks. Additionally, d-BLEU and d-COMET may be insensitive to improvements in discourse coherence within each unit. Consequently, we conducted an LTCR analysis on the in-domain BWB dataset (NRR=0) to better differentiate the three methods. The results are presented in Figure 13.

Regarding STAIR-FS4 and STAIR-2c1t, the Meta-chunking approach yields marginal improvements (+1.6 and +0.6, respectively). Both unit strategies provide relatively notable gains for STAIR-FS4, even surpassing the performance of Gemini-2.5-Pro. These findings suggest that strategic unit partitioning can effectively enhance overall terminological consistency to a certain extent.

## I Results of LoRA Fine-Tuning

Table 19 presents the results of the TOWER-based SEP-2c1t models under both full-parameter fine-tuning and LoRA fine-tuning. Although LoRA fine-tuning does not achieve the same performance as full-parameter fine-tuning, it still provides substantial improvements over the original model. In-

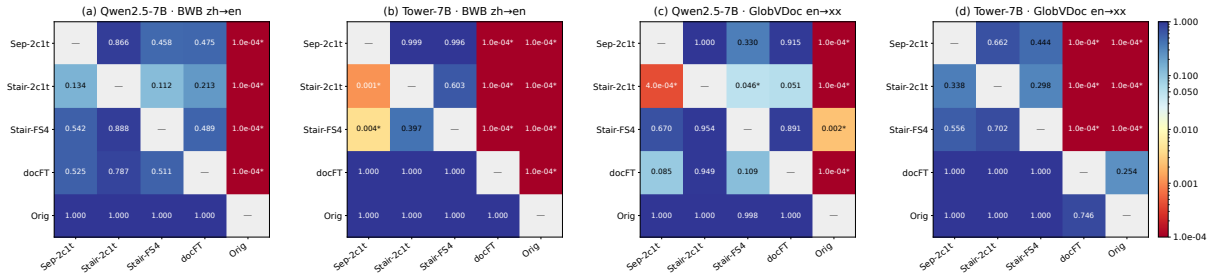

Figure 14: Pairwise one-sided significance tests on BWB zh-en and GlobVDoc en-xx for QWEN2.5-7B and TOWER-7B. Each cell reports the paired document-bootstrap p-value for the hypothesis that the row system outperforms the column system in d-BLEU. Asterisks indicate $p < 0.05$.

creasing the LoRA rank from $r = 16$ to $r = 64$ introduces a larger number of trainable parameters; however, the performance gains on the in-distribution test sets are relatively limited.

## J AI Assistance Usage

We used AI-assisted tools, including ChatGPT[15], Google Gemini[16], and Claude[17], to support code development and writing refinement (in accordance with ACL Policy on AI Writing Assistance).

**Gemba-DA**

Score the following translation from {src_lang} to {tgt_lang} with respect to human reference on a continuous scale 0 to 100 where score of zero means "no meaning preserved" and score of one hundred means "perfect meaning and grammar".

{src_lang} source: {src_text}
{tgt_lang} human reference: {ref_text}
{tgt_lang} machine translation: {tgt_text}

Without any thinking, output only JSON in the following format: {"score": <int>}

## L Algorithm

**Algorithm 1:** Dual-Boundary Matching based Chunk Alignment

**Input :** Source chunks $\mathcal{C}$, Target units $\mathcal{T}$, $\lambda$, $\sigma$, Initial $k$, $\Delta k$

**Output :** Aligned lower bound indices $J = \{j_1, \ldots, j_{|\mathcal{C}|}\}$, $j \in \{1, .., |\mathcal{T}|\}$

**Function** $\texttt{SimwRP}(u, v)$**:**
  $s \leftarrow \text{Sim}(u, v)$;
  $w \leftarrow \exp\left(-\left(\frac{\text{rp}(u)-\text{rp}(v)}{\sigma}\right)^2\right)$;
  **return** $s \times ((1-\lambda) + \lambda w)$;

Initialize score matrix $\Phi \in \mathbb{R}^{|\mathcal{C}|\times|\mathcal{T}|}$;
**while** $J = \emptyset$ **do**
  **for** $i \leftarrow 1$ **to** $|\mathcal{C}|$ **do**
    **for** $j \leftarrow 1$ **to** $|\mathcal{T}|$ **do**
      $\Phi[i, j] \leftarrow \texttt{SimwRP}(c_i^{\text{end}}, t_j)$;
      Find top-$k$ candidates $\{j_{i,1}, ..., j_{i,k}\}$;
      **for** $r \leftarrow 1$ **to** $k$ **do**
        $\Phi[i, j] \leftarrow \Phi[i, j] + \texttt{SimwRP}(c_{i+1}^{\text{first}}, t_{j_{i,r}+1})$;
  Find $j_1, \ldots, j_{|\mathcal{C}|}$ maximizing $\sum \Phi[i, j_i]$;
    subject to $j_{i-1} \leq j_i$ (Monotonicity);
    and $j_{|\mathcal{C}|} = |\mathcal{T}|$ (Boundary Condition);
**if** $J = \emptyset$ **then** $k \leftarrow \min(k + \Delta k, |\mathcal{T}|)$;
**return** $J$ ***or*** *Failure*

**Algorithm 2:** Two-Stage Dynamic Programming Algorithm for Fixed-Range Chunking

**Input:** Source units $S = \{s_1, s_2, \ldots, s_n\}$;
Target length $L^* = (m + M)/2$ derived from $[m, M]$;
Separator cost $\delta$;
Max allowed violations $K$.
**Output:** Packed segments $\mathcal{P}$.

Calculate $|s_i|$ for all $s_i \in S$;
Initialize $\mathcal{P} \leftarrow \emptyset$;
`/* Pre-processing: Isolate super-long sentences */`
Divide $S$ into blocks $\{B_1, B_2, \ldots\}$ by splitting at any $s_i$ where $|s_i| > M$;
**foreach** *block* $B \in \{B_1, B_2, \ldots\}$ *with units* $u_1 \ldots u_T$ **do**
  **if** $|B| = 1$ ***and*** $|u_1| > M$ **then**
    Add $\{u_1\}$ to $\mathcal{P}$; **continue**;
  `/* Define length function with separator cost */`
  Let $Len(i, j) = \sum_{k=i}^{j} |u_k| + (j - i) \cdot \delta$;
  `/* Stage 1: Strict Constraint DP (Attempt to keep all segments ∈ [m, M]) */`
  Initialize $dp[0] \leftarrow 0$, $dp[1 \ldots T] \leftarrow \infty$;
  **for** $i \leftarrow 1$ **to** $T$ **do**
    **for** $j \leftarrow i - 1$ **to** $0$ **do**
      $l \leftarrow Len(j + 1, i)$;
      **if** $m \leq l \leq M$ **then**
        $dp[i] \leftarrow \min(dp[i], dp[j] + (l - L^*)^2)$;
  **if** $dp[T] < \infty$ **then**
    Backtrack $dp$ to recover partition, add to $\mathcal{P}$;
  **else**
    `/* Stage 2: Relaxed DP with Violated Segment Constraints */`
    Let $dp_{rel}[v][i]$ be min cost for first $i$ units with $v$ violations;
    Initialize $dp_{rel}[0 \ldots K][0] \leftarrow 0$, others $\infty$;
    **for** $i \leftarrow 1$ **to** $T$ **do**
      **for** $j \leftarrow i - 1$ **to** $0$ **do**
        $l \leftarrow Len(j + 1, i)$;
        **if** $m \leq l \leq M$ **then**
          **for** $v \leftarrow 0$ **to** $K$ **do**
            $dp_{rel}[v][i] \leftarrow \min(dp_{rel}[v][i], dp_{rel}[v][j] + (l - L^*)^2)$;
        **else**
          $C_{out} \leftarrow (m - l)^2$ if $l < m$ else $(l - M)^2$;
          **for** $v \leftarrow 1$ **to** $K$ **do**
            $dp_{rel}[v][i] \leftarrow \min(dp_{rel}[v][i], dp_{rel}[v - 1][j] + C_{out})$;
    Find $v^*$ minimizing $dp_{rel}[v][T]$ for $v \in [1, K]$;
    Backtrack $dp_{rel}[v^*]$ to recover partition, add to $\mathcal{P}$;
**return** $\mathcal{P}$ *ordered by original unit indices*;

## Abstract

Unlike many other texts, literary works are often translated multiple times. We investigate strategies for leveraging these multi-reference datasets to improve literary machine translation. We propose a filtering framework based on semantic similarity to identify source texts whose references display meaningful variation while remaining faithful. We find that fine-tuning with medium to high semantic similarity data substantially outperforms low semantic similarity data. Moreover, using medium and high semantic similarity data achieves comparable or better performance than using the full unfiltered data.

Synthetic translations generated by LLMs are economical and convenient alternatives to human expert translations; however, we find fine-tuning on human expert translations outperforms fine-tuning on synthetically augmented data in automatic metrics and human evaluations, demonstrating the indispensable value of human expert translations for fine-tuning literary machine translation models.

## 1 Introduction

Literary translation presents unique challenges for machine translation (MT). Literary works are deeply embedded in the source language and culture; therefore, it can be difficult to reproduce the same meaning while preserving cultural context and stylistic nuance in another language. Moreover, literary translations are meant to be read. Fully explicating all interpretations would require substantial annotation or commentary (e.g., in footnotes)—what Nabokov memorably called "translations with copious footnotes reaching up like skyscrapers" (Nabokov, 1955)—and reduce readability.

As such, literary translators must balance multiple aspects of a source text when translating: meaning, form, rhyme, style, and cultural context (Jakobson, 1987; Lefevere, 1992; Hofstadter, 1997). Some emphasize lexical and syntactic imitation (formal equivalence), while others sacrifice form for comprehensibility (dynamic/functional equivalence) (Nida, 1964). Read together, different translations of the same source text collectively provide diverse interpretations and a richer understanding of the original work. For example, in Figure 1, the three translations vary in style and word choice, yet together they reveal not only the meaning and literary style of the French text, but also some of its etymological associations: trans-

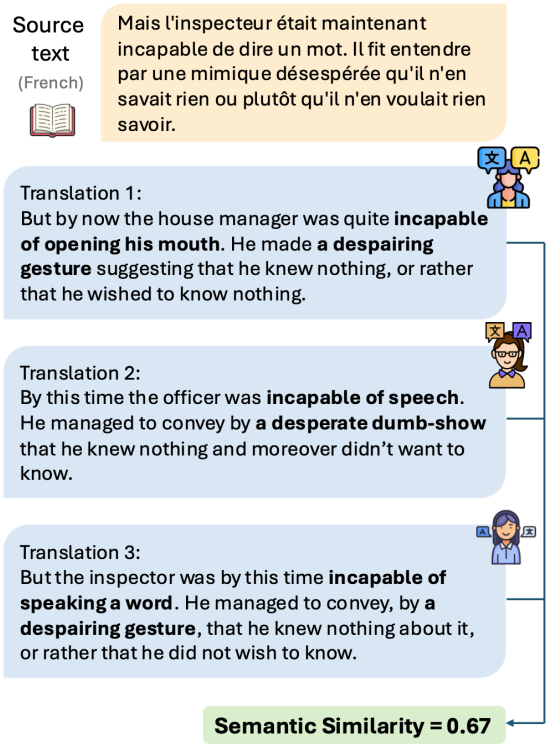

Figure 1: An example of semantic variation across human translations of the same source text. We analyze a paragraph from *Le Fantôme de l'Opéra* (*The Phantom of the Opera*) by Gaston Leroux. The original French paragraph was translated into English by three different literary translators. Using our proposed scoring system SEMSIM, the average pairwise semantic similarity across the English translations is 0.67.

*Proceedings of the Eleventh Conference on Machine Translation*, pages 818–841
October 28-29, 2026 ©2026 Association for Computational Linguistics

lation 2's "dumb-show" draws out the theatrical associations of the French word *mimique*, which is related to mime and gesture-based expression.

Prior work has explored methods to synthetically generate additional references for a source text via back-translation or paraphrasing (Madnani et al., 2008; Zheng et al., 2018; Khayrallah et al., 2020). However, these works are conducted within non-literary domains such as news, and the text is usually at sentence-level. News and literary texts differ fundamentally in purpose and style: news is generally written to be factual, direct, and unambiguous, whereas literary writing is sometimes intentionally open to interpretation, with authors using devices such as metaphor, imagery, symbolism, rhythm, and rhyme. Due to the very nature of literary text, scholars and readers in comparative literature and translation studies often compare multiple translations of a source text to deepen their understanding of the original and of how its meanings are rendered across languages (Rose, 1997; Stenberg, 2018; Szymanska, 2026).

Moreover, well-known literary works often have multiple translations, particularly in high-resource language pairs. It is reasonable to leverage the wealth of expert-produced translations that are already available. However, the question is how to effectively utilize them when training or fine-tuning an MT system. Additionally, it's worth investigating the performance gap between models trained on expert translations and those trained on synthetic paraphrases. Synthetic alternatives are more economical and may be particularly beneficial to low-resource languages where parallel data are scarce (Khayrallah et al., 2020; de Gibert et al., 2025).

In this paper, we investigate how to leverage multiple references for literary translation. Specifically, we propose a filtering approach based on semantic similarity scores: selecting source texts whose reference translations collectively preserve semantic fidelity while exhibiting meaningful lexical and syntactic variation, as measured by pairwise semantic similarity scores.

This paper examines three hypotheses:

**H1. Different ranges of semantic similarity will lead to different performance:** High and medium SEMSIM lead to substantially better translation than low SEMSIM. (Section 6)

**H2. A filtered dataset is better for fine-tuning literary MT than an unfiltered dataset:** Combining high and medium SEMSIM data achieves MT performance comparable or better than unfiltered dataset. (Section 7)

**H3. A synthetic-augmented multi-reference dataset will perform comparably to an expert-translated dataset:** Synthetic augmented dataset does not improve MT performance as reliably as human expert-translated multi-reference data and can underperform an unaugmented single-reference dataset, depending on the fine-tuning models used for augmentation. (Section 8)

For all the hypotheses, we compare performance measured by automatic metrics and evaluations from human translators. We also present zero-shot MT results from commercial and open-weight instruction-tuned models in Appendix D, and provide example outputs in Appendix I.

## 2 Related work

Literary machine translation is known to be a challenging task (Taivalkoski-Shilov, 2019; Brusasco, 2022; Corpas Pastor and Noriega-Santiáñez, 2024). Unlike news and academic writing, literary language often deploys devices such as imagery, symbolism, metaphor, rhythm, and rhyme. Literary text is deeply embedded in its linguistic, cultural and historical contexts. Polysemy is one example: when multiple meanings of a word in the source text are intended to be evoked, but in the target language there is no word with the same one-to-many mapping, there is no direct translation. In this situation, a translator will have to decide what to prioritize in a translation. As such, to deepen their understanding of the linguistic and cultural nuance of the source text, scholars in comparative literature and translation studies often compare multiple translations (Rose, 1997; Stenberg, 2018; Szymanska, 2026).

In machine translation, the idea of using multiple target translations of a source text to improve understanding of the source-target language pair has long been explored in various ways. Much of this work is through synthetically creating new target texts: from using pivot-based paraphrasers (Callison-Burch et al., 2006; Madnani et al., 2008), to back-translation in statistical and neural machine translation (Sennrich et al., 2016; Poncelas et al., 2018; Edunov et al., 2018). More recently, LLMs have been used for synthetic data generation in many different tasks (Long et al., 2024), and LLMs' ability to generate high-quality text is particularly

beneficial in low-resource settings (Scalvini et al., 2025; de Gibert et al., 2025). Although LLMs have improved the quality and complexity of paraphrase generation, they still make mistakes, particularly for outputs longer than a single sentence (Jayawardena and Yapa, 2024a,b; Su et al., 2022; Horvitz et al., 2024; Mishra et al., 2024). Most prior work focuses on non-literary domains and primarily at sentence-level.

Many have explored employing post-editing to improve literary MT (Besacier and Schwartz, 2015; Thai et al., 2022; Castaldo et al., 2025). While some have looked into fine-tuning methods for the literary MT task (Li et al., 2024; Mikelenić et al., 2025), we are unaware of work on how to optimally fine-tune MT model for the literary domain, particularly with multiple translations per source text. Moreover, no prior work has directly compared the effects of fine-tuning on human data vs. synthetic data for literary MT.

Finally, our filtering criterion differs from the general notion of "noise" in MT: we filter based on semantic similarity of target texts of the same source text, not the mismatches or semantic divergence between source and target. Nevertheless, prior work on data filtering shows that training data quality matters for MT performance (Carpuat et al., 2017; Khayrallah and Koehn, 2018; Briakou and Carpuat, 2021; Steingrímsson et al., 2023).

## 3 Experimental setup

We describe the models we use for MT and automatic metrics we use in Section 3.2, and the details of pre-processing steps in Appendix A. We discuss each hypothesis and its results using the multi-reference datasets produced from the preprocessing step in Sections 6 to 8.

### 3.1 Literary Translation Data

Popular works of world literature are often translated into English by multiple translators, and these translations can differ stylistically while remaining faithful to the original text. The Par3 dataset aligns multiple English translations of each non-English book at the paragraph level: each source paragraph has at least two distinct English translations produced by expert literary translators (Thai et al., 2022). Translating literature at paragraph-level instead of sentence-level incorporates more discourse features and has been proven to improve literary MT (Voigt and Jurafsky, 2012). Although Par3 covers 19 source languages, we conduct experiments only on the French-English and Russian-English language pairs, which account for 48% and 32% of the total source paragraphs, respectively. Although both language pairs exhibit similar trends in automatic metrics, our discussion in Sections 6 to 8 will mainly focus on French-English, since we only conducted human evaluations on this language pair.

### 3.2 Models and Automatic Metrics

We fine-tune three models for the literary machine translation task: mT5-Large (Xue et al., 2021), Gemma3-12B-PT (Team et al., 2025), and OpusMT (Tiedemann et al., 2023; Tiedemann and Thottingal, 2020), and we use BLEU as the early-stopping criterion for all models. Detailed model descriptions, training details, and the descriptions of automatic metrics are in Appendix B.

## 4 Measuring Semantic Similarity Among References of the Same Source Text

Intuitively, reference translations of the same source text should be semantically similar but not identical: if two references' semantic similarity is too high, the meaning of the two would be nearly identical, and the additional reference would provide little new learning signal; conversely, if the semantic similarity is too low, the discrepancy may indicate noise, such as source–target misalignment or overly divergent translator interpretations.

We measure semantic similarity between reference translations of the same source text using SEMSIM. This similarity score allows us to quantify the variations among different references in lexical choice or syntactic structure while expressing the same underlying meaning.

SEMSIM utilizes a semantic similarity scoring model PARAGRAM-SP (Wieting et al., 2022). PARAGRAM-SP score ranges from -1 to 1, where a lower score indicates low semantic similarity, and a higher score indicates high semantic similarity. A model similar to this one from Wieting et al. (2019b) was successfully used as a semantic similarity reward in minimum risk training for neural machine translation (Wieting et al., 2019a), building on prior minimum risk training methods for MT (Smith and Eisner, 2006; Shen et al., 2016). Since PARAGRAM-SP can only score the semantic similarity for two texts, with more than two translations, we take the average pairwise PARAGRAM-SP score as the source text's SEMSIM. Mathematically:

$$\textsc{SemSim}\ (s) = \frac{1}{|C|} \sum_{(a,b)\in C} \textsc{Paragram-SP}(a, b)$$

where $M$ is the set of human translations given a source text $s$, and $C$ is all possible combinations of a set of pairs in $M$. PARAGRAM-SP $(a, b)$ is the PARAGRAM-SP score given a pair of English translations $a$ and $b$.

Note that PARAGRAM-SP computes similarity over embeddings and does not explicitly penalize length. There is an implicit effect only insofar as a reference that omits or heavily alters content will differ in embedding space and score lower, but length alone is not the driver.

We compute SEMSIM for each source text and use these scores to filter and create new datasets. Notice that SEMSIM is computed only with a source text's English translations without relying on the source text itself.

We assume source-target alignment is verified during preprocessing, e.g., Par3 verified source-target alignment. The alignment method used in preprocessing is itself an active research area, but we believe the proposed SEMSIM score helps further filter out misaligned examples regardless of which alignment method is used beforehand. Our filtering therefore targets stylistic and semantic divergence among references that are already aligned to the source: a translation can be faithful yet very different in style.

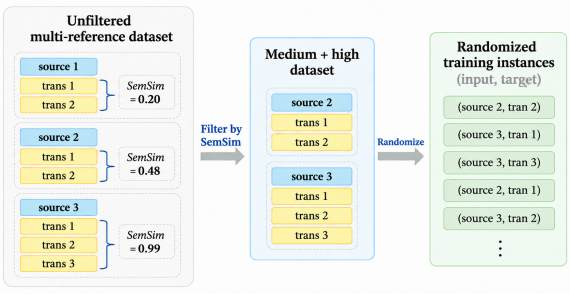

Figure 2: The pipeline of creating the medium+high semantic similarity dataset from the unfiltered dataset. SEMSIM measures the semantic similarity among a source text's target translations.

## 5 Human Evaluation

To better understand and characterize the outputs from the different systems, we conducted a human evaluation using pairwise A/B comparisons. We recruited 48 translators from North America, Europe, and Africa, through Upwork[1] and ProZ[2].

The translators are native speakers of either French or English and fluent in the other language, and most have prior experience translating literary texts. All evaluations were completed using Label Studio[3]. The translators were paid at the rate of 40 USD for approximately one hour of active annotation time, which is consistent with similar translation rates on Upwork and ProZ.

In each evaluation task, translators were presented with 30 questions. Each question contained a source text in French and two English translations. They were then asked to choose which translation they preferred (A or B). If they considered the two translations to be equally good or bad, they could select "tied". Then the translators were asked to provide a brief justification for their choice.

Detailed annotation instructions, along with an example evaluation question, are provided in Appendix H. We discuss human evaluation results comparing different models in the following sections, alongside automatic evaluation results.

## 6 Hypothesis 1: Different ranges of semantic similarity will lead to different performance.

We compute the SEMSIM score for the reference translations for each source text, and divide the source texts into three groups based on their SEMSIM scores: [-1, 0.45) is *Low*, [0.45,0.85) is *Medium*, and [0.85, 1] is *High*. We summarize the linguistic characteristics of each range in Table 11.

Each SEMSIM range is then used to fine-tune three different models described in Section 3.2 for literary machine translation. For a fair comparison, we keep the total number of training instances (#INSTN) the same, and total number of source texts (#SRC) as close as possible, and this isolates SEMSIM as the only changing variable. We run each model with three different seeds. Table 1 reports the mean and standard deviation for each automatic metric described in Appendix B.2.

Across models, metrics, and language pairs, fine-tuning on high SEMSIM data on average gives the best performance, followed by medium then low SEMSIM data. However, the performance gap be-

Table 1: Automatic metric results for mT5, Gemma, and OpusMT after fine-tuning on datasets with different semantic similarity (SEMSIM) levels: low, medium, and high. The top table uses the French-English language pair, and the bottom table uses Russian-English. To fairly evaluate the effect of SEMSIM on literary MT performance, the datasets contain the same number of training instances (#INSTN), and similar number of source sentences (#SRC). We report the mean and standard deviation across three different seeds. Medium and high SEMSIM produce comparable performance and both substantially outperform low SEMSIM.

| Setting | Preferred A | Preferred B | Tied |
|---|---|---|---|
| high vs. low | 75.8 | 10.8 | 13.3 |
| high vs. med | 48.7 | 20.2 | 31.1 |
| med vs. low | 64.2 | 12.5 | 23.3 |

Table 2: Human annotators' vote percentages from A/B testing of outputs produced by mT5-large fine-tuned on datasets with different SEMSIM levels: high, medium, and low. Annotators strongly prefer high and medium SEMSIM outputs over low SEMSIM outputs.

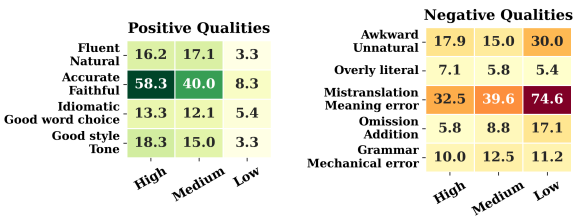

Figure 3: Frequency (%) of translation quality attributes mentioned in annotator comments. Each cell represents the percentage of comments where annotators explicitly noted a positive or negative quality attribute for a given system. High and medium SEMSIM data produce translations that are more fluent, accurate, idiomatic, and have better style and fewer errors than low SEMSIM.

tween medium and high SEMSIM is much smaller than the gap between low and medium SEMSIM.

From low to medium, mT5 shows the most gains, with BLEU increasing by 15.2 (+77.9%), COMET by 0.08 (+12.7%), and chrF++ by 0.14 (+38.9%). Gemma and OpusMT also improve from low to medium, though with smaller relative gains.

In contrast, the performance difference between medium and high is much smaller for mT5 and OpusMT: BLEU changes by less than 1 ($\pm 1\%$), COMET by at most 0.01 ($\leq 1.4\%$), and chrF++ by 0.02 ($\leq 4.3\%$). On the other hand, fine-tuning using Gemma, the performance difference between medium and high is only slightly less than low to medium: BLEU +5.3 (20.9%), COMET +0.03 (4.3%), and chrF++ increases by 0.06 (13.6%).

These results suggest that medium and high SEMSIM data are substantially better for fine-tuning literary MT than low SEMSIM data.

To assess whether these automatic metric trends align with human judgments, we hired 12 professional translators to conduct a pairwise comparison among mT5 outputs generated by fine-tuning on low, medium, and high SEMSIM data.

Source texts were randomly selected. We created four survey variants, with each variant assigned to

three translators, so that each question was rated by three translators. No source text was repeated within a survey, across survey variants, or in any other experiment in this paper.

Table 2 summarizes translators' votes as percentages in the pairwise comparison study. Translators strongly preferred high and medium SEMSIM outputs over low SEMSIM outputs, with preference rates of 75.8% vs. 10.8%, and 64.2% vs. 12.5%, respectively. By contrast, the preference difference is smaller between high and medium SEMSIM, with translators preferring high over medium by 48.7% vs. 20.2%, and many more votes on "tied" (31.1%).

To understand the linguistic characteristics of the outputs, we classify translators' comments on these pairwise comparisons using Claude Opus 4.6 API and visualize them in Figure 3. For each comment, we identify any positive and negative qualities of the translation mentioned, and we report how frequently the outputs from a system were mentioned with this quality. We provide the prompt for classifying their votes using Claude in Appendix F.

Translators described high and medium SEMSIM outputs as comparably fluent, natural, idiomatic, with high SEMSIM as slightly better than medium SEMSIM in accuracy/faithfulness and style/tone, while low SEMSIM outputs were rarely associated with positive qualities.

Conversely, translators found low SEMSIM outputs to contain substantially more mistranslation, omission and/or addition, and to be more awkward and unnatural. Many negative qualities were mentioned nearly twice as often for low SEMSIM than medium and high SEMSIM. Other negative qualities, such as overly literal and grammatical errors, occurred much less often and at similar rates as medium and high SEMSIM.

Overall, the human evaluation suggests that the automatic metric trends are consistent with human judgments. In particular, using medium and high SEMSIM data instead of low SEMSIM data improves perceived accuracy, style, word choice, and fluency, and substantially reduces mistranslation.

## 7 Hypothesis 2: A filtered dataset will lead to better performance than an unfiltered dataset.

Hypothesis 1 shows that both medium and high SEMSIM data produce substantially better automatic metric and human evaluation results than low SEMSIM data, and the performance between medium and high SEMSIM is comparable. We therefore investigate whether medium and high SEMSIM examples should be combined in practical fine-tuning scenarios. Prior work has also found that, when data quality is comparable, increasing the amount of training data can generally improve model performance (Madnani et al., 2007, 2008).

Similar to Hypothesis 1, we fine-tune each model with three different random seeds and report the mean and standard deviation in Table 3. We compare medium+high data against the unfiltered dataset under two settings: using all available examples, and using controlled subsets with the same number of sources and instances. Although unfiltered (all) contains 14% more training instances than medium+high (all), medium+high (all) performs better across most models and metrics. In particular, mT5 improves from 42.8 to 44.3 BLEU, 0.74 to 0.75 COMET, and 0.55 to 0.56 chrF++; OpusMT improves from 33.6 to 35.2 BLEU while maintaining comparable COMET and chrF++. Gemma is the exception, where the two settings perform similarly.

We observe a similar pattern in the controlled comparison, where medium+low, medium+high, and unfiltered all have the same #SRC and #INSTN. To create medium+low and medium+high datasets, we keep #SRC and #INSTN fixed by using the full medium SEMSIM subset and sampling the same amounts of low and high SEMSIM data. Unfiltered is randomly sampled to match #SRC and #INSTN as well. Under this setting, medium+high performs best overall. Compared with medium+low, medium+high improves BLEU by 3.3 for mT5 and 2.3 for OpusMT, and 0.7 for Gemma, while also giving small improvements in chrF++. Compared with the size-matched unfiltered dataset, medium+high also gives higher BLEU for all three models, while COMET and chrF++ remain comparable or slightly better. These results suggest that adding low SEMSIM data does not provide the same benefit as adding high SEMSIM data, even when the total amount of training data is held constant.

Translators also judged the two systems to be very close, preferring unfiltered in 37.8%, medium+high in 36.1%, with 26.1% marked as ties. Notably, the tie rate is large relative to the preference rates for either system, suggesting that translators often found the two outputs comparable.

The analysis on positive and negative qual-

Table 3: The top section compares models fine-tuned on medium+low, medium+high, and unfiltered datasets, where all three datasets contain the same number of training instances and a similar number of source texts. The bottom section compares fine-tuning on the full unfiltered dataset with fine-tuning on the full medium+high SEMSIM subset. We report the mean and standard deviation across three different seeds. In both settings, medium+high SEMSIM gives comparable or better performance than unfiltered data.

| **Setting** | % | **BLEU** | **COMET** | **chrF++** |
|---|---|---|---|---|
| FT w/ unfiltered | 37.8 | 45.3 | 0.78 | 0.61 |
| FT w/ med+high all | 36.1 | 45.7 | 0.78 | 0.61 |
| Tied | 26.1 | - | - | - |

Table 4: Human annotators' vote percentages from A/B testing of outputs produced by mT5 fine-tuned on the full unfiltered and the full medium+high French-English datasets.

Figure 4: Frequency (%) of translation quality attributes mentioned in annotator comments. Annotators overall found the output from fine-tuning on the full unfiltered data and the full medium+high data to be comparable.

ities also shows a similarly mixed pattern: medium+high has a slight advantage in fluency, word choice/idiomatic, and style/tone, while unfiltered is described slightly more often as accurate. Interestingly, the positive and negative comments are almost contradictory: medium+high is more fluent/natural but also more awkward/unnatural, unfiltered is more accurate/faithful but also has more omission/addition.

Many translators also commented on the limitations of the setup. Translators noted that some translations are hard to decide which is better without even longer context such as the preceding or following sentence around a paragraph. This was especially true for abrupt paragraphs such as quotations, which are common in literary text. In such cases, some translators preferred a more literal translation to be safe, while others favored a more natural and idiomatic interpretation of the original text. A natural transition at the start of a paragraph can, in isolation, look like a mistranslation without more context, especially if a translator took creative liberties with the translation (artistic license).

Table 5: Performance comparison between human-only and synthetic-augmented training data. "Human multi ref" denotes training on the full medium and high SEMSIM data with multiple human references, whereas "Human single ref" uses the same source texts with one randomly selected human reference per source. "Synthetic (Gemma3)" denotes training data created by using instruction-tuned Gemma3 to create additional target texts. We report the mean and standard deviation across three different seeds. Synthetic-augmented training data underperform human multi-reference data, but synthetic references generated by a strong instruction-tuned model such as Gemma3 can improve MT performance over a single-reference dataset when fine-tuning using mT5 and OpusMT.

Translators also noted that character names were sometimes translated by both systems. While some translators considered this a serious flaw, others overlooked it.

Overall, the automatic metrics and human evaluation suggest that medium+high data is at least competitive with the unfiltered dataset, despite the unfiltered dataset containing 14% more training examples. The controlled comparison further shows that replacing high SEMSIM examples with low SEMSIM examples hurts performance, supporting the decision to exclude low SEMSIM data.

## 8 Hypothesis 3: A synthetic-augmented multi-reference dataset will perform comparably to an expert-translated dataset.

We investigate whether augmenting a single-reference dataset with synthetic references can achieve performance comparable to that of expert-translated multi-reference datasets.

Specifically, for each source text in medium+high, we randomly select one human translation and generate paraphrases of this translation using open-weight instruction-tuned LLMs. For all the multi-reference datasets, we keep the number of target texts per source text the same. We provide model details and the prompts we used for zero-shot paraphrase generation in Appendix C. We compare using these synthetic-augmented data against our overall best-performing model, which is fine-tuned on the full medium and high SEMSIM data.

We find that synthetic-augmented datasets provide minimal improvements over the single-reference dataset, or in some cases, even degrade the performance depending on the model used to generate the synthetic references (Table 5). The best model for generating synthetic references, Gemma3, increases BLEU by 0.6 when fine-tuning with mT5, and 1.6 with OpusMT, and improves COMET by 0.01 for both mT5 and OpusMT. However, none of the synthetic datasets improve performance when fine-tuned using Gemma.

| Setting | % | BLEU | COMET | chrF++ |
|---|---|---|---|---|
| **FT w/ human** | **50.4** | 45.1 | 0.79 | 0.60 |
| FT w/ human + synthetic | 32.1 | 41.0 | 0.75 | 0.56 |
| Tied | 17.5 | - | - | - |

Table 6: Human annotators' vote percentages from A/B testing of outputs produced by mT5 fine-tuned on the full medium and high SEMSIM data and the synthetically augmented data. Synthetic data is generated using instruction-tuned Gemma3. Annotators preferred outputs of the MT system fine-tuned on the human data instead of synthetically augmented data by 18%.

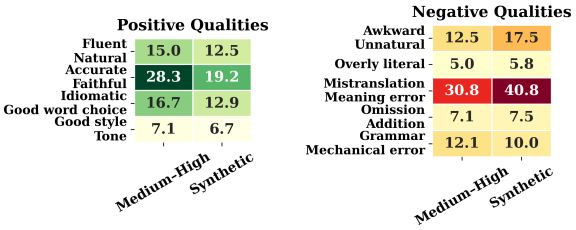

Figure 5: Frequency (%) of translation quality attributes mentioned in annotator comments. Translation outputs from model trained on human data (the full medium and high SEMSIM data) were found to be more accurate, idiomatic, and have less mistranslation than model trained on synthetically augmented data.

Moreover, none of the synthetic datasets outperform the medium+high multi-reference dataset under any model or metric. We further conduct a human evaluation comparing medium+high with the best synthetic-augmented dataset using mT5.

In Figure 8 in the appendix, we also compare the distribution of the pairwise PARAGRAM-SP scores between the ground-truth human translation and each generated synthetic translation. Compared to the PARAGRAM-SP scores between two human translations, the score between a human and a synthetic translation is on average lower across all models. The middle 50% of the distribution shifts down, as does the median. This means the SEMSIM of synthetically augmented data is lower overall.

Translators preferred translations from model fine-tuned on human data over synthetic-augmented data, with preference votes of 50.4% vs. 32.1%, and 17.5% tied.

Qualitative analysis on translators' comments further shows that expert-translated data leads to more accurate, idiomatic, and fluent translations.

Lastly, the human evaluation also includes comparisons between ground-truth expert translations and outputs from our best fine-tuned model.

Unsurprisingly, translators preferred human translations over machine translated text (55.4% vs. 31.3%). Human translations were judged to be substantially more fluent/natural (27.1% vs. 8.8%), more idiomatic (27.1% vs. 9.6%), and have much less mistranslation (12.1% vs. 34.6%).

| Setting | Percentage |
|---|---|
| human GT | 55.4 |
| FT w/ med+high all | 31.3 |
| Tied | 13.3 |

Table 7: Human annotators' vote percentages from A/B testing of outputs produced by mT5 fine-tuned on the full medium and high SEMSIM data (denoted as "FT w/ med+high all") and ground-truth human expert translations (denoted as "human GT").

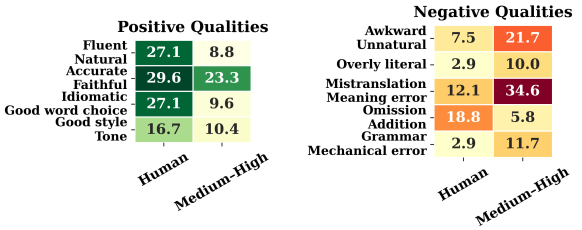

Figure 6: Ground-truth human expert translation were more fluent, idiomatic, and have better style, though more prone to omission and addition than our best MT system output.

Interestingly, translators found human translations more often involved omissions and additions (18.8% vs 5.8%), echoing the concerns raised in Hypothesis 2, where translators noted that some comparisons are difficult to judge without additional context. For example, if the name "Christine" appears in a previous paragraph, a human translator may use "she" in the following paragraph to refer to Christine, even if the original French text repeats "Christine" in that paragraph. In contrast, machine translated text is more likely to retain "Christine" in order to match the French source text.

## 9 Conclusion

Most MT fine-tuning work treats references as interchangeable ground truth, using a single reference per source or weighting all references equally, without considering whether the references agree with one another. In contrast, we use the semantic similarity among multiple references as a filtering signal—an idea motivated by the comparative-literature practice of reading multiple translations. To our knowledge, this is the first work to do so for literary MT.

We propose a framework for filtering a multi-reference dataset for literary MT, a setting where multiple translations of a source text often exist. Results from automatic metrics on both FR-EN and RU-EN show that high and medium semantic similarity data is better for fine-tuning MT systems than low semantic similarity data. Human evaluation confirms this: translators overwhelmingly prefer systems fine-tuned on high SEMSIM over low, and medium over low. When commenting on the outputs, translators rarely associate any positive qualities with low SEMSIM, while their assessments of high and medium are more comparable, with high SEMSIM holding a slight edge. Importantly, references with low semantic similarity among them are not merely misaligned or erroneous; they are also cases where translators diverge substantially in their interpretations.

We also find that while using more data generally improves performance, unfiltered data does not always help. Medium+high data can give comparable and at times better performance, all with less data. Human translators also found outputs from medium+high data more idiomatic and better in style, though overall performance is comparable to using unfiltered data. Translators also noted limitations of the setup that made comparison difficult: paragraphs were presented without preceding or following context, and translators differed in their own preferences, favoring more literal versus more natural, idiomatic interpretations.

We are not aware of any prior work that compares fine-tuning using human versus synthetic-augmented data for literary MT, particularly with human evaluation that examines the language of the output translations themselves. Comparing synthetic against human translations, we find that synthetic data, unlike human data, does not reliably improve MT. Performance depends heavily on the LLM used to paraphrase the ground-truth translation. For French-English, of the three LLMs we tested, only Gemma3 improved MT performance compared to using a single reference, and the improvement was small. For Russian-English, performance worsened, suggesting that paraphrase errors and deviation from the original translation act as noise. In other words, augmenting a dataset by zero-shot LLM paraphrasing of references can hurt MT performance. Interestingly, the best paraphrasing LLM also had, on average, a lower SEMSIM, while remaining mostly in the medium SEMSIM range (Figure 8).

This preference for human data is echoed in human evaluation: comparing outputs from models fine-tuned on human versus synthetic augmented data, translators preferred those trained on human data much more, finding them more accurate, better in word choice, and far less prone to mistranslation.

As a sanity check, we also compared the ground-truth translations with our best fine-tuned model (mT5 fine-tuned on all medium+high SEMSIM data), and translators preferred the ground truth at a rate similar to the earlier comparisons. While the ground-truth translations were most frequently credited with positive qualities, they were also, surprisingly, mentioned far more often for omission and addition. Considering how paragraphs flow, this makes sense: good flow often means being less literal, with translators moving content into the preceding or following paragraph.

Finally, we tested zero-shot translation (Appendix D). Compared to our best fine-tuned model (mT5 fine-tuned on all medium+high SEMSIM data), our model outperformed all open-weight models we tested. Among commercial models, two of three outperformed ours, one only marginally (44.8 vs. 44.3 in BLEU).

Meaningful human evaluation requires a sufficient amount of data, which limits us to high-resource language pairs, since low-quality output will also result in noisy human evaluation when errors are frequent and of many kinds. We hope our findings provide guidance for literary translation on both high- and low-resource language pairs: prioritize human translations, and if using synthetic LLM-based paraphrasing—even into a high-resource target language like English—choose the LLM carefully and inspect the paraphrased output, or performance may suffer.

Future work can compare LLM zero-shot paraphrasing with more controlled generation methods, such as pivot-based or neural approaches, especially for low-resource languages.

## Limitations

The following limitations of our paper are also directions for future work.

1. We create additional synthetic references only using LLMs in this paper. Future work can explore different methods for generating synthetic references and compare their performance. More controlled generation could po-

tentially prevent the overall semantic similarity shift demonstrated in Figure 8.

2. While we would have liked to work on low-resource languages in this paper, the premise of the paper relies on multi-reference data, which generally exists only for high-resource language pairs. Additionally, conducting human evaluation on low-quality translations in low-resource setting would be challenging. If the outputs are not adequate, it is difficult to obtain meaningful feedback from translators. However, we believe our findings can benefit future work on low-resource settings. Specifically, it is worth investigating whether filtering by semantic similarity between synthetic references can help improve low-resource MT.

3. Due to our computational constraints, we could not experiment with LLMs with even larger numbers of parameters. For example, we could only fine-tune Gemma3 with 12 billion parameters using QLoRA, and its performance was, for the most part, worse than that of mT5-Large.

4. We would also like to extend the context window by training on longer data. As discussed in Hypothesis 2, translators mentioned that without the preceding and following paragraphs, it is sometimes difficult to judge which translation is better or whether there is a mistranslation. However, due to computational constraints and the nature of the data in Par3, we are limited to paragraph-level data, which is still better than sentence-level data. Ideally, book-chapter level translation would be a great next step.

## Acknowledgments

We thank Huda Khayrallah and Brian Thompson for their early feedback on the paper. Si Wu and David Smith were supported in part by the Schmidt Sciences-funded project "Beyond Translation: Opening up the Human Record."

## A Pre-Processing

We filter out source paragraphs and translations longer than 250 words to remove extreme outliers and ensure reliable processing by sentence-based MT models like OpusMT. The 250-word cutoff is also informed by the distribution of word length in the dataset: in Figure 7, we show the distributions of both source and target paragraphs length measured by word count in the French train and validation datasets. After filtering, we only keep instances where each source paragraph has two or more human translations.

Then, for each language, we construct train, validation, and test splits at the book level, preventing any paragraph overlap across splits. We target an 80/10/10 paragraph ratio. Exact statistics for training instances for all splits and datasets are reported in Table 8 and 9.

The train and validation datasets are the starting points for more targeted experiments from Sections 6 to 8, where we will further filter by the semantic similarity among the human translations. The test dataset created is used to test all experiments for a specific language pair. The French test set contains 5,030 source texts, and Russian has 3,292. Each source text in the test set has multiple human expert translations as targets.

## B MT Models and Automatic Metrics

### B.1 Models

**mT5-large** A multilingual encoder–decoder Transformer model with approximately 1.2B parameters. It is pre-trained on the mC4 corpus, which covers 101 languages, including French and Russian (Xue et al., 2021).[4] Although mT5-large is not specifically pre-trained for translation, it can be fine-tuned for MT and other downstream tasks. We fine-tuned this model using the Hugging Face `Trainer` class. Each experiment takes less than 24 hours on a single NVIDIA H200 GPU. The learning rate $= 1e-3$, batch size $= 4$, and gradient accumulation $= 4$.

| | Train | | Validation | |
|---|---|---|---|---|
| **Setting** | **src** | **instance** | **src** | **instance** |
| low | 1,618 | 4,114 | 384 | 1,087 |
| med | 1,529 | 4,114 | 506 | 1,087 |
| high | 1,874 | 4,114 | 520 | 1,087 |
| med+low | 17,530 | 47,641 | 2,322 | 5,491 |
| med+high | 17,969 | 47,641 | 2,534 | 2,534 |
| unfiltered | 18,744 | 47,641 | 2,344 | 5,491 |
| unfiltered | 26,502 | 67,106 | 3,296 | 7,675 |
| medium+high all | 24,884 | 62,992 | 2,534 | 5,491 |
| human (single ref) | 24,884 | 24,884 | 2,534 | 2,534 |
| synthetic (Gemma3) | 24,884 | 62,992 | 2,534 | 5,491 |
| synthetic (Mistral) | 24,884 | 62,992 | 2,534 | 5,491 |
| synthetic (Qwen3) | 24,884 | 62,992 | 2,534 | 5,491 |

Table 9: Russian train and validation source and instance counts.

**Gemma-3-12B-PT** An open-weight, non-instruction-tuned language model with 12 billion parameters.[5] Given its scale and our computational constraints, we adapt the model using LoRA with 4-bit quantization (Hu et al., 2022; Dettmers et al., 2023). Gemma3 is trained on multilingual web text covering 140 languages, although the language distribution is not publicly specified (Team et al., 2025). We use LoRA rank $r = 32$ and scaling parameter $\alpha = 32$. Each experiment takes from 48 to 120 hours on a single NVIDIA H200 GPU, depending on the size of the dataset. The learning rate$= 1e-4$, batch size $= 4$, and gradient accumulation $= 8$.

**OpusMT** An open-source multilingual machine translation model from the OPUS-MT project (Tiedemann et al., 2023; Tiedemann and Thottingal, 2020).[6] The model supports multiple source languages with English as the target language and is trained on the OPUS corpus using the Marian framework (Junczys-Dowmunt et al., 2018). Each experiment takes less than 12 hours on a single NVIDIA Tesla V100 SXM2 GPU. The learning

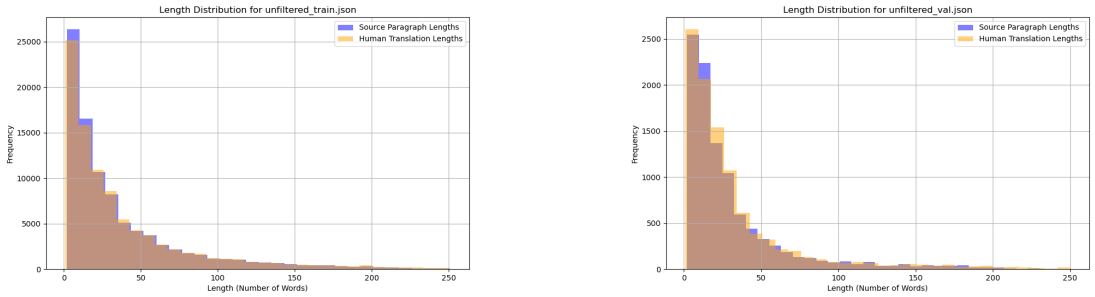

Figure 7: Distribution of paragraph word lengths in the French TRAIN (left) and VAL (right) datasets. Each instance represents a source paragraph or translation instance, showing the frequency of paragraphs by word count.

rate $= 5e-5$, batch size $= 8$, and gradient accumulation $= 4$.

### B.2 Automatic Evaluation Metrics

**BLEU** An MT evaluation metric based on modified n-gram precision with a brevity penalty (Papineni et al., 2002). We compute BLEU using multiple human references for each source input in the test set.

**COMET$_{22}^{\text{DA}}$** An MT evaluation metric that is based on sentence embeddings (Rei et al., 2020). We use wmt22-comet-da by Unbabel (Rei et al., 2022).[7] It was trained on a transformer-based multilingual masked language model, XLM-R (Conneau et al., 2020). Since COMET$_{22}^{\text{DA}}$ only accepts one reference per source text for evaluation, for each source text, we take the average of their COMET$_{22}^{\text{DA}}$ scores for each reference.

**chrF++** An MT evaluation metric based on character and word-level n-gram precision and recall (Popović, 2017).

## C Models and Prompts Used for Generating Synthetic Data

We first randomly select one human translation from each source text in the full medium+high dataset. Then, each one of these human translations is used to generate paraphrase with the following models. The following models were all able to zero-shot generate paraphrases for at least 99% of the data.

We use 1,000 as the limit for max new token, and retry with 1,200 if the output is cut off. For the few instances where we could not successfully parse the model output because the model did not follow the instructions, we salvaged as many generated paraphrases as possible, then replaced any missing paraphrases with human translations.

**gemma-3-27b-it[8]:** gemma-3-27b-it is Google's 27-billion-parameter instruction-tuned Gemma3 model (different from the 12b-pt variant we use for fine-tuning). It is designed for instruction following, and it can handle long-context window. To generate text more efficiently, we perform zero-shot text generation using vLLM (Kwon et al., 2023) with a batch size of 16. For the French TRAIN split, generation completed on a single H200 GPU in under 17 hours. We obtained outputs for all 34,864 instances. Only 2 instances produced a single paraphrase rather than the requested two. For the validation split, we successfully processed all 4,517 instances, with no single-paraphrase outputs and no discarded instances.

> System prompt: You are a helpful assistant.
>
> User prompt: Generate two paraphrases of the paragraph below. Each paraphrase should preserve the same meaning as the original, but express it in a different way. The two paraphrases

[7] https://huggingface.co/Unbabel/wmt22-comet-da

[8] Available to download on Hugging Face at https://huggingface.co/google/gemma-3-27b-it

should not be identical or trivial rewrites. Set `reference` to exactly the paragraph provided. Return ONLY valid JSON in the following format:

```
{
  "reference": "...",
  "paraphrase_1": "...",
  "paraphrase_2": "..."
}

[INPUT]
```

**Qwen3-30B-A3B-Instruct-2507**[9]**:** An instruction-tuned mixture-of-experts language model from the Qwen3 family, with 30.5 billion total parameters and 3.3 billion activated parameters. It has strong instruction following and general reasoning capabilities. Like Gemma3, we ran inference using vLLM with a batch size of 8. The TRAIN split finished under 5 hours. Of the 34,864 source paragraphs in the TRAIN split, only 54 outputs contained a single paraphrase rather than the requested two paraphrases. For the validation split, all outputs were successfully salvaged; only 1 instance contained a single paraphrase.

User prompt: Generate two paraphrases of the paragraph below. Each paraphrase should convey the same meaning as the original, but be expressed in a different way. The two paraphrases should not be identical or trivial rewrites. Set `reference` to be exactly the paragraph provided, without any changes. Return only valid JSON in the following format:

```
{
  "reference": "...",
  "paraphrase_1": "...",
  "paraphrase_2": "..."
}

[INPUT]
```

**Mistral-Small-3.2-24B-Instruct-2506**[10]**:** A 24-billion-parameter instruction-tuned model from Mistral AI. It is designed for efficient instruction following as well as long context use. We ran inference using vLLM with a batch size of 8. The TRAIN split finished in under 24 hours. For the TRAIN split, 85 outputs could not be salvaged. 1,959 instances had one single paraphrase. For the validation split, all 4,517 instances were processed: 4,290 produced complete paraphrase pairs, 220 produced a single recoverable paraphrase, and 7 were discarded and replaced with human translations.

User prompt: Generate two paraphrases of the paragraph below. Each paraphrase must preserve the original meaning but be written differently. Avoid trivial rewrites.

Return ONLY valid JSON in the following format:

```
{
  "reference": "...",
  "paraphrase_1": "...",
  "paraphrase_2": "..."
}

[INPUT]

## D Zero-shot Translation with Instruction-tuned Models

While this paper primarily explores fine-tuning MT models using datasets with different levels of semantic similarity using multi-reference data, it is also informative to know the zero-shot translation performance of commercial models (via API) and open-weight instruction-tuned LLMs. In Table 10 we show their performance measured by automatic metrics on the French test set.

Results from the automatic metrics show that while commercial models like GPT 5.4 Pro outperform our best model (medium+high (all) with mT5) by 4.2 in BLEU, 0.01 in COMET, and 0.04 in chrF++, other state-of-the-art commercial models like Gemini 3.1 pro and Claude Opus 4.6 are only marginally better or worse than our best model.

Open-weight models not only all underperform our best fine-tuned model, some even struggle to process and translate given the instructions, with a valid output rate as low as 52.9% using Mistral-Small-3.2-24B-Instruct-2506 (Table 10).

| model | cost | BLEU | COMET | chrF++ | Valid% |
|---|---|---|---|---|---|
| GPT 5.4 pro | $15.47 | **48.5** | **0.76** | **0.6** | 100 |
| Gemini 3.1 Pro | $37 | **44.8** | **0.76** | 0.55 | 99.9 |
| Claude Opus 4.6 | $7.95 | 44.2 | **0.76** | **0.6** | 100 |
| Gemma3-27b-instruct | 0 | 40.6 | 0.75 | 0.55 | 99.5 |
| Qwen3-instruct | 0 | 40.1 | 0.73 | 0.54 | 75.9 |
| Mistral-instruct | 0 | 35.4 | 0.66 | 0.50 | 52.9 |
| **our best FT** | 0 | 44.3 | 0.75 | 0.56 | 100 |

Table 10: Zero-shot machine translation performance on French-English test data. Scores in bold font are better than our best fine-tuned model—fine-tuning mT5 using the full medium and high SEMSIM data. "Valid%" counts how many test data were able to be processed and translated. Cost for Gemini is estimated.

Below, we provide details of these models.

### D.1 Commercial Models

**GPT 5.4 Pro** A commercial model developed by OpenAI with long context window, multilingual capability, and instruction following ability. We used the model with reasoning effort set to `high`.

**Gemini 3.1 pro** A commercial model developed by Google Deepmind. Similar to GPT 5.4 Pro, it has multilingual generation capability, long context window, and instruction following ability. We used the model with reasoning effort set to `high`.

**Claude Opus 4.6** A commercial model developed by Anthropic. It is capable of multilingual tasks, has a massive 1 million token context window, and instruction following ability.

For all commercial models, we use the following system prompt for zero-shot machine translation. All APIs were called in batch mode.

> System prompt: You are an expert literary translator from French to English. Translate the following French paragraph into natural, fluent English that preserves the original tone, style, and nuance. Output ONLY the English translation with no explanation or commentary.
>
> `[INPUT]`

### D.2 Open-Weight Models

For zero-shot translation, we used the same open-weight models that we used to zero-shot generate paraphrase in Appendix C. Below, we show the prompts we used for generation.

#### gemma-3-27b-it

> System prompt: You are a careful literary translator.
>
> User prompt:
> Task: Translate the following French paragraph into natural, fluent English.
> Style: literary; preserve tone, register, and meaning; avoid adding new facts.
> Output format: Return ONLY a valid JSON object with exactly this key:
>
> ```
> {
>   "prediction": "..."
> }
> ```
>
> Rules: Do NOT include markdown, code fences, commentary, or extra keys.
> Keep the English as a single string, including punctuation or quotes as needed.
>
> French paragraph:
>
> `[INPUT]`

#### Qwen3-30B-A3B-Instruct-2507

> User prompt:
> Task: Translate the following French paragraph into natural, fluent English.
> Style: literary; preserve tone, register, and meaning; do not add new facts.
>
> Return ONLY valid JSON with exactly this key:
>
> ```
> {
>   "prediction": "..."
> }
> ```
>
> Rules:
> - No markdown, no code fences, no explanations.
> - Do NOT add extra keys.
> - Keep the English as a single string.
>
> French paragraph:
> `[INPUT]`

### Mistral-Small-3.2-24B-Instruct-2506

User prompt:
Task: Translate the following French paragraph into natural, fluent English.
Style: literary; preserve tone, register, and meaning; do not add new facts.

Return ONLY valid JSON with exactly this key:

```
{
  "prediction": "..."
}
```

Rules:
- No markdown, no code fences, no extra keys, no explanations.
- Keep the English as a single string.

French paragraph:
`[INPUT]`

## E PARAGRAM-SP Score Distribution of the Synthetic Data

In Figure 8, we compare the distribution of the pairwise PARAGRAM-SP scores between the ground-truth human translation and each LLM's zero-shot paraphrased translation.

Compared to the PARAGRAM-SP scores between two human translations, the score between a human and a synthetic translation is on average lower across all models.

In the violin plot, the middle 50% of the distribution shifts down for all three models, as does the median. This means the SEMSIM of synthetically augmented data is lower overall, since SEMSIM is the average pairwise score among all references of the same source. Interestingly, Gemma3 deviates the most from the human score distribution, yet its paraphrases gave the best MT performance of the three models. Note that for all three models, the majority of the data falls in the medium SEMSIM range, whereas nearly half of the human data falls in the high SEMSIM range.

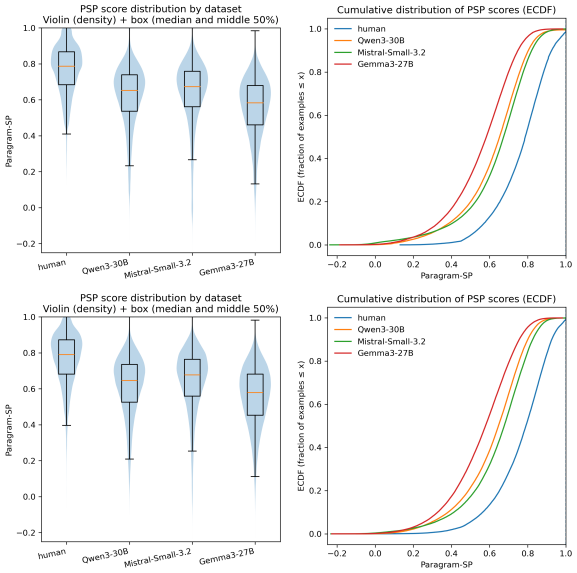

Figure 8: The distributions of the pair-wise semantic similarity score between one generated additional reference and the human translation. The top row is from the French-English data, and bottom row is from the Russian-English data. "Human" pair-wise similarity score distribution is from the multi-reference full medium+high SEMSIM dataset. Overall, the synthetic pairwise similarity score distribution shifts lower compared to the human translation distribution.

## F Prompt for Classifying Translators' comments

We used Claude Opus 4.6 to label annotator comments with fine-grained translation quality categories. For each comment, the model was given the original French source text, Translation A, Translation B, the annotator's free-text comment, and the full list of quality labels. We wrote this detailed instruction with the assistance of Claude Opus 4.6 in the chat interface. We tested multiple instructions by checking 50 outputs to ensure accuracy. Below is the prompt we use:

> You are a strict annotation analyst for literary translation evaluation (French to English). You will be given:
>
> - The original French source text
> - Translation A and Translation B (the actual translations)
> - A human annotator's comment comparing them
> - A list of quality labels
>
> For EACH quality label, decide:
>
> - "A" if the comment EXPLICITLY praises or criticizes Translation A for this quality
> - "B" if the comment EXPLICITLY praises or criticizes Translation B for this quality
> - "tie" if the comment EXPLICITLY says BOTH translations share this quality
> - "" (empty) if the comment does NOT clearly address this quality
>
> STRICT RULES:
>
> - Only tag a quality if the comment clearly and directly discusses it. Do NOT infer qualities that are merely implied.
> - Most qualities should be "" (empty) for any given comment. A typical comment only addresses 1–3 qualities.
> - Annotators often quote specific words or phrases from the translations without saying "A" or "B". You MUST match quoted words back to Translation A or Translation B to determine which system they refer to.
> - If the comment says one translation "flows better" or "is more natural", that is "fluent / natural" for that system AND "awkward / unnatural" for the other ONLY if the comment indicates the other is worse.
> - Do NOT automatically assign the opposite negative quality just because one system got a positive. Only assign it if the comment actually criticizes the other.
>
> Quality definitions:
>
> - "fluent / natural": reads smoothly, sounds like natural English
> - "accurate / faithful": correctly conveys the meaning of the French source
> - "idiomatic / good word choice": uses appropriate English expressions and well-chosen words
> - "good style / tone": preserves the literary register, mood, or voice of the original
> - "awkward / unnatural": reads clumsily, sounds unnatural or stilted
> - "overly literal": follows French syntax or phrasing too closely, word-for-word translation
> - "mistranslation / meaning error": gets the meaning wrong, misinterprets the source
> - "omission / addition": leaves out content from the source or adds content not in the source
> - "grammar / mechanical error": has grammatical mistakes, typos, or mechanical issues
>
> EXAMPLES:
>
> Example 1:
>
> Original French: [French source text]
>
> Translation A: [some translation with more natural English]
>
> Translation B: [some translation with less natural English]
>
> Comment: "I've gone with A purely because the English is more natural and flows more smoothly than B. However, there are serious issues in both: neither gets d'Artagnan's name right, neither explains what a conge is (it would have been better to write 'permissions to leave' or something like that and I'd have preferred 'pistols' to 'pistoles'."
>
> Correct labels:
>
> {"fluent / natural": "A", "accurate / faithful": "", "idiomatic / good word choice": "", "good style / tone": "", "awkward / unnatural": "B", "overly literal": "", "mistranslation / meaning error": "tie", "omission / addition": "", "grammar / mechanical error": ""}
>
> Example 2:
>
> Original French: [French source text]
>
> Translation A: [some translation preserving Milady's voice]
>
> Translation B: [some translation]
>
> Comment: "A sounds more like Milady would speak."
>
> Correct labels:
>
> {"fluent / natural": "", "accurate / faithful": "", "idiomatic / good word choice": "", "good style / tone": "A", "awkward / unnatural": "", "overly literal": "", "mistranslation / meaning error": "", "omission / addition": "", "grammar / mechanical error": ""}
>
> Respond with ONLY a JSON object. No explanation, no markdown, no backticks.

For each instance, the user prompt was constructed using the following template:

Original French: {original}

Translation A: {a_pred}

Translation B: {b_pred}

Annotator comment:

"{comment}"

Quality labels:

- fluent / natural
- accurate / faithful
- idiomatic / good word choice
- good style / tone
- awkward / unnatural
- overly literal
- mistranslation / meaning error
- omission / addition
- grammar / mechanical error

Return a JSON object mapping each quality label to "A", "B", "tie", or "". Remember: most should be empty. Only tag what the comment explicitly discusses.

## G Descriptions of Each SEMSIM Level (Table 11)

## H Human Evaluation Interface Details

Across all tasks, no source text or translation is repeated within a survey, across survey variations for the same task, or in any other task.

Translators were informed of the duration, the pay, and the nature of the task before accepting the job.

In Figure 9 and 10, we show the instructions and the UI for annotation on Label Studio, as well as an example question.

## I Example Translation Outputs from Different MT Systems (Table 12)

| SEMSIM | Description | Dataset |
|---|---|---|
| 1.0 | Completely identical. | Medium+High<br>Unfiltered |
| $[0.9 - 1.0)$ | Almost identical, except for minor punctuation differences, e.g., single vs double quotation marks, or word replacement (by a synonym or a phrase). | Medium+High<br>Unfiltered |
| $[0.85 - 0.9)$ | Differences happen more often, but they are still variations that are not meaningful. Compared to the 0.9-1.0 similarity, the difference can be clausal instead of just one or two words. However, the overall amount of information is about the same. | Medium+High<br>Unfiltered |
| $[0.45 - 0.85)$ | Very meaningful variations. The paraphrases are more likely to be visually dissimilar. Sometimes, the amount of information can differ much more: some translators are more verbose, others are more succinct. | Medium<br>Medium+High<br>Medium+Low<br>Unfiltered |
| $[-1 - 0.45)$ | Noisy paraphrases that have an overall information mismatch. Paraphrases can be misaligned or erroneous, or translators diverge too much in their interpretations. | Medium+Low<br>Unfiltered |

Table 11: Different levels of semantic similarity score (SEMSIM) and their characteristics. See Section 4 for how we compute SEMSIM given a source text and its reference translations. The dataset column indicates the datasets that include paraphrases from the corresponding SEMSIM range.

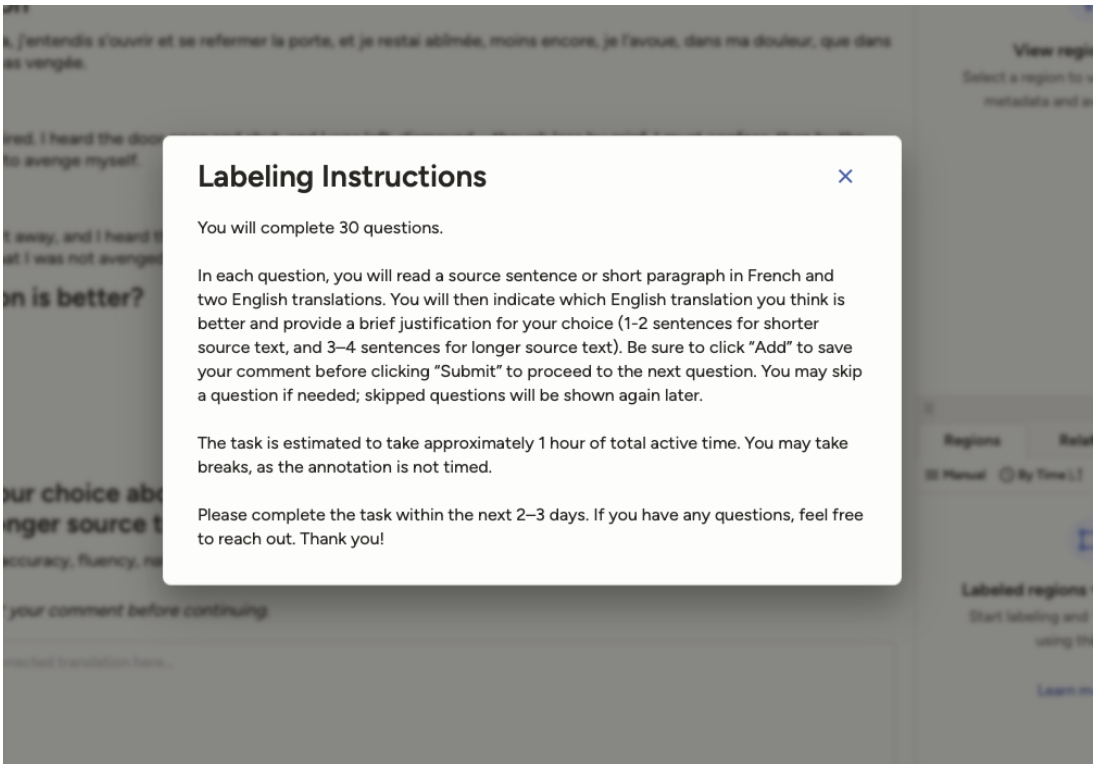

Figure 9: The instructions shown to translators before starting the annotation process. The human evaluation task was hosted on Label Studio.

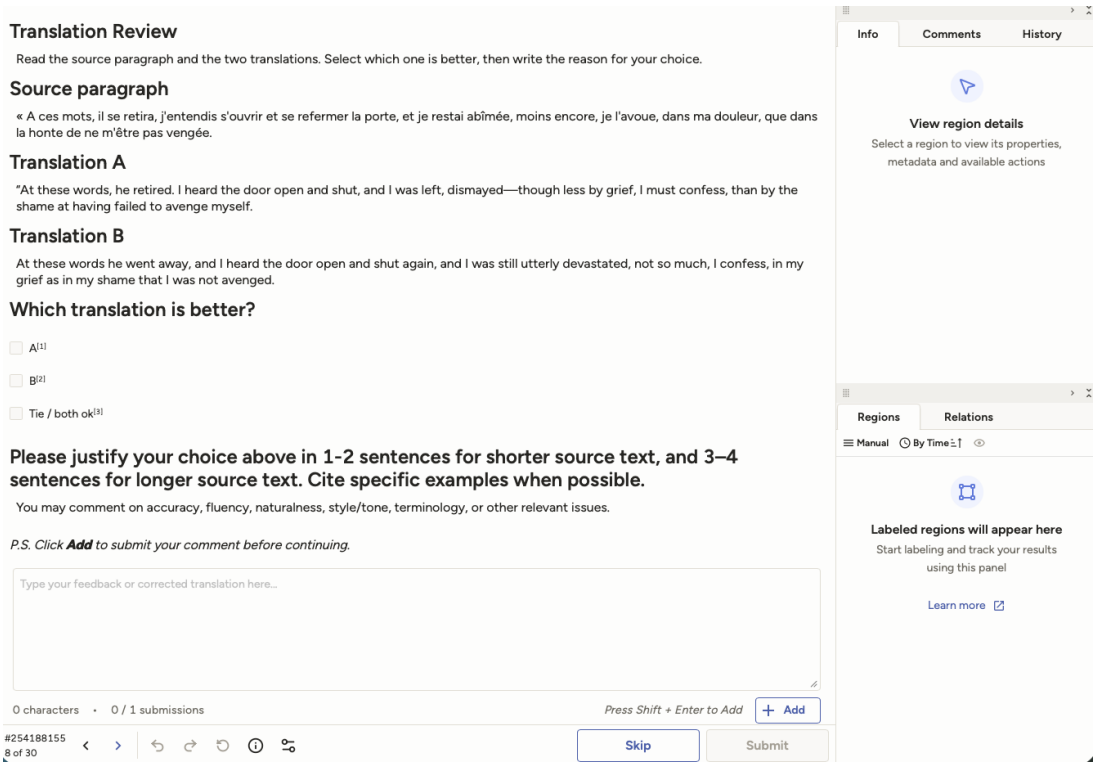

Figure 10: A screenshot of the Label Studio interface used for human evaluation, showing an example question presented to translators.

| System | Output |
|---|---|
| Source (FR) | *— Ah! voilà qui est nouveau, reprit le roi. N'allez-vous pas dire que vos trois mousquetaires damnés, Athos, Porthos et Aramis et votre cadet de Béarn, ne se sont pas jetés comme des furieux sur le pauvre Bernajoux, et ne l'ont pas maltraité de telle façon qu'il est probable qu'il est en train de trépasser à cette heure! N'allez-vous pas dire qu'ensuite ils n'ont pas fait le siège de l'hôtel du duc de La Trémouille, et qu'ils n'ont point voulu le brûler! ce qui n'aurait peut-être pas été un très grand malheur en temps de guerre, vu que c'est un nid de huguenots, mais ce qui, en temps de paix, est un fâcheux exemple. Dites, n'allez-vous pas nier tout cela?* |
| Human 1 | "Ah! That's a new one," replied the king. "Are you going to tell me that your three damned musketeers, Athos, Porthos, and Aramis, and your cadet from Béarn, haven't sprung like furies on poor Bernajoux and injured him so badly that by now he's probably dead? Are you going to tell me that they didn't lay siege to the hôtel of the Duc de La Trémouille, and that they didn't try to burn it down? Of course, that might not be such a bad thing in times of war, since it's a nest of Huguenots—but in peacetime, it sets a bad example! Speak! Isn't this what you're going to tell me?" |
| Human 2 | "Ah! here's something new!" the king picked up. "Are you going to tell me that your three damned musketeers, Athos, Porthos, and Aramis, and your lad from Béarn, didn't throw themselves like madmen on poor Bernajoux and mistreat him so badly that he's probably on his way out of this world as I speak? Are you going to say that after that they didn't lay siege to the hôtel of the duc de La Trémouille, and that they didn't intend to burn it? Which would perhaps have been no great misfortune in time of war, seeing that it's a nest of Huguenots, but which, in time of peace, is a regrettable example. Tell me, are you going to deny all that?" |
| Unfiltered (all) | "Ah! this is new," resumed the king. "Do you not say that your three damned musketeers, Athens, Porthos, and Aramis, and your Cadet de Béarn, did not rush like madmen upon poor Bernajoux, and did not so badly treat him that he is probably dying at this hour? Do you not say that they did not siege the Duke de La Trémouille's house, and did not want to burn him! which would not have been a great misfortune in war, since it is a nest of Huguenots, but which in peace is a dreadful example. Say, do you not deny all this?" |
| Medium+high (all) | "Ah! this is something new," continued the king. "Don't you say that your three damned musket-boys, Athenos, Porthos, and Aramis, and your Cadet de Béarn, did not throw themselves like mad on poor Bernajoux, and not so ill-treated him that he is probably in the process of dying at this hour! Don't you say that they did not seize the Duke de La Trémouille's house, and that they did not want to burn him! This would perhaps not have been a great misfortune in war, since it is the nest of Huguenots, but which in peace is a nasty example. Say, will you not deny all this?" |
| Synthetic (Gemma3) | "Ah! that is new," resumed the king. "Don't you say that your three damned mousquetaires, Athens, Porthos, Aramis, and your cadet of Béarn, did not throw themselves like furious beasts upon poor Bernouch, and did not treat him so badly that he is probably on the point of passing through! Don't you say that they did not take siege on the Duke de La Trémouille's house, and that they did not want to burn him! which would not have been very bad in wartime, since it was a nest of Hunchbacks, but which, in peace, is a nasty example. Say, will you not deny all this?" |
| Synthetic (Mistral) | "Ah, this is a new thing," resumed the king. "Don't you say that your three damned musketeers, Athens, Porthos, and Aramis, and your scholar of Béarn, did not throw themselves like furious beasts upon poor Bernajoux, and did not treat him so badly that he is probably in the process of passing this hour! Don't you say that they did not seize the siege of the Duke de La Trémouille's house, and did not want to burn him! which would perhaps not have been a great misfortune in war, since it is a nest of Huguenots, but which, in peace, is a dreadful example. Say, will you not deny all this?" |
| Synthetic (Qwen3) | 'Ah, that's nothing new,' the king went on. 'Don't you say that your three damned spies, Athenaeus, Porthos and Arimas, and your cadet of Benares, did not throw themselves like a madman upon poor Bernard, and did not treat him so badly that he is probably going to be passing through this hour! Don't you say that they did not take the Duke of La Trémoïlles' house, and did not want to burn it! What would have been a great misfortune in war, since it was a nest of Hunchbacks, but what is a shameful example in peace. Say, won't you hide all this?' |

Table 12: Example system outputs for a source paragraph from *Les Trois Mousquetaires* (*The Three Musketeers*) by Alexandre Dumas.

# Studying quantization trade-offs for efficient inference deployment in machine translation

**Jim Zhao[1,2*], Sohir Maskey[2], Koen Oostermeijer[2], Douglas Orr[3], Teryn Jones[2]**

## Abstract

Deploying large language models in realistic server environments poses challenges, as the system needs to provide high-quality responses with low latency. Quantization is a common approach to reduce the memory footprint and improve inference efficiency, yet its impact on latency and throughput is rarely evaluated under controlled, orchestration-level workloads. In this work we study the quantization trade-offs of EuroLLM (Martins et al., 2025) across three model sizes ranging from 1.7B to 22B for efficient deployment on a single A100 or H100 GPU. We demonstrate that combining a document-chunking strategy with W4A8 or W8A8 quantization improves the latency-throughput Pareto-curve under a wide range of workloads. Furthermore, since standard machine translation (MT) benchmarks rely on isolated sentences and fail to capture long-context dynamics, we introduce a document-level evaluation based on DocHPLT (O'Brien et al., 2025) to assess how text chunking strategies affect translation quality under quantization. Our results indicate that standard segment-level evaluation can potentially underestimate the interaction between quantization and long-context document translation, for some quantization formats, translation direction and models. Overall, our experiments show that the trade-off between inference efficiency and translation quality depends not only on the quantization format, but also on the choice of text chunking strategy.

## 1 Introduction

Large language models have revolutionized the field of machine learning and beyond, achieving close to or beyond human expert level across a wide range of domains, including coding (Coignion et al., 2024), medicine (Liu et al., 2025), and machine translation (Zheng et al., 2026). Deploying these models efficiently remains challenging. Real-world serving systems must handle concurrent requests while balancing throughput and latency (Agrawal et al., 2024). These constraints are particularly relevant when models are deployed on a limited number of GPUs. Quantization is a common approach to reduce model memory requirements and can substantially improve inference efficiency (Jarmusch and Chandrasekaran, 2026).

Most prior work studies the quality retention and inference benefits of quantization formats in isolation, primarily focusing on memory or token-level metrics. In contrast, we analyze quantization trade-offs for MT inference under document-level serving constraints, focusing on end-to-end latency and throughput. We study these trade-offs on the EuroLLM (Martins et al., 2025) model family across three model sizes ranging from 1.7B to 22B parameters for deployment on a single A100 or H100 GPU, leading to the following contributions:

- We show via controlled closed-loop synthetic online benchmarks that combining W8A8 and W4A8 with a document-chunking strategy of 200-400 tokens provides the best efficiency gains for medium-sized documents across most of the considered deployment settings.
- Furthermore, we show that segment-level MT evaluation can potentially underestimate the quality degradation under quantization for certain translation directions and quantization formats.
- Concretely, for the Ukrainian → English translation direction we observe a stronger degradation of W4A16 with growing chunk size up to 1500 input prompt tokens for EuroLLM-1.7B and up to 4K input prompt tokens for EuroLLM-9B.

The remaining paper is structured as follows: We review related work in Section 2. In Section 3 we provide details about methods used in this work. In Section 4 we present our experimental results,

[*] Work done during internship at Aleph Alpha Research.

*Proceedings of the Eleventh Conference on Machine Translation*, pages 842–859
October 28-29, 2026 ©2026 Association for Computational Linguistics

which we further discuss in Section 5. We discuss limitations in Section 6 and finally conclude in Section 7.

## 2 Related work

### 2.1 Quantization Paradigms

Quantization can improve inference efficiency by reducing the precision of model weights, activations, or the KV cache. Weight quantization reduces the model size and provides speed-ups under low batch sizes, where inference is often memory-bandwidth bound. As batch size increases, arithmetic intensity grows and inference can become compute-bound, reducing the relative benefit of weight-only quantization alone. Combining weight quantization with activation quantization overcomes this limitation by leveraging hardware-native low-precision compute formats, such as INT8, FP8, MXFP4 (Rouhani et al., 2023), NVFP4 (Xin et al., 2026), which enables arithmetic acceleration. Finally, KV quantization (Hooper et al., 2024) compresses the runtime memory footprint of the KV cache. This compression reduces memory bottlenecks under long sequences or large batch sizes, which might require CPU memory offloading.

**Post-training quantization (PTQ)** PTQ refers to methods, which quantize models after they have been fully trained. They typically use a small calibration dataset, although data-free approaches also exist (Nagel et al., 2019). Popular PTQ methods include GPTQ (Frantar et al., 2022), AWQ (Lin et al., 2025) or QQQ (Zhang et al., 2024b).

### 2.2 Efficient LLM Serving and Chunking

There is a rich line of work focused on optimizing the deployment and serving of large language models. At the scheduling level, Yu et al. (2022) introduced iteration-level scheduling, which is widely referred to as continuous batching, to efficiently process incoming requests of varying lengths. To address memory bottlenecks, Kwon et al. (2023) proposed PagedAttention to mitigate KV-cache fragmentation. These techniques are now standard in production-grade serving engines, such as vLLM (Kwon et al., 2023) and vendor specific frameworks like TensorRT-LLM (NVIDIA Corporation, 2023), which provide hardware-accelerated inference. Beyond engine-level memory management, inference efficiency can also be controlled at the input level through document chunking. While underexplored in MT, chunking strategies are heavily researched in Retrieval-Augmented Generation (RAG). For instance, Qu et al. (2025) challenged the benefits of semantic chunking over more efficient fixed-size chunking in RAGs.

### 2.3 Document-level Machine Translation

While widely used MT benchmarks, such as WMT24++ (Deutsch et al., 2025) or Flores+ (Goyal et al., 2022) primarily evaluate translations at the segment level, document-level MT has a substantial research history. Läubli et al. (2018) demonstrate that evaluation protocols based on isolated sentences can lead to different conclusions from document-level evaluations when comparing professional and machine translations. Lopes et al. (2020) compare several document-level context-aware neural MT approaches, and Maruf et al. (2021) surveys methods and evaluation protocols for document-level MT. More recently, Wang et al. (2023b) evaluate GPT-3.5 (Ouyang et al., 2022) and GPT-4 (Achiam et al., 2023) for document-level translation and find that they outperform commercial MT systems under human evaluation, highlighting the potential of decoder-only LLMs for this setting. Similarly, Karpinska and Iyyer (2023) find that translating complete literary paragraphs with GPT-3.5 (Ouyang et al., 2022) yields higher-quality translations than translating each sentence independently across 18 language pairs. However, critical errors, including occasional content omissions, remain even when the model is given document-level context.

### 2.4 Evaluation of Quantized LLMs

Li et al. (2024) evaluate quantized LLMs over a wide range of tasks, including long-context tasks, such as key-value retrieval and multi-document question answering. Marchisio et al. (2024) study how quantization affects multilingual LLMs, showing that, in line with our finding, automatic benchmarks often underestimate the quantization effects and that languages are disparately affected by quantization. Finally, in the context of MT, Marie and Fujita (2025) study how different PTQ methods affect translation quality across languages. They do not examine how quantization interacts with document context or document-chunking strategies.

Our work connects these lines of research by jointly studying quantization, document

chunking, serving efficiency, and document-level translation quality.

## 3 Methods

### 3.1 Machine Translation Models

We consider the EuroLLM (Martins et al., 2025) model family across three model sizes ranging from 1.7B to 22B. EuroLLM utilizes a standard dense decoder-only Transformer architecture. Concretely, we use the instruction-tuned variants EuroLLM-1.7B-Instruct, EuroLLM-9B-Instruct-2512, and EuroLLM-22B-2512, where the first has a context length of 4096 and the latter two have a context length of 32K. All models use RoPE (Su et al., 2024) with $\theta = 10.000$ for EuroLLM-1.7B-Instruct and $\theta = 1.000.000$ for EuroLLM-9B-Instruct-2512 and EuroLLM-22B-2512. For brevity, we will refer to the EuroLLM models simply by their model size, e.g. EuroLLM-1.7B.

### 3.2 Hardware and Format Constraints

In this work, we consider three combinations of weight and activation quantization: W8A8 (8-bit weight and activation), W4A8 (4-bit weight and 8-bit activation), and W4A16 (4-bit weight-only). Further details on the concrete quantization scheme can be found in Appendix A.2. While there is an ongoing debate regarding whether floating-point or integer formats should be preferred for LLMs (Zhang et al., 2024a), we observe that W8A8 often remains close to the translation quality of the unquantized BF16 baseline in most cases while benefiting from widely supported INT8 tensor cores. This allows the deployment of the quantized model across a broad range of GPUs (including the RTX4090, A100, and H100) using highly optimized compute kernels.

Furthermore, while more sophisticated 4-bit formats like MXFP4 (Rouhani et al., 2023) and NVFP4 (Abecassis et al., 2025) show promise, they are only natively supported on newer Blackwell architectures (Jarmusch and Chandrasekaran, 2026). Finally, extreme low bit-widths (<4 bits) (Ma et al., 2024; Maskey et al., 2026; Wang et al., 2023a; Wu et al., 2025) are excluded from this study, as they are primarily optimized for highly memory-constrained, on-device deployment rather than achieving maximum throughput across the wide range of concurrent batch sizes expected in a server setting.

### 3.3 Post-Training Quantization

We perform post-training quantization (PTQ) using GPTQ (Frantar et al., 2022) and apply SmoothQuant (Xiao et al., 2023) before performing GPTQ to reduce activation outliers before activation quantization for W8A8 and W4A8, where we choose a smooth strength of 0.8 for W8A8 and 0.4 for W4A8 quantization. For W4A16 GPTQ is applied directly. We performed GPTQ on a subset of 1024 samples subsampled from OPUS (Tiedemann, 2016), where the target translations were generated by Seed-X (Cheng et al., 2025). All linear layers in the model, except for the embedding and head layer, are quantized using the same data format.

### 3.4 vLLM Engine

We use vLLM (Kwon et al., 2023) as our serving engine, which provides state-of-the-art kernel implementations, including W4A16, W4A8 and W8A8 kernels. Furthermore, it implements additional inference optimizations, such as PagedAttention (Kwon et al., 2023) and Continuous Batching (Yu et al., 2022). We can thus evaluate the benefit of quantized models for inference under near-production conditions, without inefficient kernel implementations potentially distorting the picture. We note that vLLM does not support W4A8 kernels on A100 by default, which is why we limit experiments using W4A8 on the H100 GPU. We used vLLM version 0.26.0 for our experiments.

### 3.5 Translation evaluation

To study the translation quality retention, we benchmarked the EuroLLM-1.7B and EuroLLM-9B model on BF16, W4A16 and W8A8 on a subset of DocHPLT (O'Brien et al., 2025) on a RTX4090 GPU. We select EN $\leftrightarrow$ UK as an exemplary translation pair supported in EuroLLM and covered by DocHPLT, leading to two translation directions in total.

#### 3.5.1 Segment-level translation

For segment-level evaluation, we use chrF++ (Popović, 2017) to compare the translation quality retained by the quantized model. Segments are translated independently, then translations and references are concatenated by document before computing chrF++, which scores translations in the range $[0, 100]$, where a higher score is better.

### 3.5.2 Document-level evaluation

We construct document-level inputs from high-confidence aligned segments in DocHPLT. DocHPLT (O'Brien et al., 2025) contains parallel documents that are split into partially aligned source and reference alignment records. To construct document-level inputs without breaking this alignment, we first filter documents by alignment records with Aligner-Score $\geq 0.5$ and Bicleaner-Score $\geq 0.8$, merge overlapping records into non-overlapping bilingual blocks, and preserve their original document order before chunking. This ensures that the blocks in each documents are sufficiently well aligned. We then greedily concatenate complete blocks in the document order until the tokenized prompt reaches or exceeds a target prompt-length threshold $T$. As blocks are never split to avoid breaking existing alignment, the realized prompt length may exceed $T$. In addition, short trailing chunks are also retained when a document produces multiple chunks to obtain a full document translation. We exclude a document at threshold $T$ only when the complete document forms a single prompt shorter than $0.8T$, in order to prevent short documents from dominating estimates at larger thresholds. To control for changes in document composition, we evaluate all thresholds, models, and quantization formats on the same subset of documents eligible at the largest threshold. Each chunk is passed individually to the model and the generated outputs are concatenated in their original order to reconstruct the document translation. We compute chrF++ for each reconstructed document separately and report the unweighted mean across all eligible documents. The main reason for relying on this statistical measure is that neural metrics, such as xCOMET (Guerreiro et al., 2024), have a limited context window of 512 tokens for the combined source, reference, and translation text. Further details on the chunking and evaluation, including decoding parameters and prompt templates can be found in Appendix A.3.

## 3.6 Inference Efficiency

The inference efficiency benchmarks are split into two parts. We perform offline benchmarking in the first stage to evaluate the speed-ups from using hardware-accelerated GEMM kernels and reduced memory traffic in isolation. In a second stage, we study optimal chunking strategies of documents in a closed-loop online inference setting for different number of concurrent users on medium-sized documents. In general, chunking documents into shorter parts allows parallel processing, but increases the total number of requests, which vLLM needs to schedule. By choosing the optimal chunk length, the end-to-end latency of the full document and the throughput of documents can be improved. However, sentences might lose context if split into too short chunks, leading to degraded translations. We evaluate the trade-offs of how the chunk size affects translation quality across different languages in the final subsection. We benchmark the models using randomly generated token IDs for both inference evaluations as input prompts and disable prefix caching to ensure comparability across model sizes and different quantization formats. We report the results in terms of generated tokens.

### 3.6.1 Offline Benchmarking

We first benchmark the inference efficiency of the quantization formats via offline benchmarking. While vLLM can handle requests of different lengths efficiently via continuous batching, we measure the inference statistics for fixed input and output sequence lengths and enforce the number of output tokens to the number of input tokens by ignoring the $\text{eos}_{\text{token}}$ for simplicity. This holds approximately true for MT tasks, but also highly depends on the language pair and the tokenizer used (Martins et al., 2025). We measure the wall time and output token throughput for a range of different sequence lengths and batch sizes up to 1024.

The roofline model is a useful tool to upper bound the benefits of different quantization formats for inference efficiency by putting the compute capacity and memory-bandwidth into relation. A full derivation of the roofline model and upper bound estimates on speed-ups can be found in Appendix A.1. During low-batch decoding, inference is generally dominated by streaming model weights from memory, such that reducing weight precision can provide substantial benefits. As the batch size increases, weights are reused across more tokens and arithmetic intensity increases, reducing the benefit of weight-only quantization as projection and MLP operations become compute-bound. In this regime, activation quantization becomes important because it enables hardware-accelerated low-precision computation. Long-context decoding introduces an additional limitation: attention and KV-cache traffic grow with context length but

are unaffected by weight quantization, causing the attainable end-to-end speed-up to decrease. These predictions represent idealized upper bounds and do not account for dynamic quantization overhead, kernel utilization, or scheduling and KV-cache capacity effects during online serving.

#### 3.6.2 Closed-Loop Online Document-Level Benchmark

To benchmark the inference efficiency of quantized models more realistically, we perform a controlled closed-loop synthetic online benchmark, which consists of an additional orchestration layer to incorporate chunking strategies of full documents and to measure E2E latencies on the document level. We simulate document lengths corresponding to 1200 tokens under a growing number of concurrent users of up to 500 users and different chunk sizes ranging from 50 to 400 tokens.

## 4 Results

### 4.1 Offline Benchmarking

The results of the offline benchmarks can be found in Figure 1 with further results in Appendix A.5. Across the three size regimes we observe that quantization formats have marginal benefits for small model sizes < 2B parameters. For medium-sized models of around 9B, W4A8 and W8A8 show efficiency gains across all batch sizes, while W4A16 becomes as fast as BF16 at large batch sizes as the model becomes compute-bound. Finally for large MT models of 22B, we observe a difference between the H100 and A100 due to the higher compute-to-memory-bandwidth ratio on the H100. While H100 has a ridge point at $\approx I_{\text{ridge}^{\text{H100}}} = 295\,\text{FLOP/byte}$, A100 has a ridge point at $\approx I_{\text{ridge}^{\text{A100}}} = 153\,\text{FLOP/byte}$ (see Appendix A.1 for more details). Thus, W4A16 remains competitive on the H100, while it saturates back to the BF16 baseline on the A100 at the highest batch sizes considered. We observe that for larger batch sizes, throughput actually can reduce, as is the case for the 22B model on A100. This observation is not predicted by a simple roofline model.

### 4.2 Closed-Loop Online Document-Level Benchmark

Based on the offline benchmark and quantization results, we limit the comparison to BF16, W8A8, and W4A8. The results can be found in Figure 2. We make the following observations based on the results: Quantization is not always beneficial. In particular for the 1.7B model deployed on a H100, BF16 achieves higher throughput at lower latencies than W8A8 quantization. The reason for this is that the W4A8 and W8A8 schemes add overhead by applying dynamic activation quantization. In addition, the online benchmark further shows that document chunking can provide additional efficiency gains. The Pareto-optimal chunking strategy depends on the specific deployment setting and workload. At low concurrency, it is always preferable to use the smallest acceptable chunk length to allow for parallel processing, while for higher concurrency the Pareto-optimal chunk length varies mostly between 200 and 400 tokens. At the highest considered concurrency on the 22B model under BF16 precision, a trade-off between higher throughput and lower latency is also observable. While shorter chunk length allow for a better KV cache management and lead to a higher throughput, the tail latency also increases considerably. The quantized variants under the same workload do not show this behavior. We speculate that this is because they have more memory headroom by saving 20-30 GB of model memory. Apart from the 1.7B model deployed on a H100 GPU all other configurations provide efficiency gains by combining W4A8 or W8A8 quantization with a chunking strategy. While chunking of documents improves the inference efficiency, it might affect the translation quality by losing relevant context for correct translations. We discuss the effect of chunking strategies on translation quality in the next subsection.

### 4.3 Effect of Chunking Strategy on Translation Quality

Unlike the synthetic random-token workloads used in the previous section to cleanly isolate scheduling performance, evaluating translation quality requires real-world data. In this section we evaluate MT quality on document-level translations. Our results reveal that standard segment-level evaluation can underestimate the interaction between quantization and long-context document translation for certain quantization formats, translation directions and models.

The results for the UK → EN language pair can be found in Figure 3 with further results on EN → UK in Appendix A.4. A corresponding WMT24++ analysis, which can be found in Appendix A.4 shows a weaker and less consistent

Table 1: DocHPLT scores of EuroLLM-1.7B and EuroLLM-9B across different quantization formats in terms of chrF++. Target thresh refers to the target prompt-length threshold. Mean scores of chrF++ computed across subset of $N = 27$ documents of DocHPLT. Brackets show bootstrapped 0.95 confidence intervals. For more details, please refer to Section 4.3.

| Model | Format | Evaluation (chrF++ ↑) | | |
|---|---|---|---|---|
| | | Indep-segment translation (UK → EN) | Document-level eval Target thresh=100 tok | Document-level eval Target thresh=1500 tok |
| EuroLLM-1.7B | BF16 | 65.7, CI[58.2, 70.6] | 67.6, CI[59.2, 72.6] | 35.6, CI[28.7, 41.1] |
| | W8A8 | 58.6, CI[51.9, 64.3] | 65.3, CI [57.2, 70.3] | 30.7, CI [24.5, 36.0] |
| | W4A16 | 63.6, CI[56.5, 69.0] | 66.2 , CI[58.7, 70.6] | 6.3, CI[4.9, 8.5] |
| | | | Target thresh=100 tok | Target thresh=4000 tok |
| EuroLLM-9B | BF16 | 65.2, CI[60.3, 68.8] | 69.6, CI[65.1, 72.4] | 65.23, CI[60.0, 70.12] |
| | W8A8 | 63.4, CI[58.4, 67.1] | 68.3, CI[63.4, 71.2] | 60.22, CI[52.2, 66.2] |
| | W4A16 | 61.3, CI[56.2, 65.4] | 64.8, CI[60.5, 68.0] | 45.6, CI[ 36.8, 54.4] |

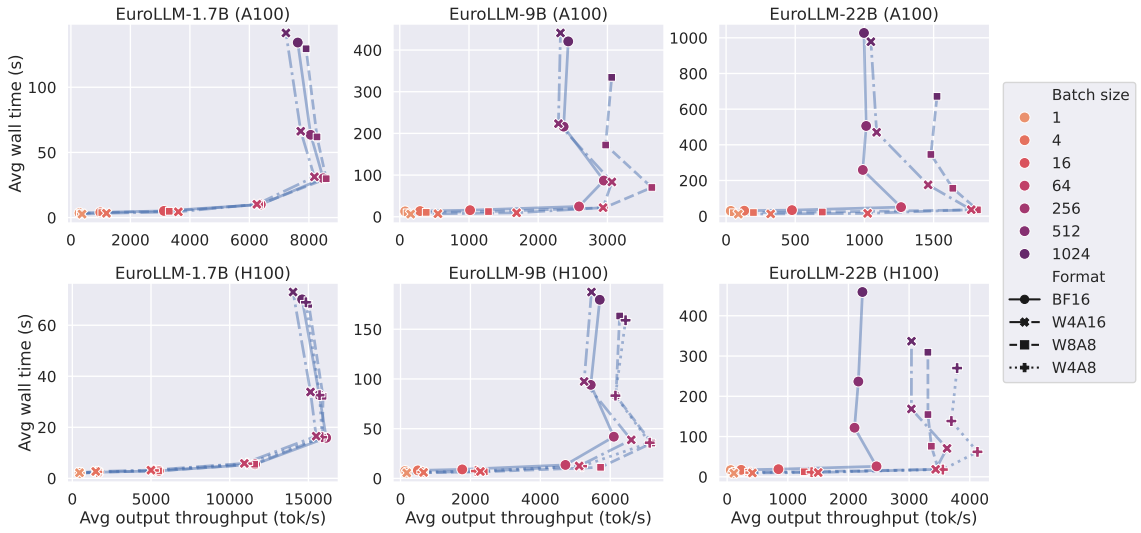

Figure 1: Offline benchmark measuring average output throughput in tok/s against average wall time for a sequence length of 1000 tokens across three sizes regimes on a A100 (top row) and a H100 (bottom row). Further results on other sequence lengths can be found in Appendix A.5.

effect up to a token threshold of 1000. The figures show that even though EuroLLM-1.7B has a context length of 4096, it translates longer inputs considerably worse, even at full BF16 precision. This observation is considerably weaker for the BF16 checkpoint of EuroLLM-9B, which was explicitly trained for long contexts up to 32K. In addition, our evaluation shows that standard segment-level MT benchmarks, such as WMT (Deutsch et al., 2025) or Flores+ (Goyal et al., 2022) can potentially underestimate the degradation of quantized MT models under long context for certain translation directions and quantization formats. This is highlighted in Table 1 as well as the right side of Figure 3, in which the W4A16 quantized checkpoints of EuroLLM-1.7B and EuroLLM-9B suggest a lower degradation on segment-level translations than what is observed if longer chunks are being translated directly. We note however that this effect is considerably weaker for W8A8 up to the considered sequence length as well as for the reverse translation direction EN → UK, as can be seen in Figure 5.

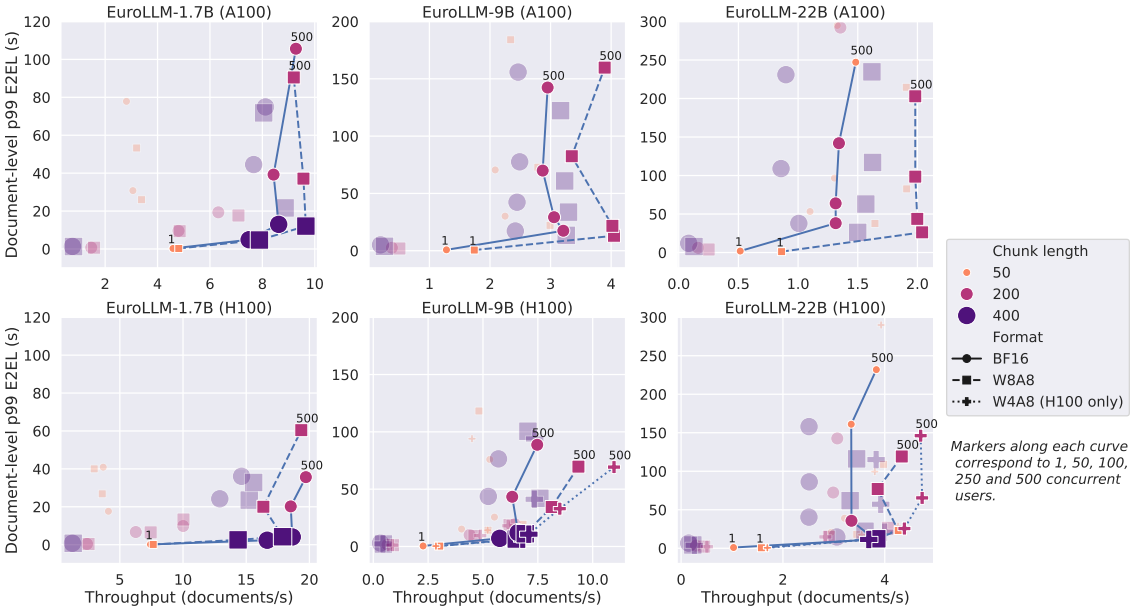

Figure 2: Closed-loop online benchmark for user concurrency from 1 to 500 users measuring throughput in documents/s against p99 full-Document latency for different chunking strategies on a document length of 1200 tokens across three model sizes on a A100 (top row) and a H100 (bottom row). Note that we did not benchmark W4A8 on the H100 for the 1.7B model size.

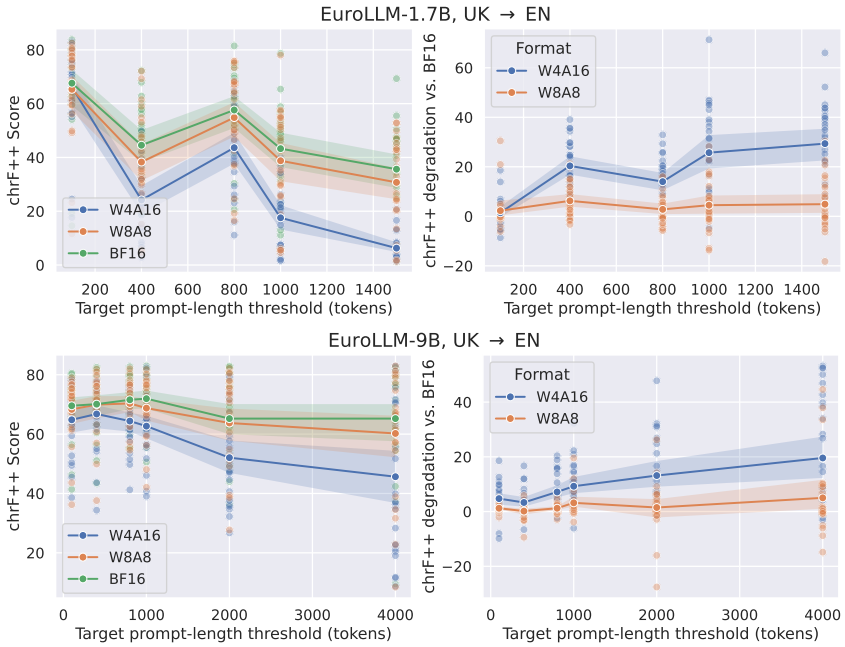

Figure 3: Chunk length vs. chrF++ Score for EuroLLM-1.7B (top row) and EuroLLM-9B (bottom row) across different quantization formats averaged across a subset of 27 documents from DocHPLT. Subplots on the right corresponds to paired per-document BF16 - quantized differences, where positive values mean degradation relative to BF16. Shaded area corresponds to bootstrapped 95% CI of document-level means. Note the different $y$ limits for better visibility. Every point corresponds to individual document scores. Additional results on other language pairs be found in Appendix A.4.

## 5 Discussion

The closed-loop online benchmarks have shown that document chunking can improve model serving efficiency. Across model sizes, mainly medium-sized and larger MT models benefit from quantization, while small models < 2B only show marginal benefits or even slight slow down compared to the BF16 baseline due to the overhead introduced by

dynamic activation quantization. The efficiency gains across the full range of workloads arise from a combination of higher compute capacity by making use of INT8 tensor cores and reducing the model size, where the latter is beneficial both at low workloads when inference is memory bandwidth-bound as well as during capacity-bound serving under high user concurrency where memory savings benefit KV cache management and scheduling efficiency during online inference.

Furthermore, our experiments on how chunk length affects translation quality have shown that standard segment-level MT benchmarks can potentially underestimate the degradation for longer context translation for certain translation directions and quantization formats, which needs to be carefully evaluated case-by-case. While in some cases the quantized checkpoint follows the BF16 baseline closely, it can lead to a measurable degradation in MT quality in other cases, such as the W4A16 quantized checkpoints of EuroLLM-1.7B and EuroLLM-9B evaluated on UK $\rightarrow$ EN. We hypothesize that the different context length ranging from 4K to 32K of the models considered as well as the data that the models have been trained on play a major role. For instance, EuroLLM-1.7B is instruction-tuned only on segment-level translation pairs (Martins et al., 2025). In addition, the sentence-level calibration data of OPUS (Tiedemann, 2016) could have biased the quantized model checkpoints toward shorter translation thresholds. Although identifying the mechanistic reason underlying the sensitivity induced by quantization is still open and out of scope for this work, we hypothesize that a short Quantization-aware training (QAT) or distillation run with long context translation samples can help to close this gap. If the Pareto-optimal chunk length in terms of efficiency is longer than for translation quality, one could resolve this discrepancy by simulating shorter chunks using appropriate block-diagonal attention masks (though this adds additional overhead), but in the other case it results in a trade-off between achieving higher inference efficiency and better translation quality. We note however that we do not construct a joint quality–efficiency Pareto frontier in this work, since translation quality is evaluated only for a subset of the models and quantization formats considered in the inference benchmarks.

We summarize key takeaways of our work below:

1. **Quantization to W8A8 or W4A8 can improve the latency-throughput tradeoff, depending on hardware and model size.** Among the configurations supported in our vLLM setup, for models of 9B parameters and above, W8A8 on the A100 and W4A8 on the H100 can provide improved throughput at similar latency. At higher batch sizes, activation quantization is particularly important on the A100, whose lower compute-to-memory-bandwidth ratio causes inference to become compute-bound sooner.

2. **Quantization and document chunking should be optimized jointly for inference efficiency.** Across most evaluated deployment settings, combining W8A8 or W4A8 with chunk lengths of approximately 200–400 tokens improves the latency-throughput Pareto frontier for medium-length documents.

3. **Sentence-level MT benchmarks can underestimate long-context degradation.** Evaluations based on isolated segments can underestimate how translation quality changes with longer context and can therefore conceal degradation that occurs during document-level inference, in particular when deploying quantized models. This strongly depends on the considered quantization format and translation direction.

## 6 Limitations and Future Work

In this work, we only considered GPTQ (Frantar et al., 2022) combined with (Xiao et al., 2023) as a quantization method and it is possible that more sophisticated PTQ methods or QAT do not show degradation for longer contexts observed on the quantized EuroLLM models. We also did not control for the calibration data used for PTQ, and it remains to be verified whether longer context calibration data can reduce the degradation. We note that we apply dynamic activation quantization, which added an overhead in the inference benchmark, which could potentially be removed. While static activation quantization can help, it risks to potentially degrade the translation quality. Further, we point out that W4A8 was not tested on A100 due to missing vLLM support. It thus remains an open question, whether W4A8 will be preferable over W8A8 once corresponding software-support exists. Furthermore, we only evaluated how trans-

lation quality changes with chunk lengths on two translation directions, so they might be different for low-resource languages.

Our quality evaluation was also performed only across a subset of 27 UK $\rightarrow$ EN, respectively 13 EN $\rightarrow$ UK documents of DocHPLT, which needs to be extended to more documents in future work. While we ran quality experiments up to a threshold of 4K tokens, it is still not close to the 32K context length of EuroLLM-9B, so we were not able to characterize the behavior of EuroLLM-9B close to its context limit. Finally, in this work we focused only on weight and activation quantization. We leave the consideration of KV cache quantization for inference and quality retention for future work.

## 7 Conclusion

In this work, we have studied quantization trade-offs for efficient inference deployment for machine translation on the EuroLLM model family on a A100 and a H100 GPU. By evaluating the inference efficiency across three models, spanning 1.7B to 22B under closed-loop synthetic online benchmarks on vLLM, we find that for model sizes of 9B and above W8A8 generally provides the strongest Pareto performance in the evaluated configurations on the A100, while W4A8 provides the strongest Pareto performance on the H100. For small models < 2B W8A8 leads to marginal efficiency gains or even slight slowdown. In our synthetic document-serving benchmark we show that chunking medium-sized documents into chunks of 200-400 tokens is Pareto-optimal for inference efficiency. Finally, we observe that translation quality is better for shorter thresholds, while the robustness for longer sequences differs for model sizes, quantization format, and translation direction.

# A Appendix

## A.1 A concrete GEMM-only roofline model

We first consider an idealized model that includes only GEMM FLOPs and the movement of GEMM operands between HBM and the GPU. For

$$Y = XW, \qquad X \in \mathbb{R}^{M\times K}, \quad W \in \mathbb{R}^{K\times N},$$

the number of FLOPs and transferred bytes are approximated by

$$F_{\text{gemm}} = 2MKN,$$
$$Q_{\text{gemm}} = b_a MK + b_w KN + b_a MN,$$

where $b_a$ and $b_w$ denote the number of bytes per activation and weight, respectively. The arithmetic intensity is therefore

$$I_{\text{gemm}} = \frac{2MKN}{b_a MK + b_w KN + b_a MN}.$$

For a square hidden projection with $K = N = d$, this becomes

$$I_{\text{gemm}}(M; d) = \frac{2Md^2}{b_w d^2 + 2b_a Md}. \tag{1}$$

For $M \ll d$, weight traffic dominates and

$$I_{\text{gemm}}(M; d) \approx \frac{2M}{b_w}.$$

Consequently, with BF16 activations, the ideal arithmetic intensity is approximately $M$, $2M$, and $4M$ FLOP/byte for BF16, INT8, and INT4 weights, respectively.

We instantiate the analysis for the three EuroLLM models, see Table 2 for their architectural details.

The roofline model predicts the achievable GEMM performance, measured in FLOP/s, as

$$P_{\text{gemm}} = \min\left(P_{\text{peak}}, \text{BW}_{\text{HBM}} I_{\text{gemm}}\right),$$

where $P_{\text{peak}}$ denotes the hardware's theoretical peak compute throughput in FLOP/s and $\text{BW}_{\text{HBM}}$ its peak HBM bandwidth in bytes/s. The product $\text{BW}_{\text{HBM}} I_{\text{gemm}}$ is the maximum compute throughput that can be sustained by the available memory bandwidth.

Using dense BF16 Tensor Core throughput, an H100 SXM has an approximate ridge point of

$$I^{\text{H100}}_{\text{ridge}} = \frac{989 \text{ TFLOP/s}}{3.35 \text{ TB/s}} \approx 295 \text{ FLOP/byte},$$

while an A100 80GB SXM has

$$I^{\text{A100}}_{\text{ridge}} = \frac{312 \text{ TFLOP/s}}{2.039 \text{ TB/s}} \approx 153 \text{ FLOP/byte}.$$

Here we assume that weight-only quantized kernels unpack and dequantize weights on-chip and use the BF16 Tensor Core compute ceiling. This is an optimistic upper bound.

With BF16 activations, the approximate number of GEMM rows (calculated via Equation (1)) required to reach the compute-bound regime are shown in Table 3.

During decoding, $M = B$, where $B$ is the number of tokens processed together. At batch size one, all three EuroLLM models are therefore strongly memory-bandwidth bound. In this ideal model, INT8 and INT4 weights reduce weight traffic by factors of two and four and provide corresponding speedups.

As the batch size increases, the same weights are reused across more tokens. For example, the INT4 projection GEMMs become nominally compute-bound on H100 at batch sizes of approximately 104, 86, and 82 for EuroLLM-1.7B, EuroLLM-9B, and EuroLLM-22B, respectively. Beyond this point, further reducing weight traffic does not improve the idealized GEMM runtime.

During prefill, $M = BS$, where $S$ is the prompt sequence length. Consequently, even at batch size one, the projection and MLP GEMMs become compute-bound after only a few hundred prompt tokens. The GEMM-only model therefore predicts that weight-only quantization is most useful for low-batch decoding and much less useful for long-sequence prefill.

These theoretical considerations also generalize directly to activation quantization, provided that the hardware and kernels support computation in the chosen activation format. The effect of activation precision can be modeled by substituting the corresponding number of activation bytes into $b_a$ in Equation (1) and using the peak compute throughput of the corresponding hardware format. For example, if INT8 computation provides twice the peak throughput of BF16 while HBM bandwidth remains unchanged, the hardware ridge point doubles. Consequently, the GEMM remains memory-bound up to approximately twice the batch size, allowing further weight quantization to provide speedups over a correspondingly larger range of batch sizes. Reducing the activation size from two bytes to one

Table 2: Architectural details of EuroLLM models.

| Model | $L$ | $d$ | $d_{\text{ff}}$ | $n_q/n_{\text{kv}}$ | $d_{\text{kv}}$ | Parameters |
|---|---|---|---|---|---|---|
| EuroLLM-1.7B | 24 | 2048 | 5632 | $16/8$ | 1024 | 1.657B |
| EuroLLM-9B | 42 | 4096 | 12288 | $32/8$ | 1024 | 9.152B |
| EuroLLM-22B | 54 | 6144 | 16384 | $48/8$ | 1024 | 22.637B |

Table 3: Approximate number of GEMM rows required to reach the compute-bound regime under BF16 activations, calculated via Equation (1).

| Model | GPU | BF16 weights | INT8 weights | INT4 weights |
|---|---|---|---|---|
| EuroLLM-1.7B | H100 | 415 | 207 | 104 |
| | A100 | 180 | 90 | 45 |
| EuroLLM-9B | H100 | 345 | 172 | 86 |
| | A100 | 165 | 83 | 41 |
| EuroLLM-22B | H100 | 327 | 163 | 82 |
| | A100 | 161 | 81 | 40 |

byte further decreases activation traffic, although this effect is small when weight traffic dominates.

**Why decode can nevertheless benefit less than predicted.** The GEMM-only model predicts no dependence of decode GEMMs on the existing context length. The projection and MLP GEMMs have $M = B$, irrespective of whether the context contains 1,000 or 30,000 tokens. Thus, under this model, decode latency would be constant with respect to context length. The observed context-length dependence comes primarily from attention and its KV-cache traffic.

For a model with $L$ layers and KV dimension $d_{\text{kv}}$, reading the BF16 key and value cache during one decoding step requires approximately

$$Q_{\text{KV}} = 2BLSd_{\text{kv}}b_a,$$

where the factor two accounts for keys and values. Unlike weight traffic, this traffic grows linearly with both batch size and context length.

The corresponding attention FLOPs are approximately

$$F_{\text{attn}} \approx 4BLSd,$$

giving an idealized attention arithmetic intensity of

$$I_{\text{attn}} \approx \frac{2d}{b_a d_{\text{kv}}} = \frac{2g}{b_a}, \qquad g = \frac{d}{d_{\text{kv}}}.$$

All three EuroLLM models have eight KV heads with head dimension 128, and therefore $d_{\text{kv}} = 1024$. Their GQA ratios and BF16 attention intensities are:

| Model | $g = d/d_{\text{kv}}$ | $I_{\text{attn}}$ [FLOP/byte] |
|---|---|---|
| EuroLLM-1.7B | 2 | 2 |
| EuroLLM-9B | 4 | 4 |
| EuroLLM-22B | 6 | 6 |

These values are far below the ridge point of either the A100 or H100. Decode attention is therefore strongly memory-bandwidth bound even when the projection and MLP GEMMs become compute-bound.

For the whole-model estimate, let $N_W$ denote the number of weights that must be streamed during one decoding step. We exclude the input embedding table because inference reads only the embeddings of the current tokens, but include the full output projection:

| Model EuroLLM | $N_W$ | BF16 weight bytes | INT4 weight bytes |
|---|---|---|---|
| 1.7B | 1.395B | 2.79 GB | 0.70 GB |
| 9B | 8.628B | 17.26 GB | 4.31 GB |
| 22B | 21.851B | 43.70 GB | 10.93 GB |

This assumes that all streamed matrices, including the output projection, are quantized. In practice, some implementations leave embeddings or the language model head in BF16.

In the fully memory-bound approximation, the upper-bound speedup from BF16 to INT4 weights

is

$$\text{speedup}_{\text{W4}} \leq \frac{2N_W + Q_{\text{KV}}}{0.5N_W + Q_{\text{KV}}}.$$

This approaches $4\times$ when weight traffic dominates, but approaches $1\times$ when KV-cache traffic dominates. Moreover, weights can be reused across the batch, whereas each sequence has its own KV cache. Large offline batches therefore make KV traffic important at much shorter context lengths.

The context length at which BF16 KV traffic equals the INT4 weight traffic is

$$S_{\text{cross}} = \frac{0.5N_W}{2BLd_{\text{kv}}b_a}.$$

For the concrete EuroLLM models, this gives:

| Model | $B = 1$ | $B = 4$ | $B = 64$ |
|---|---|---|---|
| EuroLLM-1.7B | 7,094 | 1,774 | 111 |
| EuroLLM-9B | 25,077 | 6,269 | 392 |
| EuroLLM-22B | 49,395 | 12,349 | 772 |

For EuroLLM-1.7B, KV-cache traffic already exceeds the INT4 weight traffic at approximately 111 tokens for an offline batch of 64. For EuroLLM-9B, the corresponding crossover occurs at approximately 392 tokens. For EuroLLM-22B, its larger weight matrices delay the crossover to approximately 772 tokens.

At the native maximum context lengths, the memory-traffic upper bound predicts:

| Model and context | $B = 1$ | $B = 4$ | $B = 64$ |
|---|---|---|---|
| EuroLLM-1.7B, $S = 4096$ | $2.90\times$ | $1.91\times$ | $1.08\times$ |
| EuroLLM-9B, $S = 32768$ | $2.30\times$ | $1.48\times$ | $1.04\times$ |
| EuroLLM-22B, $S = 32768$ | $2.80\times$ | $1.82\times$ | $1.07\times$ |

These numbers are upper bounds based only on total HBM traffic. They already show that a nominal $4\times$ reduction in weight bytes need not translate into a $4\times$ end-to-end decode speedup.

This explains why weight-only quantization does not always yield the speedup suggested by the reduction in model size. At small decode batches and short contexts, weight traffic dominates and the GEMM-only roofline predicts a large gain. At larger batches, weights are amortized across tokens and the GEMMs may become compute-bound. At long contexts, KV-cache reads and attention dominate the remaining memory traffic, so reducing weight bytes has progressively less effect.

Finally, the idealized model ignores the cost of unpacking and dequantizing weights, quantization scales and zero points, small-$M$ GEMM underutilization, kernel-launch overhead, normalization and positional-encoding kernels, paged-KV-cache indirections, communication, and sampling. It also assumes that every matrix is quantized and that all HBM traffic reaches peak bandwidth. These effects can make the realized speedup substantially smaller than the roofline upper bound.

### A.2 Details on Quantization Formats

We provide additional details to the three quantization formats that we consider in this work: W8A8, W4A8, and W4A16 weight quantization. In W8A8, the weights are rescaled by the absmax of each row along the output dimension, while the activations are similarly quantized dynamically along the token dimension. As discussed in (Xiao et al., 2023), this maps well to hardware-accelerated GEMM kernels, as one can apply the scaling factors after the matrix multiplication:

$$\mathbf{Y} = \text{diag}(\Delta_{\mathbf{X}}^{\text{BF16}}) \cdot (\bar{\mathbf{X}}^{\text{INT8}} \cdot \bar{\mathbf{W}}^{\text{INT8}}) \cdot \text{diag}(\Delta_{\mathbf{W}}^{\text{BF16}}),$$

where $\mathbf{Y} \in \mathbb{R}^{d_{\text{in}} \times d_{\text{out}}}$ refers to the output matrix, $\bar{\mathbf{X}}^{\text{INT8}} \in \mathbb{R}^{d_{\text{in}} \times n}$ and $\bar{\mathbf{W}}^{\text{INT8}} \in \mathbb{R}^{n \times d_{\text{out}}}$ refer to the quantized activation and weight matrices, stored in INT8, and $\Delta_{\mathbf{X}}^{\text{BF16}} \in \mathbb{R}^{d_{\text{in}}}$ and $\Delta_{\mathbf{W}}^{\text{BF16}} \in \mathbb{R}^{d_{\text{out}}}$ refer to the activation scale vector, respectively the weight scale vector, stored in BFloat16.

For W4A8, weights are quantized with a group size of 128 following (Zhang et al., 2024b), while activations are dynamically quantized along the token dimension. Finally for W4A16 weight quantization, weights are also quantized with a group size of 128 while activations remain unchanged. All linear layers in the model, except for the embedding and prediction head layer, are being quantized using the same data format.

### A.3 Details on document-level evaluation

We provide additional details on the document-level evaluation in this section. The prompt template used for the evaluation of both models can be found in Table 4, which we took from (Martins et al., 2025). We choose a temperature of $T = 0$, $\text{top}_p = 0.8$, and max_tokens $= 4096$ as decoding parameters and evaluate document chunking for target prompt-length thresholds in $\{100, 400, 800, 1000, 1500\}$ tokens for EuroLLM-1.7B and in $\{100, 400, 800, 1000, 2000, 4000\}$

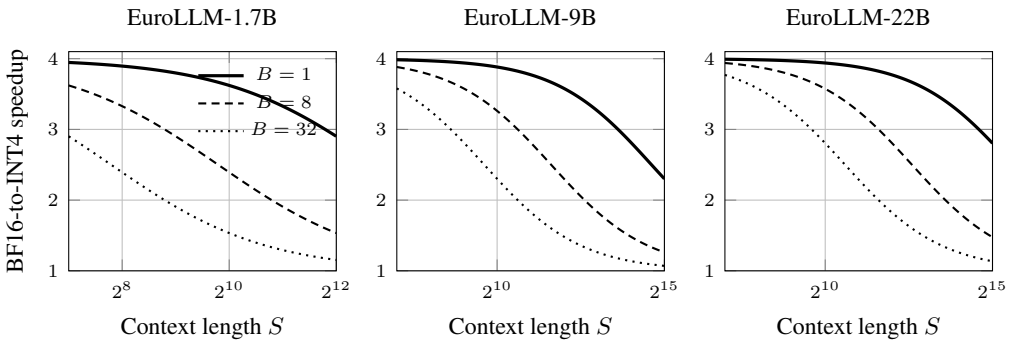

Figure 4: Memory-bandwidth upper bound on the speedup from BF16 to INT4 weights for the three EuroLLM models with a BF16 KV cache. Increasing context length or batch size increases KV-cache traffic, which is unaffected by weight-only quantization. The relative memory-bound speedup is independent of the GPU's absolute HBM bandwidth, although absolute latency is lower on the H100.

tokens for EuroLLM-9B on DocHPLT. On WMT24++ we evaluate document chunking for target prompt-length thresholds in $\{100, 200, 400, 500, 600, 800, 1000\}$. We note that we do not split segments and keep trailing chunks. This means that the chunk lengths can overshoot on some chunks and documents can end with a chunk much shorter than the threshold. Note that the target thresholds also include the rendered chat template. Across the four translation directions we have 27 matched documents for UK $\rightarrow$ EN, 13 documents for EN $\rightarrow$ UK from DocHPLT, as well as 19 matched documents for DE $\rightarrow$ EN and 11 documents for EN $\rightarrow$ DE from WMT24++. The common document subset was formed by performing an intersection of valid documents across all models, formats and target thresholds for each translation direction. We compute the chrF++ scores by setting word_order $= 2$. The transformers version used for the experiments was 5.14.1

### A.4 Further Results on Chunk Length vs. Translation Quality

We provide further experimental results on how chunk length affects translation quality for English to Ukrainian translation on a subset of DocHPLT (Figure 5). Earlier experiments on EN $\leftrightarrow$ DE on WMT24++ can be found in Figure 6 and Figure 7. The results show that whether an increased degradation with context length depends not only on the quantization format and translation direction, but also on the model itself. Note that WMT24++ contains considerably shorter documents, such that translation quality is only evaluated up to a threshold of 1000 tokens limiting its power to say anything for long document translations.

### A.5 Further Results on Offline Benchmarking

We provide further results on offline benchmarking models from the EuroLLM family for sequence lengths of 100 tokens in Figure 8.

## Abstract

Current human evaluation of machine translation typically assesses single outputs in isolation, a paradigm that suffers from high annotator noise and cost. We introduce Contrastive Error Span Annotation (cESA), a protocol that presents multiple translations of the source input (text, video, audio, image). In cESA, the annotator sees multiple translations of the same document, marks major and minor error spans, and then assigns a score from 0% to 100% on absolute scale. By allowing annotators to access the shared context across multiple outputs, cESA facilitates more consistent and efficient judgments. We validate cESA using a large-scale human evaluation of English→Japanese translations of 12 models, demonstrating reductions in annotation time and noise compared to standard pointwise evaluation. Unlike existing contrastive ranking methods, cESA yields absolute quality judgments that enable simple, interpretable non-parametric model rankings without the need for post-hoc corrections.[1]

## 1 Introduction

Human evaluation ultimately decides research direction and deployment decisions. Unfortunately, it comes at a high cost because the annotation noise needs to be balanced by large scale. Many attempts have been made to improve human evaluation of translation by modifying the instructions and types of assessments (Graham et al., 2013a, 2013b, 2017; Freitag et al., 2021a; Kocmi et al., 2024; Zouhar et al., 2025; Ferstler et al., 2026). However, most of these modifications happen within the framework where a source input is shown next to a single translation. In contrast, some approaches show multiple outputs at the same time, but either in a scenario where *all* model outputs can be shown next to each other (Bojar et al., 2016; Novikova et al., 2018) or with only a *subset* of model outputs shown next to each other with post-hoc estimation of model quality (Callison-Burch et al., 2007; Sakaguchi et al., 2014; Sakaguchi and Van Durme, 2018). Showing multiple outputs at the same time is beneficial for multiple reasons, as supported by psychometrics, known as *joint vs. separate evaluation* (Hsee, 1996): (1) finding mistakes in one translation helps in finding mistakes in another translation of the same input (Meyer and Schvaneveldt, 1971), (2) seeing the space of possible translations helps in objective assessment (Hsee, 1996), and (3) sharing the same document context and not duplicating reading times makes the overall annotation faster (Sweller, 1988).

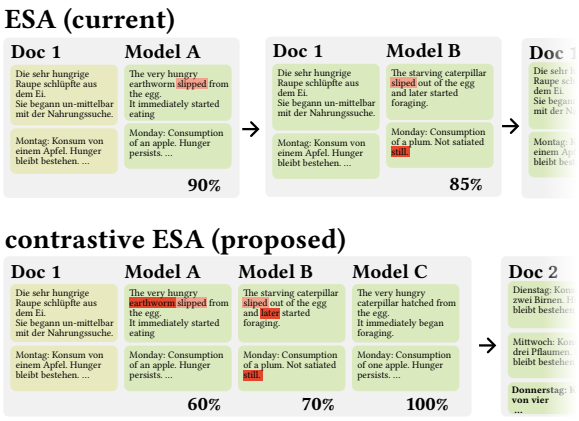

Figure 1: Comparison of pointwise and contrastive ESA. In the standard pointwise ESA (top), some errors go undetected. In contrastive ESA (bottom), multiple outputs are shown at the same time, which also speeds up the annotation.

In this work, focused on human annotations, we propose simple but effective modifications to the standard pointwise Error Span Annotation (Kocmi et al., 2024) by annotating multiple document-level translation outputs next to each other in the scenario with many outputs in the competition, which cannot all be shown at the same time. The result is a new standardized and tested annotation protocol, cESA (Contrastive Error Span Annotation). We further answer practical questions to make this annotation protocol production-ready at scale:

- What is the optimal number of outputs to show next to each other, what are the tradeoffs, and other necessary user interface aspects?
- What is the nature and severity of biases when showing multiple outputs at the same time?

We define the cESA annotation protocol in Section 3 together with measures of what quantitatively makes a good annotation protocol. We use cESA for human evaluation experimentally in Section 4 on WMT25 translation evaluation (Kocmi et al., 2025b). We show that against standard pointwise ESA, our cESA with three models at the same time can save up to 31% of the annotation cost (average time 77.8s → 53.7s) per item while increasing the annotation quality, as measured by higher annotation stability and inter-annotator agreement.

**Using cESA.** Based on our findings, we encourage future evaluators of translations to adopt this evaluation protocol, which we make available in an existing annotation interface, that can be launched with minimal setup (Listing 1).

## 2 Related Work

The general WMT translation shared task (Kocmi et al., 2025b, inter alia) is an example of a periodic large-scale evaluation effort. Annually, across many language directions, many models are evaluated, which necessitates high-quality yet economic human annotation protocols. For good scientific practices, the annotation protocol itself needs to be formalized and tested before being used as a measurement instrument (Schuff et al., 2023; Thomson et al., 2024; Belz et al., 2024), even if similar approaches might have been ad-hoc used for evaluation without the goal of verifying the quality of the annotation protocol (Popel et al., 2020, inter alia).

**Pointwise evaluation.** We distinguish between *pointwise* and *contrastive* evaluation paradigms. Machine translation is commonly evaluated with protocols where a single source and single output is shown. The simplest is Direct Assessment (DA, Graham et al., 2017) with a single-number judgment per translation. More complex, Multidimensional Quality Metrics (MQM, Freitag et al., 2021b) have expert annotators mark erroneous spans, their severity, and their category. The Error Span Annotation (ESA, Kocmi et al., 2024) attempts to strike the balance between depth and economic feasibility by skipping the error categorization and still including the final numerical judgment. Importantly, Knowles and Lo (2025) call for context-aware human evaluation, which improves the calibration of scores and reduces noise.

**Contrastive evaluation.** In contrast, evaluating with absolute scores in isolation is noisy (Knowles and Lo, 2025)[2] and evaluating with ranking or comparison holds promise for more accuracy (Thurstone, 1927; Briakou et al., 2023). Even WMT has used ranking with multiple outputs at the same time (Bojar et al., 2016). This specific evaluation approach showed all model outputs at the same time, which is difficult to scale to document-level evaluation. Recently, Song et al. (2025) extended standard MQM with side-by-side

[2]This problem is exacerbated by common annotation tools not supporting navigating to previous screens to update annotations once, for example, a new error mode is discovered.

Figure 2: Two screenshots of document-level contrastive ESA (cESA) with four model outputs shown next to each other. Each segment translation has a marked list of error spans minor or major and final score from 0 to 100%. See more screenshots and annotation guidelines in Appendix A and Appendix B.

MQM, which yielded higher-quality annotations. However, this approach does not clearly scale up beyond two document outputs. Increasingly, automated evaluation metrics have also been transitioning from single input that is being scored to taking multiple translations at the same time (Züfle et al., 2025; Moosa et al., 2024).

Outside of machine translation evaluation, the dominant paradigm has been comparison, due to the absence of absolute score evaluation protocols. For example, Chatbot Arena (Chiang et al., 2024) and K-Sort Arena (Li et al., 2025) has the crowd choose between two models and $K$ outputs respectively. EASL and RankME (Sakaguchi and Van Durme, 2018; Novikova et al., 2018) combine ranking and absolute score assessment where, similar to contrastive ESA, multiple outputs are shown next to each other. However, instead of ranking, each output is assigned with a score.

The disadvantage of such contrastive approaches is that either (1) all models are at some point compared to all other models uniformly, or (2) a mechanism needs to be devised to obtain a fair model comparison post-hoc. This is because in the second case, some models might have been compared to only the best models and are thus at a disadvantage. For the second option, Callison-Burch et al. (2007) suggest average rank, but which prevents absolute measurements (i.e. average translation quality). There are many other nuanced approaches, which typically use some parametric Bayesian modelling, such as via Trueskill (Herbrich et al., 2006; Minka et al., 2018), to obtain the model ability (Sakaguchi et al., 2014; Sakaguchi and Van Durme, 2018; Chiang et al., 2024). This comes at the cost of having the final model ranking be latent and given by a parametric model, which makes it difficult to naturally interpret, as opposed to a simple average across evaluation items. Instead, we treat this as a human-focused problem such that the final ranking can be obtained non-parametically.

## 3 The cESA annotation protocol

In this section we define the contrastive error span annotation (cESA) protocol in detail. The cESA protocol shows a sequence of source documents on separate screens (one shown in Figure 2). On each screen, the source document is split across multiple segments and translated $k$ times with different models or translators. The task of annotators is to mark error spans in the translations with minor or major severity and assign a final score from 0% to 100% to each translation. Annotators have

• ***85-100% (Very Good)*** *Complete meaning transfer; perfectly natural; no or minimal proofreading.*
• ***65-80% (Good)****: Near-complete transfer, minor inaccuracies; mostly natural, minor awkwardness; needs light proofreading.*
• ***45-60% (Acceptable)****: Main ideas conveyed, noticeable inaccuracies or omissions; uneven naturalness, awkward phrasing; usable only after substantial revision.*
• ***25-40% (Borderline)****: Partial transfer; frequent misinterpretation or omission confusing the message; often unnatural; requires major rewrite.*
• ***0-20% (Not acceptable)****: Violation of meaning; large portions mistranslated, missing, or incoherent; unusable without complete retranslation.*

Listing 2: Score anchors for cESA scores.

the opportunity to navigate to previous screens to update their annotations. In contrast to the existing ESA annotation protocol (Kocmi et al., 2024), the possible scores are defined with steps of 5% (so 0%, 5%, 10%, …, 100%), with more detailed anchors of what specific scores mean and tutorials. These anchors should also be used to objectively interpret cESA-annotated data (Listing 2).

See the detailed annotation guidelines and interactive tutorial, shown to all participants at the beginning, in Appendix A.

## 4 Human Evaluation

We run two human evaluation campaigns, which verify the efficacy of our two changes to the ESA annotation protocol in isolation:

- Small-scale standard ESA vs. cESA ($k = 1$) annotation of four translation models.
- Large-scale cESA annotation of ten translation models with $k \in \{1, 2, 3, 4\}$ number of model outputs shown at once on the same screen.

We re-use the data from the WMT 2025 general translation shared task (Kocmi et al., 2025b), specifically the English→Japanese translation subset with 97 segments across 38 documents in total, balanced across diverse domains of news, video, and social screenshots. These inputs vary in length between 1 up to 4 large segments (paragraphs) per document and between 10 to 120 words per segment.

The small-scale campaign covers 4 translation models with 1 extra duplicated translation to compute the inter- and intra-annotator agreement (i.e., will the same annotator give the same ratings to the same output in the same condition; Abercrombie et al., 2025). The large-scale campaign covers ten translation models[3] with 2 extra duplicated translations to estimate annotator agreement and also to align it such that all configurations (cESA with $k \in \{1, 2, 3, 4\}$) can show all translations across 12, 6, 4, and 3 screens, respectively. One of the translations is a human translation. All evaluations are run twice with different sets of annotators to estimate inter-annotator agreement (measuring the consistency across annotators).

The human experiment is designed with a within-subject design and randomly ordered conditions to eliminate subjective and learning effects on average. The experiment is controlled such that the annotator sees all translations for a particular document split across multiple screens, but only in a particular condition. For example, if one annotator saw a specific document in cESA (k=3), they saw all 12 translations (2 of which are duplicates) across multiple screens. They did not see the same document in other configurations, such as cESA (k=1). The annotators are professional translators fluent in English and Japanese, similar to the annotation crowds used in evaluation campaigns, such as WMT (Kocmi et al., 2025b).

They are shown the overall guidelines (Appendix A) but also an interactive tutorial (Appendix C). All annotations happen in the otherwise same annotation interface. The annotators could also navigate to previously annotated items and update their annotations. After completing the annotations, annotators filled an exit questionnaire.

### 4.1 Evaluation results

We show the overall aggregate results across both evaluation campaigns in Table 1, which we now discuss. Beyond annotation speed, which is a proxy for evaluation costs, we are interested in the following measurements:

- Intra-annotator agreement: how similar are two annotations of the same translations by the same annotator? This is quantified by mean absolute error between the two annotations.
- Inter-annotator agreement: how similar are two annotations of the same translations by two different annotators? This is quantified by mean absolute error between the two annotations.

[3]Gemini-2.5 Pro (Gemini Team, 2025), Algharb (Wang et al., 2025), Command-A-MT (Kocmi et al., 2025a), Claude 4 (Anthropic, 2025), DeepSeek-V3 (DeepSeek-AI, 2025), Online-B (anonymized publicly available MT), Mistral-Medium (Mistral AI, 2025), Yolu (Kocmi et al., 2025b, appendix C.33), Laniqo (Guttmann et al., 2025), and professional human translation. The small-scale campaign has human translation, Gemini, Online-B, and Laniqo translations.

| Campaign | Protocol | Time/seg.↓ | Time/err.↓ | InterAA MAE↓ | IntraAA MAE↓ | Stability↑ | Errors | Score distribution |
|---|---|---|---|---|---|---|---|---|
| (ablation) | ESA | 151.0s ±0.05 | 53.9s ±0.02 | 15.9 ±1.162 | 5.9 ±1.030 | 0.964 ±0.001 | 2.8 |  |
| | cESA (k=1) | 167.3s ±0.06 | 48.0s ±0.02 | 13.4 ±0.913 | 5.5 ±0.865 | 0.961 ±0.001 | 3.5 |  |
| (main) | cESA (k=1) | 77.8s ±0.01 | 40.5s ±0.01 | 20.0 ±1.065 | 9.7 ±1.542 | 0.801 ±0.001 | 1.9 |  |
| | cESA (k=2) | 55.4s ±0.03 | 42.2s ±0.02 | 19.0 ±1.012 | 14.1 ±2.316 | 0.785 ±0.001 | 1.3 |  |
| | cESA (k=3) | 53.7s ±0.04 | 35.3s ±0.03 | 17.0 ±1.049 | 10.5 ±1.851 | 0.812 ±0.001 | 1.5 |  |
| | cESA (k=4) | 59.3s ±0.06 | 38.2s ±0.04 | 19.0 ±1.046 | 8.4 ±1.487 | 0.796 ±0.001 | 1.6 |  |

Table 1: Aggregate results from two human evaluation campaigns (small- and large-scale performed by distinct crowds, separated by —). Time/seg and Time/err are average time per segment (translated "paragraph" in a document) and time per annotated error span. Inter/Intra shows annotator disagreement with themselves and with each other, as measured by mean absolute error (0 is best, 100 is worst). Stability is average model ranking correctness (Kendal $\tau_b$) of a random subset $p \in [10\%, 90\%]$ across 100 runs. Errors list the average number of error spans per segment. The ± shows 99% confidence interval using BCa bootstrapping with 10k samples.

- Stability: if we had only a portion of the data, would we arrive at the same model ranking? This is quantified as ranking similarity (Kendall $\tau_b$) of ranking based on a subset against model ranking on the whole data, averaged across 10%, …, 90% of the data.

**Main result: cESA (k=1) is higher quality than ESA.** The top part of Table 1 shows the results of small-scale ESA vs cESA (k=1). By simply updating the guidelines and the interface (clearer guidelines, detailed tutorial, color-coded discretized scales), we can obtain lower inter- and intra-annotator disagreement and higher stability. This is despite the annotators already having worked with the ESA protocol before but not cESA.

This is confirmed by the annotators specifically preferring the discretized (3.3 vs 3.8 on Likert-5) and anchored (3.5 vs 4.2 on Likert-5) scale.

**Main result: Annotating three models at the same time is faster.** The bottom part of Table 1 shows the results for the large-scale cESA evaluation with k=1, 2, 3, and 4.[4] By increasing the number of shown model outputs next to each other, we lower the average annotation time. However, this lowering happens just once when we transition from k=1 to k=2 model outputs and does not decrease further with more outputs. The optimum, in terms of annotation time and quality (indicated by lowest disagreement and highest stability), is when k=3 model outputs are shown next to each other. Same patterns occur across different input types (news, social media screenshots, videos), as shown in Table 2.

| Protocol | News | Social | Speech |
|---|---|---|---|
| cESA (k=1) | 81.1s ±0.07 | 55.4s ±0.07 | 100.3s ±0.02 |
| cESA (k=2) | 51.0s ±0.13 | 39.2s ±0.28 | 87.0s ±0.07 |
| cESA (k=3) | 43.0s ±0.22 | 55.7s ±0.46 | 71.3s ±0.09 |
| cESA (k=4) | 57.5s ±0.38 | 42.7s ±0.49 | 85.2s ±0.19 |

Table 2: Average time per segment for large-scale campaign (Table 2 second column, bottom part) split across different input types. *News* are text-only, *Social* contain screenshots of social media posts, and *Speech* are short narrated videos.

Again, the preference is corroborated by the annotators themselves stating their maximum number of models they can annotate at the same time (2, 2, 3, 3, 3, 4).

### 4.2 Potential Biases

We now focus on cESA only and address concerns of potential biases in presenting multiple outputs at the same time. While we find some evidence of bias on individual ratings as expected, their practical impact on quality evaluation remains negligible.

**Position bias.** The translation's position on the screen could potentially skew its score, because, for instance, the first shown translation could be inspected with more scrutiny. This is a common confounder occurring in most crowdsourcing campaigns (Lee et al., 2019). We mitigate the impact on final model ranking (Table 3) by shuffling

[4]The difference in cESA k=1 in small-scale (top) and cESA k=1 in large-scale (bottom) evaluation is caused by the difference in the annotation crowd and the selection of models.

| | cESA (k=1) | cESA (k=2) | cESA (k=3) | cESA (k=4) |
|---|---|---|---|---|
| Gemini-2.5-Pro | 80.4 | 85.4 | 83.2 | 82.5 |
| Algharb | 80.1 | 86.2 | 82.6 | 82.4 |
| Human | 75.5 | 81.2 | 81.3 | 81.1 |
| CommandA-MT | 76.5 | 82.2 | 78.1 | 78.2 |
| Claude-4 | 76.1 | 81.2 | 78.9 | 78.4 |
| DeepSeek-V3 | 72.5 | 80.7 | 77.1 | 77.5 |
| ONLINE-B | 72.4 | 78.6 | 76.0 | 75.0 |
| Mistral-Medium | 70.9 | 77.7 | 76.1 | 76.3 |
| Yolu | 66.4 | 75.0 | 70.8 | 70.3 |
| Laniqo | 58.0 | 68.7 | 64.5 | 66.0 |

Table 3: Model ranking according to the four configurations of cESA (main campaign). The final model ranking is based on collected score averages.

| | Pos. #1 | Pos. #2 | Pos. #3 | Pos. #4 |
|---|---|---|---|---|
| cESA (k=1) | 72.5 | | | |
| cESA (k=2) | 76.9 | 76.9 | | |
| cESA (k=3) | 77.1 | 77.1 | 77.4 | |
| cESA (k=4) | 76.6 | 76.6 | 75.5 | 77.8 |

Table 4: Score distribution of translations shown at a particular position on each screen (main campaign).

| | Max sim | Mean sim |
|---|---|---|
| cESA (k=2) | 0.4 | 0.4 |
| cESA (k=3) | 0.0 | −0.4 |
| cESA (k=4) | −0.5 | −1.1 |

Table 5: Differences in specific model output's scores in cases it was in a more similar context than on screens with more dissimilar other model outputs. The contexts are computed either with "maximum similarity" or "mean similarity".

the order, though we still investigate the severity of this bias. Contrary to expectations, the results shown in Table 4 show that there is very little distributional differences based on the position on the annotation screen.

**Surrounding similarity bias effect.** We investigate to what extent translations similarity affects the number of annotated errors. One possible problem is that when similar model outputs are presented, they will receive more annotated errors because the annotator already knows what to look for and can thus spend the rest of the annotation effort on finding more errors.

A direct correlation between similarity and assigned scores is confounded by source difficulty: easy and short inputs naturally result in both high similarity and high scores, consistent with minimum Bayes risk (Müller and Sennrich, 2021). We instead test a counterfactual proxy: if a specific model had less similar neighbors, would it receive fewer error annotations? Our experimental setup permits this measurement, as identical models are evaluated across multiple screens in varying contexts. For example, assume that for a particular translation, model A's output is very similar to B's and C's output but dissimilar to D and E. Then, if similarity does bias the scoring in the way that in a more similar context a given translation gets lower scores, the score of A in the following configuration A B C would be lower than the score of A in A D E.

We compute the similarity using symmetric chrF (Popović, 2015)[5] and consider comparing similarity within screens based on maximum or mean similarity. This similarity is computed between A and the rest of the screen. Each screen with A then gets a single scalar (maximum or mean) similarity based on which we compute the final statistics.

The proportion of times this happens is shown in Table 5, which hints at almost no effect of −0.2 points as sometimes more similarity increases the model score and vice versa.

**Surrounding quality bias effect.** We also analyze the effect of surrounding quality to determine whether the presence of strong models unfairly penalizes weaker ones, or whether the presence of weak models artificially inflates the reported performance of stronger models. This is occasionally referred to as the decoy effect (Eickhoff, 2018) and has been observed in translation evaluation (Bojar et al., 2011, 2016; Graham et al., 2014). We use a similar strategy as for similarity bias. If C is much better than A and B, would evaluation in A C lead to a lower score of A than evaluation in A B ?

The effect size is shown in Table 6, which hints at a very small but consistent bias: the presence of a stronger model on the screen causes model output to receive, on average −0.5 lower score.

[5]We chose a surface-level string similarity intentionally because a semantic-based one would abstract away from translation model paraphrases and erroneous choices.

| | Max score | Mean score |
|---|---|---|
| cESA (k=2) | −0.3 | −0.3 |
| cESA (k=3) | −0.6 | −1.4 |
| cESA (k=4) | −0.2 | −0.7 |

Table 6: Differences in specific model output's scores in cases it was in a more "competitive" context than on screens with lower-scoring other model outputs. The contexts are computed either with "maximum score" or "mean score".

| | Within-screen | Between-screen |
|---|---|---|
| cESA (k=1) | N/A | 22.2 |
| cESA (k=2) | 14.7 | 18.9 |
| cESA (k=3) | 12.9 | 17.8 |
| cESA (k=4) | 15.0 | 19.6 |

Table 7: Average absolute score difference between model outputs on the same screen (within-screen) and across screens (between-screen).

This is less than model average differences (see Table 3) and also alleviated by the model outputs per screen chosen randomly.

**Within-screen calibration.** Lastly, we discuss the calibration effect of multiple model outputs on the same screen. The overall distribution and span of the score is the same across all configurations cESA (k=1, 2, 3, 4); see last column of Table 1. At the same time, the difference between the scores of the same model output on the same screen and even across screens is smaller, as per Table 7. This means that simply having multiple models next to each other helps with higher annotation consistency.

## 5 Conclusion

In this work we advanced the state-of-the-art human annotation protocol for translation evaluation by building on existing ESA and introducing its updated and contrastive version, cESA. We evaluated it on diverse inputs of varying modalities and lengths and showed that it consistently yields higher-quality annotations than available alternatives. At the same time, we found no impactful biases that are introduced by this setup and the collected annotation scores can be used directly as averages for model comparison.

For evaluation practitioners, we recommend showing k=3 model outputs next to each other, which balances the speed up in time with annotation quality and does not overstrain annotators.

For ease of use, this annotation protocol is implemented in an existing ready-to-use annotation platform (Listing 1) together with tutorials in 18 language pairs.

## Limitations

There are other potential biases in human annotation protocols, such as the order in which model outputs are presented (Knowles, 2021). We sidestep this by shuffling the documents and by allowing annotators to go back and change previous responses, which was not the case in previous annotation interfaces.

## Ethics statement

The annotators were paid a standard industry wage and gave consent for their anonymized data to be used in a scientific study and published. The data does not contain any potentially harmful content.

## A cESA and ESA Annotation Guidelines

The full annotation guidelines are shown in Listing 3 and Listing 4. They are included by default when using the Pearmut tool (Listing 1). The annotation guidelines are shown at the top of the screen at all times (Figure 3).

***Task**: Read the source text and competing translations. Highlight all errors. Rate each translation (each column is an output from a single model/translator). At the end, click Next in top-right corner.*

***Highlighting errors:***
- *Select text containing an error to mark it as Minor. Then assign severity by hovering over the error span.*
- *Minor error: Imperfections or stylistic issues that do not impact the core message (e.g., awkward phrasing).*
- *Major error: Confuses meaning, misrepresents the source, or violates the message (e.g., incorrect information, confusing wording).*
- *Missing text: Highlight the* `[MISSING]` *tag if the translation omits important source text.*

***Important rules:***
- ***Multiple errors:** Use separate highlights for each error.*
- ***Hallucinations:** Highlight unsupported extra text; mark as Major.*
- ***Wrong language:** Highlight the entire text, mark as Major, and assign a score of 0.*
- ***Consistency:** Check translation consistency (e.g., technical terms) across the document.*

***Rating scale (0-100%):***
- *85-100% (Very Good): Complete meaning transfer; perfectly natural; no or minimal proofreading.*
- *65-80% (Good): Near-complete transfer, minor inaccuracies; mostly natural, minor awkwardness; needs light proofreading.*
- *45-60% (Acceptable): Main ideas conveyed, noticeable inaccuracies or omissions; uneven naturalness, awkward phrasing; usable only after substantial revision.*
- *25-40% (Borderline): Partial transfer; frequent misinterpretation or omission confusing the message; often unnatural; requires major rewrite.*
- *0-20% (Not acceptable): Violation of meaning; large portions mistranslated, missing, or incoherent; unusable without complete retranslation.*

*For unexpected problems and remarks, use comment box in ⚙ (top right).*

Listing 3: Annotation guidelines for the cESA protocol (ours).

***Error spans:** Click on the start of an error, then click on the end to mark an error span. Hover over an existing highlight to change error severity (minor/major) or remove it.*

***Error severity:***
- ***Minor**: Style, grammar, or word choice could be better.*
- ***Major**: Meaning is significantly changed or is hard to understand.*
- ***Tip**: Mark the general area of the error (doesn't need to be exact). Use separate highlights for different errors. Use* `[missing]` *at the end of a sentence for omitted content. Score each translation using the slider based on meaning preservation and quality.*
- ***Important**: The relative order of scores matters; ensure better translations have higher scores than worse ones.*
  - *0: Broken/Nonsense*
  - *33%: Flawed: substantial issues.*
  - *66%: Good: small issues with grammar, fluency, or consistency.*
  - *100%: Perfect: meaning and style align completely with the source.*

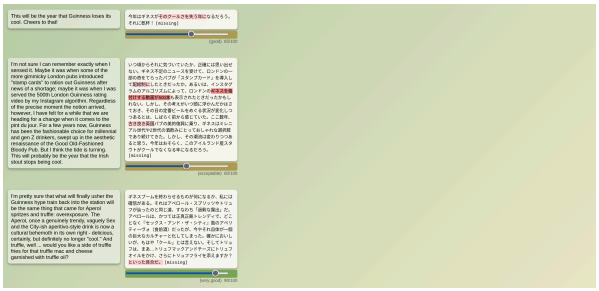
## B Screenshots

See Figure 3 for screenshots of the four configurations across domains (you will need to zoom in).



cESA (k=4) with four model translations of a video next to each other and the annotation guidelines at the top.

cESA (k=3) with three model translations of a multiple paragraphs in a document next to each other.

cESA (k=2) with two model translations of a social media thread next to each other.

cESA (k=1) with one model translation of a document.

Figure 3: Screenshots of four configurations of contrastive ESA in Pearmut. The widths of the model output panels were intentionally kept the same to avoid any UI-based effects on the annotation.

## C Tutorials

Each annotator was shown a tutorial task in addition to the general guidelines, which they could refer to. These tutorials, shown in Figure 4, are in the format of X→English despite the task being English →X so that we guarantee the existence and severity of errors on the English side. We provide these tutorials for future practitioners for Egyptian Arabic, Belarusian, Czech, German, Estonian, Armenian, Indonesian, Icelandic, Italian, Japanese, Kazakh, Korean, Russian, Northern Sami, Thai, Ukrainian, Traditional Chinese, and Chinese into English and can further be extended.

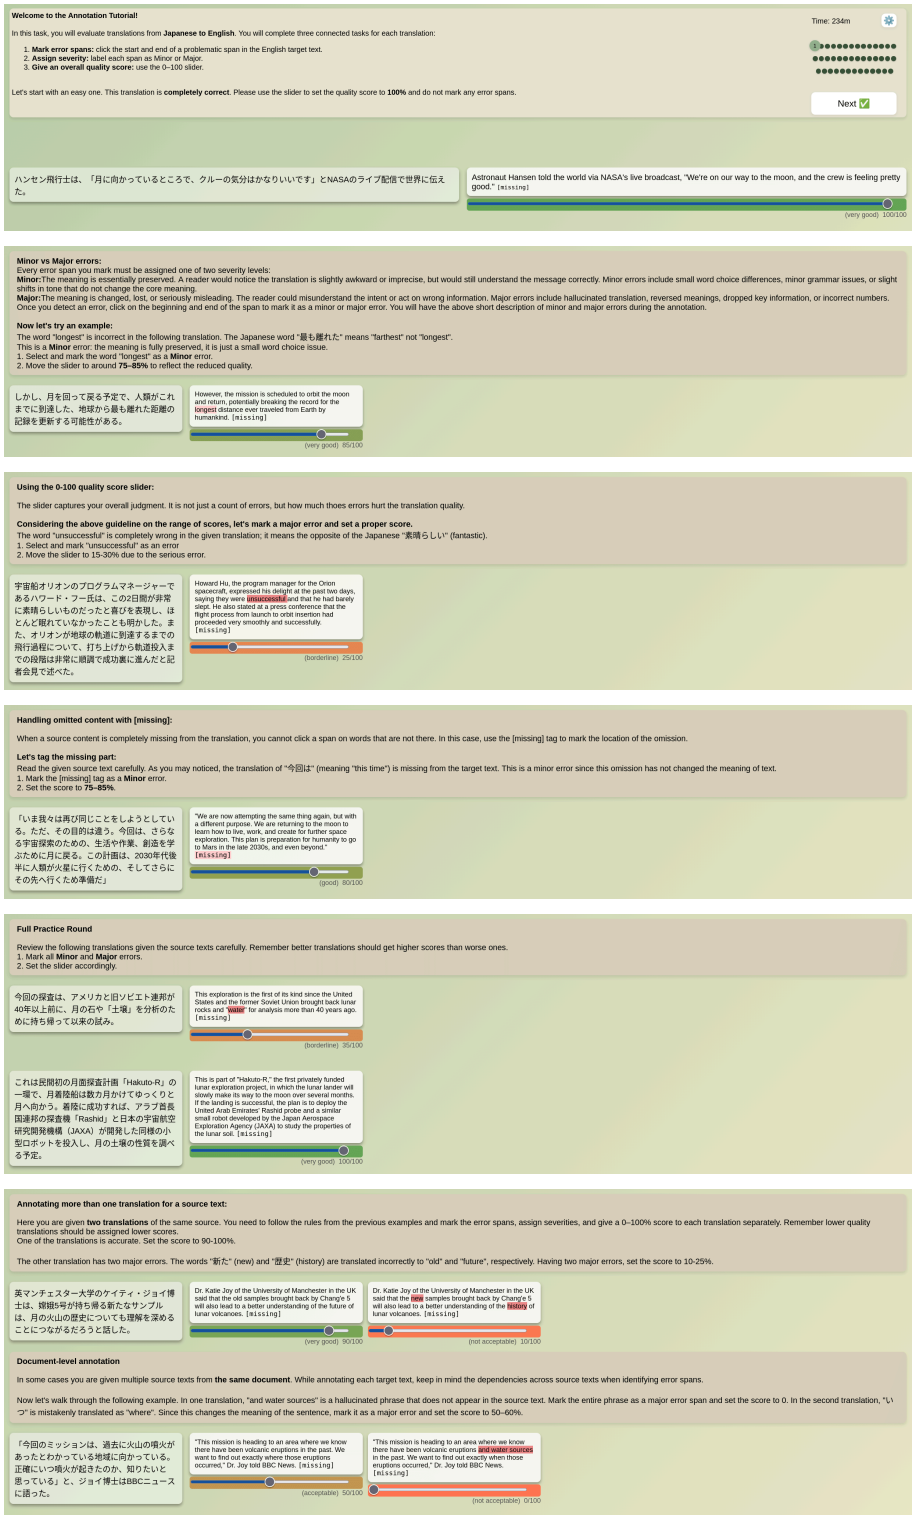


Figure 4: Sequence of six introductory tutorial steps that teaches the annotators the translation evaluation task.

## Abstract

This paper presents the results of the General Machine Translation Task organized under the 2026 Conference on Machine Translation (WMT). Participants build systems for any of the 23 language pairs spanning four to five domains. This year we brought major changes to the human evaluation: (1) new annotation platform Pearmut for better reproducibility, (2) new human protocol "contrastive Error Span Annotation" for higher quality and side-by-side evaluation, and (3) Dynamic human evaluation that allows assessing all submitted models while evaluating higher-performing models more frequently. Beyond human evaluation, we (4) extended difficulty sampling with a human-driven stage, (5) added two new domains, (6) made the test sets fully document-level without requiring segment-level alignment and relying on HTML or JSON structure, (7) prepared some human references by post-editing open-weight model outputs, and (8) introduced contextual instructions governing formality and structural style. We evaluated 46 systems in total: 30 submitted by participants and 16 consisting of translations from large language models (LLMs) and industry translation providers.

## 1 Introduction

The Eleventh Conference on Machine Translation (WMT26) was held in conjunction with the 2026 Conference on Empirical Methods in Natural Language Processing (EMNLP 2026). This 21st iteration of the conference builds on previous editions (2006; 2007; 2008; 2009; 2010; 2011; 2012; 2013; 2014; 2015; 2016; 2017; 2018; 2019; 2020; 2021; 2022; 2023; 2024; 2025) and hosted thirteen shared tasks on various aspects of machine translation (MT). This paper describes two of these tasks, the General Machine Translation shared task and MT Test suites.

The goal of the General Machine Translation shared task is to explore the translation capabilities of current systems across different domains and a broad range of language pairs. We focus on the following domains: news, social/user-generated content, speech, software, educational, and fact-checking texts. These domains were chosen to cover diverse styles while remaining broadly accessible; thus allowing for evaluation by human annotators without in-domain expertise. However, due to limited access to monolingual data, the set of evaluated domains is not identical across all language pairs.

Our evaluation includes the following 23 language pairs:

Czech→Ukrainian,
Czech→German,
Czech→Vietnamese ***(new)***,
Simplified Chinese→Japanese,
English→Egyptian Arabic,
English→Armenian ***(new)***,
English→Belarusian ***(new)***,
English→Simplified Chinese,
English→Traditional Chinese,
English→Czech,
English→Estonian,
English→German,
English→Icelandic,
English→Indonesian ***(new)***,
English→Japanese,
English→Kazakh ***(new)***,
English→Korean,
English→Ladin ***(new)***,
English→Ligurian ***(new)***,
English→Northern Sami ***(new)***,
English→Russian,
English→Thai ***(new)***,
English→Ukrainian.

Furthermore, this year focused on improving the shared task definition, data preparation and evaluation process in the following aspects:

- Contrastive Error Span Annotation protocol replaces previously used ESA and MQM by showing multiple translations to the human annotators at the same time next to each other.
- Dynamic evaluation where better systems are human-evaluated on more items allows all submitted models to be human-evaluated.
- Pearmut replaces Appraise as the platform for human evaluation due to higher reproducibility, more features, and ease of use.
- Extend source-only difficulty sampling with an human-driven Artificial Crowd stage, selecting sources whose translations receive the lowest average human evaluation scores.
- Add two new domains: Software, with English UI strings in JSON format requiring key and placeholder preservation; and Fact-checking, with Czech journalistic texts debunking false claims.
- Test sets are fully document-level and we no longer require participants to keep segment-level alignment.
- We prepared human references in two setups: fully translated by humans from scratch as in the past, as well as via post-editing of open weight models.
- We introduce instruction following context which instruct systems to follow particular formality, structure style.
- We no longer publish automatic evaluation scores as we cannot prevent participating systems in hill-climbing any of the metrics (Kocmi et al., 2025; Lavie et al., 2025).

Finally, test suites remain the part of the General MT task and for the third year they focus on translations produced by LLMs. These specialised test sets focus on phenomena which cannot be detected by the generic evaluation set-up.

**Findings of the General MT Task.** We make the following observations:

★ **The number of participants:** Participation slightly decreased this year, with a total of 30 submissions. Again, the majority of participants used LLMs in their systems, and one system fully relies on the rule-based approach. (Section 4).

- ★ **Human translations:** Human references reached the top cluster for 8 of the 12 provided language pairs (Section 6.4). Furthermore, while post-edited human translations consistently outperform their underlying base models, it remains inconclusive whether post-editing or translating from scratch is the superior strategy.
- ★ **Social domain was the most challenging:** The social domain texts were most challenging to translate, while software-related texts were the easiest (Section 6.4). The speech domain, being the most difficult last year and second most difficult this year, also remains as a challenge. The news domain seems to be more difficult than last year, probably due to the improved difficulty sampling.
- ★ **Lumen led the constrained track,** ranking in the top cluster for 20 of 23 language pairs in constrained track, followed by Qingqiu-MT-9B (Section 6.3).
- ★ **Language-specific models have potential:** Grammatist, LiLa, and CUNI-AR reached the top-performing participant cluster in every translation direction they entered, although other targeted submissions did not show the same pattern (Section 6.4).
- ★ **The best system** overall was Wayfinder, scoring in the top cluster for 17 out of 23 language pairs. It was followed by Gemini 3.1 Pro (15 language pairs), TRIVE (14 language pairs), and Lumen (13 language pairs). Notably, while the top three systems are all built utilizing Gemini, Lumen stands out as a fine-tuned model, making its competitive performance as a constrained system particularly encouraging.
- ★ **Significant cost variations:** The financial cost of translation varies widely and scales closely with model performance. Expenses span from a high of $252 for Gemini, through $83 for Google Translate, down to $4 for Tiny Aya.
- ★ **Low-resource languages** remain challenging. Although the top-ranked systems for some of these languages score above 80, most systems do not exceed 60. For some languages, challenges beyond data scarcity are also evident, including inconsistent use of language varieties and archaic forms (Section 6.4).
- ★ **Targeted test suites** reveal that current MT systems show consistent failures on figurative language, genre shifts, and terminological nuance, alongside pervasive stereotype-driven gender bias and a marked tendency toward hallucination and semantic detachment from source content – weaknesses that aggregated human evaluation scores largely fail to expose (Section 7).

All submissions to the General MT Task, along with sources, references, system translations, and human judgments, are available in the dedicated GitHub repository.

## 2 Test Data

In this section, we describe the test data collection process (Section 2.1) and the creation of human reference translations (Section 2.2). This year, we retain the difficulty-based sub-sampling procedure for source texts introduced last year and further extend it with an additional phase (Section 2.1.1). Motivated by the ever-increasing capabilities of modern MT systems, difficulty-based sub-sampling is designed to make our test sets more challenging by selecting source documents that are estimated to be more difficult to translate. This year, we implemented human-driven difficulty sampling in a form of artificial crowd. Furthermore, we include a toxicity-filtering step that prevents source documents containing toxic content from being included in the test set (Section 2.1.2).

### 2.1 Collecting test data

As in previous years, the test sets consist of source texts and their translations, created specifically for the shared task and released publicly as translation benchmarks. We collected public or openly licensed source data from a range of domains, focusing on the most recent data to minimize potential overlap with the pretraining and fine-tuning data of the systems under evaluation. Importantly, for all language pairs, the source texts were originally written in the source language and subsequently a subset of twelve language pairs were translated into the target languages by human translators. This approach is crucial to avoid "translationese" in the source texts, which can negatively affect evaluation accuracy (Toral et al., 2018; Freitag et al., 2019; Läubli et al., 2020; Graham et al., 2020).

**Domain and language coverage.** We collected data from six domains (news, social, speech, software, education, and fact-checking) and three source languages (Chinese, Czech, and English). However, not all domains are represented in all three source languages. Detailed statistics on the

| Language pair | News | Social | Speech | Software | Education | Fact-checking |
|---|---|---|---|---|---|---|
| | | | #words | | | |
| English→* | 6,363 | 11,425 | 8,656 | 2,485 | - | - |

Table 1: Per-domain statistics of our test sets, calculated on the source side. To compute word counts, we used simple whitespace tokenization for Czech and English and the spacy-pkuseg word segmentation tool for Chinese (Luo et al., 2019). Sentence segmentation was carried out using the language-specific spaCy models for English and Chinese, and the multilingual spaCy model for Czech (Honnibal et al., 2020), given that a language-specific one is not available.

test sets, including the language coverage of each domain, are provided in Table 1.

#### 2.1.1 Difficulty sampling

To identify documents that are particularly challenging for modern MT systems, we apply a two-step difficulty-based sub-sampling procedure based on the approach of Proietti et al. (2025). In Step 1, we estimate the difficulty of the collected source documents using their best-performing source-only estimator, sentinel-src-25. This model is an improved version of `sentinel-src`, a regression model based on XLM-RoBERTa Large (Conneau et al., 2020) and trained to predict translation quality using only the source text (Perrella et al., 2024). For each document, we estimate the difficulty of each segment and average the resulting scores to obtain a document-level difficulty score. We then retain the most difficult documents for inclusion in the test sets.

In Step 2, we estimate translation difficulty using the approach that Proietti et al. (2025) refer to as Artificial Crowd: (1) we translate the source texts using a crowd of translation systems, which serve as proxies for modern MT systems; (2) we ask human annotators to evaluate the generated translations; and (3) we subsample the most difficult documents, defined as those receiving the lowest human evaluation scores. Specifically, we translate the English source texts into Italian using a crowd of translation systems: Tower-Plus-9B (Rei et al., 2026), aya-expanse-8B (Dang et al., 2024), and NLLB-moe-54B (NLLB Team et al., 2022). We selected older or smaller models rather than more recent MT systems, aiming to minimize overlap with the participating systems and thereby confine this bias to models that are unlikely to be included in the final analyses, because artificial crowd-based difficulty sampling may bias the test set against the MT systems used as the crowd to generate translations, as it selects documents that are difficult for these systems to translate.

We then conduct a human evaluation campaign in which all three translations of the same input are evaluated side by side on a four-point Likert scale. We use the Pearmut annotation tool (Zouhar and Kocmi, 2026), and report the annotation guidelines in Table 2. Finally, we retain the most difficult documents, defined as those with the lowest aver-

Evaluate each Italian translation against the English source using the Acceptability slider.
**4 clearly acceptable:** faithful and natural, no meaningful edits needed.
**3 mostly acceptable:** meaning preserved, only minor issues.
**2 problematic:** noticeable errors or awkwardness, editing needed.
**1 unacceptable:** serious errors, omissions, or mistranslations.

Table 2: Guidelines provided to human annotators during Step 2 of the difficulty-based subsampling procedure (Section 2.1.1).

age translation scores. A document-level score is computed by averaging the scores of its segments,[1] while each segment-level score is computed as the average human score assigned to the translations produced by aya-expanse-8B and Tower-Plus-9B.[2]

Importantly, source-based difficulty subsampling (Step 1) is applied only to the news, social, and fact-checking domains, across all three source languages. The remaining domains either do not contain enough samples to support further subsampling or, in the case of the software domain, are included only in Step 2. Artificial Crowd-based difficulty subsampling (Step 2) is applied only to English source texts from the news, social, and software domains. Because Step 2 is more expensive than Step 1, as it involves human annotation, we restrict it to English source documents as English is the source language represented in the largest number of translation directions in our test set. The news and social domains are the only domains to undergo both stages of difficulty subsampling, with Step 1 followed by Step 2.

#### 2.1.2 Toxicity filtering

To identify documents containing toxic content, we used the MuTox toxicity detector (Costa-jussà et al., 2024). We assigned a toxicity score to each segment using MuTox; we then discarded a document if any of its segments received a toxicity score above a predefined threshold, which we heuristically set to 0.95.

#### 2.1.3 Instruction following context

With the increasing popularity of instruction-following LLMs, translation systems can be asked not only to preserve the meaning of the source text, but also to follow natural-language requirements concerning style, register, or output structure. We therefore extended the test sets with explicit translation instructions to use as additional context.

For each test item, we added a field to the additional context containing a translation instruction. Besides specifying the target language and requesting only the translation, the instruction described how the text should be translated for the given domain. For example, it requested a formal journalistic style for news and fact-checking, colloquial language for speech, informal and expressive language for social media, preservation of JSON keys and placeholders for software, and terminology suitable for educational material. Reformulated variants of these instructions were provided to the human annotators and are listed in Section A.1.

#### 2.1.4 Test sets statistics

**Source text segmentation.** To balance the evaluation across domains and source languages, we aimed for a consistent size for each source-language–domain combination, namely approximately 150 to 200 segments per domain (see Table 1). A segment contains one or more paragraphs, where each paragraph is defined by a line break (a `<br>` HTML tag) in the source document. In multi-segment documents, we enclose segments in `<p>`, `</p>` HTML tags, separated by a single newline `\n`. Whenever possible, we also try to keep the average segment length at approximately 60 words. Maintaining approximately the same number of segments per domain enables micro-averaging of segment-level scores without any single category disproportionately influencing the final scores.

The composition of the test sets remains domain-specific because of the different characteristics of the source texts. For example, the software domain, which consists of JSON data, contains only 2,485 words, while the speech domain contains fewer segments (approximately 120 per source language) than the other domains. Furthermore, the speech domain consists of single-segment documents, whereas the other domains contain multi-segment documents.

In the following paragraphs, we provide additional details about the data collection process for each domain.

**News domain.** (all translation directions) For this domain, the data was prepared similarly to previous years (Kocmi et al., 2025). We collected

[1]The only exception is the software domain, for which we assembled the final documents ourselves by combining the JSON key-value pairs with the lowest average translation scores. Thus, the software domain was subsampled at the key-value level rather than at the document level.

[2]NLLB-moe-54B achieved a particularly low average score of 1.98 on the news domain, compared with 2.76 for aya-expanse-8B and 3.17 for Tower-Plus-9B. We considered NLLB-moe-54B insufficiently representative and excluded it.

news articles published in early 2026 on online news sites and extracted the text while preserving paragraph boundaries. We specifically aimed to extract articles that were more challenging to translate. For English, we limited the news crawl to opinion pieces on the basis that they tend to use a more complex, literary style than the straightforward event reporting. For Czech and Chinese, we extracted a larger pool of news to follow up with down-sampling.

**Social domain.** (all translation directions) Mastodon is a federated social network that is compatible with the W3C standard ActivityPub (Webber et al., 2018). Users publish short-form content known as "toots", with the possibility of replying to other toots to form threads. This year, we focused on different servers with the aim of increasing a broader coverage of domains and languages. Though a particular server may claim to focus on specific languages or regions, in practice many languages and dialects are frequently present, reflecting the true nature of how humans use language. Regardless, we focused on mastodon.sg in an attempt to get Chinese data and witter.cz to get native Czech data. These servers do contain native Chinese and Czech data, but also contain other languages including lots of English. We also collected data from funami.tech, masto.nu, mastodon.com.pl, sakurajima.moe, and mastodon.ee which were nominally in Japanese, Dutch, Spanish, Polish, and Estonian, but in practice contained lots of English data. All data was scraped intermittently over a 6 week period in March and April of 2026.

As in the previous edition of the task, we aimed to collect threads made up of multiple toots in order to create documents. Therefore, in addition to scraping random toots from the previous hour, we also did targeted scraping of missing toots within partially sourced threads (identified using the 'in_reply_to_id' attribute of already sourced toots). To avoid spam and uninformative toots, we removed empty toots, texts that appeared several times (probable spam) and toots from accounts we heuristically identified as being news outlets or bots (containing the keywords 'bot', 'news', 'weather', 'sports', 'feeds' or 'press' in their handle). We created threads from the individual toots with a minimum and maximum length of 2 and 15 respectively, ignoring toots that had already been included thread (in cases where toots appear in several forks). Individual toots are separated with double newlines, and newlines within toots are preserved. As with the previous edition, we aimed to provide screenshots capturing the thread and including any accompanying images. The screenshots were used by human evaluators to aid translation. Unfortunately, automatically capturing screenshots was more difficult than in the previous edition, and several issues prevented us from obtaining screenshots for all scraped toots. These included toots published on other servers but visible on Mastodon, which had different and unexpected formatting, and toots that were no longer available on the platform. These issues caused most of the difficulties in obtaining screenshots for Chinese and Czech toots. In following years, we will need to overcome these challenges, one possibility being to artificially construct the screenshots using a uniform format from the downloaded metadata of toots.

**Speech domain.** (all translation directions) The speech corpus was compiled from Creative Commons (CC BY) licensed videos retrieved through the YouTube Data API in English, Czech and Mandarin Chinese. In WMT25 the retrieval queries named specific topics, and the resulting corpus was dominated by a few narrow domains; this year we used around one hundred deliberately broad queries (e.g. *short film drama*, *stage play*) so that the difficulty would come from the naturalness of spontaneous speech rather than from terminology. Candidate channels were filtered by view and subscriber counts, which removes low-quality uploads effectively, and by the language of the title and description; the spoken language was then verified from the audio.

Roughly 15,000 videos per language entered the pipeline. Segment boundaries were placed on silence: utterances were grouped into blocks separated by pauses of at least two seconds, and adjacent blocks were merged greedily into segments of 20 to 35 seconds in which speech occupies more than 30% of the duration, with half a second of padding on each side. At most five candidate segments were taken from any one video. Automatic filtering and LLM scores over the audio and the transcript were used only to rank the resulting candidates — by how self-contained a segment is without its neighbours, how safe and how everyday its subject matter is, how much hearing or seeing the scene would help resolve translation ambiguities, and how expressive the delivery is — leaving about 1,500 candidates per language. **The final selec-**

**tion was manual**: every remaining candidate was watched and its transcript read, both to check copyright and admissibility and to discard clips where the ASR had broken down. Transcription and diarisation were performed with the Speechmatics batch transcription, using the per-language model at the *enhanced* operating point with speaker diarisation.

Inspecting some 500 high-scoring candidates showed that segments whose translation depends on the *video* — what is on screen, gestures, objects, actions — are considerably easier to find than segments where the *audio* alone, through prosody, emotion and delivery, carries the decisive signal. Since few participants exploited the video modality in the previous edition, the manual selection in all three source languages deliberately favoured material for which an ASR transcript alone is not sufficient; for English, where the pool was largest, we estimate that about one half of the segments require the video and about one quarter the audio. At four participating systems this year report using visual or audio-visual context (AdaptiveMT, Cohere CAT+, Dubformer, PseudoRef). The same criteria were applied throughout, but what they could select from differed: in the Czech subset the video and the audio contribute less, simply because Czech Creative Commons material on YouTube covers a much narrower range. Its value lies instead in genuinely spontaneous speech, whose naturalness MT systems tend not to preserve.

For the same reason the speech domain is exempt from the difficulty sampling of Section 2.1.1. Text-only difficulty estimation cannot see what makes these segments hard — an utterance that reads as plain text may be translated far better once the video is available — so it would select against exactly the material the domain is built around. A further filter would also have shrunk a corpus that was, in every language, only just large enough.

The resulting corpus contains 133 English documents (9,108 tokens, 59 minutes of audio), 114 Czech (6,937 tokens, 53 minutes) and 114 Chinese (6,900 tokens, 54 minutes);[3]. The median clip lasts 26 to 28 seconds. Each document is a single segment, in contrast to the multi-segment documents of the other domains.

The automatic transcripts were subsequently corrected against the video by annotators following the guidelines in Section A.7. Participating systems received the *automatic* transcript together with the original video, while the corrected transcripts were used to produce the human reference translations and the translations offered for post-editing. Both versions are released, which makes the transcription error of this domain directly measurable: against the corrected transcript, the released automatic transcript has a median word error rate of 2.9% for English and 7.6% for Czech, and a median character error rate of 12.7% for Chinese.

Two conventions of this domain are worth stating explicitly, as both are enforced through the translation instructions rather than through the data. First, the transcripts preserve spontaneous speech as it was spoken — repetitions, false starts and unfinished phrases — but translations are asked to omit disfluencies. ASR output is inconsistent in whether it renders them at all, so rewarding their translation would systematically penalise systems that work from the audio directly for material absent from the transcript; and the choice of whether to render a hesitation is a configuration decision rather than a translation difficulty. Second, systems are asked to place each sentence on its own line, and speaker labels, although used when preparing the references, are not exposed to participants or to annotators — in both cases so that systems which do not rely on our ASR segmentation are not disadvantaged during evaluation.

**Software Domain.** (translating from English) The software domain subset was collected and provided by Alconost. It consists of short UI texts aggregated from several different applications, and introduces a typical software localization challenge. To preserve contextual clues for the translation systems, the data is structured in a JSON format utilizing key-value pairs. The keys act as descriptive identifiers detailing the string's purpose in the UI, such as a "marketing button submission", while the corresponding values hold the actual English source strings. A special feature is the presence of embedded placeholders within the text. Systems must successfully carry these placeholders and JSON keys over into the target language without translating or altering them.

**Education domain.** (translation from Czech into German, Ukrainian, Vietnamese)
The Educational domain includes selected exercises from an online portal Škola s nadhledem for elementary-school students from various sub-

[3]Tokens are counted as maximal word-character sequences for English and Czech and with jieba for Chinese, punctuation excluded.

jects (chemistry, geography, Czech language, etc.). Some segments are not full sentences but short phrases. The reference translations into Ukrainian and German for this domain were created by professional translators within the EdUKate project. Last year, each page of an exercise was treated as a separate document, while this year, each exercise (with all its pages) was compiled into a single document. To meet the target of 9k words per domain and 100 words per segment, we excluded documents with less than 90 words. Longer documents were split into multiple segments along page boundaries to ensure that no segment is longer than 200 words.

**Fact Checking domain.** (translation from Czech into German, Ukrainian, Vietnamese)
The fact-checking domain contains debunking analyses from the Demagog.cz website, which regularly monitors Czech media, including spoken debates, and selects specific statements that can be verified. For each such statement, an analysis assesses its factual accuracy. This analysis is typically a few paragraphs long, cites supporting materials, and concludes by classifying the statement as correct, incorrect, misleading, or unverifiable. See a sample analysis.

### 2.2 Human Translations

The human translations were prepared by professional translators coordinated by the partners responsible for the individual language pairs. The partners received the Translator Brief provided in Appendix A.5. Unlike in WMT25, where all the human translations were produced from scratch (Kocmi et al., 2025), this year we also encouraged controlled human post-editing of automatic translations. While the Translator Brief describes the post-editing setup, partners were explicitly given the option to depart from post-editing and produce translations from scratch when, based on their preliminary analysis and knowledge, they expected this to result in higher-quality human translations. The overall goal was therefore to give partners sufficient flexibility to choose the procedure they considered most appropriate for producing the highest-quality possible human translations.

For Czech→Vietnamese and Czech→German, *two* human translations were created independently: translation from scratch and translation by post-editing. This allows us to directly compare humans, machines and the combination of humans and machines in the translation task.

**Post-editing setup.** For each language pair, we provided candidate translations generated by two open-weight models: Qwen3.5-397B-A17B and Gemma-4-31B-IT. Our preferred procedure was for partners to first inspect the source documents together with the outputs of both models, select the model that appeared to provide the better starting point for that language pair, and then use the selected model across all documents in the pair.

This was a preferred rather than mandatory procedure. Partners were explicitly allowed to deviate from it when they expected another strategy to produce higher-quality human translations, including translating entirely from scratch, using the output of a different MT system, or choosing different starting models for different documents. For instance, partners could use a system specifically adapted to the language pair in particularly low-resource settings. Whenever human post-editing was used, we required partners to return the automatic translations that had actually served as the starting point. This allowed us to retain the provenance of the final human translations while prioritizing their quality over strict procedural uniformity.

**Selection of open-weight models for human post-editing.** Before producing the human translations, we compared several open-weight models on WMT25 English-source test data covering the 12 target languages shown in Table 3. We evaluated their translations using reference-less GEMBA-ESA with GPT-5.4 as the judge. Qwen3.5-397B-A17B and Gemma-4-31B-IT achieved the two highest macro-average scores, 82.9 and 80.3, respectively, outperforming the remaining open-weight candidates. We therefore selected them for generating the default automatic translations provided as possible starting points for human post-editing. Their per-language results also differ substantially in some cases, motivating the decision to provide both candidates and let partners determine which output was most suitable for their language pair.

**Domain-specific context.** For the Speech domain, the automatic translations provided for possible post-editing were generated from the cleaned transcripts after human correction of the automatic transcriptions, following the transcript cleanup guidelines reported in Appendix A.7. For the Social domain, we additionally provided screenshots of the original conversations, where available, so

| Model | Avg. | $ar_{egy}$ | cs | de | et | id | is | ja | ko | th | uk | vi | $zh_{Hans}$ |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| **Qwen3.5-397B-A17B** | **82.9** | 78.7 | **83.1** | 87.0 | **80.4** | 84.5 | **70.0** | 85.5 | 85.3 | 83.1 | 84.4 | 86.1 | 86.2 |
| **Gemma-4-31B-IT** | 80.3 | **85.7** | 77.1 | **88.6** | 52.1 | **86.9** | 43.1 | **89.3** | **89.8** | **88.4** | **86.7** | **87.1** | **88.4** |
| Command-A-Translate | 69.9 | 72.7 | 76.4 | 81.4 | 51.0 | 76.0 | 39.7 | 77.1 | 78.0 | 57.5 | 74.5 | 76.6 | 77.4 |
| DeepSeek-V4-Pro | 68.9 | 54.7 | 66.4 | 72.8 | 61.8 | 76.7 | 49.8 | 74.6 | 69.7 | 68.8 | 70.5 | 73.7 | 87.0 |
| TranslateGemma-27B | 67.1 | 61.0 | 67.2 | 70.6 | 58.2 | 71.1 | 51.4 | 67.5 | 64.0 | 70.9 | 73.4 | 75.0 | 75.2 |

Table 3: Reference-less GEMBA-ESA scores (Kocmi and Federmann, 2023b,a), using GPT-5.4 as the judge (OpenAI Team, 2026), for the open-weight models considered in our preliminary comparison on WMT25 English-source test data. Columns report scores for English→target translation, and Avg. is the macro-average across the 12 target languages. Bold scores indicate the best result in each column. Bold model names indicate the two open-weight models selected to generate the default automatic translations provided as possible starting points for human post-editing.

that translators could use their visual and conversational context when producing the final translations. The domain-specific prompts used to generate the Qwen3.5-397B-A17B and Gemma-4-31B-IT translations provided as possible starting points for human post-editing are reported in Appendix A.6. These automatic translations were generated using document-level translation.

**Final production strategies.** Because partners were free to select the procedure they considered most appropriate for their language pair, the final production strategies differed across languages. Table 4 summarizes the choices for the language pairs for which completed human translations were obtained. Five language pairs used only human post-editing, while five were translated only from scratch. For Czech→German and Czech→Vietnamese, the partners instead provided two separate sets of human translations: one produced entirely from scratch and one produced through human post-editing. Both sets were included separately in the human evaluation.

The results (Section 6.2) indicate that across the evaluated languages, post-edits rank higher than the primary initial system, Gemma-4-31B. We unfortunately did not include Qwen3.5-397B-A17B in the human evaluation as it was never exclusively selected by our partners, limiting a direct comparison. For Czech→Vietnamese, the post-edited reference tops the ranking, significantly outperforming the initial system.

For Czech→Vietnamese and Czech→German, we prepared human translations both from scratch and via post-editing. The results show that both approaches yield strong translations, but different ranking makes it inconclusive whether one strategy strictly outperforms the other.

Overall, the 12 language pairs therefore resulted in 14 independently produced human translations: seven based on human post-editing and seven translated from scratch. Since each language pair was coordinated by a different partner and the translation production strategy was deliberately flexible, some variability in the resulting human translations across languages is expected.

| Language pair | Human translation(s) | PE starting system |
|---|---|---|
| Czech→German | Scratch + PE (two refs.) | Gemma/Qwen, per document |
| Czech→Vietnamese | Scratch + PE (two refs.) | Gemma/Qwen, per document |
| Chinese→Japanese | PE | Gemma |
| English→Arabic (EG) | PE | Gemma |
| English→Czech | PE | Gemma/Qwen, per document |
| English→Estonian | Scratch | — |
| English→German | PE | Gemma/Qwen, per document |
| English→Icelandic | Scratch | — |
| English→Japanese | PE | Gemma/Qwen, per document |
| English→Ladin | Scratch | — |
| English→Ligurian | Scratch | — |
| English→Northern Sámi | Scratch | — |

Table 4: Production strategies used for the completed human translations. PE denotes post-editing and Scratch denotes translation from scratch. For Czech→German and Czech→Vietnamese, two sets of human translations were produced and included in the human evaluation. "Gemma/Qwen, per document" indicates that the automatic translation used as the starting point for post-editing was selected separately for each document.

**Synthetic references.** We release one synthetic reference for each of the documents with retained human-evaluation evidence. As a translation can be assessed in several contrastive screens, we first average its retained cESA scores and major error span counts for each source segment and system. For each candidate translation in a document, we then

average these per-segment cESA values over the document and select the highest-scoring candidate, breaking ties by fewer average major error spans. All selected candidates have cESA evidence for every segment in their document. To preserve document coherence, we retain the selected complete translation by default. We consider a segment for repair when its per-segment average cESA is below 80, or its average major error count is above zero; it is replaced only if another translation displayed and human-assessed for that same segment has a higher average cESA score, or the same average cESA score and fewer average major error spans. This repairs 862 segments (6.8%) and raises the in-sample mean cESA score from 91.88 to 93.34, while lowering the mean major error count from 0.137 to 0.092. The resulting system-level cESA scores for all evaluated directions are reported in Table 5.

## 3 Training Data

Similar to the previous years, we provide a selection of parallel and monolingual corpora for model training. The parallel data selection include large multilingual corpora such as Europarl-v10 (Koehn, 2005), Paracrawl-v9 (Bañón et al., 2020), CommonCrawl, NewsCommentary-v18.1, WikiTitles-v3, WikiMatrix (Schwenk et al., 2021a), TildeCorpus (Rozis and Skadiņš, 2017), OPUS (Tiedemann, 2012), CCAligned (El-Kishky et al., 2020), CCMatrix (Schwenk et al., 2021b), UN Parallel Corpus (Ziemski et al., 2016), NLLB Data (NLLB Team et al., 2022), OPUS-100 (Zhang et al., 2020), and language-specific corpora such as Yandex-Corpus, ELRC EU Acts, JParaCrawl (Morishita et al., 2020), Japanese-English Subtitle Corpus (Pryzant et al., 2018), KFTT (Neubig, 2011), TED (Cettolo et al., 2012), and back-translated news. This year's monolingual data include the following: News Crawl, News Commentary, CommonCrawl, Europarl-v10 (Koehn, 2005), Leipzig Corpora (Goldhahn et al., 2012), and language specific resources such as LangUk. We have automated the data preparation pipeline using MTDATA (Gowda et al., 2021) and instructions to download datasets were provided on the task webpage at www2.statmt.org/wmt26/mtdata.

## 4 System Submissions

This year, 30 systems participated in the General MT Task, slightly fewer than in the previous year (36 systems). Most systems covered two or more language pairs, while seven focused on a single primary language pair.

All participating systems are listed in Table 6. Participating teams that did not submit a system description are marked as Anonymous in all tables as they did not fulfill the shared task criteria to be presented. Section 4.1 discusses general trends in the architectures and training strategies used by the participating systems.

In line with previous years, we included translations from 16 systems, comprising a publicly available MT service (Google Translate), proprietary LLMs such as GPT-5.5, and open-weight LLMs such as Mistral Medium 3.5. The systems added by organizers are listed in Table 7.

### 4.1 Architectures and Strategies

Each participating team was required to submit a form detailing their approach along with a description paper. This section discusses the submissions with a summary of strategic details, such as the approach or base model, provided in Table 6.

**Architectures.** As in the previous year, LLMs were the predominant approach: 27 of the 30 submissions involve LLMs, including one mixed-architecture system. Three systems use encoder–decoder architectures, either fully or as one component of the system. One hybrid system combines statistical machine translation (SMT) with encoder–decoder NMT, while another system relies entirely on rule-based machine translation (RBMT).

**Base models.** The most frequently reported base-model family was Qwen (9 submissions), followed by Gemma/TranslateGemma, OpenAI GPT, and Gemini (6 submissions each). Eighteen submissions described training or adapting their models, while 11 used existing models without additional training; the remaining submission used a rule-based system.

**Post-editing and inference-time techniques.** Teams often combined multiple approaches; the most commonly reported techniques for post-editing and inference-time processing were prompt engineering and rule-based validation or correction (14 submissions each), followed by format reconstruction or checking (12).

Clear differences emerged between the two tracks. Agentic orchestration and ensembling were

| Direction | cESA | Direction | cESA | Direction | cESA |
|---|---|---|---|---|---|
| Czech→German | 95.30 | English→Armenian | 96.43 | English→Russian | 96.41 |
| Czech→Ukrainian | 94.32 | English→Indonesian | 96.41 | English→Northern Sámi | 75.98 |
| Czech→Vietnamese | 98.16 | English→Icelandic | 96.50 | English→Thai | 94.81 |
| English→Arabic (Egyptian) | 87.61 | English→Japanese | 98.47 | English→Ukrainian | 97.34 |
| English→Belarusian | 93.03 | English→Kazakh | 94.39 | English→Simplified Chinese | 90.48 |
| English→Czech | 90.23 | English→Korean | 91.49 | English→Traditional Chinese | 92.55 |
| English→German | 92.52 | English→Ligurian | 91.14 | Simplified Chinese→Japanese | 89.98 |
| English→Estonian | 92.65 | English→Ladin | 86.26 | | |

Table 5: System-level cESA score of the hybrid synthetic reference in every evaluated direction. For each source segment, we use the arithmetic mean of retained human scores for the selected translation; the reported direction score is the arithmetic mean over those segment scores, exactly as for the official system-level cESA results.

reported exclusively by unconstrained-track systems (9 and 7 submissions, respectively). Automatic post-editing was also more common in the unconstrained track (6/17; 35.3%) than in the constrained track (3/13; 23.1%).

**Data preparation.** Overall, 20 of the 30 submissions reported using some form of data filtering, including basic filtering, elaborate filtering, or both. Synthetic data generation was reported by 18 submissions. The two tracks differed considerably in their reported data-preparation practices. Most constrained-track systems used data filtering and synthetic data (12/13), compared with 8/17 and 6/17 unconstrained-track systems, respectively.

### 4.2 LLM Benchmark

LLMs have become popular tools for machine translation (Ataman et al., 2025; Chatterji et al., 2025). Following the last year, we provide a systematic and unbiased evaluation of the most popular language models on our blind test sets.

**Evaluated models.** The LLMs included in the evaluation were selected as follows: we chose popular LLM families that performed reasonably well in last year's shared task or exhibit strong multilingual capabilities and, for each family, selected the most recent available version for the constrained track and one for the unconstrained track. In addition, we included Google Translate as an industry-standard point of comparison. The final list of systems is presented in Table 7.

**Prompting LLMs for translation.** We developed a unified translation pipeline to collect outputs from all LLMs under an identical evaluation setup. We adopted a zero-shot, instruction-following approach and translated complete documents in a single pass using the officially provided prompt instructions.[4] Specifically, for open-weight LLMs, we used vLLM and Huggingface Transformers with Accelerate (fallback for models not supported in vLLM) to run the inference. We used the sampling temperatures recommended in the corresponding documentation and usage examples. We also provided a system prompt for models that supported this functionality. Although we initially evaluated models in thinking mode when available, these models were unable to generate translations within the practical constraints of our hardware resources (80 GB of GPU memory). Consequently, thinking mode was disabled for all models except for DeepSeek and Command A+.

**API inference and cost.** We collect the following systems via their respective service APIs: Gemini 3.1 Pro, GPT 5.5, Google Translate, Command A+, DeepSeek V4 Pro, Tiny Aya Global. Table 8 shows the number of input and output tokens as determined by each model's tokenizers. The estimated costs shown are for the main test set containing 23 language pairs and do not include the test suites. For the systems collected via API, we left their setup to the default parameters including high reasoning being used.

The cost per translation varies greatly, from $252 for Gemini to $4 for Tiny Aya, which also reflects the translation quality.

### 4.3 Constrained and Unconstrained Tracks

To promote fair comparison and encourage replicability, the WMT26 General MT Task distinguished between two tracks: *Constrained* and *Unconstrained*. These tracks differ in terms of model size, licensing, and reproducibility requirements.

[4]The code used to collect translations is available at: github.com/wmt-conference/wmt-collect-translations.

| Team | Approach | Model | Size | Data | Training | Post-proc | Best rank |
|---|---|---|---|---|---|---|---|
| **RULE-BASED MACHINE TRANSLATION (RBMT)** | | | | | | | |

| Tiny Aya Global | 3B | 7-14 (en-cs) | Tower+ | 9B | 16-17 (en-is) |

Table 7: Systems added by the organizers to the General MT shared task, all of them pretrained models used at inference time without weight updates. Model sizes are reported in billions of parameters (B); mixture-of-expert is denoted as active / total parameters; — denotes unavailable information.

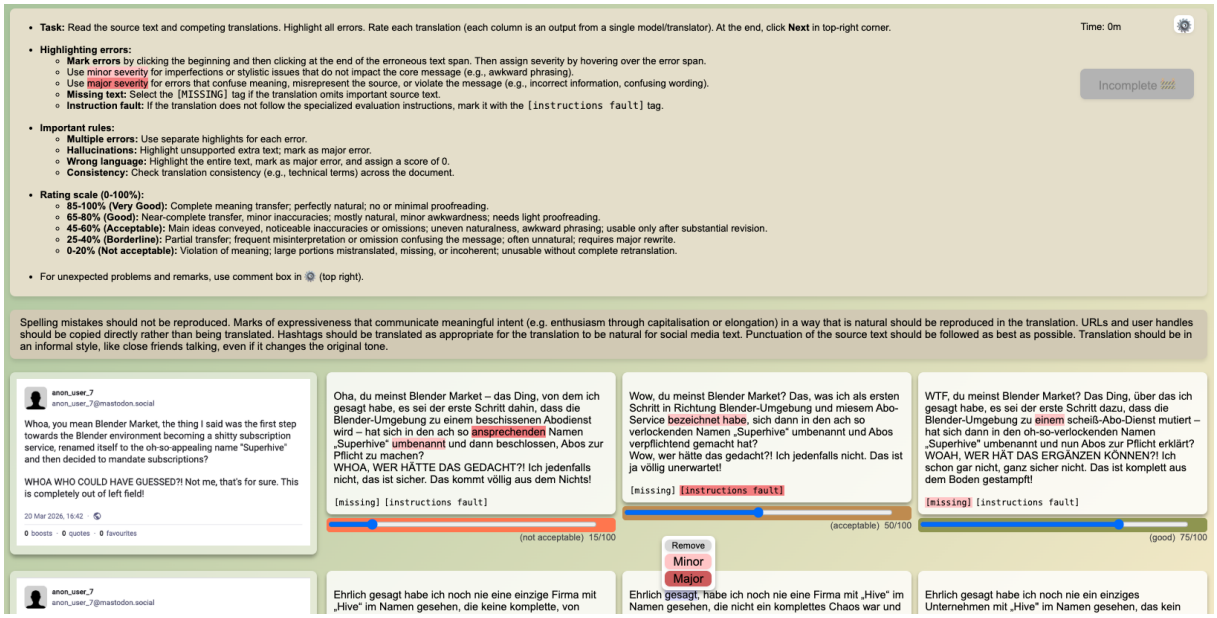
| System | Tokens (in/out) | Cost |
|---|---|---|
| Gemini 3.1 Pro | 2.1M / 20.6M | $251.7 |
| GPT 5.5 | 2.0M / 4.1M | $133.5 |
| GoogleTranslate (approx.) | 4.1M chars | $82.9 |
| Command A+ | 1.9M / 5.8M | $62.6 |
| DeepSeek V4 Pro | 2.1M / 10.9M | $41.5 |
| Tiny Aya Global (approx.) | 2.0M / 1.9M | $3.9 |
| GoogleTranslate (21 lps) | 3.8M chars | $76.1 |
| Tiny Aya Global (18 lps) | 1.6M / 1.5M | $3.0 |

Table 8: Input and output token usage, language-pair coverage, and estimated standard API cost using July 2026 prices. Google Translate and Tiny Aya Global do not support all languages, so we linearly approximated cost for all 23 languages while sharing the real cost below the table.

**Constrained Track:** Systems in this track must adhere to the following criteria:

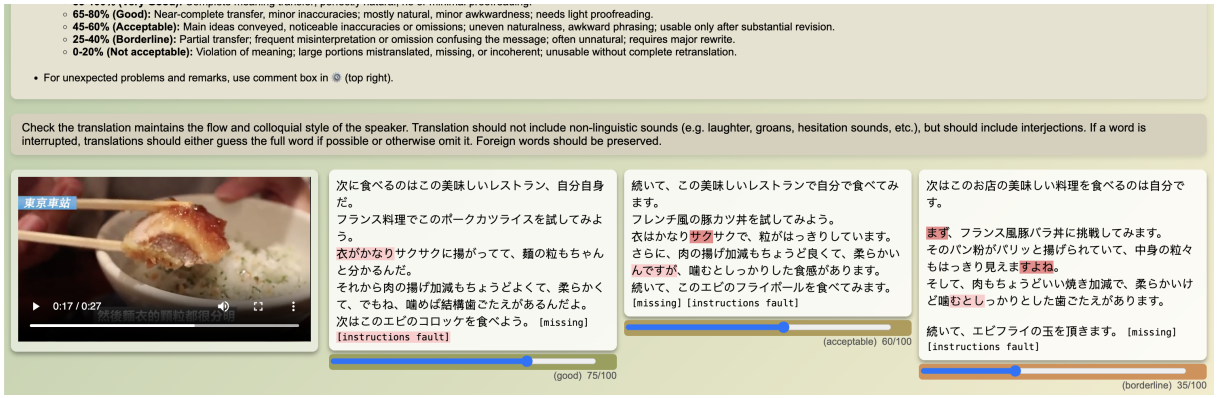
- Any training data, models, and frameworks may be used, provided that their use permits the final model weights to be publicly released
- The final model must contain fewer than 20 billion parameters. Larger models may be used during intermediate stages (e.g., for distillation), but the submitted outputs must be produced by a final model that complies with the size limit. For mixture-of-experts models, the total parameter count is considered; for ensembles, the parameter counts of all component models are summed.
- Model weights must be released under an open-source license allowing at least unrestricted non-commercial use and further research use.

This track is designed to foster transparency and reproducibility, allowing other research groups to replicate and build upon submitted systems.



**Unconstrained Track:** This track imposes no restrictions on model size, training data, or licensing. It includes systems built with proprietary tools, closed-source models, or undisclosed training pipelines, such as commercial LLMs (e.g., GPT-based systems). While participation in this track is open, systems are expected to provide as much detail as possible about their setup to support interpretability.

Although this year we did not restrict training data for either track, we curated a set of corpora that covers the majority of publicly available resources to support participants.[5]



To assist participants in the constrained track, we provided a non-exhaustive list of suggested models under the 20B parameter limit, including: textual models: Aya Expanse 8B, Aya 101 (13B), Cohere R 7B, Gemma 3 12B, GPT-OSS 20B, LLaMA 3.1 8B, Qwen 2.5 7B, Ministral 3 14B, Mistral 7B, EuroLLM, NLLB; and multimodal models: Whisper, Seamless M4T.

Systems were evaluated within their respective tracks: constrained systems were compared only against other constrained systems, while unconstrained systems were evaluated in a broader context that includes all submissions.

| English→Chinese(Simpl.) | Professional paid translators. | 2 | 89.3s | 2.1 | 17.8 |
| English→Chinese(Trad.) | | 2 | 92.8s | 2.2 | 31.2 |
| English→Japanese | Microsoft annotators: bilingual target-language native speakers, professional translators or linguists, experienced in machine translation evaluation. | 49 | 36.5s | 0.7 | 17.6 |
| English→Korean | | 8 | 76.9s | 1.4 | 19.5 |
| English→Armenian | Native speakers and professional translators. | 15 | 66.5s | 2.8 | 22.0 |
| English→Kazakh | | 21 | 52.8s | 1.4 | 17.8 |
| English→Belarusian | | 15 | 71.2s | 3.4 | 18.7 |
| Chinese→Japanese | Professional translators. | 13 | 39.5s | 1.5 | 17.5 |
| English→Ladin | Unpaid academic/institutional annotators. | 8 | 52.4s | 3.3 | 21.6 |
| English→Estonian | Professional translators from Luisa Language Solutions and volunteers from Sámi Giellagáldu and Sámi allaskuvla. | 6 | 43.2s | 2.2 | 13.3 |
| English→Northern Sámi | | 4 | 108.2s | 4.8 | 14.2 |
| Czech→Vietnamese | ÚFAL Charles University paid annotators: linguists, annotators, researchers, and students who were native speakers of one of the languages and high proficiency in the other. | 9 | 125.5s | 3.3 | 29.4 |
| Czech→German | | 11 | 84.7s | 2.1 | 17.9 |
| English→Czech | | 14 | 48.9s | 2.3 | 19.5 |
| Czech→Ukrainian | | 8 | 53.4s | 1.8 | 17.2 |
| English→Ukrainian | Toloka AI paid annotators: Bilingual native target-language speakers who were high-performing on the platform. | 92 | 53.4s | 1.7 | 19.9 |
| English→Arabic | | 102 | 16.7s | 0.6 | 5.0 |
| English→Russian | | 87 | 41.2s | 1.9 | 17.4 |
| English→Icelandic | Bilingual target-language native speakers, paid translators with 3–25 years of experience in Icelandic↔English translation. | 6 | 38.8s | 2.2 | 21.2 |
| English→German | Cohere annotators: professional in-house employees experienced with annotations of general LLM outputs, bilingual speakers native in German. | 7 | 73.3s | 1.8 | 21.7 |
| English→Thai | Professional translators from Venga Global. | 15 | 68.1s | 2.4 | 16.8 |
| English→Indonesian | | 10 | 44.1s | 1.2 | 21.7 |
| English→Ligurian | Volunteer native Ligurian speakers working in English, all with prior translation experience. | 5 | 33.6s | 4.8 | 18.1 |

Table 9: Overview of Annotators' profiles, Number of annotators, Time per segment, Total errors per segment, and Mean absolute error. All paid annotators were paid a fair wage in their respective countries.

## 5 Human Evaluation Methodology

The human evaluation is carried out through the Pearmut platform for all language pairs (Zouhar and Kocmi, 2026).

**Contrastive Error Span Annotation Protocol.** We use the cESA annotation protocol (Zouhar et al., 2026c) where 3 translations of the same input are presented side by side, which speeds up the annotations as the annotators do not have to reread the same source multiple times, and can more easily compare errors between the different translations. The annotators first mark the translation error spans as *Minor* and *Major* in all 3 translations and then assign an overall score between $0-100$ to each. The output of the cESA is a list of error spans, their severity, and an overall score from 0 to 100. A detailed description of the score categories is also provided to annotators, explaining what specific scores mean. Figure 1 shows an example of the cESA interface.

**Domain-specific Instructions.** In addition to the general guidelines, we provide annotators with specific detailed instructions based on the domain of the sample to align with the test set instruction following context (e.g., in the social domain, annotators are asked to translate hashtags in an appropriate natural way for social media text). See the instructions for each domain in Section A.1.

**Segmentation for human evaluation.** Although systems translated each test item at the document level, the human evaluation required segment-level translations to parse for the interface. We therefore parsed each document-level system output into segments before annotation. Whenever possible, we recovered segment boundaries from the test-set structure, such as HTML tags or JSON key-value pairs. When the system failed to correctly preserve them, we automatically aligned the translation with the source segments to obtain the best possible segment correspondence.

**Dynamic allocation.** For WMT2026, we skipped the pre-selection of systems based on automatic metrics. As a result, all systems were human-evaluated. However, we care primarily about identifying the top systems and less about distinguishing between the systems ranked 29th and 30th. To this end, we use dynamic evaluation (Zouhar et al., 2026a), where after a "cold start phase" of 20 documents, the top-performing systems are human-evaluated on more documents. The models are selected iteratively and stochastically any time an annotator wishes to annotate. Model $m$'s probability of being chosen is proportional to $\frac{1}{\text{rank}_m}$, where $\text{rank}_m$ is the current (not final) rank of the model. This setup concentrates the budget on separating the top-ranked systems, at the cost of a less reliable ranking among the remaining ones. In Figure 2, we show a trace of dynamic data allocation for the Czech→German evaluation. After the cold start phase, top-ranked models are evaluated on more documents.

**Increasing quality of annotations.** The annotators are asked to follow a short interactive tutorial in X→English at the beginning. The goal of the tutorials is to familiarize the annotators with Pearmut and the document-level cESA annotation task. An example of the 7-step tutorial is shown in Figure 6.

To ensure that annotators carefully follow the given instructions, we randomly add 3-5 "loud attention checks" shown to the annotator. For these attention checks, we know beforehand what the ranking of the 3 systems should be and if the annotator attempts to submit annotations that do not follow this ordering, a message is shown that they should pay more attention. This real-time accountability ensures annotators remain aware that their work is evaluated. Examples of attention checks are provided in Figure 5.

Lastly, to enhance the reliability of collected annotations, we filter out annotators with low reliability scores. For each annotation, we compute its likelihood given the annotations from all other annotators, and we exclude annotators with outlier annotation likelihoods (≈1% of annotators):

$$\frac{1}{N}\sum_{m_1,m_2}\exp\left(-\frac{(s_1-s_2-\mu_{m_1,m_2})^2}{2\sigma^2_{m_1,m_2}+\epsilon}\right) < 0.75$$

Where $N$ is the total number of evaluations, $s_1$ and $s_2$ are scores assigned by the user to models $m_1$ and $m_2$, the $\mu_{m_1,m_2}$ is the population mean score difference between $m_1$ and $m_2$, and $\sigma^2_{m_1,m_2}$ is the sum of score variances for $m_1$ and $m_2$.

**Analysis of annotators.** We provide an overview of annotators' profiles as well as annotation volume, time (a proxy for cost), and inter-annotator disagreement (mean absolute error in scores) in Table 9. While annotation speed and the number of annotated errors vary considerably, neither is predictive of inter-annotator agreement.

# 6 Human Evaluation Results

## 6.1 Overall Ranking of Systems

| Model | Avg. Rank | English→Japanese | English→Egyptian Arabic | Czech→Vietnamese | Czech→Ukrainian | English→Indonesian | Czech→German | English→Ukrainian | English→Chinese (Simp.) | English→Russian | Chinese (Simp.)→Japanese | English→Korean | English→Thai | English→Czech | English→German | English→Chinese (Trad.) | English→Kazakh | English→Estonian | English→Icelandic | English→Armenian | English→Belarusian | English→Northern Sami | English→Ligurian | English→Ladin |

Figure 3: Averaged *cursory* look at overall model ranking. Average rank is calculated as the average position over all language pairs the system participated in. For holistic and fair system comparison see the per-language results in Section 6.2.

## 6.2 Ranking of All Systems for each translation direction

A short gray line marks whenever a model is significantly better than the subsequent model. A longer black line marks whenever all previous models are significantly better than all subsequent models. Statistical testing with ($\alpha = 0.05$) is done using a one-sided paired or independent bootstrap test on the mean differences (100 resamples).

### 6.3 Ranking of Constrained Systems for each translation direction

In this section, we present results for only the constrained systems against one another as systems from constrained track do not compete against unconstrained systems.

A short gray line marks whenever a model is significantly better than the subsequent model. A longer black line marks whenever all previous models are significantly better than all subsequent models. Statistical testing with ($\alpha = 0.05$) is done using a one-sided paired or independent bootstrap test on the mean differences (100 resamples).

Table 10: Human evaluation average scores for the top-performing system per language, by domain. Social and speech domains show most headroom for improvement.

### 6.4 Discussion

**System ranks and scores.** The tables in Section 6.2 show that only some systems achieved average scores in the "Very good" range (85–100, representing near-perfect transfer), and only for a small number of language pairs. However, the maximum scores vary notably across the language pairs, from 61 (English→Northern Sami) to 90 (English→Japanese and Czech→Vietnamese). The lowest scores also vary across the languages, from 0.1 for English→Northern Sami to 57.4 for English→Japanese.

Among the constrained systems in Section 6.3, Lumen emerges as the clear winner, ranking in the top cluster for 20 of the 23 language pairs. It is followed by Qingqiu-MT-9B, which ranks second place.

Wayfinder was the best system overall when unconstrained systems are included (only skipping human reference), appearing in the top cluster for 17 of 23 language pairs, followed by Gemini 3.1 Pro (15 times), TRIVE (14 times), and the constrained system Lumen (13 times). It is especially encouraging that Lumen, a small constrained system, reached the top cluster while competing against unconstrained systems.

Three systems targeting only one or two translation directions reached the top-performing participant cluster in every direction they entered: Grammatist and LiLa for English→Ladin and English→Ligurian, and CUNI-AR for English→Egyptian Arabic. This highlights the potential of language-specific specialization, although other targeted submissions did not show the same pattern.

Finally, human translations, often treated as a "gold standard," place in the top cluster for only eight language pairs out of twelve. This finding highlights the inherent difficulty of translation, though it could also reflect the stylistic or lexical preferences of the annotators.

**Domain difficulty.** In Table 10, we present the scores of the top-performing system for each translation direction and each domain. Focusing on the top-performing system mitigates the effect of low-performing outliers. While absolute scores are not directly comparable across language pairs (due to different sets of systems, annotators, and sources), certain patterns can be observed: the social domain received the lowest scores (between 43 and 92, over 90 only for two language pairs and 5 between 80 and 90), followed by the speech domain (between 51 and 88, over 80 for 13 language pairs). News received higher scores (between 47.6 and 93.7, seven language pairs over 90 and thirteen between 80 and 90). The software domain, on the other hand, received the highest scores (between 72 and 100, with 15 language pairs over 90), possibly due to the specific vocabulary and consistent style.

**Results for low-resource languages vary considerably.** For some low-resource target languages,

systems approach or exceed human baselines, while Ladin and Ligurian show much larger gaps: human translation from scratch scores 77.2 and 84.7 ESA, respectively, compared with 49.4 and 66.0 for the best systems. Qualitative inspection of these two languages suggests challenges beyond data scarcity alone.

For Ladin, annotators reported that systems mix forms from different contemporary varieties rather than consistently producing the requested Val Badia variety. One possible contributing factor is the loss of variety metadata when datasets are pooled under ISO 639-3 language codes, collapsing distinctions present in the original resources. For Ligurian, annotators reported that several systems produced unnatural or archaic forms. We hypothesize that this reflects exposure to transcriptions of medieval manuscripts on Ligurian Wikisource, and learner-written or template-generated content from Ligurian Wikipedia, where linguistic quality issues have been previously documented (Lusito and Maillard, 2021). These two cases suggest that low-resource translation is not simply a problem of insufficient data: careful curation – particularly with respect to quality and linguistic variation – can also play an important role.

## 7 Test Suites Task: "Mind the Gap - Exposing LLM Translation Blind Spots"

This is the eighth consecutive year that test suites have been part of WMT's General MT task and the third year that they have focused on translations produced by LLMs. Automated or human-curated (Zouhar et al., 2026b) challenge sets are increasingly needed to expose critical blind spots that cannot be detected by the generic evaluation setup, and help answer what the nature of the failures are, beyond mere aggregate scores.

### 7.1 Setup of the Test Suites Sub-task

Test suites extend the standard test sets to target specific aspects of machine translation (MT) output. As in previous editions (Bojar et al., 2018), evaluation was carried out in a decentralised manner. Test suite providers were invited to submit their customised test sets that are integrated into the standard test sets by the organisers of the General MT Shared Task. After system outputs are generated by the system participants of the main General MT task, they are returned to the providers for evaluation according to their respective methodologies. Detailed findings are presented in the individual test suite description papers, and a consolidated overview is provided below.

### 7.2 Submissions

Nine participants took part in the test suite task this year (Table 11), covering several language pairs, translation phenomena and domains. Descriptions of each submission, along with their main findings, can be found below.

**AlphaMWE (Han et al., 2026).** LLMs' performance on machine translation (MT) tasks is often dependent on the data availability in the specific domains and language pairs that they are trained on. To examine whether multiword expressions (MWEs) still present a bottleneck for LLMs regarding language understanding and translation, the participants measure the performance of 31 WMT2026 MT systems using portions of the publicly available multilingual parallel corpus AlphaMWE as test suites. The analysis focuses on English to Chinese (zh), Polish (pl), German (de), and Arabic (ar), including Modern Standard Arabic (MSA) and two dialectal varieties, Egyptian and Tunisian Arabic. The participants carried out automatic evaluations using BLEU, chrF++, and BERTScore to select the top three systems per language pair, followed by human evaluation of selected systems.

The findings show that figurative and MWE-related phenomena remain challenging, automatic metrics sometimes disagree, and human evaluation uncovers language-specific errors hidden by aggregate scores.

**ASC: AMI Syntactic Constructions (Sigurðsson et al., 2026).** The English→Icelandic syntactic divergence test suite is intended to study how well systems do when translating syntactic constructions found in English that do not have a direct equivalent in Icelandic. Manual evaluation of the results reveals a large gap between the best-performing models and the lower-scoring ones. The results also demonstrate that while the best-performing models achieve high accuracy in various categories of syntactic constructions, they still struggle with others.

**CoST: Complex Structures Test (Yadav et al., 2026).** LLMs have advanced machine translation substantially, but generic benchmarks often

| Test suite | Focus | Language pairs | Segments | Tokens |
|---|---|---|---|---|
| ASC | syntactic constructions | en→is | 690 | 6,002 |
| AlphaMWE | multi-word expressions | en→{aeb, ar, arz, de, pl, zh} | 2,541 | 54,914 |
| CoST | complex structures | en→hi | 1,947 | 172,619 |
| EURAC | legal terminology | it→de | 3,833 | 104,563 |
| GENDER1PERSON | author gender form | en→{cs, hr, ru} | 3,000 | 569,754 |
| KUEST | game localization | en→ko | 1,796 | 20,842 |
| LLM-TR | hallucination, over-generation | en→{cs, de, es, et, ru} | 4,585 | 67,975 |
| Lost-in-Morphology | morphological phenomena | ko→en | 3,536 | 37,596 |
| TR-Gender-Bias | occupational gender bias | tr→en | 200 | 2,234 |

Table 11: Overview of the participating test suites.

fail to expose where these systems struggle with complex linguistic structures and stylistic nuance. CoST, a challenge suite of 1,947 English→Hindi sentences spanning eight genres—autobiography, conversation, legal, mixed, narration, play, poetry, and technical writing—previously introduced for WMT24, is used to evaluate 22 systems submitted to the WMT26 General Translation Shared Task for English→Hindi with reference-free, reference-based, and manual evaluation.

The results reveal a consistent genre-level pattern: systems perform well on narrative text such as autobiography and play but degrade sharply on poetry, legal, and conversational text. The authors further identify a distinct failure mode in poetry translation, where systems reproduce memorised canonical Hindi verse instead of translating the given English text, and manual analysis surfaces recurring issues in named-entity handling, wrong-language output, and lexical choice, several of which persist from their prior evaluation in WMT24.

**EURAC: Legal Terminology Challenges in German Language Varieties (Di Natale et al., 2026).** Language varieties and dialects remain an open challenge for machine translation (MT). Moreover, existing benchmarks rarely combine the evaluation of specific varieties with domain-specific knowledge. EURAC introduces a termbase-derived MT benchmark for legal terminology across four German varieties: Germany, Austria, Switzerland, and South Tyrol (a low-resource German variety spoken in Italy). In the *inter-variety* setting, models translate Italian source sentences by selecting the correct South Tyrolean German term among semantically equivalent terms from other German varieties. In the *intra-variety* settings, they test sense disambiguation and ontological relation capabilities using homographic and ontologically related distractors for all four language varieties.

The authors find that distinguishing language varieties remains difficult. High performance on low-resourced South Tyrolean terminology is partly driven by indirect exposure to terms shared with better-resourced varieties; when this overlap is removed, even the best-performing models collapse toward small models. Additionally, there is mild evidence of dominant-variety interference, although stronger systems more often err toward the geographically and culturally closer Austrian variety. Generally, locale-oriented adaptation appears more challenging than linguistic and semantic reasoning, where the ontological relation task is largely saturated and no generalized bias is shown against a specific variety. The participants conclude that model scaling mainly reinforces dominant language varieties and that LLM-based MT shifts part of the performance bottleneck from individual term rarity to the underrepresentation of domain-variety intersections across training and alignment stages.

**GENDER1PERSON (Popović and Lapshinova-Koltunski, 2025).** This test suite is used for measuring the ability of systems to use an inclusive gender form when translating from English into three Slavic languages: Czech, Russian, and Croatian. The test suite consists of 1 000 Amazon product reviews, uniformly distributed over 10 different product categories. The few-shot prompt was formulated to ask for inclusive forms consisting of both masculine and feminine variants separated by the symbol "/". For each system, a score is calculated as a ratio of words in the translation containing the "/" symbol and the number of the first-person pronoun "I" in the original English text.

The results show that for each language pair, there is a group of systems with a clear tendency to generate inclusive forms: Gemini 3.1 Pro, DeepSeek v4 Pro, TRIVE, and GPT OSS 120B. On the other hand, Google Translate and SRPOL never generate such forms, while SalamandraTA and CommandA+ only rarely.

**KUEST: Korean Game Usage Evaluation Suite for LLM Translation (Choi et al., 2026).** Despite the growing demand for multilingual game localization, systematic evaluation frameworks for game translation constraints remain largely unexplored. As part of the WMT26 Test Suite Track, the authors propose KUEST, a test suite comprising 1,796 English→Korean segments across four core categories, and evaluate 27 submitted systems.

Experimental results demonstrate that standard metrics obscure true model capabilities (e.g., the overall 1st-place system dropping to 15th in creative translation). Furthermore, we reveal residual capability fragmentation—category-specific variance that survives the shared general-competence factor and inverts top-tier rankings—and observe a "prompt gap" where context metadata degrades performance. As such, KUEST serves not only as a test suite but also as an evaluation framework that multi-dimensionally dissects domain-specific translation blind spots hidden behind single composite scores. The dataset is available at huggingface.co/datasets/JudyChoi/KUEST.

**LLM Translation Challenge: "I'm Sorry, I Can't Translate That" (Vasileva, 2026).** LLMs have significantly raised the bar for translation quality in recent years. However, they are still prone to novel failure modes, including hallucinations and overgenerations, where the generated translation is partially or fully detached from the source text and contains information that is not present in the input. To facilitate the analysis of these behaviors and assess the robustness of LLM-based translation systems, the participants introduce a challenge set specifically designed to probe scenarios that they have observed to be particularly prone to overgeneration, hallucination, and other forms of semantic detachment from the source.

The test suite results show that general-purpose LLMs are far more prone to failures than dedicated MT systems: many baseline LLMs have more than 50% of their segments flagged (and in some cases more than 60%), while participant submissions mostly remain below 5%, likely due to added QE/filtering stages in their pipelines. A few general-purpose models (Mistral Medium 3.5, Gemma 4-4B/31B, GPT-5.5) are an exception to this trend with sub-10% rates, showing robustness isn't strictly tied to model type. Failures cluster around specific phenomena, including sensitive content (safety mechanisms preventing models from translating and resulting in refusal to translate), truncated inputs (incomplete inputs result in overgeneration, where outputs contain content not present in the source), and instructions (misread as commands to follow rather than as input to translate). Translation-specific systems submitted by participants substantially outperform general-purpose LLMs on DNT (Do Not Translate), punctuation, and emoji challenge categories, but truncated inputs and inputs that contain instructions remain hard for both system types.

**Lost in Morphology (Lee et al., 2026).** The participants present a 3,536-item Korean→English challenge suite spanning nine phenomena and evaluated on 23 systems submitted to WMT26. The suite targets ellipsis punctuation, stacked particles, wordplay, topic/subject marking, evidentiality, scrambling, auxiliary chains, connective endings, and ideophones. They match each phenomenon to its observable evidence: deterministic rules for visible or lexically constrained contrasts, structured LLM observations for semantic features, joint scoring for minimal pairs, distributional metrics for multi-variant frames, and a strategy-aware panel for wordplay. Learned judges and classifiers must pass subset-specific admission tests before their outputs contribute to a system score.

Results reveal failures hidden by aggregate MT quality. Ellipsis is usually preserved, but one model family deletes the marked utterance in most of its failures. Particle fidelity falls from 0.95 at stack depth 1 to 0.70 at depth 4, while distinct scalar particles collapse into bare English even. Evidential and auxiliary meanings are often neutralised although the core proposition survives, and wordplay remains the hardest subset: the best system scores 0.385 against 0.546 for the curated references. Judge validation is itself diagnostic: the only conflict-free wordplay judge fails through ceiling saturation, whereas three judges that are also evaluated systems pass without detectable family preference. The suite therefore measures both translation failures and the reliability limits of the instruments used to identify them.

**TR-Gender-Bias: Occupational Gender Bias and Male Default in Turkish (Öztop, 2026)** Turkish has no grammatical gender: its third-person pronoun "o" refers to a man, a woman, or an inanimate object alike, so a system translating into English must supply a gender the source never

states. The participants introduce tr_gender_bias, a reference-free Turkish→English test suite of 200 templated items, each built around a single human referent, and use it to measure how 24 machine translation systems and large language models assign gender when the source withholds it. The suite has three parts: ambiguous items whose only signal is an occupational stereotype grounded in labor-force statistics, items whose gender is fixed by a kinship term or a name against that stereotype, and neutral controls. Every output is scored under a six-way, abstention-aware taxonomy that treats neutralization, hedging, and malformed output as distinct outcomes.

Under ambiguity, stereotype-driven gender assignment is universal, significant for all 22 testable systems after correction, and uniformly male-skewed, with no system ever favoring the feminine. Gender that the context states, by contrast, is now resolved almost perfectly, a marked change from earlier evaluations in which stereotype overrode context. The systems split into committers and neutralizers, and neutralizing with singular they removes both stereotype bias and male skew at no cost in accuracy. Gender bias in current translation is therefore less a failure to use context than an unsettled policy for what to do when the source leaves gender genuinely open.

### 7.3 Aggregated test suite results

To facilitate a cross-test-suite comparison of system performance, we juxtapose the rankings obtained from all available test suites for each language direction. Table 12 summarizes the results for language directions covered by at least two test suites. The systems are arranged to highlight overall agreement and disagreement across evaluations. For reference, the human-based rankings from the official General MT test set are included in the first column. The primary ordering criterion is the human ranking on the General MT test set, while ties are resolved using the mean ranking across the remaining test suites. Table 13 presents an aggregate ranking across all test suites, computed as the weighted average of ranks across test suites and language pairs, with weights proportional to the respective number of test items.

These orderings are intended to improve readability and support visual inspection of ranking patterns. It must be noted that they originate from heterogeneous evaluation settings, including different test collections, varying dataset sizes, and distinct ranking methodologies. Uncertainty estimates are not consistently available or directly compatible across evaluation methods, and therefore confidence intervals have not been incorporated into the analysis.

Overall, the specialized test suites show a positive but clearly imperfect relationship with the WMT26 human evaluation. Systems that perform well in the human evaluation tend to perform better in the test suites, but the test suites do not follow the human ranking closely. English→Russian shows the strongest and most consistent alignment. Both GENDER1PERSON and LLM-TR reach approximately $\rho = 0.586$. English→German shows moderate alignment as AlphaMWE reaches $\rho = 0.519$, while LLM-TR reaches $\rho = 0.480$. English→Czech is less consistent as LLM-TR retains a moderate correlation of $\rho = 0.403$, but GENDER1PERSON falls to only $\rho = 0.268$. Pooling the language-specific LLM-TR observations after normalizing the ranks within each language gives an overall correlation of approximately $\rho = 0.49$ across 80 system-language observations. Thus, LLM-TR captures a meaningful cross-language quality signal, but around half of the ordering variation remains unrelated to the WMT26 human ordering. This is also consistent with the intended role of test suites.

There are few striking differences between the human evaluation ranks and the test suite scores. Gemini 3.1 Pro is highly ranked by humans but performs poorly when scored by LLM-TR in all three language pairs and AlphaMWE in English→German. This suggests that strong overall human-rated output does not necessarily imply resistance to the hallucination and over-generation phenomena. It is also noteworthy that Tiny Aya Global falls from human rank 7 to ranks 21 and 26 on two English→Czech test suites; GPT 5.5 has a consistently worse LLM-TR ranking than its human ranking across all three languages (most notably, human rank 1 versus LLM-TR rank 14 in English→German); and Dubformer shows a specific gender-handling weakness in English→Russian, ranking 1st in human evaluation and 2nd in LLM-TR but 14th in GENDER1PERSON.

Focusing on the reverse pattern, for English→Russian, SCIR-TG-MT is ranked 30th by the humans but tied at 4th on LLM-TR, a

Table 12: System ranking for English→{Czech, Russian, German} according to human evaluation and test suites.

26-position difference. This is the largest absolute rank discrepancy in the three datasets. A similar, though smaller, pattern occurs for systems such as CUNI-EdUKate in English→German, which is human-ranked 27th but LLM-TR-ranked 8th, and CUNI-MH-v3, which is human-ranked 20th but LLM-TR-ranked 7th.

### 7.4 Test Suite Findings Summary

The evaluation of multiple test suites across diverse language pairs and domains provides a qualitatively oriented but empirically justified perspective to the performance of MT systems, revealing systematic issues that are not obvious in the generic scores.

Figurative and idiomatic multiword expressions remain difficult, with automatic metrics often disagreeing and human evaluation exposing errors aggregate scores hide. For English→Icelandic, even top systems struggle with select syntactic constructions, with a wide performance gap between the strongest and weakest models. For Korean→English, particle and evidential meaning degrade under structural complexity; wordplay is the hardest phenomenon overall. General-purpose LLMs are far more prone to hallucination and semantic detachment than dedicated MT systems, especially with sensitive content, truncated input, and embedded instructions.

For English→Hindi, narrative and dialogue text is handled well, but quality drops sharply for poetry, legal, and conversational registers, with a tendency to reproduce memorized canonical translations instead of the source. For German legal terminology, apparent competence in a low-resource variety mostly reflects term overlap with better-resourced varieties, not genuine mastery. For English→Korean game localization, aggregate scores mask large category-specific variance, and added context can counterintuitively reduce quality.

Table 13: Aggregated ranking from all test suites. W/R: weighted-average test suite rank; H/R: GenMT human rank

languages, systems split sharply between those that consistently generate inclusive forms and those that rarely do. For Turkish→English occupational gender bias, all systems default to stereotype-driven, male-skewed assignments under ambiguity —except those using gender-neutral phrasing, which avoid the bias with no accuracy loss.

## 8 Conclusions

This year we focused on improving the quality and reproducibility of human evaluation, the final arbiter of translation quality. We switched to Pearmut annotation tool, cESA annotation protocol, and made use of dynamic evaluation rather than relying on selection of systems based on automatic metrics. The novel dynamic allocation method enabled us to include all systems in human evaluation, with better systems getting more annotations, which helped us to avoid introducing bias from automatic evaluation as in previous years.

The WMT 2026 General Machine Translation Task covered 23 language pairs and up to six domains. We prepared a more challenging test set by utilizing novel human-based difficulty sampling. In total, we evaluated 46 systems: 30 participant submissions and 16 LLMs or popular online translation services whose outputs we collected. Participation decreased slightly compared with last year but remained high, with most teams using LLMs.

We used contrastive ESA as the human evaluation protocol, which consists of marking errors and assigning scores for three systems next to each other at once.

Analysis of domains showed the social domain as the most challenging, followed by speech, while software texts were the easiest to translate.

Specialised test suites revealed remaining weaknesses in figurative and idiomatic multiword expressions, wordplay, sensitive content, truncated input, inclusive gender forms, as well as domains and genres with specific terminology and/or style such as legal texts, game localisation, poetry.

## Limitations

**Access to test data:** Researchers who had access to the internal repository (i.e., ALL source documents) before the blindset was released to public: Archchana Sindhujan, Chi-Kiu Lo, Diptesh Kanojia, Tom Kocmi, Eleftherios Avramidis, Martin Popel, Ondrej Bojar, Lorenzo Proietti, Rachel Bawden, Samuel Larkin, Stefano Perrella.

Sergey Dukanov had access only to the speech domain source data (no access to internal repo).

**Generality:** We tested the general capabilities of MT systems. However, we have simplified this approach and only used six domains. Out of various possible modalities, we used audio and text.

**Human evaluation:** Although we use human judgments as the gold standard, we should men-

tion that human annotations are noisy (Wei and Jia, 2021) and their performance is affected by the quality of other evaluated systems (Mathur et al., 2020). Lastly, different annotators use different ranking strategies, which may affect the system ranking.

## Ethical Considerations

Inappropriate, controversial, and explicit content was filtered out prior to translation, keeping in mind the translators and not exposing them to such content or obliging them to translate it.

Collection of human judgments using Pearmut was fully anonymous. Automatically generated accounts associated with annotation tasks with single-sign-on URLs were distributed among pools of annotators, and we do not store any personal information. We do store the mapping between which annotator (pseudoanonymized) annotated which segments. Annotators received the standard professional translator's or evaluator's wage with respect to their countries.

## Acknowledgments

This report would not have been possible without the partnership with Alconost, Árni Magnússon Institute for Icelandic Studies, Charles University, Cohere, Council for Ligurian Linguistic Heritage, Dubformer, German Research Center for Artifical Intelligence (DFKI), Google, Istitut Ladin Micurà de Rü, Institute of the Estonian Language, Microsoft, NTT, Tencent, The Sámi Parliament of Norway, The Sámi University of Applied Sciences, Toloka, University of Tartu, University of Tokyo. Furthermore, we are grateful to Toshiaki Nakazawa, Konstantin Dranch, Mao Zheng, Antonina Zaleschenok, Miliana Bær, Sierge Rasmus, and Lars Ailo Bongo.

Vilém Zouhar gratefully acknowledges the support of the Google PhD Fellowship. Sara Rajaee is funded in part by the Netherlands Organization for Scientific Research (NWO) under project number VI.C.192.080. Ondřej Bojar acknowledges the support by the grant CZ.02.01.01/00/23_020/0008518 (Jazykověda, umělá inteligence a jazykové a řečové technologie: od výzkumu k aplikacím"). The reference translations and manual evaluations were also supported by the National Recovery Plan funded project MPO 60273/24/21300/21000 CEDMO 2.0 NPO, by the grant 10131474 (Czech AI Factory, CZAI) by EuroHPC JU and by TAČR grant EdUKate (TQ01000458). Eleftherios Avramidis was partially funded by the German Federal Ministry of Research, Technology and Space (BMFTR) via the project RoGSiLT (grant number 16IW26001). Rachel Bawden's participation was supported by the French national research agency (ANR) as part of the MaTOS project (grant number: ANR-22-CE23-0033). This work has been using data and tools provided by the LINDAT/CLARIAH-CZ Research Infrastructure (https://lindat.cz), supported by the Ministry of Education, Youth and Sports of the Czech Republic (Project No. LM2023062).

## A.2 Human Annotation Attention Checks

Figure 5: A screenshot of loud attention checks in the human evaluation campaigns. The annotators must assign a lower score to the lowest quality translation to pass the annotation step.

# A Translator and Annotator Details

## A.1 Human Annotation Domain-Specific Instructions

- **news:** Ensure the translation is formal and consistent with journalistic standards.
- **factchecking:** Ensure the translation is formal and consistent with journalistic standards.
- **speech:** Check the translation maintains the flow and colloquial style of the speaker. Translation should not include non-linguistic sounds (e.g. laughter, groans, hesitation sounds, etc.), but should include interjections. If a word is interrupted, translations should either guess the full word if possible or otherwise omit it. Foreign words should be preserved.
- **social:** Spelling mistakes should not be reproduced. Marks of expressiveness that communicate meaningful intent (e.g. enthusiasm through capitalisation or elongation) in a way that is natural should be reproduced in the translation. URLs and user handles should be copied directly rather than being translated. Hashtags should be translated as appropriate for the translation to be natural for social media text. Punctuation of the source text should be followed as best as possible. Translation should be in an informal style, like close friends talking, even if it changes the original tone.
- **software:** Translation should translate the content of the JSON, without translating keys (such as `"general.duration.years"`) and placeholders (e.g. `"{{count}}"`).
- **edu:** Translation should be accurate and maintain the instructional nature of the content. Ensure that technical terms are translated correctly and consistently.

## A.4 Human Annotation cESA Instructions

The following instructions were shown in the annotation interface and could be accessed at any time.

- ***Task:*** *Read the source text and competing translations. Highlight all errors. Rate each translation (each column is an output from a single model/translator). At the end, click* ***Next*** *in the top-right corner.*
- ***Highlighting errors:***
  - ***Mark errors*** *by clicking the beginning and then clicking at the end of the erroneous text span. Then assign severity by hovering over the error span.*

## A.3 Human Annotation Tutorials

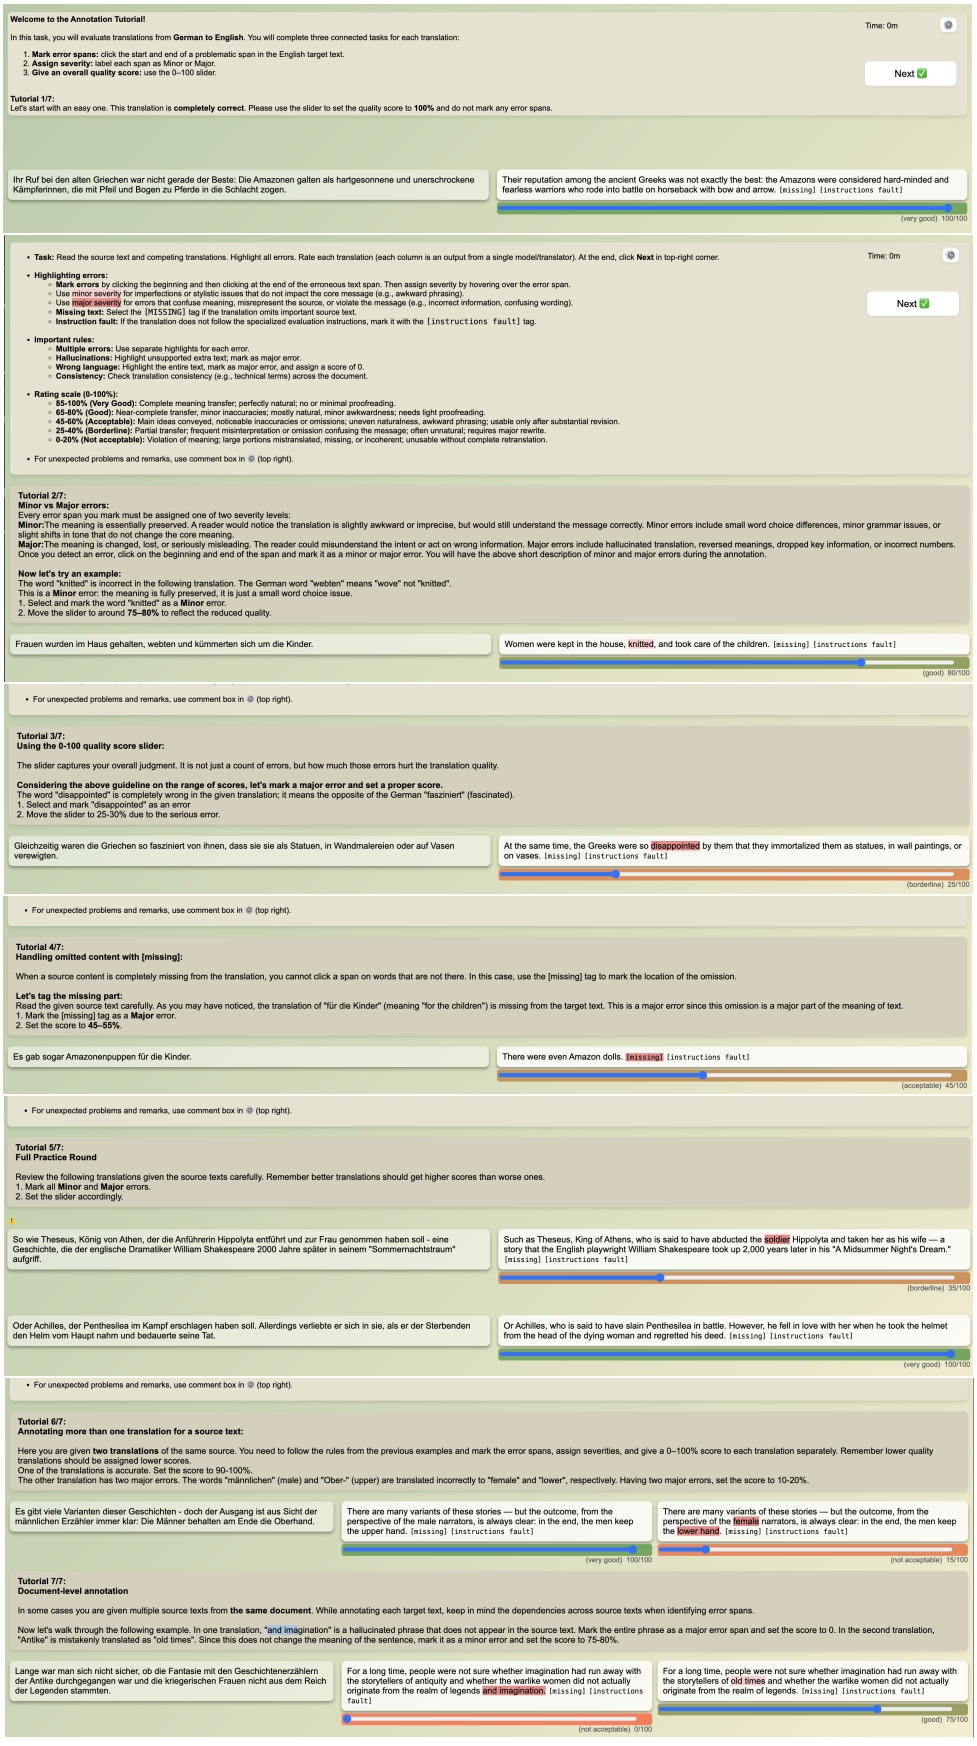

Figure 6: The screenshots of 7-step optional tutorials used at the beginning of each annotation campaign (with varying language) to familiarize the annotators with Pearmut platform and the cESA protocol.

  - *Use minor severity for imperfections or stylistic issues that do not impact the core message (e.g., awkward phrasing).*
  - *Use major severity for errors that confuse meaning, misrepresent the source, or violate the message (e.g., incorrect information, confusing wording).*
  - ***Missing text:*** *Select the* `[MISSING]` *tag if the translation omits important source text.*
- ***Important rules:***
  - ***Multiple errors:*** *Use separate highlights for each error.*
  - ***Hallucinations:*** *Highlight unsupported extra text; mark as major error.*
  - ***Wrong language/dialect:*** *Mark the text as a major error; borrowed words are allowed if they are valid in given language.*
  - ***Consistency:*** *Check translation consistency (e.g., technical terms) across the document.*
- ***Rating scale (0–100%):***
  - ***85–100% (Very Good):*** *Complete meaning transfer; perfectly natural; no or minimal proofreading.*
  - ***65–80% (Good):*** *Near-complete transfer, minor inaccuracies; mostly natural, minor awkwardness; needs light proofreading.*
  - ***45–60% (Acceptable):*** *Main ideas conveyed, noticeable inaccuracies or omissions; uneven naturalness, awkward phrasing; usable only after substantial revision.*
  - ***25–40% (Borderline):*** *Partial transfer; frequent misinterpretation or omission confusing the message; often unnatural; requires major rewrite.*
  - ***0–20% (Not acceptable):*** *Violation of meaning; large portions mistranslated, missing, or incoherent; unusable without complete retranslation.*
- *For unexpected problems and remarks, use the comment box in the top right corner.*

### A.5 Translator Brief for Post-Editing

The following instructions were given to human translators:

*In this project we wish to translate data from several domains for use in the evaluation of Machine Translation (MT). The translations produced by you will be compared against the translations produced by a variety of different automatic MT systems to compare their capabilities against human performance represented by your translation. They will be released to the research community to provide a benchmark, or "gold-standard" measure for translation quality. The translation therefore needs to be a high-quality rendering of the source text into the target language, as if it was originally written directly in the target language. However, there are some constraints imposed by the intended usage:*

- *All translations must be produced by human post-editing.*
- *Translators must preserve paragraph boundaries. In the source files, paragraphs are always separated by empty lines, although each paragraph may itself span multiple lines. The translation must contain the same number of paragraphs as the source, with the same paragraph boundaries. Within each paragraph, translators may adjust the number of sentences as needed.*
- *In some cases, the automatic translations provided for post-editing may contain a different number of paragraphs, or different paragraph breaks, from the corresponding source documents. In these cases, please treat the source documents as authoritative for the paragraph structure. The final reference translations must follow the source documents, preserving the same number of paragraphs and the same paragraph boundaries, with paragraphs separated by empty lines.*
- *Translators should avoid inserting parenthetical explanations into the translated text and obviously avoid losing any pieces of information from the source text. We will check the translations for quality and will reject translations that contain errors.*
- *If the original data contains errors, typos, or other problems, do not change the source documents (which should not be modified in any way), instead try to prepare a correct translation as if the error had not been in the source.*
- *The data contain four or five domains (news, social, speech, software), each folder containing one domain source and each domain needing a specific handling. Maintain the formality of the source text, i.e. news texts are formal, social domain texts are likely to be informal.*

*The source files will be delivered as text files (sometimes known as "notepad" files), with paragraphs separated by an empty line. We need the translations to be returned in the same format. The translation file needs to have the same name as the original source file.*

*News Domain and Fact-Checking Domain. The texts are news articles and should be translated in a formal style, consistent with journalistic writing in the target language. The translation should accurately convey the meaning, tone, and nuances of the source text while reading naturally as a news article originally written in the target language.*

*Speech Domain. Your task is to translate the speech from the provided video. For this domain, each source file corresponds to one segment of video. Alongside the video, we provide a human-edited transcript of the spoken content. The transcript has already been corrected, but it should be used only as a guideline for translation from the video. The transcripts have been used to generate the automatic translations.*

*Preserve the flow, degree of formality, and colloquial style of the speaker(s), including informal wording, jargon, common contractions, repetitions, omissions, and unfinished phrases when they are part of natural speech. Do not make the style more formal or more polished than the source video.*

*If a word or phrase is unintelligible in the video and cannot be reconstructed from the context with reasonable certainty, make your best guess. If a speaker stops mid-word, either translate the intended full word if it can be inferred from the context or omit it; do not leave unfinished word fragments in the translation.*

*Do not include non-linguistic sounds such as laughter, groans, breathing, or hesitation sounds unless they clearly contribute to the meaning. Common interjections and filler words may be translated when they are part of the speaker's expression or the natural flow of the speech. Words spoken in a foreign language should be left as they are.*

*If some words are sung rather than spoken, include them only when they contribute to the meaning of the video.*

*Videos correspond to different domains: they differ in formality, style, topics and number of speakers. Translate into the target language using wording and a register that match the characteristics of the source video as closely as possible.*

*Social Domain. The source texts are from the social network Mastodon (similar to Twitter). Each file represents a thread or part of a thread from one or several users. Different posts within a thread are separated with empty lines. Individual posts can also span several lines. The texts have been selected so that they do not contain offensive or sensitive content (hate speech, taking-drugs, suicide, politically sensitive topics, etc.). However, profanities were kept as they were taken to be illustrative of the sociolect of online language. If, however, you do not feel comfortable with translating something, please let us know.*

*The texts are user-generated social media content and may contain spelling errors, slang, acronyms, informal wording, marks of expressivity, etc. The translation should sound natural as social media text in the target language, while preserving the meaning, style, familiarity, and expressive intent of the source text as much as possible. The translation must always use an informal style, even if the source sounds relatively formal.*

- *Spelling mistakes should not be preserved in their translations, i.e. the translation should be spelt correctly.*
- *Marks of expressivity, such as asterisks, repeated characters, or other emphasis devices, should be preserved when they communicate meaningful intent (e.g. enthusiasm through capitalisation or elongation). The exact form does not need to be copied mechanically: for example, elongated words (e.g. gooood) should be rendered in a natural way in the target language, and the exact number of repeated characters does not need to match the source unless it makes a clear difference in quality or meaning.*
- *There will be abbreviations and acronyms (e.g. btw -> by the way, fwiw -> for what it's worth). These do not need to be translated using an abbreviation or acronyms unless an abbreviation/acronym is the best translation choice in the target language.*

- *Users (@user123) and URLs should be left as they are, i.e. not translated.*
- *Platform-specific elements such as hashtags should be translated as hashtags, but the content should be translated appropriately into the target language.*
- *Additional punctuation should be added only if not doing so would seriously alter the comprehension of the text. Otherwise, we recommend following the punctuation of the source text.*

*Please always refer to the screenshots included alongside the source texts. These screenshots show the original context of the entire thread contained in the source text file and should be consulted during translation. The screenshots may also contain images attached in the thread that can provide further context for the translation.*

*Software Domain. The source texts in this domain come from software data and are provided in JSON format. Translate only the user-facing natural-language content, i.e. the text that appears as JSON values. Do not translate JSON keys, placeholders, and other technical content. The final output must be a valid JSON and must match the input format, preserving the overall source structure. Placeholders, such as {{website_name}}, {{count}}, or similar elements, must be copied exactly, not translated.*

### A.6 LLM Translation Instructions

To generate the automatic translations, we prompted LLMs with domain-specific translation instructions. The prompts used for each domain are reported below. The placeholders `{TRG}`, `{TRG_CODE}`, and `{SRC}` were instantiated with the corresponding target language, target-language code, and source language, respectively. For the Speech domain, we used the final transcripts after human correction (see Appendix A.7) of the automatic transcriptions only when providing translations for human post-editing. For both the Speech domain and the Social domain, the automatic translations were generated using a text-only prompt, without providing the accompanying videos or screenshots to the LLMs. These automatic translations were generated by translating each source document as a whole.

*News Domain and Fact-checking Domain. You are a professional {TRG} translator, tasked with providing translations suitable for use in {TRG} ({TRG_CODE}). Your goal is to accurately convey the meaning and nuances of the original text while adhering to {TRG} grammar and vocabulary and ensuring that the translation is natural. The original text is a news article. Ensure the translation is formal and consistent with journalistic standards. Produce only the {TRG} translation, without any additional explanations or commentary. Maintain the HTML formatting of the original source text. Please translate the following text into {TRG} ({TRG_CODE}):*

*Speech Domain. You are a professional {TRG} translator, tasked with providing translations suitable for use in {TRG} ({TRG_CODE}). Your goal is to accurately convey the meaning and nuances of the original text while adhering to {TRG} grammar and vocabulary and ensuring that the translation is natural. The original text is automatically transcribed from spoken language and can contain errors. Maintain the flow and colloquial style of the speaker in the translation. Do not include non-linguistic sounds (e.g. laughter, groans, hesitation sounds, etc.), but do include interjections. If a word is interrupted, either guess the full word if possible or otherwise omit it. Keep foreign words as they are when translating. Produce only the {TRG} translation, without any additional explanations or commentary. Output the text such that each sentence is on a separate line. Please translate the following text into {TRG} ({TRG_CODE}):*

*Social Domain. You are a professional {TRG} translator, tasked with providing translations suitable for use in {TRG} ({TRG_CODE}). Your goal is to accurately convey the meaning and nuances of the original text while adhering to {TRG} grammar and vocabulary and ensuring that the translation is natural. The original text is user-generated content from a social media platform. Do not reproduce spelling mistakes. Reproduce marks of expressiveness that communicate meaningful intent (e.g. enthusiasm through capitalisation or elongation) in a way that is natural in {TRG}. Copy URLs and user handles directly rather than translating them. However, translate hashtags as appropriate for the translation to be natural for social media text. Follow the punctuation of the source text as best as possible. Additional punctuation should be added only if not doing so would seriously alter the comprehension of the text.*

*Translate text in an informal style, like close friends talking, even if it changes the original tone. Produce only the {TRG} translation, without any additional explanations or commentary. Maintain the HTML formatting of the original source text. Please translate the following text into {TRG} ({TRG_CODE}):*

*Software Domain. You are a professional {TRG} translator, tasked with providing translations suitable for use in {TRG} ({TRG_CODE}). Your goal is to accurately convey the meaning and nuances of the original text while adhering to {TRG} grammar and vocabulary and ensuring that the translation is natural. The original text is from software data. Translate the content of json, without translating keys and placeholders (i.e. copy them rather than translate them). Produce only the {TRG} translation, without any additional explanations or commentary. Produce a valid json output that matches the input format. Please translate the following text into {TRG} ({TRG_CODE}):*

*Educational Domain. You are a professional {TRG} translator, tasked with providing translations suitable for use in {TRG} ({TRG_CODE}). Your goal is to accurately convey the meaning and nuances of the original text while adhering to {TRG} grammar and vocabulary and ensuring that the translation is natural. The original {SRC} text consists of biology, chemistry, and geography exercises extracted from an educational web portal for children aged 9–16. Produce only the {TRG} translation, without any additional explanations or commentary. Maintain the HTML formatting of the original source text. Please translate the following text into {TRG} ({TRG_CODE}):*

### A.7 Speech Transcript Cleanup Guidelines

For the Speech domain, the automatically generated transcripts were manually corrected by human annotators before being used both to generate the automatic translations provided for possible human post-editing and as source material for translations from scratch. The following instructions were given to the annotators responsible for this transcript cleanup:

*You will be given: a video and its automatically created transcription. The speech in the transcription is divided into sentences, and each sentence has start and end timings and a speaker code (explained below). Please carefully watch the video and correct the transcription.*

- *Make sure that the written text fully corresponds to the spoken text. Rewrite all the words and phrases that were transcribed incorrectly, add all the missing words and phrases, delete all the words that were added by mistake. Correct spelling and punctuation.*
- *Make sure the text is correctly split into sentences.*
- *Correct the voice codes if necessary.*
- *Correct spelling and punctuation if necessary.*
- *Try to keep punctuation simple. Make sure all the crucial commas, question marks and exclamation points are in their places, but don't worry about the difference between types of dashes and quotes. Don't use bold or italics.*
- *Don't ever ever insert any comments into the text (such as "laughter" or "said he angrily"). The text must contain only the words that are meant to be spoken aloud. Remove such comments if present.*
- *The speech on the video can be unintelligible, if, for example, the environment is noisy, the speaker mumbles or has a strong accent. If you can't recognize a word or a phrase and it can't be reconstructed based on the context with a reasonable level of certainty, make your best guess.*
- *Remove laughter, groans, and other non-speech vocal sounds from the transcription.*
- *You may include in the transcription commonly used interjections (examples: wow, ouch, ah, shh) and filler words (like, I mean, well, etc.).*
- *Hesitation words (sounds used when a speaker is not sure what to say next, examples: um, er) should be omitted. They must appear in the transcription only in the rare cases when they contribute to the meaning. For example, when we need to show that the speaker is at a loss what to say, or else the long pause would appear unnatural. Or when someone says "er..." and then comments upon it. You have to rely on your own judgment in such cases.*
- *Do not correct the style. Colloquial speech, jargon, incomplete phrases, informal words and commonly used contractions (ok, gotta, coupla, yeah) may be left as they are.*

- *If the speaker stops mid-word, the word should be guessed from the context or omitted. Both variants are fine. Just don't leave the word unfinished, because it would lead to translation errors.*
- *Repetitions, omissions and unfinished phrases are fine in natural speech, you may leave them in the text.*
- *Do not translate words spoken in a foreign language, leave them as they are.*
- *Some words in the video may be not spoken but sung. Include them in the transcription if they contribute to the meaning of the video. The song in the background can usually be omitted without any loss. If sung words are part of the conversation, they certainly have to be transcribed. If your case is somewhere in-between, act according to your judgment.*
- *If at some point two or more speakers talk simultaneously, try to hear all the words, write all the phrases one after another, and give them the correct overlapping time codes.*
- *Annotate speakers assigning the same unique label for phrases of the same speaker.*
- *Timecodes have been created automatically. They are usually correct, but there may be mistakes if the speech was not recognized properly, so please keep an eye on them and correct them if they are considerably off.*
- *When splitting a phrase into several phrases or when adding a new phrase, please give your new phrases correct timecodes.*

## B System Submission Summaries

This section lists all the submissions to the translation task and provides the authors' descriptions of their submission.

### B.1 AdaptiveMT (Lee, 2026)

We describe AdaptiveMT, our submission to the English→Korean condition of the WMT26 General Machine Translation task in the unconstrained track. AdaptiveMT is a language-general adaptive translation harness with target-language-specific profiles; this run uses the Korean profile. The system uses a controller–executor–reducer agent harness. For each document, the harness analyzes the source, generates independent candidate translations from two heterogeneous models, compares them with token-level and semantic diffs, and synthesizes a final translation with a judge model. Mandatory QA hooks and deterministic Korean-specific guards run before finalization; failures trigger bounded local repair. Multimodal documents use structured visual context extracted from images or sampled video frames before translation. We processed all 2,078 distributed blindset records under two Korean target tags; the subsequently released General MT evaluation set contains 198 English→Korean documents tagged kor_Hang. On this official subset, the harness made 1,441 successful LLM calls at an estimated list-price inference cost of $12.03, and all 198 documents finished with passing hooks. In blindset-wide diagnostics, synthesis eliminated observed candidate-level mechanical errors, and a GPT-5 judge preferred the final output over a bare GPT-4.1 baseline on 600 sampled documents (44.5% vs. 30.0%, 25.5% ties).

### B.2 AMI (Steingrímsson et al., 2026)

We describe the AMI team's submission to the WMT 2026 General Translation shared task, participating in the English→Icelandic translation direction. Building on our 2025 submission, which relied on a 3B-parameter model and substantial rule-based post-processing, this year we aim to reduce that dependency and rely more on the translation model itself. We continually pre-train a Qwen3-4B checkpoint on a mixture of Icelandic, English, code, math, and structured data, then fine-tune it with LoRA on a retrieval-augmented, domain-conditioned instruction-tuning dataset covering five domains. At both training and inference time, source sentences are enriched with dictionary entries and back-translated example translations similar to the sentence being translated, retrieved by a dedicated RAG server, and served through a self-healing inference client that retries and validates generations. We report COMET and chrF++ scores comparing this system against last year's submission, a larger Llama-3.1-8B model adapted with the same recipe, and an instruction-tuned Qwen3-4B baseline, alongside ablations that isolate the contribution of each part of the retrieval-augmented prompt. The models are available on HuggingFace: Qwen3-4B-wmt26-AMI-en-is and Llama-3.1-8B-wmt26-AMI-en-is.

### B.3 Apertium-sme-eng (Pirinen, 2026)

We describe the creation of a new rule-based machine translation model built from two existing models. We built Apertium system between North Sámi and English based on existing translation models between North Sámi and Finnish, and Finnish and English. There were two expert-driven processes involved in building of the system: firstly crossing and validating the bilingual dictionaries and secondly translating and modifying the grammatical and structural rules. We briefly explain why there are no preexisting systems for this language pair and what limitations and ethical issues are related to it. We will also evaluate some of the training and development corpora provided in the shared task to examine the harm that low-quality machine translation can cause to vulnerable minority languages.

### B.4 Cohere CAT+ (Kocmi et al., 2026)

We present North Small Translate, an open-weight, LLM-based machine translation (MT) model with instruction-following capabilities built on the same foundation as Cohere's Command A Plus, a mixture-of-experts architecture with 25 billion active parameters out of 218 billion total parameters. North Small Translate is trained using difficulty sampling to obtain challenging documents and a five-step training protocol combining supervised fine-tuning, direct preference optimization, and online reinforcement learning. We prioritized throughput through a non-reasoning base model and supplemented with optional agentic capabilities to unlock translation quality gains. North Small Translate is trained to perform MT-related tasks, including post-editing and quality estimation, as well as related tasks such as general instruction following. The model achieves top MT performance across 50 languages in the class of models under 1T parameters, with no need to run expensive reasoning at inference time.

### B.5 CUNI-AR (Jon et al., 2026)

We describe the Charles University CUNI-AR submission to the WMT26 General Translation shared task for English into Egyptian Arabic. Our pipeline is built around GEMBA (LLM-as-judge quality) estimator that scores translations independently for accuracy and dialect authenticity. We use it throughout our pipeline: to filter training data, to construct preference pairs for DPO, to select best checkpoints, and to pick the best hypothesis per segment at inference time. Our primary translation model is Gemma-4-12B-it finetuned via QLoRA, we also finetune Jais-2-8B-Chat and Aya-expanse-8B. Gemma-4-12B-it provides a high-quality Egyptian Arabic translation, so SFT yields only marginal quality gains in automatic metrics; DPO is able to improve the metrics it optimizes for, but the real gain in translation quality is to be assessed by human evaluation. The final submission selects the best-scoring translation per segment from 31 candidate checkpoints, with the unmodified base model contributing 31% of the output.

### B.6 CUNI-EdUKate and CUNI-MH-v3 (Hrabal et al., 2026)

We describe our constrained CUNI-MH-v3 (based on Qwen3-14B) and unconstrained CUNI-EdUKate (based on Granite 4.1 8B) submissions for the WMT26 General MT shared task. Both submissions use a three-stage training procedure: QLoRA supervised fine-tuning on synthetic sentence pairs, continued supervised fine-tuning on a smaller mixture of paragraph-level and instruction-oriented examples, and iterative preference optimization with automatically generated and scored preference pairs. We document the data construction, training setup, checkpoint selection, and evaluation. We also share the training data and model checkpoints for our constrained system. The models are available on HuggingFace: CUNI-MH-v3-encs, CUNI-MH-v3-csvi, CUNI-MH-v3-csuk, CUNI-MH-v3-csde.

### B.7 Dubformer (Dukanov et al., 2026)

We describe the system Dubformer entered in the WMT26 General MT shared task, an unconstrained system built on our video-dubbing pipeline. It rests on two commitments. A document is never translated as raw text: it is first decomposed into a structure chosen for its do- main — scenes carrying speaker and audio- visual context for spoken dialogue, markup- masked segments for web documents, value- only segments for localization resources — so that non-linguistic material is protected by construction and everything needed for consistency is in front of the model at once. And no translation is taken on trust:

every segment is checked by a second model from a different family for hallucination and for drift from the meaning of the source, and a segment it rejects is re-translated with the reason attached rather than filled in from a fallback.

### B.8 Grammatist (Frontull et al., 2026)

We describe Grammatist, our submission to the unconstrained track of the WMT 2026 General Machine Translation Task, developed in direct collaboration with community members of two regional languages of Italy, Ladin and Ligurian. Ladin and Ligurian represent challenging scenarios for machine translation (MT), as they have limited resources for conventional data-driven approaches. However, this scarcity of large-scale parallel data does not reflect a lack of linguistic documentation: both languages are extensively documented in dictionaries and grammar books, which contain valuable knowledge but are not readily exploitable by conventional MT approaches. Grammatist addresses this gap by making this information available to a large language model (LLM) at inference time. The framework is both agentic and model-agnostic: it dynamically consults dictionaries and grammar books during translation to retrieve the information most relevant to the input. Any LLM can serve as the underlying base model, enabling Grammatist to benefit from advances in increasingly capable models. For the WMT 2026 task, we apply Grammatist to structured document-level translation from English into Ligurian and Ladin.

### B.9 Grial-SalamandraTA (Cozzini et al., 2026)

This work describes the Grial-TA team submission to the constrained track of WMT2026 General Machine Translation Task for the following language pairs: English→Icelandic, English→Ladin and English→Ligurian. Our submission leverages full fine-tuning of theSalamandraTA-7b-instruct model. Two separated models were fine-tuned: one for Icelandic and one for Ligurian and Ladin. The model is available on HuggingFace: MTUOC-recipes.

### B.10 HW-TSC (He et al., 2026)

Machine translation based on large language models (LLMs) has achieved remarkable progress in recent years. However, relying on a single translation model and fixed translation instructions often limits translation quality, especially for multilingual and multi-domain scenarios. To address this issue, we propose HW-TSC-Agent, a multi-stage translation agent framework that integrates translation model fine-tuning, dual-model candidate generation, and instruction-aware translation refinement into a unified pipeline. First, we perform Supervised Fine-Tuning (SFT) and Contrastive Preference Optimization (CPO) on openPangu-Embedded-7B using high-quality bilingual data to enhance its multilingual translation capabilities. The fine-tuned openPangu-Embedded-7B and HY-MT2-7B are then used to generate candidate translations. Finally, source-language analysis, candidate translations, and task-specific instructions are incorporated into a dynamic prompt, which guides DeepSeek-V4-Flash to compare, refine, and fuse the candidate translations to produce the final output. Our system is submitted to the WMT2026 General Machine Translation Shared Task, covering 13 translation directions. On the WMT2025 English→Chinese development test set, enriching the dynamic prompt generally improves translation quality over an instruction-only DeepSeek-V4-Flash baseline.

### B.11 Krosny (Volchek and Poritski, 2026)

This paper describes our submission to the WMT26 General Machine Translation shared task for the English → Belarusian direction. In lower-resourced morphologically rich languages like Belarusian, open-weight large language models (LLMs) frequently struggle with orthographic fidelity, hallucinated vocabulary, and negative transfer from related high-resource languages. To address these issues, we implemented Krosny, an iterative, resource-augmented pipeline built on top of TranslateGemma 12B. The system translates each segment in three stages: (1) dictionary-augmented generation, (2) refinement using a reference grammatical database, and (3) rule-based post-processing followed by an LLM-as-a-judge candidate selection. We find a small but consistent improvement over the baseline TranslateGemma 12B. In comparison with other constrained-track systems of WMT26, the performance of Krosny is mid-tier. We release the source code of our implementation (https://github.com/volchek/Krosny-WMT26).

### B.12 LiLa (Bueno et al., 2026)

We describe LiLa, our submission to the constrained track of the WMT 2026 General Machine Translation Task. Motivated by recent advances in large language models (LLMs) and their increasing availability as open models, we investigate the adaptation of LLMs for Ligurian and Ladin, two low-resource languages included in the shared task. We evaluate several adaptation strategies for Gemma-4, including Instruction Tuning (IT-only), continuous pre-training followed by Instruction Tuning (CPT+IT), and Low-Rank Adaptation (LoRA), and compare them with a dedicated encoder-decoder pipeline based on fine-tuned No-Language Left Behind (NLLB) models. Our experiments show that, under the evaluated conditions, fine-tuned NLLB models achieve higher automatic translation scores than the investigated LLM adaptation strategies. Based on these results, our final submission adopts a fine-tuned NLLB-based translation pipeline. We discuss the main observations from the different approaches explored during development. We release the code and models produced in these experiments through a publicly accessible GitHub repository https://github.com/schtailmuel/wmt26-lila/.

### B.13 Lumen (Wang et al., 2026)

We present Lumen, our submission to the WMT2026 General Machine Translation Shared Task. We focus on instruction-specialized translation, where systems must produce accurate translations while satisfying fine-grained requirements on style, terminology, and structured output. Lumen follows a four-stage pipeline. First, continued pre-training and supervised fine-tuning jointly strengthen multilingual translation competence and the ability to follow translation-specific instructions, such as terminology, style, and format constraints. Second, we extend the originally offline $M^2PO$ preference-optimization framework into an online preference-optimization stage: the current policy samples candidate translations, an LLM judge assigns continuous direct-assessment scores, and the resulting multi-pair preferences are used to update the model. Third, on-policy distillation transfers stronger translation-instruction-following behavior from a larger teacher model to the Qwen3-14B student, improving translation-instruction adherence while retaining a 14B primary translation backbone. Finally, structure-aware inference and postprocessing preserve required formats, while selective repair addresses clear structural or decoding failures before submission. We participate in 23 translation directions. Under an absolute 1–5 LLM-judge rubric that evaluates translation-instruction following and translation quality separately, Lumen reaches an overall mean score of 4.60. Despite using a 14B translation backbone, it achieves performance comparable to leading proprietary systems in both translation quality and translation-instruction following.

The model is available on HuggingFace: Lumen_wmt26.

### B.14 MakotoAI (Nishihama, 2026)

We describe MakotoAI, an unconstrained submission to the WMT26 General Machine Translation shared task covering all 23 language pairs (4,897 documents). The system performs no training or fine-tuning: it is a lightweight orchestration layer over six off-the-shelf commercial LLMs, in which each language pair is routed to the single model that won a blinded pre-competition shootout for that pair. Translation is document-level with the full task instruction provided in-prompt. Structured output (JSON and HTML domains) is repaired by a small deterministic normalization pass rather than by model-based retry: an ablation on real test data found that a post-hoc validate-and-retry instruction layer was inert on clean documents and net-negative on JSON documents, while deterministic fence and preamble stripping achieved the intended effect at zero inference cost. Quality assurance combined an exhaustive deterministic instruction-adherence scan, a two-judge LLM evaluation whose self-grading bias we measured to be directional by model family, and the organizers' official alignment checker, against which the final submission scores 1,914 of 1,914 structurally checkable documents aligned. Four defective documents (three truncations, one repetition-loop degeneration) were detected and regenerated, one requiring escalation to a different model; all four are disclosed. The entire system runs on commodity hardware; total API cost to produce and verify the submission was just under $25. We argue that for API-orchestrated MT, verification discipline and deterministic post-processing are higher-leverage than added inference-time machinery.

### B.15 PseudoRef (Kanojia et al., 2026)

The WMT26 General MT task evaluates systems on 10 language pairs that have no human references (neither translated from scratch nor post-edited from MT output by humans). We describe how we built the pseudo-references for these pairs and six other language pairs (in which some forms of human references are available): seven models translate the 3,277 official documents under up to five prompt conditions, giving a total of 26 system–prompt combinations; then three reference-free quality estimation (QE) models score every candidate; and a per-document selector picks one translation, which GPT-5.5 post-edits where needed. Working without references exposed a failure mode of QE-guided selection: the metrics rank fluent output in the wrong language above correct translations. Adding a confidence-scaled language identification penalty to the score fusion drives the wrong-language count to zero, and the resulting selector still scores better on MetricX than the rank-fusion baseline it replaces. Since no references were available for these pairs while we were building them, we calibrate every selection decision on last year's WMT25 human judgments. The human evaluation, released after construction, shows the cost of getting selection wrong: our references stand with the strongest participating systems when the selector kept a frontier-model candidate, and fall up to 17 ESA points below them when it did not. We release the selection method and the provenance of every reference.

### B.16 Qingqiu-MT-9B (Xia et al., 2026)

We present Qingqiu-MT-9B, an instruction-following multilingual translation model developed for the constrained track of the WMT26 General Machine Translation shared task. Our model supports translation among 20 languages and covers 22 of the 23 official language pairs. It uses a source-grounded synthesis pipeline with separate LLM-based steps for generating instance-specific translation instructions and their corresponding translations. The resulting corpus covers diverse translation requirements, task complexity, instruction formulations, domains, document lengths, and glossary constraints, reducing reliance on fixed prompt templates and supporting generalization to unseen translation instructions. Our model is based on Qwen3.5-9B and trained through two-stage full-parameter supervised fine-tuning (SFT) followed by reinforcement learning (RL). The first SFT stage performs broad adaptation on a large-scale, medium-quality corpus, while the second refines the model on a smaller, higher-quality set. The RL stage further optimizes the model with Group Relative Policy Optimization (GRPO). During development, we use an LLM-based, rubric-guided contrastive method that scores candidates by dimension and aggregates an overall score to assess translation quality. Experiments show that Qingqiu-MT-9B demonstrates strong generalization and competitiveness among similarly sized models. We release the model at Qingqiu-MT-9B.

### B.17 ReMova (Pilinka et al., 2026)

This paper presents a Belarusian-specific data-cleaning pipeline and fine-tuning for English→Belarusian machine translation. Our cleaning pipeline distinguishes itself from others by employing a correction tool that addresses the issue of the two orthographies of the Belarusian language, noise in the training data, interference from other languages, and other misspelling issues common in Belarusian on the internet. A matched ablation on unfiltered training data shows substantial benefits from filtering for all fine-tuned models, with the LLM-based models gaining roughly twice as much from filtering as the dedicated encoder-decoder MT system, supporting the view that for Belarusian MT one of the primary bottlenecks is data quality. The model is available on HuggingFace: ReMova-TranslateGemma-en-be.

### B.18 RFMT (Matsuda et al., 2026)

We participated in the constrained (open-weight) track of the WMT 2026 General MT Task for the English→Japanese and Simplified Chinese→Japanese directions. Our system builds on Marco-MT-Algharb, a strong open-weight translation model from the previous WMT General MT task. We further fine-tuned this model to generate more natural Japanese translations. To this end, we constructed a Context-Aware JApanese Linguistic Acceptability dataset (CAJALA). During annotation, human annotators were shown multiple paraphrased variants of a segment within its document-level context and asked to select

the most natural one. We then back-translated the CAJALA dataset to create parallel data for Direct Preference Optimization (DPO). We also trained the model to perform fill-in-the-middle (FIM) translation, in which the model reconstructs target-side segments from their surrounding document. At inference, we use Minimum Bayes Risk (MBR) decoding, followed by selective FIM post-editing of low-quality segments. The model is available on HuggingFace: RFMT.

### B.19 SalamandraTA (Mash et al., 2026)

We present the BSC submission to the WMT26 General Machine Translation shared task: a 7B decoder-only model covering 23 directions, adapted from the SALAMANDRA family through vocabulary replacement, two rounds of continued pre-training (monolingual, followed by instruction-formatted parallel data), supervised fine-tuning on a translation-only instruction mixture, and preference optimisation applied selectively to six weak directions via CPO-SimPO with LoRA adapters. Submissions are decoded with Minimum Bayes Risk selection over a candidate pool filtered for truncation, degeneracy and off-target script. As official human evaluation was unavailable at the time of writing, we report a stage-wise internal evaluation on FLORES+ and WMT24++, together with automatic scores for the submitted system on the 12 test-set directions for which references have been released. Instruction tuning accounts for almost all measurable gain, but its size differs by an order of magnitude between the two evaluation sets; preference optimisation moves automatic metrics by less than the drift among untreated directions. The model is released under a Research-Only Licence and is available on request.

### B.20 SCIR-TG-MT (Cao et al., 2026)

This paper presents SCIR-TG-MT, our primary submission (ID 44) to the unconstrained track of the WMT 2026 General Machine Translation shared task. The system covers ten translation directions using DeepSeek-V4-Pro and STRIDE (Structured Translation with Risk-Informed Directional Execution), an OpenCode translation skill. STRIDE converts source-side evidence and task instructions into a translation contract, an execution route, generation constraints, and selected checks. On five WMT25 development directions, STRIDE raises average SacreBLEU from 31.24 to 31.80 and COMET-22 from 83.61 to 84.17. A cumulative ablation on three directions separates the effects of routing, controls, and validation.

### B.21 SRPOL (Dobrowolski et al., 2026)

We propose a method to improve machine translation quality by ensembling multiple large language models within a multi-agent framework. The method addresses the problem of ensembling models with different tokenizations by abstracting away from token-level representations and operating at the level of generated text. The approach integrates several established concepts in MT, including ensembling, quality estimation, and reranking into one translation system. The log-likelihood reranking applied in this paper significantly improves results, even without ensembling. Experimental results show improvements comparable to COMET-MBR.

### B.22 TartuNLP/Tähetorn (Fishel and Yankovskaya, 2026)

We present an open-weight translation model for Estonian and its low-resource "relatives" in the Finno-Ugric language family. The training data includes 12 languages paired with Estonian as well as 23 more Finno-Ugric languages and varieties. The translation model use Unbabel Tower+ 9B as its starting point. The model is available on HuggingFace: Tahetorn9B.

### B.23 TransCore (Yu et al., 2026)

This paper describes TransCore, the NewTranx submission to the WMT26 General Machine Translation Shared Task constrained track. Our system is built upon the Qwen3-8B large language model and adopts a two-stage supervised fine-tuning framework trained exclusively on publicly available data. Our approach focuses on high-quality multilingual data construction, including parallel corpus construction, knowledge-distilled corpus construction, and instruction-following data construction. For the parallel corpus, we construct a high-quality multilingual training corpus through multilingual data collection and automatic quality filtering. For knowledge distillation, we construct a KD corpus from publicly

available monolingual resources using a large language model, followed by automatic quality filtering. To support the instruction-following evaluation introduced in WMT26, we further construct instruction data covering immutable entity preservation, document-level translation, and structured translation, which are incorporated into the first-stage supervised fine-tuning. Our system participates in four language directions of the WMT26 General Machine Translation Shared Task: English→Indonesian, English→Kazakh, English→Thai, and Chinese→Japanese.

The models are available on ModelScope: TransCore-EnId, TransCore-EnKk, TransCore-EnTh, TransCore-ZhJa

### B.24 TRIVE (Yang et al., 2026)

For the WMT26 General Machine Translation Task (Unconstrained Track), we propose TRIVE (Tri-Fusion Verified Translation Agent), a model-agnostic multi-agent translation framework. TRIVE organizes translation as a closed loop of Generation–Fusion–Verification–Correction: it first generates candidates in parallel under three complementary strategies—Faithful, Fluent, and Free—then synthesizes a draft that balances semantic fidelity and natural expression, and finally iteratively refines the output via rule-based validation and large language model evaluation. Because each module is implemented primarily via prompting, TRIVE can be directly overlaid onto diverse backbone models without task-specific fine-tuning. Experiments show that overlaying TRIVE on multiple backbones consistently improves instruction-following translation quality. Finally, we submitted Gemini-3.5-Flash + TRIVE as our primary system to WMT26.

### B.25 UvA-MT (Wu et al., 2026)

This paper presents UvA-MT's submission to the WMT 2026 General Machine Translation shared task, competing in the unconstrained track across all 23 translation directions. This year, we fully leverage the test-time methods of Large Language Models (LLMs) for machine translation. Specifically, (1) we use sequential sampling with a refinement prompt to generate a pool of translation candidates for each source sentence, a strategy shown to outperform traditional parallel sampling; and (2) we employ LLMs as pairwise judges to select the best candidates via a round-robin voting mechanism, with offline evaluation on the WMT25 benchmark showing a very clear improvement over point-wise best-of-N selection. Lastly, we simply apply these two strategies for the submission of WMT26.

### B.26 Wayfinder (Shao et al., 2026)

This paper presents Wayfinder, our submission system for the WMT26 General Machine Translation (GenMT) shared task. GenMT evaluates document-level translation under natural-language instructions, where structural preservation, formatting constraints, and output cleanliness are part of translation quality. Rather than training a new translation model, Wayfinder treats four API-based system outputs as a document-level candidate pool and produces one final hypothesis through a four-stage agentic pipeline. It aggregates source, instruction, metadata, candidates, and a DeepSeek-V4-Pro ranking-then-scoring signal; applies an anonymized pick-or-rewrite agent; and runs a conservative postcheck for severe objective defects. During development, a judge-guided loop compares outputs with a GPT-5.5 baseline, analyzes loss cases, updates prompts and repair constraints, and selectively reprocesses difficult documents. In automatic pairwise evaluation against GPT-5.5, Wayfinder obtains a pooled document-level weighted win rate of 0.6537 and remains above parity in every evaluated direction. The results suggest that candidate-pool translation, constrained agentic selection, conservative repair, and selective judge-guided iteration are practical components for instruction-conditioned shared-task MT.

### B.27 Yandex and Yandex-8B (Popov et al., 2026)

We describe Yandex and Yandex-8B, our unconstrained and constrained submissions to the WMT26 General Machine Translation task. Our previous WMT25 submission, a 7B translation specialist, shows strong Fluency but comparatively weaker Accuracy. To combine its translation behavior with the capacity of a much larger model without replaying the full 7B training pipeline at 235B scale, we add two forms of supervision to the instruction-tuning data of an in-house 235B pretrained model: direct translation

targets generated by the 7B specialist and in-house translation-related tasks. The resulting Yandex model improves both Accuracy and Fluency and reduces the LLM-based error score relative to the same 235B model tuned only on general instructions. Relative to the 7B specialist, it improves Accuracy and reduces the error score, while their Fluency point estimates remain similar. Yandex then provides hard targets for Yandex-8B, which is trained for English→Russian, English→Belarusian, English→Kazakh, and English→Armenian using direct and instruction-conditioned translation data. Across four directions, Yandex-8B obtains the highest paragraph-level ChrF++ and the highest Accuracy and Fluency under our LLM-based evaluation among five public baselines. The constrained model is available on HuggingFace: Yandex-8B.

## Abstract

We present the findings of the WMT26 Shared Task on Automated Translation Quality Evaluation Systems, continuing last year's unification of the earlier separate WMT Metrics and Quality Estimation shared tasks. This year we evaluated three complementary views of segment-level translation quality on a common test set: fine-grained error-span detection, continuous quality-score prediction, and a new task on identifying error-free translations. Submissions to upstream tasks were also converted automatically to downstream predictions. The evaluation covered 21 translation directions using human cESA judgments from the WMT26 General Machine Translation task, with optional reference translations generated as either native, post-edited, or pseudo-references, depending on the translation direction. Official evaluation data was complemented by five submitted challenge sets. Across all three primary tasks, unsupervised LLM-as-a-judge approaches outperformed all traditional and supervised metrics, while open-weight models such as Gemma 4 were found to be competitive with proprietary frontier models. Reference-free LLM judges are highly competitive, and the benefit of adding a reference largely depends on its provenance and on the evaluator model family. [1]

## 1 Introduction

The WMT26 Shared Task on Automated Translation Quality Evaluation Systems evaluates the performance of state-of-the-art automated systems that assess the quality of text-to-text translations. It builds on many previous years of WMT shared tasks in both MT metrics and quality estimation, which were unified for the first time into a single track last year (Lavie et al., 2025). Automated translation quality evaluation systems play a critical role in the research, development, and deployment of machine translation systems, including multilingual LLMs. They are also critical components in automated translation workflows for large-scale commercial translation use cases.

The shared task consists of three primary subtasks and one additional subtask shown in Table 1. The primary subtasks are: (1) segment-level error detection and span annotation, (2) segment-level quality score prediction, and (3) detection of error-free segments. A common curated evaluation data set was provided for these three tasks, consisting of material obtained from the WMT26 Shared Task on General Machine Translation. It was augmented by a number of "challenge sets" developed by the task organizers and members of the research community. The fourth subtask solicited the submission of these challenge sets.

A central goal of this year's shared task was to study these three primary evaluation formulations jointly rather than as independent problems. We therefore use a common evaluation set across Tasks 1–3 and organize them as a conceptual pipeline: fine-grained error annotations are also converted into segment-level quality scores, and both error annotations and quality scores are in turn also converted into binary error-free judgments. This de-

Table 1: Illustration of the four subtasks: span-level error detection, segment-level quality score prediction, error-free detection, and challenge sets.

sign allows us to examine not only which systems perform best within each task, but also whether current automated evaluators can capture translation quality consistently across these different levels of granularity.

Below are some of the key details and changes implemented for this year's shared task:

- **Subtasks**: We continue last year's subtasks on segment-level quality score prediction, segment-level error-span/severity annotation, and the solicitation of challenge sets. The subtask on quality-informed error correction is dropped; it is replaced by a new subtask on detecting error-free segments.
- **Cross-Subtask Participation**: To broaden participation and facilitate a more comprehensive analysis of current MT evaluation capabilities, we released a single test set to be used in common across the three primary subtasks. We also defined mechanisms to automatically convert submissions from one subtask to another.
- **Language Pairs**: Following last year's philosophy, we attempted to offer our shared task in as many of the language pairs supported by the WMT26 General Machine Translation task as possible. We ultimately released test data covering 21 of the 23 language pairs: see Table 2. Several of these pairs are new compared to 2025. To help guide participants for whom evaluating the full set proved computationally infeasible, we identified a priority subset of eight language pairs.
- **Additional Resources**: Preparation of this year's test set brought together different types of references, different translation instructions per domain, and new guidelines for scoring translation quality. We made these resources available to participants.
- **Human Evaluation**: Human evaluation was carried out by the WMT26 General Machine Translation task (Kocmi et al., 2026a). This year it used the Contrastive Error Span Annotation (cESA) protocol[2] (Zouhar et al., 2026a) with a variable number of human annotations per MT system, depending on the system's performance (Zouhar et al., 2026b).
- **Meta-Evaluation**: We evaluate auto-evaluators using meta-metrics that differ substantially from those used in previous years. For segment-level error detection and span annotation, we adopt the MPP ("Match with partial overlap and partial credit") $F$-score (Perrella et al., 2026); see Section 5.1. In segment-level quality score prediction, we newly use "group by screen" Pairwise Difference Pearson (DiIanni and Deutsch, 2025) at the segment level and maintain "group by source" Soft Pairwise Accuracy (Thompson et al., 2024) at the system level; see Section 6.1. Our new task on detection of error-free segments is meta-evaluated with the Matthews Correlation Coefficient (Matthews, 1975); see Section 7.1.
- **Code and Data Release**: The evaluation set, raw data for each subtask, and code to generate the meta-analyses in this paper are released publicly at `https://github.com/wmt-conference/wmt26-mteval`.

Our main findings are:

- **Unsupervised LLM-as-a-judge systems lead across all three primary tasks.** In both fine-grained error detection and quality-score prediction, the highest-ranking systems are dominated by prompted LLM evaluators without task-specific fine-tuning, while conventional lexical and supervised neural metrics rank substantially lower (Section 5.2 and Section 6.2). LLM-based systems similarly dominate detection of error-free segments (Section 7.2).
- **Evaluation performance depends strongly on the underlying LLM, but no single model family dominates every setting.** Gemini-based evaluators are particularly strong for error-span detection and quality scoring, while GPT-based systems lead the direct error-free classification submissions. Open-weight Gemma 4 systems are largely competitive with the strongest proprietary evaluators across tasks (Sections 5.2–7.2).
- **Strong LLM evaluators can operate effectively**

[2] github.com/zouharvi/cESA

**without references, and the value of a reference depends on its provenance and quality.** Native human references consistently improve the Task 1 LLM baselines we analyze, whereas post-edited and pseudo-references sometimes reduce performance; corresponding reference-based variants generally improve quality-score prediction in Task 2 (Sections 5.2.1 and 6.3.2).

- **Reasoning can improve evaluation quality, but its effect is model-dependent and appears to saturate.** Reasoning substantially improves Qwen-based evaluators while providing smaller gains for Gemma, and increasing GPT-5.6 Sol from medium to xHigh reasoning yields essentially unchanged Task 1 accuracy (Section 5.2.2).

- **Task-specific optimization is not always necessary for error-free detection.** Strong Task 1 and Task 2 systems that were converted automatically to binary predictions are competitive with direct Task 3 submissions, and frequently fall within the same statistical significance clusters (Section 7.3.1).

- **Robust multilingual evaluation remains challenging.** Rankings vary across translation directions and can change substantially for lower-resource languages and when evaluation is expanded beyond the eight priority directions (Sections 6.2 and 7.3.2; Appendix B).

- **Challenge sets uncover gaps.** The challenge sets described in Section 8 expose pervasive complementary failure modes, including local metric disagreement, error-correction insensitivity, gender bias, Unicode robustness, and omission/addition asymmetries, that are largely hidden and not captured by aggregate benchmark performance.

The remainder of the paper is organized as follows. Section 2 defines the four subtasks and the conversion mechanisms connecting the three primary tasks. Section 3 describes the shared evaluation data and human annotations, and Section 4 summarizes participant systems and organizer baselines. Sections 5, 6, and 7 present the results and analyses for error-span detection, quality-score prediction, and error-free classification, respectively; Section 8 describes the submitted challenge sets. Section 9 summarizes our conclusions and directions for future work.

## 2 Tasks

We organized three primary subtasks that address segment-level translation quality from three perspectives: (1) detection of fine-grained error spans and error severities within the segment, (2) prediction of the segment's overall quality score, and (3) classification of the segment as error-free or not. A fourth subtask solicited the submission of challenge sets that test the three judgments of quality under particular scenarios or in particular targeted ways, as defined by the challenge set designer in each case.

Newly this year, we ordered the three main subtasks as a conceptual pipeline and defined automatic mechanisms to convert submissions received by one subtask to the subtask(s) downstream of it.

Each subtask, as well as the automatic conversion mechanisms between subtasks, is described below.

### 2.1 Task 1: Segment-Level Error Detection and Span Annotation

Given a source text, its translation, and optionally a reference translation, the goal of Task 1 is to detect translation errors and identify the precise location of each error within the translation along with its severity. For each translation, participants are asked to predict error spans as character offsets (i.e., start and end character indices) as well as an error severity (`Major` or `Minor`) for each identified error. Ground-truth offsets and error severity are obtained from the cESA human annotations (Zouhar et al., 2026a) generated at the WMT General MT shared task (Kocmi et al., 2026a). Submissions are evaluated and ranked based on their ability to correctly detect translation errors and assess their severity, using the MPP meta-evaluation strategy (Perrella et al., 2026).[3]

### 2.2 Task 2: Segment-Level Quality Score Prediction

The goal of Task 2 is to predict a numerical quality score for each source–target segment pair in the evaluation set, with a reference translation optionally being provided. Participants this year were asked to predict the cESA score (Zouhar et al., 2026a), which ranges from 0 to 100 (higher is better). Submissions are evaluated and ranked based on their predictions' correlations with human-annotated cESA scores — again generated by the

[3] Additional details are provided in Section 5.1.

General MT shared task — at both the segment and corpus levels.

We convert Task 1 annotations to Task 2 by assessing fixed penalties for each reported error, using an MQM-style weighting scheme. Beginning at a score of 100, we subtract 10 points per major error and 2.5 points per minor error.[4] The minimum possible score is 0; any additional penalties that would further reduce the score are ignored. Translations annotated with a single major error spanning the entire segment are assigned a score of 0. Empty translations marked as a single major omission are also scored as 0.

### 2.3 Task 3: Detection of Error-Free Segments

Task 3 is a new subtask focused on a concrete application of translation quality evaluation systems: detection of error-free segments. While traditional quality estimation focuses on continuous scores (Task 2) or fine-grained error spans (Task 1), this task simplifies the objective to a binary classification: "Is this translation error-free?" The goal is to identify segments that can be published or consumed without further human intervention. Participants must predict a binary label for each source–target pair; references are not allowed. Submissions are evaluated and ranked based on their alignment with gold labels derived from human annotations, measured by the Matthews correlation coefficient.

We derive binary labels from a Task 1 submission via a simple test: segments where the Task 1 submission predicts no errors are labeled as error-free, while segments with one or more predicted error spans (including omissions) are labeled as containing errors. To convert Task 2 submissions, we asked Task 2 participants to provide a custom threshold for their models' scores as well as an indication of whether the boundary is exclusive ($>$) or inclusive ($\geq$).[5] Any segment where the model score passes the threshold is classified as error-free; all others are classified as containing errors.

### 2.4 Task 4: Challenge Sets

While the first three subtasks are focused on the development of stronger and better automated quality evaluation systems, the goal of this subtask is for participants to create test sets with challenging evaluation examples that current evaluation systems fail to identify or score correctly. Challenge sets can relate to any (or all) of the other subtasks. In order to shed light on different evaluation perspectives, Task 4 takes place in a decentralized manner: contrary to the main subtasks, the test sets are not provided by the organizers but by different research teams, who are also responsible for analyzing and presenting the results.

This subtask is inspired by the *Build It or Break It: The Language Edition* shared task (Ettinger et al., 2017), which aimed at testing the generalizability of NLP systems beyond the distributions of their training data.

## 3 Evaluation Data

### 3.1 Data Sourcing and Preparation

Similar to previous years' editions, the source sides, MT outputs, and reference texts for our shared task are mainly derived from the WMT26 Shared Task on General Machine Translation (Kocmi et al., 2026a).

The test data sources cover the news, social media, software, speech, educational, and fact-checking domains. In the General MT shared task, some of this test material was multimodal: the social-media content was provided with screenshot images, and the speech data was provided as video files with uncorrected automatic transcripts. However, for our shared task, we released as our primary version the text content of the social-media posts and a *corrected* transcript of the video files. (The images and videos remained available separately, as additional information that participants could use.)

Candidate translations were likewise sourced from General MT, in the form of *all* of the MT systems submitted to that shared task. This represents a difference from last year, when only a selection of the higher-performing translation systems was chosen. We also included among the candidate translations any available references, whether human- or automatically derived. Overall, our participants were therefore asked to judge the quality of up to 47 different translations per source segment, and in no case fewer than 23.

The language pairs in our official test set are summarized in Table 2. This year, the General MT shared task did not release native human references for all language pairs. Native references

[4] Note that the relative error weights in MQM are normally set to a 5-to-1 ratio. We decided to use a 4-to-1 ratio based on an analysis of last year's data showing that it produced a slightly higher correlation with human-annotated ESA scores.

[5] If this information is not provided, we default to a threshold of $\geq 85$.

| Code | Source | Target | Priority | Ref Type | # Src in Test | % Annot | # Pairs in Test | % Annot |

Table 2: Language pairs covered by the official test set. Eight of them were identified to participants as high-priority pairs; the nature of the available reference for each pair is as noted. A dynamically chosen portion of each language pair's material was human-annotated. Columns show the number of source segments and source–target pairs in the test set, along with the fractions that were annotated.

were available in seven language pairs: ces-deu, ces-vie, eng-ekk, eng-isl, eng-lij, eng-lld, and eng-sme. In four pairs, the reference consisted of post-edited MT output: eng-arz, eng-ces, eng-deu, zho-jpn. The remaining 10 language pairs were originally *referenceless*. In nine of them (eng-bel, eng-hye, eng-ind, eng-kaz, eng-rus, eng-tha, eng-ukr, eng-zho_CN, eng-zho_TW), we created pseudo-references via a five-stage pipeline (Kanojia et al., 2026) in which seven LLMs and MT systems generate candidates under different prompt conditions, three reference-free QE metrics score them, and a per-document selector keeps one, with constrained LLM post-editing applied where the selection is weak. Selection was led by MetricX-24 and calibrated on common language pairs from the WMT25 human judgments, constrained by a structure gate and a language-identification penalty. We ran the final language pair, ces-ukr, as a completely reference-free scenario. The nature of the reference in each segment — human, post-edit, pseudo, or null — was labeled in the test set for participants to condition on if desired.

Two language pairs from General MT (eng-jpn and eng-kor) do not appear in our shared task. These were removed from our evaluation set when it became apparent that no gold-standard human quality annotations would be collected for eng-kor, and the human annotations for eng-jpn were in doubt. Within the 21 language pairs that did comprise our official test set, we selected a reduced set of documents based on how likely we believed they were to be heavily covered by the General MT human annotations. (Annotations this year were carried out to varying extents for different qualities of MT systems; later documents are only likely to be covered for the best-performing systems.) This set consists of 160 documents for Czech-source language pairs and 120 documents for all others.

Our final official evaluation set thus comprised 252,919 segment pairs. With challenge sets included, the total size was 363,242 segment pairs.

Because of the significant size, we designated a subset of eight language pairs as high priority for participants who otherwise found the whole set computationally or economically infeasible. The priority pairs — ces-deu, ces-vie, eng-arz, eng-ekk, eng-ind, eng-isl, eng-sme, and zho-jpn — were chosen to cover a range of language families, resource levels, and reference types, while being biased towards settings where we expected the gold-standard human annotations to be more reliable.

**Additional resources.** In addition to identifying the reference type and the domain label of each segment, we released a separate set of domain-specific translation and evaluation instructions. The trans-

lation instructions consist of the same directions provided to the human translators, along with the consequent LLM prompts used for baselines. The evaluation instructions consist of the same information given to the human annotators in making gold-standard judgments of translation quality following the cESA annotation protocol (Zouhar et al., 2026a). Our intent is to provide participants of our shared task with a finer-grained definition of what a correct translation looks like in each domain and how to numerically score it on a 0–100 scale. Both sets of instructions are available online per-domain, online global, and by Kocmi et al. (2026a).

### 3.2 cESA Human Evaluation

As mentioned previously, human evaluation was carried out according to the Contrastive Error Span Annotation (cESA) protocol (Zouhar et al., 2026a), with a variable number of human annotations per MT system depending on the system's performance (Zouhar et al., 2026b). The process runs independently for each language pair. After a burn-in period, during which all MT systems receive a fixed number of annotations, further source segments and candidate translations are selected dynamically until the annotation budget is exhausted. Each screen of the cESA interface presents the human annotator with three candidate translations for the same source segment.

The fraction of source segments and the fraction of source–target segment pairs from the test set that are covered by human evaluation thus vary from language to language. These statistics are illustrated in the rightmost four columns of Table 2. Many language pairs are well covered by the annotation campaign, but some are not. We received especially few annotations for ces-vie, eng-sme, and eng-zho_CN.

## 4 Participants

This section summarizes the systems submitted to our primary subtasks. The challenge set participants are detailed in Section 8.

### 4.1 External Submissions

Table 3 lists the submissions we received from the community for Tasks 1, 2, and 3. Some participants submitted a single model to multiple tasks; others submitted two variant models with the same name to the same task. These details are elided in the table, where we show only task-level participation per model name. With each submission, we asked participants to also hand in a model card that included a free-text system description. These descriptions are given in Appendix A. Participants were finally asked to submit a separate system description paper explaining their full approach. See the appendix and the participants' separate publications for more information on each submitted system.

### 4.2 Baselines

We use LLM-as-a-judge baselines alongside traditional automatic metrics, both neural and string-based, covering Tasks 1 and 2 directly; Task 3 predictions for every baseline are derived automatically via the conversion mechanisms of Section 2, with no special-casing for baselines. Some LLMs are prone to repeating error spans within a segment's Task 1 output. We removed exact duplicates matching on start and end offset, keeping the major-severity annotation when the severities disagreed. We run all Task 1 baselines both with and without a reference translation, falling back to the reference-free configuration for language pairs that lack one. Exact prompts used for LLM-as-a-judge baselines are included in Appendix E.

We detail task-specific baselines below.

#### 4.2.1 Task 1

**xCOMET (Guerreiro et al., 2024)** xCOMET XL (3.5B) and XXL (10.7B) are neural models trained to jointly predict MQM-style error spans and a sentence-level quality score for a translation, supporting source-only, source+reference, and reference-only modes. We run both XL and XXL in the source+reference and the source-only configuration with word-level predictions, giving four xCOMET baselines in total (XL/XXL $\times$ with-/without reference).

**GEMBA-ESA LLM-as-a-judge baselines** For our remaining Task 1 baselines, we prompt a range of open- and closed-weight LLMs following a two-stage GEMBA-ESA protocol (Kocmi and Federmann, 2023b,a): in Stage 1, given the source, the hypothesis, and (where enabled) a reference translation, the model is prompted to enumerate error spans with severities; in Stage 2, the model is separately prompted, *conditioned* on its own Stage 1 output, to produce a final 0–100 quality score, which we also report as these systems' Task 2 predictions (Section 4.2.2).

Stage 2 is capped at 64 output tokens for every

baseline. Gemma 4 and Qwen 3.6 are served locally using vLLM (Kwon et al., 2023): we decode greedily (temperature 0) with a 512-token Stage 1 cap when reasoning is disabled, and sample at temperature 0.6, top-$p$ 0.95, with an 8192-token Stage 1 cap when reasoning is enabled. Using the same token limits, Gemini 3.6 Flash is queried via its standard API at medium thinking level; GPT 5.6 via the OpenAI Batch API, at medium reasoning effort for Terra and at `medium` and `xHigh` for Sol. For the English-Armenian language pair, Qwen 3.6 and Gemma 4 token limits are multiplied $\times 4$ as many more tokens were produced consistently for segments in this language pair in order to have completed predictions. All reference-aware variants use the provided reference type (human, post-edited, or pseudo-reference) and adapt prompt wording accordingly.

The specific configurations we ran per model are given below:

- **QWEN 3.6 (Qwen Team, 2026)**: Qwen 3.6 35B-A3B is an open-weight mixture-of-experts model with a toggleable reasoning mode. We run it with the GEMBA-ESA protocol above in all four combinations of reasoning enabled/disabled and reference used/not used.
- **GEMMA 4 (Team, 2026)** Gemma 4 31B-IT is an open-weight instruction-tuned model with a toggleable reasoning mode. As with Qwen 3.6, we run it in all four combinations of reasoning enabled/disabled and reference used/not used.
- **GEMINI 3.6 FLASH (Google DeepMind, 2026)** Gemini 3.6 Flash is a closed-weight model. We run it at medium reasoning effort and without a reference translation. We use the Google AI Studio API for querying.
- **GPT 5.6 (OpenAI, 2026)** We additionally run two closed-weight variants of GPT 5.6, Terra and Sol, both without a reference translation. GPT 5.6 Terra is run at medium reasoning effort; GPT

5.6 Sol is run at both `medium` and `xHigh` reasoning effort, giving three baselines in total. We limit all three baselines to the 8 priority language pairs due to budget constraints, with the `xHigh` reasoning GPT 5.6 Sol model able to complete 6 of the 8 pairs within timing constraints. The OpenAI Batch API is used for querying.

#### 4.2.2 Task 2

We computed scores for several baseline systems in order to compare submissions against previous well-studied metrics.

**Reused Task 1 baselines** The XCOMET and GEMBA-ESA LLM baselines described in Section 4.2.1 natively produce a Task 2 quality score as part of the same prediction (for XCOMET) or the same two-stage prompting pipeline (for the LLM baselines). We reuse those predictions directly.

**SacreBLEU baselines** We used the following metrics from SacreBLEU (Post, 2018):

- **BLEU (Papineni et al., 2002)** is based on the precision of $n$-grams between the MT output and its reference, weighted by a brevity penalty. We used the SacreBLEU command line with default arguments with `-sl` argument to obtain segment-level BLEU.[6]
- **SPBLEU (NLLB-Team et al., 2022)** is the BLEU score computed with subword tokenization by the standardized FLORES-200 SentencePiece model. We used the SacreBLEU command line with `-sl` argument to obtain segment-level SPBLEU.[7]
- **CHRF (Popović, 2015)** uses character $n$-grams instead of word $n$-grams to compare the MT output with the reference. We used the SacreBLEU command line with default arguments and the `-sl` argument for segment-level CHRF.[8]

**BERTSCORE (Zhang et al., 2020)** leverages contextual embeddings from pre-trained transformers to create soft alignments between words in hypothesis and reference segments using cosine similarity. Based on the alignment matrix, BERTSCORE returns a precision, recall, and F1 score. We used F1 without TF-IDF weighting.

**COMET-22 (Rei et al., 2022a)** is a learned metric fine-tuned using direct assessments from previous WMT translation shared tasks. This metric relies on sentence embeddings from the source, translation, and reference to produce a final score. We used the default model `wmt22-comet-da` provided in version 2.0.2 of the Unbabel/COMET framework. This model employs XLM-RoBERTa large as its backbone model and is trained on data from the 2017 to 2019 WMT shared tasks, in combination with the MLQE-PE corpus (Fomicheva et al., 2022).

**COMETKIWI (Rei et al., 2022b)** is a reference-free learned metric that functions similarly to BLEURT, but instead of encoding the translation along with its reference, it uses the source. We used the `wmt22-cometkiwi-da` model, which was a top-performing reference-free metric from the WMT 2022 shared task. This metric is fine-tuned on the same data as `wmt22-comet-da` using version 2.0.2 of the Unbabel/COMET framework.

**YISI-1 (Lo, 2019)** is an MT evaluation metric that measures the semantic similarity between a machine translation and human references by aggregating the IDF-weighted lexical semantic similarities based on the contextual embeddings extracted from pre-trained language models (BERT-base-chinese for evaluating Chinese and XLM-RoBERTa for evaluating other target languages in this shared task).

#### 4.2.3 Task 3

For all Task 3 baselines, we use auto-conversion from both Task 1 and Task 2 baselines described above in Sections 4.2.1 and 4.2.2.

## 5 Task 1 Results and Analysis

### 5.1 Meta-Evaluation

Task 1 employs the MPP ("match with partial overlap and partial credit") meta-evaluation measure recommended by Perrella et al. (2026). Given sets of hypothesis and ground-truth error spans, MPP establishes a one-to-one matching between them. It then computes per-span precision and recall, based on the proportion of overlapping characters between each hypothesis span and its matched ground-truth span. Sample-level (or corpus-level, depending on the desired granularity) precision and recall are obtained by averaging the per-span precision and recall values, respectively, and the final

[6] nrefs:1|case:mixed|tok:13a|smooth:exp|version:2.6.0. For into-Chinese, into-Japanese, and into-Korean language pairs, we used tok:zh, tok:ja-mecab, and tok:ko-mecab as the tokenizer, respectively.

[7] nrefs:1|case:mixed|tok:flores200|smooth:exp|version:2.6.0

[8] chrF2|nrefs:1|case:mixed|nc:6|nw:0|space:no|version:2.6.0

$F$-score is computed as the harmonic mean of the resulting average precision and recall.

For each translation direction, we compute a single MPP $F$-score by micro-averaging across data samples. We do not report macro-averaged results across data samples, as this approach was found to be biased toward auto-evaluators that return fewer errors because of the sparsity of errors in MT error detection (Perrella et al., 2026). Finally, the MPP precision, recall, and $F$-score values obtained for each translation direction are macro-averaged to derive summary statistics for the entire test set.

#### 5.1.1 Severity weighting

In previous years, span-level meta-evaluation measures were implemented with a 0.5 severity penalty to discount the contribution of errors whose predicted severity did not match the ground-truth severity (Blain et al., 2023; Zerva et al., 2024; Lavie et al., 2025). However, as noted by Lyu et al. (2026) and Perrella et al. (2026), this approach only penalizes severity mismatches and does not account for the fact that predicting a `Minor` error where no ground-truth error is present is less severe than predicting a `Major` error at the same location. More generally, `Major` errors should have a greater impact on the final $F$-score than `Minor` errors.

Thus, rather than applying a simple severity penalty, this year we adopt the severity weighting strategy proposed by Aur et al. (2026), whereby `Minor` and `Major` errors contribute to the final $F$-score in proportion to their respective weights, while severity mismatches remain penalized. Specifically, we assign weights of 0.25 and 1 to `Minor` and `Major` errors, respectively,[9] such that each error span's contribution to the final $F$-score is proportional to its severity weight.[10]

#### 5.1.2 Implementation details

We compute MPP using the implementation provided in the span-mt-metrics-eval GitHub repository, with the following evaluation configuration:

```
from span_mt_metrics_eval import compute

predictions = [...]
references = [...]

result = compute(
    predictions,
    references,
    measure="MPP",
    matching="one_to_one",
    matching_algorithm="greedy",
    averaging="micro",
    severity_weights={
        "minor": 0.25,
        "major": 1.00,
    },
)
```

**Reweighting multiply annotated translations.** The dynamic cESA annotation protocol employed in this year's General MT shared task may result in the same translation being evaluated multiple times if it appears in more than one Pearmut screen.[11] To make use of all available annotations, we replicate each auto-evaluator assessment once for each ground-truth annotation associated with the same translation. However, without further adjustment, this would cause some assessments to weigh more heavily in the final precision, recall, and $F$-score simply because the corresponding translation was evaluated multiple times. We address this issue by reweighting the contribution of each assessment using the `segment_weights` input parameter of the `span_mt_metrics_eval.compute` function. Specifically, each replicated assessment is assigned a weight of $\frac{1}{N}$, where $N$ is the number of ground-truth annotations associated with the corresponding translation. In this way, each translation contributes equally to the final precision, recall, and $F$-score, while all available human annotations are retained.

### 5.2 Main Results

Table 4 reports the ranking of all auto-evaluators, including participant submissions and organizer baselines, across the eight priority translation directions. Auto-evaluators that did not cover all eight translation directions are excluded from this ranking; their performance is reported only in the per-translation-direction results in Appendix B.1.

**Unsupervised LLM-based auto-evaluators are state of the art** The top of the ranking is occupied entirely by unsupervised, LLM-based approaches to error detection, whereas the xCOMET baselines rank at the very bottom. This contrasts with last year's results, when xCOMET models were still competitive with LLM-based approaches.

[9] As mentioned in Section 2.2, we derive these weights from an analysis of last year's data, which showed that this weighting scheme yielded a slightly higher correlation with ESA scores.

[10] We refer the reader to Perrella et al. (2026) for the formal definition of MPP and to Aur et al. (2026) for the formal definition of the severity weighting strategy.

[11] In cESA, a Pearmut screen consists of a source document and a set of three MT systems that are evaluated simultaneously in a contrastive manner.

| Rank | Cluster | Auto-evaluator | Underlying model | P | R | F1 |
|---|---|---|---|---|---|---|
| 1 | 1 | Gemini-3.6-Flash* | Gemini 3.6 Flash | 39.21 | 32.95 | 34.07 |

Table 4: Task 1 ranking for the set of eight priority translation directions. * marks reference-free submissions. † marks fine-tuned systems. Light-grey rows indicate organizer baselines. The ensemble components listed in the model card are E1 [Gemini 3.5 Flash; Gemma 4 12B; Gemma 4 31B]. Similar to previous years (Freitag et al., 2023, 2024; Lavie et al., 2025), statistical significance uses the PERM-BOTH hypothesis test introduced by Deutsch et al. (2021a), with clusters computed greedily ($p \leq 0.05$, unadjusted, two-sided, 10000 draws).

We also note that most submissions are unsupervised, while the only two fine-tuned LLM-based auto-evaluators (Qwen-based Omission and Rule-based Omission) also rank near the bottom. A promising direction for future research in MT error detection is therefore to investigate whether, and under what conditions, fine-tuning remains beneficial relative to unsupervised LLM-as-a-Judge approaches.

**Auto-evaluators based on the same underlying model occupy similar ranks** Submissions and baselines group together according to their underlying model. The top four positions are all occupied by Gemini-based auto-evaluators. The only Gemini-based system that ranks lower is PhraseT1-02, which is an ensemble of auto-evaluators based on three models: Gemini 3.5 Flash, Gemma 4 12B, and Gemma 4 31B. By contrast, PhraseT1-01– which is based solely on Gemini 3.5 Flash – ranks third, suggesting that ensembling Gemini predictions with those of other models reduced performance relative to using Gemini alone. However, this result may be attributable to the specific ensembling strategy rather than to the models themselves. In particular, all error annotations produced by the individual models were retained in the ensemble prediction, leading to higher recall at the cost of lower precision.

Ranks 5 through 13 are predominantly occupied by auto-evaluators based on Gemma 4 31B, with the exceptions of ranks 9 and 11, occupied by GPT 5.6 Sol and GPT 5.6 Terra, respectively. Interestingly, all reference-based Gemma 4 auto-evaluators rank higher than their reference-free counterparts. We examine the performance differences between reference-based and reference-free auto-evaluators in greater detail in Section 5.2.1.

Ranks 14 through 21 comprise auto-evaluators based on Command A+, Qwen 3.6 35B A3B, and GPT 4.1 Mini, together with the PhraseT1-02 ensemble. The $F$-score range across these ranks is wider, spanning from 29.77 to 23.46, with the lowest score obtained by the reference-based Qwen 3.6

| Auto-evaluator | Ref-free | Ref-based | ΔF1 |
|---|---|---|---|
| Gemma 4[#] | 31.72 | 32.58 | +0.86 |
| Qwen 3.6[#] | 29.77 | 29.38 | −0.39 |
| Gemma 4 | 32.02 | 32.08 | +0.06 |
| Qwen 3.6 | 24.62 | 23.46 | −1.16 |
| xCOMET XL | 13.77 | 16.74 | +2.97 |
| xCOMET XXL | 13.93 | 17.85 | +3.92 |
| | Non-thinking | Thinking | ΔF1 |
| Gemma 4 | 32.08 | 32.58 | +0.49 |
| Qwen 3.6 | 23.46 | 29.38 | +5.91 |
| Gemma 4[*] | 32.02 | 31.72 | −0.31 |
| Qwen 3.6[*] | 24.62 | 29.77 | +5.15 |

Table 5: Effect of reference use and thinking in task 1. [#] marks thinking auto-evaluators. [*] marks reference-free auto-evaluators.

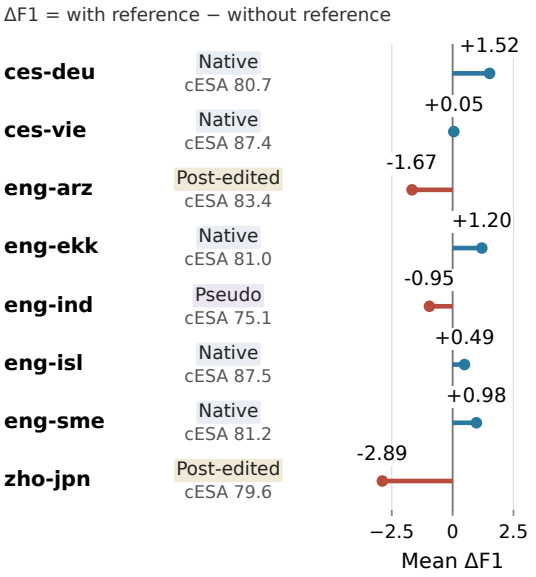

Figure 1: Breakdown of the effect of reference use on MPP $F$-score across translation directions. Average scores only include Gemma 4 and Qwen 3.6 baselines.

variant with reasoning disabled.[12]

Finally, ranks 22 through 27 are occupied entirely by fine-tuned auto-evaluators, including the widely used encoder-based xCOMET models.

**Auto-evaluators are recall-oriented.** Across most submissions and baselines, recall is higher than precision. This tendency is particularly pronounced among reference-based evaluators, which we find to predict more errors than their reference-free counterparts (see Section 5.2.1). Interestingly, three of the four Gemini-based auto-evaluators achieve higher precision than recall, suggesting that Gemini is more conservative than other models in detecting translation errors. Similarly, Qwen-based Omission and Rule-based Omission– two fine-tuned, Qwen-based auto-evaluators – also achieve higher precision than recall, possibly as a consequence of their fine-tuning setup.

### 5.2.1 Are references still needed?

To measure the effect of reference translations, we analyze auto-evaluators that were run in both reference-based and reference-free settings. Specifically, we compute the MPP $F$-score under both conditions and report the resulting ΔF1 scores in Table 5. As expected, references are highly beneficial for xCOMET models, which were pre-trained less extensively than modern LLM-based approaches and are therefore likely to have more limited multilingual capabilities. References may thus simplify the task and allow these models to perform effectively across a wider range of translation directions. By contrast, the effect of reference use on the LLM-as-a-Judge baselines is mixed: references mildly improve performance for Gemma 4, while slightly degrading it for Qwen 3.6. We investigate this pattern further by measuring the effect of references for each translation direction, averaged across the Gemma 4 and Qwen 3.6 models, and report the results in Figure 1.

An interesting pattern emerges: reference use improves performance, albeit sometimes only marginally, in all settings where the provided reference was produced by human translators from scratch – i.e., `Native` in the figure. By contrast, `Post-edited` and `Pseudo`-references appear to be detrimental to evaluation performance, with average reference-free Gemma 4 and Qwen 3.6 scores higher than the average of their reference-based counterparts.

One possible explanation is reference quality, if `Native` references were systematically of higher quality than `Post-edited` and `Pseudo` references. However, the average cESA scores of the references across translation directions, reported in Figure 1, do not support this as the sole explanation. For example, the `Post-edited` references for en→arz achieve a higher average cESA score than many `Native` references. We therefore hy-

[12] We caution that the results for the Qwen 3.6 baselines should be interpreted carefully, as we observed many duplicated errors and several cases of endless repetition, particularly in variants run with reasoning enabled. It is unclear whether this issue resulted from suboptimal generation parameters – which were nevertheless kept identical across all baselines, as reported in Section 4.2 – or from a failure mode of the model itself.

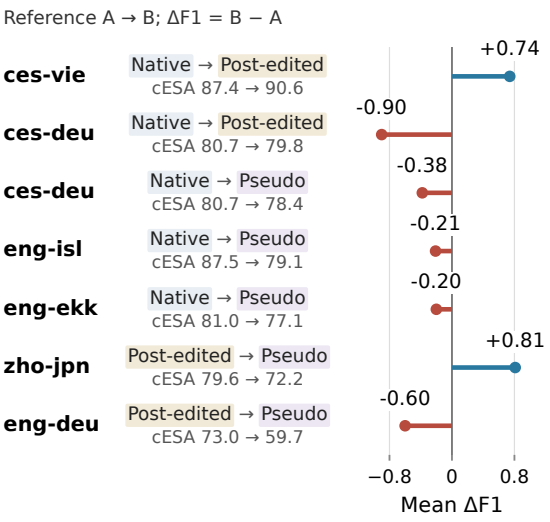

Figure 2: Effect of reference type and quality across translation directions. Average scores only include Gemma 4 and Qwen 3.6 baselines.

pothesize that the observed effect may also be related to the greater similarity of `Post-edited` and `Pseudo` references to other system translations, which could bias reference-based evaluation in favor of systems producing similar outputs.

**The impact of reference type on reference-based evaluation** We investigate the extent to which reference type and quality affect the performance of reference-based evaluation. To this end, we compare the performance of reference-based auto-evaluators across different reference types and report the results in Figure 2. Specifically, we average the $\Delta$MPP $F$-score across five reference-based auto-evaluators, including both submissions and baselines, for three pairwise comparisons: (1) `Native` vs. `Pseudo` , (2) `Native` vs. `Post-edited` , and (3) `Post-edited` vs. `Pseudo` .

Across translation directions covered by multiple reference types, `Native` references appear to provide the strongest signal: in only one case (ces→vie) do `Native` references yield a lower average MPP $F$-score than `Post-edited` or `Pseudo` references. Indeed, in this case, the `Post-edited` reference received a higher cESA score than the `Native` reference (90.6 vs. 87.4). More generally, in six of the seven translation directions considered, the reference type associated with the higher MPP $F$-score is also the one assigned a higher cESA score by human annotators. This suggests that reference quality may be an important factor underlying the performance differences observed in Figure 2. The only exception is zho→jpn, where a lower-quality `Pseudo` reference leads to a higher MPP $F$-score than a higher-quality `Post-edited` reference.

**Reference-based auto-evaluators find more, shorter errors** We investigate whether the use of reference translations makes auto-evaluators more severe or more lenient. To this end, we measure the effect of references on the number of predicted errors, average error length, and average error severity, and report the results in Table 6.

The pattern is consistent across both auto-evaluators and across reasoning settings: when reference translations are available, models tend to identify more translation errors, while the detected error spans are, on average, shorter than those produced by reference-free auto-evaluators. We hypothesize that access to reference translations makes certain errors easier to detect and localize more precisely, resulting in the observed increase in the number of predicted errors and decrease in average error span length. Finally, we observe a slightly lower average severity weight, suggesting that reference-based LLM-as-a-Judge auto-evaluators identify a greater proportion of `Minor` errors relative to `Major` errors than their reference-free counterparts.

### 5.2.2 What is the impact of thinking?

Similar to the previous analysis of reference-based versus reference-free evaluation, this section examines the impact of thinking on MPP $F$-score and on the number, length, and severity of detected errors. The analysis is restricted to the Gemma 4 and Qwen 3.6 baselines, as these are the only auto-evaluators that were run both with and without thinking.

As shown in Table 5, thinking has different effects on the Qwen 3.6 and Gemma 4 baselines, substantially improving performance for the former while having little to no effect on the latter. The statistics in Table 6 provide further insight into how thinking affects these auto-evaluators' predictions. Here, the pattern is consistent across models: auto-evaluators with thinking detect fewer and shorter errors than their non-thinking counterparts. In addition, thinking reduces the average severity weight, indicating that auto-evaluators with thinking identify a higher proportion of `Minor` errors relative to `Major` errors. All of these effects are substantially stronger for Qwen 3.6 than for Gemma 4, which may explain why the corresponding differences in

| Auto-evaluator | Errors per prediction | | | Mean span length | | | Mean severity weight | | |
|---|---|---|---|---|---|---|---|---|---|
| | Ref-free | Ref-based | Δ | Ref-free | Ref-based | Δ | Ref-free | Ref-based | Δ |
| Gemma 4[#] | 2.40 | 3.13 | +0.73 | 21.20 | 18.03 | −3.16 | 0.57 | 0.52 | −0.05 |
| Qwen 3.6[#] | 3.11 | 4.10 | +0.99 | 21.43 | 20.14 | −1.29 | 0.55 | 0.50 | −0.04 |
| Gemma 4 | 2.61 | 3.65 | +1.04 | 21.69 | 20.32 | −1.36 | 0.61 | 0.53 | −0.07 |
| Qwen 3.6 | 3.93 | 5.23 | +1.29 | 27.43 | 26.49 | −0.94 | 0.67 | 0.64 | −0.03 |
| | Non-thinking | Thinking | Δ | Non-thinking | Thinking | Δ | Non-thinking | Thinking | Δ |
| Gemma 4 | 3.71 | 3.18 | −0.53 | 19.69 | 17.50 | −2.19 | 0.53 | 0.51 | −0.02 |
| Qwen 3.6 | 5.36 | 4.15 | −1.21 | 25.84 | 19.88 | −5.95 | 0.63 | 0.50 | −0.13 |
| Gemma 4[*] | 2.67 | 2.44 | −0.24 | 21.25 | 20.27 | −0.98 | 0.60 | 0.57 | −0.04 |
| Qwen 3.6[*] | 3.97 | 3.15 | −0.82 | 27.34 | 20.95 | −6.39 | 0.67 | 0.54 | −0.13 |

Table 6: Effect of reference use and thinking on predicted errors in task 1. [#] marks thinking auto-evaluators. [*] marks reference-free auto-evaluators. Errors per prediction include omissions; mean span length is computed over non-omission spans; and mean severity weight includes omissions.

MPP $F$-score are considerably larger for Qwen 3.6.

Overall, references and thinking have effects in the same direction with respect to error span length and severity weight, as both reduce average span length and mean error severity. By contrast, they have opposite effects on the number of predicted errors: reference-based auto-evaluators identify more errors, whereas auto-evaluators with thinking identify fewer.

**GPT Sol Medium vs. xHigh** In the context of our analysis of thinking, we also investigate the effect of increasing the thinking level from Medium to xHigh for one of our baselines, namely GPT 5.6 Sol. However, we were unable to run GPT 5.6 Sol with xHigh thinking on the full set of eight priority translation directions, and some API queries exceeded our maximum allowed number of completion tokens. To ensure a fair comparison between the two settings, we therefore restrict the analysis to the subset of translations for which both variants completed their reasoning and returned valid outputs.

The results in Table 7 show that increasing thinking effort has little to no impact on MPP $F$-score. GPT 5.6 Sol with xHigh thinking identifies slightly more errors, but these errors are also slightly shorter on average. As a result, precision, recall, and $F$-score remain nearly unchanged. These findings suggest that lower thinking effort may achieve comparable MT evaluation accuracy while reducing token usage. However, the scope of this analysis is limited, as it considers only a single model at two thinking levels. We therefore encourage future work to investigate this question more systematically.

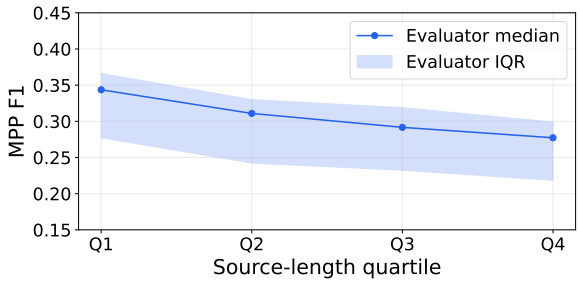

Figure 3: Average auto-evaluator MPP $F$-score at varying source lengths.

### 5.2.3 Does evaluation accuracy depend on text length?

Here, we investigate the impact of source length on evaluation accuracy. Specifically, for each of the eight priority translation directions, we divide the data into four quartiles based on source segment length and compute the median MPP $F$-score for each quartile across all auto-evaluators and translation directions. We measure source length as the number of source tokens returned by the XLM-RoBERTa tokenizer (Conneau et al., 2020).

The results are presented in Figure 3, which shows that MPP $F$-score decreases as source length increases. This suggests that auto-evaluators are less accurate at detecting errors in translations of longer source segments.

## 6 Task 2 Results and Analysis

### 6.1 Meta-Evaluation

Task 2 evaluates whether an auto-evaluator's score judgments align with human cESA quality scores. We use complementary meta-metrics at two granularities. At the segment level, the relevant question is whether the evaluator assigns an appropriate score difference to competing translations of the

| Auto-evaluator | P | R | F1 | Errors per prediction | Mean span length | Mean severity weight |
|---|---|---|---|---|---|---|
| GPT-5.6 Sol - medium | 23.08 | 38.78 | 28.94 | 2.89 | 21.41 | 0.40 |
| GPT-5.6 Sol - xhigh | 23.42 | 37.79 | 28.92 | 3.07 | 19.68 | 0.38 |
| $\Delta$ (xhigh $-$ medium) | $+0.34$ | $-0.99$ | $-0.02$ | $+0.18$ | $-1.73$ | $-0.02$ |

Table 7: GPT-5.6 Sol thinking-effort comparison.

same source item. At the system level, the question is whether aggregating those judgments leads to the same conclusions as humans when comparing MT systems. Accordingly, the final Task 2 score is the equally weighted mean of a segment-level and a system-level meta-metric, after first averaging each component equally across the eight priority translation directions. This design also reflects a broader shift in MT evaluation toward comparative judgments: recent human evaluation protocols increasingly assess translations side by side, improving agreement and sensitivity to subtle quality differences (Song et al., 2025; Zouhar et al., 2026a). A similar direction is emerging for automatic evaluation, with recent methods increasingly evaluating candidate translations comparatively rather than in isolation (Moosa et al., 2024; Züfle et al., 2025; Proietti et al., 2026).

**Screen-based PDP.** For the segment-level component, we use Pairwise Difference Pearson (DiIanni and Deutsch, 2025, PDP). PDP concatenates score differences between translations of the same source item and computes one Pearson correlation between the automatic and human difference vectors. Unlike the segment-level $\text{acc}^*_{eq}$ meta-metric used for the score prediction task in the last three editions of the shared task (Deutsch et al., 2023; Freitag et al., 2023, 2024; Lavie et al., 2025), PDP preserves the magnitude of a predicted preference without computing a tie-calibration threshold from the test data. The combination of differences for the same source into a single correlation further avoids noisy segment-wise Pearson correlations based on few observations, while excluding comparisons between unrelated source items (DiIanni and Deutsch, 2025), which could favor auto-evaluators that rely on patterns spuriously correlated with translation quality (Perrella et al., 2024b).

Importantly, PDP has also been shown to better reward human evaluators than $\text{acc}^*_{eq}$, which can disadvantage their more discrete score distributions and the resulting ties relative to the continuous scores produced by many automatic metrics (Proietti et al., 2025a; DiIanni and Deutsch, 2025). This property may also be relevant for LLM-as-a-judge methods: at WMT25, these methods were among the strongest auto-evaluators at the system level, but they performed substantially worse at the segment level under $\text{acc}^*_{eq}$. Since LLM judges can also produce comparatively discrete score distributions and exact ties, PDP may provide a more suitable segment-level meta-evaluation of such evaluators.

The WMT26 General MT human evaluation uses contrastive error span annotation (cESA): a Pearmut screen presents three translations of one source item simultaneously, and annotators assign each translation both error spans and a holistic score (Zouhar and Kocmi, 2026; Zouhar et al., 2026a; Kocmi et al., 2026a). We therefore use screen-based PDP ("group by screen"). For every pair of translations shown together in a screen, we add both ordered score differences to the PDP vectors. Thus, a three-translation screen contributes six ordered differences. If the same item and system pair occurs on multiple screens, we first average its available human scores within that co-screen comparison, so it contributes once. This construction relies exclusively on the direct contrastive comparisons elicited by cESA, which are the most reliable form of human evidence available in this setting (Zouhar et al., 2026a).

**Source-based SPA.** For the system-level component, we use Soft Pairwise Accuracy (Thompson et al., 2024, SPA). For every pair of MT systems, SPA compares the $p$-values obtained from permutation tests on the human and automatic segment scores, and awards soft credit according to their agreement. It thus evaluates not only whether an auto-evaluator prefers the same system as humans, but also whether it reflects the uncertainty of that comparison. We use 1,000 permutation resamples for every SPA calculation, consistent with the original SPA setup and the last two editions of the shared task (Thompson et al., 2024; Freitag et al., 2024; Lavie et al., 2025), and give equal weight to every pair of MT systems.

We use source-based SPA ("group by source"): for a system pair, we retain every source item on

which both systems have a human score, regardless of whether their translations appeared together on a screen. When a translation was assessed on multiple screens, its human score is the arithmetic mean of its retained assessments. We prefer it to screen-based SPA because it retains substantially more common source items per pair, avoiding the highly sparse and heterogeneous co-screen support induced by the contrastive assignment. Appendix C analyzes both grouping decisions (i.e., group-by-screen and group-by-source) on the eight primary directions and compares their resulting rankings, as the choice of grouping can fundamentally alter the evaluation question being posed and, consequently, the interpretation of meta-evaluation results (Perrella et al., 2024a; Proietti et al., 2025b).

### 6.2 Main Results

Table 8 reports the Task 2 ranking across the eight priority translation directions. It includes only direct Task 2 participant submissions and baselines that produced scores for every translation with human scores in all eight directions. The 40 eligible auto-evaluators comprise 18 participant submissions and 22 baselines. Systems with incomplete coverage appear only in the per-direction results in Appendix B.2. PDP and SPA are averaged equally across directions, and *Avg Corr* is their arithmetic mean.

**Unsupervised LLM auto-evaluators are state-of-the-art** The first 16 positions are occupied by auto-evaluators based on unsupervised LLM-as-a-Judge approaches, and none is fine-tuned, as marked in Table 8. The highest-ranked system not based on an LLM is chrF at rank 17, followed by COMET22 at rank 19. Thus, the aggregate point estimates favor LLM judging without task-specific fine-tuning over the conventional lexical and supervised metrics included here.

**Auto-evaluators based on the same underlying model occupy similar rank** The ranking also groups systems by their underlying model. Gemini 3.6 Flash ranks first. The GPT-5.4 and GPT-5.6 systems occupy ranks 2, 5, 8, and 9; the Gemma 4 31B systems rank 6, 7, 10, 12, 15, and 16; and the Qwen 3.6 systems rank 11, 13, 14, and 18. The pattern is not determined by the base model alone. Reference use, reasoning, prompting, and ensembling still change results within each family.

**Results vary by translation direction** Across the priority directions, the winner is not always the same: GPT-5.6 Sol Medium ranks first for Czech to German and English to Indonesian; GPT-5.6 Terra for Czech to Vietnamese; Gemini 3.6 Flash for English to Arabic; bytepop_pro10 for English to Estonian and Icelandic; bytepop_pro9 for English to Northern Sámi; and the reference-based Gemma 4 auto-evaluator with reasoning ranks first for Chinese to Japanese. At the same time, each direction's ranking is moderately to strongly associated with the eight-direction ranking (Spearman $\rho = 0.838$–$0.952$). The direction tables show larger changes outside the priority set: spBLEU ranks first for English to Ligurian and English to Ladin, despite ranking 22nd in Table 8. This result reinforces evidence that multilingual automatic evaluators, including reference-free LLM systems, remain often unreliable in low-resource settings (Sindhujan et al., 2025; Li et al., 2025).

### 6.3 Analysis

#### 6.3.1 Automatic Task 1-to-Task 2 conversions

We evaluate automatic Task 1-to-Task 2 conversions separately from the direct Task 2 ranking. For each predicted Task 1 assessment, the conversion starts at 100 and subtracts 10 points for each `Major` error and 2.5 points for each `Minor` error, with a lower bound of zero (Section 2.2). Thus, these values are determined directly by the submitted error spans rather than by an independently predicted holistic score.

Table 9 reports the conversion track on the eight priority directions only. It includes the 36 systems with complete converted predictions on every human-supported translation: 12 Task 1 participant submissions and 24 organizer baseline variants.

For the LLM-as-a-Judge baselines, we additionally test the effect of removing repeated predicted spans. Repeated spans have a limited effect on a directly submitted Task 2 score, which is elicited as a holistic judgment in the second stage of the GEMBA-ESA prompt. They can have a much larger effect after automatic conversion because every retained span directly incurs an error penalty. We compare the original baseline outputs with variants deduplicated by identical start offset, end offset, severity, and category. Positive differences below refer to the deduplicated score minus the original score.

The effect is concentrated in Qwen 3.6. Its

Table 9: Task 1-to-Task 2 conversion ranking on the eight priority translation directions. Each score is the equal-direction mean; Avg Corr is the arithmetic mean of PDP and SPA. * marks reference-free systems. † marks fine-tuned systems. Light-grey rows are organizer baselines. [dedup] and [no dedup] identify the two Task 1 baseline snapshots. The four xCOMET pairs are identical before and after deduplication and are shown once. Ensemble E1 contains Gemini 3.5 Flash, Gemma 4 12B, and Gemma 4 31B. Statistical significance clusters use two-sided source-level permutation tests (1,000 draws per evaluator pair, unadjusted $p \leq 0.05$), following the resampling framework of Deutsch et al. (2021b); cluster labels use the greedy procedure adopted in recent WMT Metrics evaluations (Freitag et al., 2024; Lavie et al., 2025).

reference-based reasoning variant improves from 0.562 to 0.663. The reference-free reasoning and reference-based no-reasoning variants similarly gain +0.052 and +0.037, respectively. The largest absolute change is +0.101 for Qwen 3.6 reference-based reasoning, confirming that the baseline family most affected by deduplication is Qwen 3.6. The remaining variants move by at most 0.004. The four xCOMET pairs are identical before and after deduplication, and appear only once in Table 9.

**Direct score prediction is substantially stronger than span-to-score conversion;** A comparison of Table 9 with the direct Task 2 results in Table 8 reveals a consistent gap between holistic score prediction and scores reconstructed from Task 1 error annotations that are not due to duplicate spans. For example, Gemini 3.6 Flash obtains an Avg Corr of 0.830 as a direct Task 2 evaluator but 0.703 after converting its Task 1 spans; GPT-5.6 Terra drops from 0.821 to 0.729, and the reference-based reasoning variant of Gemma 4 drops from 0.814 to 0.690. The same pattern holds for the xCOMET baselines. Thus, while the Task 1 annotations contain information that can be converted into a meaningful overall quality score, they do not appear to constitute a sufficient representation of the holistic quality judgment. A fixed weighted count of detected Major and Minor errors clearly fails to capture information about the nature and cross-dependency of errors, as well as any quality signals not directly represented by its predicted spans. This contrasts with the Task 1/2-to-Task 3 conversions in Section 7.3.1, where converted predictions are often competitive with systems optimized directly for the downstream task.

### 6.3.2 Effects of reference translations

We examine reference use in three complementary ways. First, Table 59 in Appendix D compares strictly matched reference-free and reference-based baselines on the eight priority directions. Each pair uses the same underlying model and decoding setting. As in Task 1, references are most beneficial for xCOMET: the reference-based XL and XXL variants improve Avg Corr by +0.103 and +0.095, respectively. The gains are smaller but consistently positive for the Gemma 4 and Qwen 3.6 LLM-as-a-Judge pairs (+0.014 and +0.014 for the reasoning variants). Thus, the value of a reference depends strongly on the evaluator family.

We next hold the MT outputs and human evidence fixed while changing only the reference supplied to reference-based auto-evaluators. The available challenge material does not span all eight priority directions: the main human versus PseudoRef comparison is available on 4 priority directions, and the from-scratch versus post-edited comparison on 2. For the former, the main human reference is from scratch for Czech to German, English to Estonian, and English to Icelandic, and post-edited for Chinese to Japanese. Tables 60 and 61, also in Appendix D, report these results. We exclude all designated and alternative reference candidates from both sides of each comparison in the test set as translations to score. We include only direct Task 2 systems with complete predictions on the matched challenge set samples.

Replacing the main human reference with PseudoRef lowers Avg Corr for 13 of 17 auto-evaluators. In contrast, from-scratch versus post-edited human references have less impactful changes: nine systems decrease and eight increase. The available evidence therefore suggests that replacing a human reference with PseudoRef can alter Task 2 performance, whereas the two human reference production methods are nearly interchangeable in this small matched sample.

Finally, Table 62 in Appendix D describes the submitted score scales themselves on human-supported translations, rather than meta-evaluation performance. This is the Task 2 analogue of Task 1's analysis of whether references make an auto-evaluator more severe or lenient. Gemma 4 and the reasoning Qwen 3.6 baseline become more severe when supplied with a reference, with mean reference-based minus reference-free shifts of –2.4 and –2.8 points. In contrast, xCOMET XL and XXL shift upward by +5.7 and +4.8 points. These shifts should not be interpreted as quality gains or losses: they describe raw score behavior.

These experiments, along with Task 1 results, suggest that strong LLM evaluators are considerably less dependent on references than earlier learned metrics, while also exposing that different types of available references are not equally useful.

### 6.3.3 Reasoning-level impacts

The benefit of reasoning is strongly model-dependent. Table 8 allows controlled comparisons for Gemma 4 and Qwen 3.6, for which we ran otherwise matched variants with and without reasoning in both reference-based and reference-free settings. For Gemma 4, enabling reasoning produces only a small improvement: "Avg Corr" increases from

0.808 to 0.814 with a reference and from 0.794 to 0.800 without one. The effect is considerably larger for Qwen 3.6, increasing from 0.764 to 0.800 in the reference-based setting and from 0.742 to 0.786 in the reference-free setting.

For Qwen 3.6, most of the improvement comes from segment-level discrimination. With a reference, reasoning increases PDP from 0.617 to 0.682 while SPA increases only from 0.911 to 0.917. Without a reference, PDP increases from 0.593 to 0.669, compared with an SPA increase from 0.891 to 0.904. The corresponding changes for Gemma 4 are much smaller at both granularities. Thus, for Qwen, reasoning primarily improves the evaluator's ability to distinguish quality differences among translations of individual source segments, while system-level rankings are already relatively stable without reasoning.

This pattern closely mirrors Task 1, where reasoning substantially improves Qwen 3.6 but has little effect on Gemma 4 (Section 5.2.2). Across the two tasks, the evidence therefore does not support reasoning as a uniformly beneficial property of an evaluator; rather, its value appears to depend strongly on the underlying model family.

#### 6.3.4 LLM judges are strong at both levels of evaluation granularity

One motivation for adopting PDP as the segment-level meta-metric was the pronounced gap observed at WMT25 between the system- and segment-level performance of LLM-as-a-Judge evaluators. As shown by (Perrella et al., 2024b), $\text{acc}^*_{eq}$ penalizes evaluators that produce discrete assessments (LLM judges or human annotators) compared to auto-evaluators that produce assessments on a continuous scale. Indeed, last year's LLM judges were among the strongest system-level evaluators but performed substantially worse at the segment level. We do not observe the same pattern under this year's Task 2 evaluation.

The strongest LLM judges rank highly on both components of the Task 2 meta-evaluation. Gemini 3.6 Flash and GPT-5.6 Sol obtain PDP correlations of 0.736 and 0.735, respectively, compared to 0.601 for chrF and 0.610 for COMET22. Their system-level SPA values are likewise strong at 0.924 and 0.920, although SPA scores are more compressed across evaluator families: chrF reaches 0.890 and COMET22 0.862. Thus, the advantage of the leading LLM judges is particularly pronounced at the segment level under PDP and is still evident after aggregation to the MT-system level.

This result should not be interpreted as establishing that PDP alone explains the difference from WMT25: the test data, human evaluation protocol, evaluator models, and meta-evaluation measure all changed between editions. Nevertheless, it shows that poor segment-level performance is not an inherent property of LLM judges, and highlights that conclusions about automatic evaluators can depend on the choice of meta-evaluation methodology.

## 7 Task 3 Results and Analysis

### 7.1 Meta-Evaluation

Since Task 3 evaluates a binary label with potential label imbalance, we use the Matthews correlation coefficient (Matthews, 1975, MCC) as the main metric for this task. We also report precision, recall, and $F_1$ score to give a clearer picture of a system's performance (with "error-free" as the positive label). For ranking and significance testing, we macro-average across translation directions.

For each metric pair, we run a permutation test (100,000 draws) on the difference in macro-average MCC, exchanging predictions jointly at the source-segment level.[13] We then cluster greedily as in recent WMT shared tasks (Freitag et al., 2024; Lavie et al., 2025): descending the ranking, a metric joins the current cluster only if it does not differ significantly ($p < 0.05$, unadjusted two-sided) from every member, otherwise it starts a new one. Separate clusters therefore do not imply that every cross-cluster pair differs significantly. Further details are given in Appendix F.1.

### 7.2 Main Results

Table 10 reports rankings for the 18 direct Task 3 submissions and the converted organizer Task 1 baselines that cover all 8 priority language pairs. Auto-converted submissions, language pairs beyond the 8 priority ones, and Task 2 baseline conversions are discussed later in Section 7.3.

**LLM-based submissions are state-of-the-art** As with Task 1 and Task 2, LLM-as-judge has become the de facto standard for error-free detection as well. In fact, among the systems included in Table 10, all but the two xCOMET baselines are LLM-based, and those two baselines are also the

[13] Following PERM-INPUTS (Deutsch et al., 2021b): one decision per segment, applied to every associated prediction, including repeats across language pairs. The 2,357 items form 1,392 such units.

| Rank | Cluster | Submission | Underlying model | $MCC_{\times 100}$ | P(%) | R(%) | F1(%) |
|---|---|---|---|---|---|---|---|
| 1 | 1 | Wukongopterus | GPT-5.4 | 32.55 | 43.71 | 78.45 | 53.72 |

Table 10: WMT26 Task 3 priority-direction ranking: direct Task 3 submissions and converted organizer Task 1 baselines covering all 8 priority language pairs (ces-deu, ces-vie, eng-arz, eng-ekk, eng-ind, eng-isl, eng-sme, zho-jpn), macro averaged over those pairs. MCC is the primary metric (adjusted with $\times 100$ to align with the scale for other metrics); precision (P), recall (R) and F1 take error-free as the positive class. Light-grey rows are organizer baselines. Omitted for not covering every pair: Lexicala-QE-Ensemble (Majority-Vote) (6 of 8), Lexicala-QE-Ensemble (STAPLE) (6 of 8) and PTT-MULTITAN-v2 (no priority pairs). Their results appear in the per-language tables. Cluster groups systems that are not significantly different, by a paired permutation test over source segments (100,000 permutations, two-sided, $\alpha = 0.05$) on the macro-averaged MCC, with WMT's greedy clustering. Ensemble components named in the model cards are [E1] RAGthoven Error-Free: Gemma 4 31B IT; Mistral Large 3; Gemini 3.1 Pro.

lowest ranked, which further underscores the dominance of LLM-based systems. The per-language breakdown tables show that xCOMET-XXL still achieves mid-tier performance on language pairs covered by prior human evaluation data (e.g., eng-isl, eng-ukr, eng-zho), but generalizes poorly to low-resource languages and to language pairs that do not involve English.

**Recall seems to be the overall bottleneck** Looking at the precision and recall of the systems, many of them reach a similar precision level of 0.40–0.55. The range of recall, however, is much wider, which makes recall the more decisive of the two. This concurs with the observation in the Task 1 results (Section 5.2), where many LLMs err on the "cautious" side and tend to flag errors, with Gemini 3.5 Flash again being an outlier.

## 7.3 Analysis

### 7.3.1 Comparison with Converted Submissions from Task 1 and 2

For a more holistic view of how different approaches to Task 3 compare with each other, we conducted automatic conversions of Task 1 and Task 2 submissions following the methodology outlined in Section 2.3. Although it was not required, all systems that did not opt out of automatic Task 2 to Task 3 conversion provided a threshold for such conversions, which we use throughout this section. The optimality of these thresholds is discussed in Section 7.3.3. Table 11 shows results including automatically converted systems on the same 8 priority language pairs as Table 10. This reveals a few further trends that were not apparent in Table 10.

**Task-specific optimization for error-free detection does not clearly pay off** Once converted systems are included in the comparison, one natural question to ask is: do predictions from Task 3 participants significantly outperform binary labels derived from automatic conversions of Task 1 and Task 2 submissions? Table 11 gives a largely negative answer: while Wukongopterus remains the top-scoring Task 3 submission, its margin over all of its Task-2-converted siblings is too small to be considered significant. The same holds for other participants that submitted to Task 3 and at least one other track: the FACET (Soongsil University) Task 3 system does not meaningfully outper-

Table 12: WMT26 Task 3 priority-direction ranking, per-language-pair MCC (×100). Avg. is the macro average that determines the ranking; the best value per language pair is in bold. Light-grey rows are organizer baselines. Below the rule are the systems that covered only some of the priority pairs: they are unranked and have no average, since it would be taken over a different set of pairs, but their per-pair scores are shown where they competed. Ensemble components named in the model cards are [E1] RAGthoven Error-Free: Gemma 4 31B IT; Mistral Large 3; Gemini 3.1 Pro; [E2] Lexicala-QE-Ensemble (Majority-Vote): Gemini 2.5 Flash; DeepSeek V4 Flash; Qwen Plus; [E3] Lexicala-QE-Ensemble (STAPLE): Gemini 2.5 Flash; DeepSeek V4 Flash; Qwen Plus.

form the automatic conversions of its Task 1 and Task 2 systems. The Task 3 system from Lexicala (not shown here because of its language coverage) meaningfully outperforms the automatic conversions in only one language pair (eng-ekk). The only exception is the First try system from AIST, which significantly outperforms the automatic conversions of its Task 1 systems. It is worth pointing out that their Task 3 systems use very different base models from their Task 1 systems, so the two sets of systems may have been developed separately.

**Source system matters more than source task for conversion** Comparing the performance of binary labels converted from Task 1 with those converted from Task 2, we see no clear trend as to which is the better conversion path. Instead, we notice that conversions from the same system tend to cluster together in the rankings. This corroborates a trend noted in Section 5.2: systems based on the same underlying model tend to occupy similar ranks. The choice of the base system to convert from, and in particular the choice of a strong underlying model, therefore appears to be the most consequential decision here.

**Compact, open-weight models show potential** In last year's results, large closed-source language models such as Gemini 2.5 Pro and GPT-4.1 dominated the top of the LLM-as-judge ranking. For Task 3, one departure from that result is that some systems based on relatively small open-weight models, such as cuni-v14 and cuni-cat-v4, are competitive with closed-source frontier models served behind APIs (e.g., GPT-5.6 Terra, GPT-5.6 Sol, Gemini 3.6 Flash, Gemini 3.5 Flash). Since neither of these two systems relies on fine-tuning, we believe there is further potential in specializing small open-weight models to build even stronger LLM judges that are friendly to local deployment.

### 7.3.2 Beyond Priority Language Averages

Table 12 shows a per-language breakdown of the systems included in Table 10, as well as the Lexicala systems, which were excluded from Table 10 because they do not cover all priority language pairs. While the top two systems generally achieve strong results across the board, a few systems outperform them on individual language pairs. For example, the Lexicala system achieves top-tier performance on eng-ekk and eng-sme, while PhraseT3-01 is competitive on eng-ind. A few systems are dragged down substantially by eng-sme, namely the Gemma 4 Reasoning and Qwen 3.6 No Reasoning baselines, which calls for more careful validation before deploying such systems on low-resource language pairs.

Table 13 expands Table 11 to all 21 language pairs, covering the subset of systems that support

| Rank | Cluster | Submission | Underlying model | Track | $MCC_{\times 100}$ | P(%) | R(%) | F1(%) |

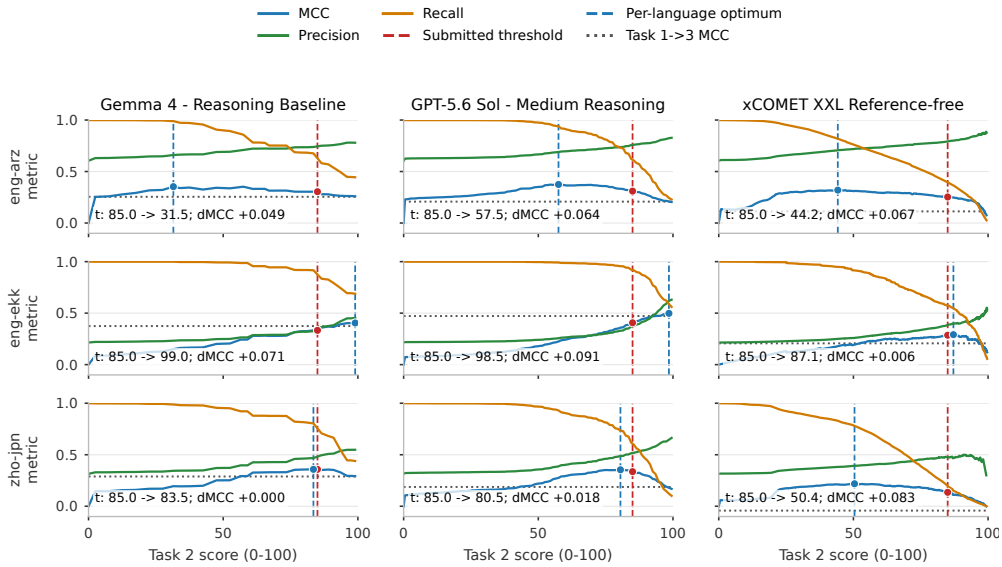
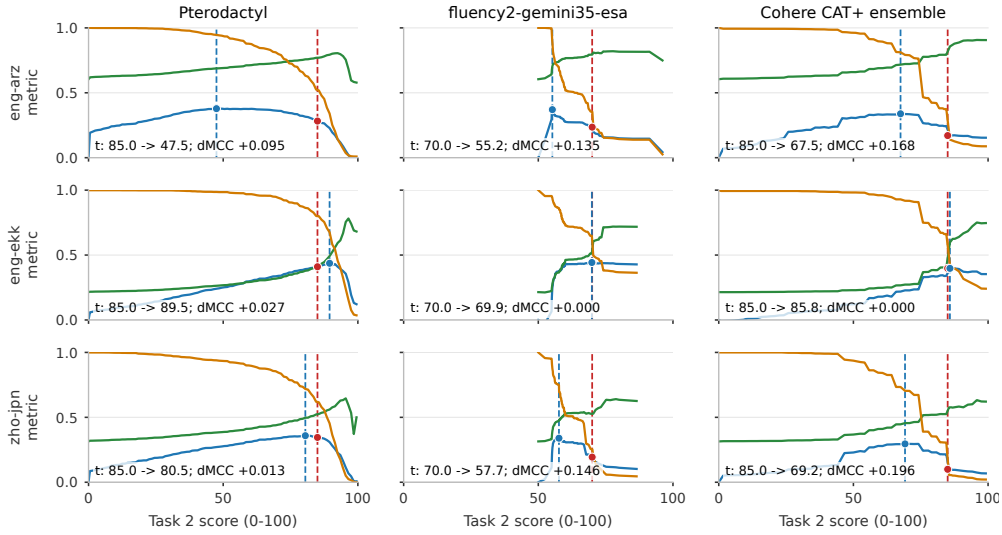
Table 13: WMT26 Task 3 ranking over all 21 language pairs, restricted to systems that cover every pair and macro averaged over pairs. Columns, tracks and row shading are as in Table 11. 13 further systems did not cover all 21 language pairs and are omitted; their results appear in the per-language tables. Cluster is defined as in Table 10, with the same test applied over all 21 pairs. Ensemble components named in the model cards are [E1] Austriadactylus: GPT-5.4; GPT-5.6 Terra.



them. While the most interesting trends are already well represented by the priority language pairs, the most notable change is that the Gemini 3.6 Flash baseline now overtakes the previously top-ranking Wukongopterus and Austriadraco systems and claims first place, with its advantage confirmed by statistical significance testing. The FACET systems also overtake First try [874374] in the ranking, potentially driven by the wider multilingual support of GPT-4.1 Mini (2025-04-14) compared with Babel-83B-Chat.

PTT-MULTITAN-v2 does not appear in any of the tables above, as it does not cover any of the priority language pairs. It is also the only non-LLM submission to this task. Detailed per-language results in the Appendix show that it performs largely on par with xCOMET-XL and xCOMET-XXL on the language pairs it covers.



#### 7.3.3 Conversion Threshold from Task 2 Submissions

As mentioned above, one important variable in Task 2 to 3 conversion is the score threshold above which a segment is considered "error-free". In all previous analyses, we stick with the thresholds provided by the participants. Here, we investigate the optimality and sensitivity of these thresholds. Rather than adopting numerical optimization methods, we optimize thresholds with a deterministic sweep over all distinct submitted score boundaries, applying an inclusive conversion rule ($\geq$) without splitting tied scores. For each setup, we select the threshold that maximizes MCC, choosing a central cutpoint within tied optimal plateaus and favoring the plateau nearest the submitted threshold. Because selection and evaluation use the same assessments, these results should be treated as post-hoc hindsight rather than as independently validated improvements.

One choice that has to be made for such threshold optimization is whether individual thresholds are needed for each language pair, or whether a unified threshold for all language pairs (which is what we asked task participants to provide) is largely sufficient. To answer this question, we experiment with two versions of the optimization objective: in the first, we run the optimization described above

(a) Selected organizer baselines. All submitted thresholds are fixed at 85.

(b) Selected participant submissions.

Figure 4: Task 2 to 3 conversion threshold sensitivity for selected organizer baselines (a) and participant submissions (b). Rows show `eng_Latn-arz_Arab`, `eng_Latn-ekk_Latn`, and `zho_Hans-jpn_Jpan`; columns span lower-precision/higher-recall to higher-precision/lower-recall submitted operating points. Curves give MCC (blue), precision (green), and recall (orange). Curves omit the extreme high-threshold tail and its final endpoint. Vertical red and blue dashed lines mark submitted and per-language optimal thresholds; annotations give threshold changes ($t$) and corresponding MCC changes (`dMCC`). Dotted gray lines in (a) give matching Task 1 to 3 MCC. Scores use the submitted 0–100 scale, error-free is positive, and predictions use score $\geq$ threshold.

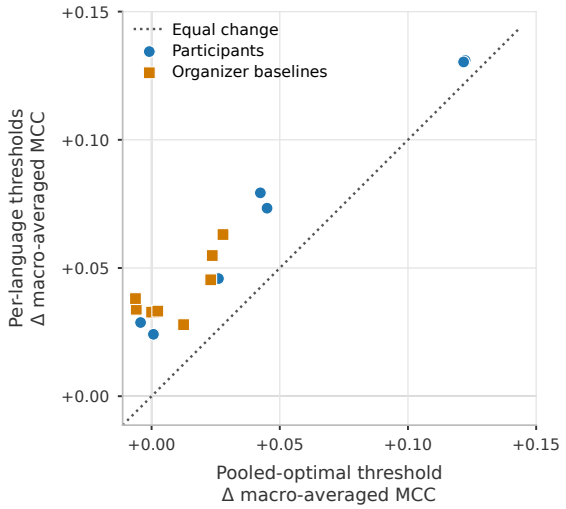


Figure 5: MCC impact of optimizing Task-2 score thresholds globally across all language-pairs versus separately for each language-pair, for the 21 systems covering all eight priority language-pairs. The horizontal axis shows micro-averaged MCC change from one global optimized threshold; the vertical axis shows macro-averaged MCC change from independently selected per-language thresholds. Circles are participant submissions and squares are organizer baselines; the dotted diagonal marks equal numerical change.

separately for each language pair; in the second, we run a single unified optimization on data points pooled across all language pairs, effectively optimizing micro-averaged MCC.[14]

Figure 5 compares per-language optimization with unified optimization. First, in the vast majority of cases, optimizing the threshold yields gains in macro-averaged MCC. In some cases (FACET and doc-FACET), the MCC gain is as large as 0.12. The few cases where optimization results in a drop are caused by the slight mismatch between micro- and macro-averaging of MCC during optimization and evaluation. Second, there is a gap of approximately 0.03 MCC between systems using a jointly optimized threshold and those using per-language optimized thresholds. The largest gap is 0.04 (from GPT-5.6 Terra). Multiple factors contribute to this gap, one of which is how well the scoring scales are calibrated across languages.

Figure 4 shows a selected set of organizer baselines and participant submissions on a few language pairs. The selection is made to give a good representation of the different precision and recall profiles found among the converted systems. When measured by MCC, the optimal conversion threshold varies widely across language pairs and scoring systems. It is therefore not surprising that task participants often make substantially sub-optimal choices of conversion threshold for their own systems. This underscores the need to optimize scoring thresholds on a held-out set when deploying a scoring-based automatic evaluator for error-free translation detection, whenever a held-out set of human judgments is available.

Running this analysis on the baselines also allows us to compare Task 1 to 3 and Task 2 to 3 conversions under a setup with a controlled underlying system and prompt. Figure 4a shows that for all selected language $\times$ system combinations, there is at least one threshold that allows Task 2 to 3 conversion to outperform its Task 1 to 3 counterpart. In fact, when this analysis is expanded to all 9 baseline systems on the priority language pairs, only two combinations favor Task 1 to 3 conversion across the board. The size of the gap between the two conversion paths, however, varies considerably by language pair. So does the range of thresholds over which Task 2 to 3 conversion comes out ahead. It is also worth noting that for both xCOMET-XL and xCOMET-XXL, Task 1 to 3 conversion can hardly compete with its Task 2 to 3 counterpart on many language pairs.

## 8 Challenge Sets

For the fourth year, the shared task included a dedicated challenge set subtask. Inspired by the *Build it or break it: The Language Edition* shared task (Ettinger et al., 2017), the subtask complements evaluation on generic test data with targeted test sets designed to probe specific capabilities and failure modes of automated translation evaluation systems. Rather than aiming to represent naturally occurring translation data broadly, challenge sets focus on particular phenomena or difficult cases that may not be adequately captured by standard evaluation. The subtask is organized in a decentralized manner: the challenge sets are contributed by independent research teams, who define the phenomena to be tested and are subsequently responsible for analyzing and reporting the behavior of participating systems on their data.

[14] In principle, one could also optimize macro-averaged MCC directly, but this requires more complicated tracking of how much each individual data point affects the overall metric, which we did not implement.

| Challenge Set | LPs | Phenomena | Items |
|---|---|---|---|
| AGGREE | 6 | Metric disagreement | 350 |
| FECE | 3 | Error correction evaluation | 3000 |
| GAMBIT+ | 7 | Gender bias | 9156 |
| LIGATUR | 2 | Unicode robustness | 171 |
| QEbreak | 10 | QE scoring biases | 2886 |

Table 14: Overview of the participation in the challenge sets subtask.

### 8.1 Subtask Structure

The challenge set subtask is organized into three stages: the *Breaking Round*, the *Scoring Round*, and the *Analysis Round*:

1. During the *Breaking Round*, participating teams (*Breakers*) submit challenge sets constructed to probe specific weaknesses or difficult phenomena in automated translation evaluation. A challenge set may address one or more of the three main subtasks: segment-level error detection and span annotation, segment-level quality score prediction, and detection of error-free segments. Depending on the target subtask, an example may contain one or more translation hypotheses and may include zero, one, or multiple reference translations.

2. In the *Scoring Round*, the challenge sets are added to the evaluation data of the relevant subtask(s). Participating evaluation systems (*Builders*) then produce the corresponding scores or predictions, while the organizers also obtain outputs from the baseline systems.

3. In the *Analysis Round*, the resulting system outputs are returned to the teams that submitted each challenge set. The *Breakers* then evaluate how the participating systems behave on the targeted phenomena and report their findings.

### 8.2 Challenge Set Descriptions and Individual Findings

This year, there were five submissions, covering a wide range of phenomena and language pairs. Table 14 provides an overview of the submitted challenge sets. A short description of every submission follows:

**AGGREE** (Griesbeck and Geierhos, 2026) is an aggregation-grounded challenge set for the diagnostic evaluation of segment-level MT metrics. It is motivated by the observation that high agreement between metrics at the system level can conceal substantial disagreement on individual segments. The challenge set contains 350 naturally occurring system outputs across six language pairs drawn from WMT23 and WMT24, selected from cases where automatic metrics disagree locally or diverge from available human judgments. The examples were mined using diagnostics for inter-metric disagreement and metric-human mismatch and were then filtered using strict automated quality-control criteria. AGGREE is intended to characterize local metric reliability and disagreement patterns rather than to quantify performance degradation relative to standard test sets.
