# Introduction

The Eleventh Conference on Machine Translation (WMT 2026) took place on October 28–29, 2026, immediately following the 2026 Conference on Empirical Methods in Natural Language Processing (EMNLP 2026) in Budapest, Hungary.

This is the eleventh time WMT has been held as a conference. The first time WMT was held as a conference was at ACL 2016 in Berlin, Germany, the second time at EMNLP 2017 in Copenhagen, Denmark, the third time at EMNLP 2028 in Brussels, Belgium, the fourth time at ACL 2019 in Florence, Italy, the fifth time at EMNLP-2020, which was held as an online event due to the COVID-19 pandemic, the sixth time at EMNLP 2021 at Punta Cana, Dominican Republic, the seventh time at EMNLP 2022 in Abu Dhabi, United Arab Emirates, the eight time at EMNLP 2023 in Singapore, the ninth time at EMNLP 2024 in Miami, USA, and the tenth time at EMNLP 2025 in Suzhou, China. Prior to being a conference, WMT was held 10 times as a workshop. WMT was held for the first time at HLT-NAACL 2006 in New York City, USA. In the following years the Workshop on Statistical Machine Translation was held at ACL 2007 in Prague, Czech Republic, ACL 2008, Columbus, Ohio, USA, EACL 2009 in Athens, Greece, ACL 2010 in Uppsala, Sweden, EMNLP 2011 in Edinburgh, Scotland, NAACL 2012 in Montreal, Canada, ACL 2013 in Sofia, Bulgaria, ACL 2014 in Baltimore, USA, EMNLP 2015 in Lisbon, Portugal.

The focus of our conference is to bring together researchers from the area of machine translation and invite selected research papers to be presented at the conference.

Prior to the conference, in addition to soliciting relevant papers for review and possible presentation, we conducted 12 shared tasks. These consisted of 5 translation tasks: General Translation, Indic Translation, Arabic-Asian Translation, Chinese-Southeast Asian Translation, Terminology, Model Compression, Creole Translation, and Video Subtitle Translation, two evaluation tasks: MT Test Suites and Automated Translation Evaluation, two multilingual tasks: Multilingual Instruction and Multitask LLMs with Limited Resources, and finally the Open Language Data Initiative.

The results of all shared tasks were announced at the conference, and these proceedings also include overview papers for the shared tasks, summarizing the results, as well as providing information about the data used and any procedures that were followed in conducting or scoring the tasks. In addition, there are short papers from each participating team that describe their underlying system in greater detail.

Like in previous years, we have received a far larger number of submissions than we could accept for presentation. WMT 2026 has received 85 full research paper submissions (not counting withdrawn submissions). In total, WMT 2026 featured 46 full research paper presentations and 155 shared task presentations.

The invited talk entitled "Towards Omnilinguality in AI: MT as a Starting Point for Language Coverage and Capability Parity was given by Marta Ruiz Costa-jussà from FAIR, Meta in Barcelona, Spain.

We would like to thank the members of the Program Committee for their timely reviews. We also would like to thank the participants of the shared task and all the other volunteers who helped with the evaluations.

Barry Haddow, Tom Kocmi, Philipp Koehn, and Christof Monz

## Keynote Talk

# Towards Omnilinguality in AI — MT as a Starting Point for Language Coverage and Capability Parity

**Marta Ruiz Costa-jussa**
Meta
**2026-10-28 11:00:00 –**

**Abstract:** Of the more than 7,000 languages spoken today, language technologies fully support only a few dozen. This talk defines omnilinguality as full AI capabilities that do not decay as we move down the long tail. We use machine translation as a starting point, since MT is the one task that has scaled to over 1,600 languages — progress driven substantially by community effort: WMT's shared tasks and benchmarks, open evaluation datasets, and open initiatives that let speaker communities contribute their own languages. We present BOUQuET, BLASER 3 and the XSTS+R+P protocol as evaluation decisions designed for the long tail. We then turn to the limits of MT as a proxy for general-purpose multilingual AI: it says little about cultural grounding, reasoning, or multi-turn agentic behaviour. OmnilingualGAIA2 quantifies some of those gaps — a cross-lingual drop of [8.8–18.4] pass@3 points in frontier agents that does not close with model scale, and which a controlled stratified attribution finds to be predominantly model-driven (55%), with translation-pipeline contamination bounded at 6.4% of scenario–language pairs and a smaller residue of verifier defects. We argue that omnilinguality is the right arena for testing advanced LLM and agentic techniques and for inventing new methods to scale general-purpose evaluation, and we close with concrete responsibilities for the WMT community.

# Table of Contents

*Efficient Multilingual Neural Machine Translation via Corpus-Driven Vocabulary Pruning: An English-Arabic Case Study.*
Ahmed Amine Aliane, Nasredine Semmar and Hassina Aliane . . . . . 1

*TACTICS: Taxonomy-Aware Intelligent Corpus Sampling for Machine Translation*
Prasanth Bathala, Anubhav Shrimal, Sukhdeep Singh Kharbhanda, Pradyumna Lanka and Rohit Dhaipule . . . . . 14

*Synthetic Slang Generation for Benchmarking Machine Translation*
Eric Bennett . . . . . 33

*The Constitution Speaks Nheengatu: An Open MT System and Reproducible Corpus Pipeline for the Amazonian Língua Geral*
Fabrício Carraro, Rodolfo Zevallos, Rodrigo Gonçalves De Souza, Caio Faustino Da Silva and John E. Ortega . . . . . 47

*ChakmaNMT: Machine Translation for a Low-Resource and Endangered Language via Transliteration*
Aunabil Chakma, Aditya Chakma, Masum Hasan, Soham Khisa, Chumui Tripura and Rifat Shahriyar . . . . . 64

*TermJudge: A Document-Level Metric Judging, Not Counting, Terminology in Machine Translation Evaluation*
Nicolas Dahan, François Yvon and Rachel Bawden . . . . . 82

*BaatCheet: A Multilingual Corpus for Dialogue Translation in Indian Languages*
Priyanka Dasari, Yuvrajsinh Bodana, Vandan Mujadia, Arafat Ahsan, Dipti Sharma and Parameswari Krishnamurthy . . . . . 116

*StalePO: Anchored Token-Level Preference Optimization using Legacy Post-Edits in Machine Translation*
Rohit Dhaipule, Sukhdeep Kharbanda, Prasanth Bathala, Pradyumna Lanka and Anubhav Shrimal 146

*Balancing Global Quality and Pronoun-Specific Feedback for Context-Aware Machine Translation*
Harshit Dhankhar, Baban Gain, Asif Ekbal and Yogesh Tripathi . . . . . 157

*Compact Models for Machine Translation in the Bioinformatics Domain: Synthetic Data, Domain Adaptation, and Expert Evaluation*
Jurgi Giraud and Andrew Gargett . . . . . 168

*ChainAlign: Cross-Lingual Sentence Alignment via Sparse Co-linear Chaining*
Owen Goldner and Connor Gramazio . . . . . 183

*LocQE: Principled Domain Adaptation for Localisation Quality Estimation by Leveraging Post-Edits*
Kathy Haemmerl, Gabriel Bretschner and Joern Wuebker . . . . . 199

*Low-resource machine translation using a general-purpose LLM informed by a dedicated NMT model and lexical resources: A case study on Ainu–Japanese translation*
Nagito Hara, Karol Nowakowski, Michal Ptaszynski, Lloyd Overacker and Masahiro Toyoura 220

*SNAPP: Segment-Level Neural Alignment Post-Processing for Low-Resource Parallel Sentence Mining*
Niklas Hettich, Shu Okabe and Alexander Fraser . . . . . 239

*Dynamic Lagging using Stable-Prefix Training for Simultaneous Translation*
Hieu Hoang, Amittai Axelrod and Matt Post . . . . . 254

*Evaluating Pragmatic Appropriateness in English–Vietnamese Machine Translation with Dyadic Profiles*
Zheng-Yu Huang and Richard Tzong-han Tsai . . . . . 269

*Which Metric for Which Script? A Quantified Meta-Evaluation of Automatic Metrics and LLM Judges for Low-Resource Indic Machine Translation*
Rudali Huidrom, Vikas Kumar, Hoomexsun Pangsatabam, Pinaki Das, Kshetrimayum Boynao Singh and Anand Konjengbam . . . . . 281

*Align, Integrate, and Fire: Efficient Token-Level Alignment for Zero-Shot SpeechLLMs*
Abderrahmane Issam, Yusuf Can Semerci, Jan Scholtes and Gerasimos Spanakis . . . . . 304

*IndicQE-APE: A Consolidated Benchmark for Quality Estimation and Automatic Post-Editing over Indic Languages*
Diptesh Kanojia, Archchana Sindhujan, Sourabh Deoghare, Daria Sokova, Shenbin Qian, Girish Koushik, Tharindu Ranasinghe, Constantin Orasan, Chrysoula Zerva, Ricardo Rei, Frederic Blain, André Martins, Marco Turchi, Matteo Negri, Anoop Kunchukuttan, Mitesh M. Khapra and Pushpak Bhattacharyya . . . . . 318

*Text-Only vs. Image-Aware VLM Judges for Manga Translation Evaluation*
Subaru Kimura and Jun Suzuki . . . . . 345

*From Error Detection to Credit Assignment: Do xCOMET Error Spans Provide Useful Policy Credit for Chinese–Malay Translation?*
Zi Chen Koo . . . . . 368

*Translationese as a Rational Response to Translation Task Difficulty*
Maria Kunilovskaya . . . . . 380

*RT-SFT: Text Style Transfer from Non-Parallel Corpora by Roundtrip Translation*
Ruoxi Liu and Philipp Koehn . . . . . 398

*Multilingual Reasoning Cascades Need More Context*
Arnav Mazumder, Dengjia Zhang, Shuyue Stella Li, Yulia Tsvetkov and Niyati Bafna . . . . . 412

*Lost in Mimicry: Verified Training-Free Post-Editing for LLM Translationese*
Dongwon Noh, Donghyeok Koh, Yeon-Soo Lim, Seohyeong Jeong, Yunsu Kim, Gyuwan Kim, Soojong Do, Jinyeong Bak, Sugyeong Eo and Cheoneum Park . . . . . 462

*MITRA-MT: Continued Pretraining, Parallel Corpus Mining, and Multi-Directional Machine Translation for Sanskrit, Tibetan, and Buddhist Chinese*
Sebastian Nehrdich and Kurt Keutzer . . . . . 492

*Mitrasamgraha: A Comprehensive Classical Sanskrit Machine Translation Dataset*
Sebastian Nehrdich, David Allport, Jivnesh Sandhan, Manoj Balaji Jagadeeshan, Sujeet Kumar, Sven Sellmer, Pawan Goyal and Kurt Keutzer . . . . . 507

*LAND: Learning an Adaptive Number of Draws for Bayesian Best-of-N Selection*
Koen Oostermeijer and Teryn Jones . . . . . 520

*How many raters do we need to recognize a bad translation via perplexity?*
Antonín Otmar and Ondřej Bojar . . . . . 530

*Comparing Machine and Human Simultaneous Interpreting*
Dongpeng Pan and Kilian Seeber . . . . . 541

*An Analysis of Source-Side Diversity in Machine Translation Evaluation*
Esther Ploeger, Johannes Bjerva, Dong Nguyen and Robert Östling . . . . . 554

*TransClean: A Benchmark for Detecting and Extracting Clean Translations from Large Language Model Outputs*
Shenbin Qian and Yves Scherrer . . . . . 574

*Unlocking Reasoning Capability on Machine Translation in Large Language Models*
Sara Rajaee, Sebastian Vincent, Alexandre Berard, Marzieh Fadaee, Kelly Marchisio and Tom Kocmi . . . . . 590

*DoDS-IITPKD: LoRA Fine-Tuning and LLM Post-Editing for Low-Resource Indic Machine Translation*
G.l. Salvin, Amisha Ramesan, Abigairl Chigwededza, Shrikant Budde and Swapnil Hingmire607

*Making COMET Comparable Across Scripts: Diagnosis and Correction of Tokeniser-Induced Script Bias in Indic MT Evaluation*
G.l. Salvin and Swapnil Hingmire . . . . . 613

*Fine-Tuning LLMs for Translation: General Forgetting Mitigation Does Not Preserve MT-Specific Instruction Following*
Niklas Scholz, David Thulke, Abdallah Nasir, Will Allred, Evgeny Matusov and Hermann Ney 631

*AQI: a composite human-calibrated metric for machine translation quality assessment*
Anastasiya Serdioukova and Denis Zhilko . . . . . 654

*Mind Which Bird You Favour: Parameterizing Adequacy-Fluency Balance in Meta-Evaluation of Machine Translation*
Behzad Shayegh and Niloofar Kazemi . . . . . 673

*In-Context Learning for Upper Sorbian to German Translation: Comparing Lexical and Morpho-Syntactic Information*
Qimin Sheng, Marion Di Marco and Alexander Fraser . . . . . 698

*Retrieval-Augmented Terminology Translation for English-Russian: A Multi-Domain Study*
Maria Sukhareva and Ekaterina Enikeeva . . . . . 711

*Obligatory Slots: Under Reference-Free Evaluation, Dropping a Distinction the Source Never Made Is Free*
Luxshan Thavarasa, Jubeerathan Thevakumar and Sivasuthan Sukumar . . . . . 727

*AmanaMT: Translation Direction Predicts Automatic Metric Reliability*
Isaac Thompson . . . . . 747

*ImgMT: Wikipedia-based Dataset For Evaluating Text-in-Image Translation*
Šárka Uramová, Petar Petrov, Josef Jon, Ondřej Bojar and Michal Novák . . . . . 765

*Doc2FRC: Length-Consistent Document-Level Machine Translation via Fixed-Range Chunking*
Xiaotian Wang, Youyuan Lin, Zhan Shen and Hitomi Yanaka . . . . . 782

*Learning from Many Voices: Literary MT Using Multi-Reference Human and Synthetic Data*
Si Wu, John Wieting and David Smith . . . . . 818

*Studying quantization trade-offs for efficient inference deployment in machine translation*
Jim Zhao, Sohir Maskey, Koen Oostermeijer, Douglas Orr and Teryn Jones . . . . . 842

*Contrastive ESA: Human Evaluation of Multiple Translations at Once*
Vilem Zouhar, Roman Grundkiewicz, Sara Rajaee, Parker Riley, Rachel Bawden, Philipp Koehn, Marine Carpuat and Tom Kocmi . . . . . 860

*Findings of the WMT26 General Machine Translation Shared Task: Contrastive Dynamic Human Evaluation at Scale*
Tom Kocmi, Ekaterina Artemova, Eleftherios Avramidis, Rachel Bawden, Ondřej Bojar, Sergey Dukanov, Anton Dvorkovich, Mark Fishel, Markus Freitag, Samuel Frontull, Thamme Gowda, Roman Grundkiewicz, Barry Haddow, Stan Kharevich, Philipp Koehn, Zheng Li, Jean Maillard, Christof Monz, Alexander Murauski, Kenton Murray, Masaaki Nagata, Stefano Perrella, Martin Popel, Maja Popović, Lorenzo Proietti, Sara Rajaee, Parker Riley, Mariya Shmatova, Steinthór Steingrímsson, Lisa Yankovskaya and Vilem Zouhar . . . . . 873

*Findings of the WMT26 Shared Task on Automated Translation Quality Evaluation Systems: Compact Open Models are Competitive Quality Evaluators*
Alon Lavie, Greg Hanneman, Stefano Perrella, Shuoyang Ding, Eleftherios Avramidis, Lorenzo Proietti, Chi-Kiu Lo, Ammon Shurtz, Chrysoula Zerva, Archchana Sindhujan, Vilem Zouhar, Diptesh Kanojia, Frederic Blain, Brian Thompson, Giorgos Filandrianos, Orfeas Menis Mastromichalakis, Tom Kocmi and Pranav Gupta . . . . . 924

*Findings of the WMT26 Multilingual Instruction Shared Task: Small Models Are Not Yet Polyglots*
Patricia Schmidtova, Ekaterina Artemova, Seth Aycock, Niyati Bafna, Shobhit Banga, Manmeet Kaur, Tom Kocmi, Philipp Koehn, Danni Liu, Nam Luu, Sara Papi, Beatrice Savoldi, Mariya Shmatova, Hanuman Sidh, Evfrosiniya Zerminova, Vilem Zouhar, Maike Züfle and Pinzhen Chen . . . . . 1024

*Findings of the WMT26 Terminology Translation Task: The Hard Part is Finding the Terms, Not Using Them*
Adrian Charkiewicz, Pinzhen Chen, Thierry Etchegoyhen, Harritxu Gete, Kamil Guttmann, Xu Huang, David Ponce, Artur Nowakowski, Frederic Odermatt, Arturo Oncevay, Dawei Zhu, Vilem Zouhar and Kirill Semenov . . . . . 1046

*Findings of the WMT 2026 Shared Task on Model Compression: No Free Lunch at Extreme Compression*
Thamme Gowda, Marco Gaido, Roman Grundkiewicz and Matteo Negri . . . . . 1080

*Findings of WMT 2026 shared task on Low-resource Indic Languages Translation*
Partha Pakray, Santanu Pal, Advaitha Vetagiri, Kshetrimayum Boynao Singh, Sandeep Dash, Arnab Maji, Saralin Lyngdoh, Lenin Laitonjam, Anupam Jamatia, Ajit Das, Sunita Warjri, Uzzal Sharma, Koj Sambyo and Riyanka Manna . . . . . 1091

*Findings of the WMT 2026 Shared Task on Low-Resource Arabic-Asian Language Translation*
Sahinur Rahman Laskar, Firoj Alam, Bishwaraj Paul, Irfan Ahmad, Maya Silvi Lydia and Pankaj Dadure . . . . . 1117

*Findings of the WMT26 Chinese–Southeast Asian Multilingual MT Shared Task*
Tianyu Dong, Ziyan Chen, Jingsong Liu and Shaolin Zhu . . . . . 1131

*Findings of the Second Shared Task for Creole Language Machine Translation, at WMT 2026*
Nathaniel Robinson, Ruth-Ann Armstrong, Claire Bizon Monroc, Rasul Dent, Pranav Gupta, Raj Dabre, Andre Coy and Kenton Murray . . . . . 1138

*Findings of the WMT 2026 Shared Task of the Open Language Data Initiative*
Laurie Burchell, David Dale, Jean Maillard, Idris Abdulmumin, Antonios Anastasopoulos, Isaac Caswell and Philipp Koehn . . . . . 1159

*Findings of the WMT26 Video Subtitle Translation Shared Task: Context and Candidate Selection Matter*
Zheng Li and Mao Zheng . . . . . 1169

*Findings of the WMT 2026 Shared Task: Multitask LLMs with Limited Resources*
Shu Okabe, Marion Di Marco, Kathy Haemmerl, Daryna Dementieva, Lukas Edman, Marko Měškank, Anita Hendrichowa and Alexander Fraser . . . . . 1180

*LiLa at WMT 2026 General MT Task: Exploring Beyond NMT and Learning the Limits of LLM Adaptation for Ligurian and Ladin*
Mirelle Bueno, Lucas Domingues, Samuel Frontull, Jean Maillard and Sushil Garg . . . . . 1203

*SCIR-TG-MT's Submission for the WMT 2026 General Machine Translation Task*
Xiayu Cao, Baohang Li, Zekun Yuan, Zekai Ye and Xiaocheng Feng . . . . . 1213

*GRIAL-TA participation in the WMT26 General Translation Shared Task: SalamandraTA7bFFT*
Marta Cozzini, Antoni Oliver, Gonzalo López-Sánchez, Mercè Vàzquez, Patricia Morales-Hurtado and Sergi Alvarez-Vidal . . . . . 1221

*Dubformer at WMT26 General MT: Translating the Video, Not the Transcript*
Sergey Dukanov, Maria Tsyurupa and Anton Dvorkovich . . . . . 1231

*Relay-MT: Multi-agent LLM Ensembling for Machine Translation – Samsung R&D Poland Submission for WMT2026*
Adam Dobrowolski, Paweł Przybysz, Marcin Szymański, Paweł Przewłocki and Artur Janicki1235

*Grammatist at WMT 2026 General MT Task: An Agentic LLM Framework for Machine Translation with Explicit Linguistic Knowledge*
Samuel Frontull, Jean Maillard, Christopher Haberland, Ruth Videsott and Stefano Lusito . . 1248

*HW-TSC's Submission to the WMT 2026 General Machine Translation Track*
Yu He, Xiaoqing Lan, Daimeng Wei, Jiaxin Guo, Yuanchang Luo, Hengchao Shang, Zongyao Li, Jinlong Yang, Zhanglin Wu and Boqi Huang . . . . . 1258

*CUNI-MH and CUNI-EdUKate at the WMT26 General MT Shared Task*
Miroslav Hrabal, Josef Jon and Ondřej Bojar . . . . . 1264

*CUNI-AR Team at WMT26 General Translation Task for Egyptian Arabic*
Josef Jon, Rawan Bondok, Miroslav Hrabal and Ondřej Bojar . . . . . 1271

*In the Blind: Building Pseudo-References for MT Evaluation*
Diptesh Kanojia, Chi-Kiu Lo, Archchana Sindhujan, Samuel Larkin, Greg Hanneman and Alon Lavie . . . . . 1284

*North Small Translate: Advanced Cost-Effective Translation (Cohere CAT+)*
Tom Kocmi, Alexandre Berard, Phil Blunsom, Samuel Cahyawijaya, Shaun Cassini, Ona De Gibert, Aidan Gomez, Nithya Govindarajan, Shun Kiyono, Olivia Lasche, Lawrence Rogers, Kelly Marchisio, Nikita Moghe, Yash More, Camila Moran-Hidalgo, Yiyang Nan, Michael Sachs, Trisha Starostina, Daan Van Stigt, Spencer Rarrick, Sebastian Vincent, Ivan Zhang and Nicholas Frosst . 1305

*AdaptiveMT at WMT26: A Controller–Executor–Reducer Agent Harness for Document-Level Translation*
Soyoung Lee . . . . . 1318

*BSC Submission for WMT26 General Machine Translation Shared Task*
Audrey Mash, Jonathan Ayebakuro, Ella Bohman, Xixian Liao, Francesca De Luca Fornaciari and Maite Melero . . . . . 1327

*RFMT at WMT 2026 General Translation Task*
Ryosuke Matsuda, Keito Kudo, Ryo Fujii, Takumi Ito, Makoto Morishita and Jun Suzuki . . . 1344

*MakotoAI at WMT26: Per-Pair Model Selection with Deterministic Output Normalization for the General Machine Translation Task*
Chris Nishihama . . . 1372

*ReMova: Fine-tuning LLMs for English to Belarusian translation*
Mikita Pilinka, Aliaksandr Kliuyeu, David Samuel and Yves Scherrer . . . 1378

*Apertium-sme-eng for WMT2026 shared task—creating new pair by crossing dictionaries and translating rules*
Flammie Pirinen . . . 1391

*Yandex at WMT26: Translation Adaptation at 235B and Hard-Label Distillation to 8B*
Dmitrii Popov, Elizaveta Kozlova, Ekaterina Taracheva, Elizaveta Makhotina, Artem Mekhraliev, Miron Baratelia, Ekaterina Enikeeva and Nikolay Karpachev . . . 1397

*Wayfinder: An Agentic Ensemble-and-Postcheck System for WMT26 GenMT*
Liangying Shao, Xinwei Wu, Yichong Huang, Jifang Wang, Ruoxi Xu, Ling Shi, Baosong Yang and Linlong Xu . . . 1405

*What a DRAG (it is being small): The AMI Submission to the WMT 2026 General Translation Shared Task*
Steinthór Steingrímsson, Sveinbjörn Thórdharson and Jón Dadason . . . 1414

*Krosny at WMT26 General Translation Task: Dictionary Augmentation and Iterative Refinement for English–Belarusian Translation*
Oksana Volchek and Vladislav Poritski . . . 1425

*Lumen at WMT2026: Instruction-Specialized Translation via Quality-Aware Training and On-Policy Distillation*
Hao Wang, Yangyang Liu, Xiaohu Zhao, Heng Liu, Zifu Shang, Tianhao Li, Ruize Gao, Jialong Tang, Shiao Shao, Haoran Wei, Baosong Yang, Linlong Xu, Longyue Wang and Weihua Luo . . . 1430

*UvA-MT's Participation in the WMT26 General Translation Shared Task*
Di Wu, Sergey Troshin, Wafaa Mohammed, Seth Aycock, Evgeniia Tokarchuk, Vlad Niculae and Christof Monz . . . 1440

*QINGQIU-MT-9B: An Instruction-Following Multilingual Translation Model*
Tian Xia, Chao Chen, Mengpeng Yang, Jingxu Yang, Yabo Sun and Qiang Liu . . . 1447

*TRIVE: A Tri-Fusion Verified Translation Agent*
Mengpeng Yang, Tian Xia, Jingxu Yang, Chao Chen, Yabo Sun and Qiang Liu . . . 1463

*TransCore: The NewTranx Submission to the Constrained Track of the WMT26 General Machine Translation Shared Task*
Hao Yu, Ziyan Chen, Hongyu Zhao, Yulong Zhang, Xiaogang Wang, Kaiyu Huang and Degen Huang . . . 1477

*KUEST: Korean game Usage Evaluation Suite for LLM Translation*
Minjoo Choi, Jaejun Jung, Gunwoo Han, Junhyeop Kim, Yiji Yoon, Hyemi Kim, Yeonseo Cho and Jinwoo Jang . . . 1484

*Terminology Resources as (MT) Benchmarks: Evaluation of Legal Terminology Challenges in German Language Varieties by EURAC*
Paolo Di Natale, Elena Chiocchetti, Natascia Ralli, Marlies Alber and Egon Stemle . . . 1506

*Mind the Gap: Exposing LLM Translation Blind Spots Using the AlphaMWE Multilingual Parallel Corpus*
Lifeng Han, Jiahui Liang, Anna Latusek, Karim El Haff, Amal Haddad Haddad, Josua Höfgen, Kilian Evang, Min Ma and Maryia Zhyrko . . . . . 1533

*Lost in Morphology at WMT26: A Korean-English Test Suite for LLM Translation Blind Spots*
Deun Sol Lee, Dae Woong Kim and Yun Ha Seo . . . . . 1555

*Evaluating Occupational Gender Bias and Male Default in Turkish-to-English Machine Translation*
Yusuf Öztop . . . . . 1568

*Translating Syntactic Structures: An English-Icelandic Test Suite for Syntactic Divergence*
Einar Sigurdsson, Steinthór Steingrímsson, Bjarki Ármannsson, Atli Jasonarson, Helga Svala Sigurdardottir and Jón Markússon . . . . . 1577

*I'm Sorry, I Can't Translate That: A Challenge Set for Refusal to Translate, Overgeneration and Hallucination in LLM Translation Systems*
Lisa Vasileva . . . . . 1594

*Finding the Gaps in LLM Translation with CoST*
Saumitra Yadav, Ananya Mukherjee and Manish Shrivastava . . . . . 1602

*Phrase at WMT26 Automated MT Evaluation Task*
Alan Eckhardt, Ondrej Glembek and Craig Stewart . . . . . 1615

*FECE: A Challenge Set for Evaluating Fine-Grained Translation Error Correction*
Jie Ding and Xiangyu Duan . . . . . 1624

*Pterodactyl: Pushing the Limits of Efficient Automated Translation Evaluation*
Evelyn Garland and Carola Berger . . . . . 1638

*AGGREE: An Aggregation-Grounded Challenge Set for Segment-Level MT Metric Evaluation*
Lena Griesbeck and Michaela Geierhos . . . . . 1644

*CUNI at the WMT26 Automated MT Evaluation Shared Task*
Miroslav Hrabal and Ondřej Bojar . . . . . 1652

*HUFS-DILAB at WMT 2026 Automated Translation Quality Evaluation Task 1: Language-Pair Prompt Routing for Error Span Annotation*
Jisoo Jang, Haewon Cho and Seungtaek Choi . . . . . 1658

*FACET at WMT 2026 Automated Translation Quality Evaluation Task*
Ahrii Kim, Chanjun Park and Seong-Heum Kim . . . . . 1667

*PragmaSpan at WMT26: Taxonomy-Guided Few-Shot Error Span Detection and an Empirical Analysis of MPP*
Soyoung Lee . . . . . 1678

*Benchmarking Gender Bias in Machine Translation Evaluation Metrics across Occupations*
Orfeas Menis Mastromichalakis, Giorgos Filandrianos, Wafaa Mohammed, Giuseppe Attanasio and Chrysoula Zerva . . . . . 1689

*Translation Metrics Cannot Judge What Their Tokeniser Deletes: LIGATUR and AEGIS Submissions to the WMT26 Shared Task on Automated Translation Quality Evaluation*
Animesh Mishra, Krishang Sharma and Sonia Khetarpaul . . . . . 1700

*Algebras FluencyScore at WMT26 Automated Translation Quality Evaluation*
Airana Mongush and Dmitrii Pukhov . . . . . 1711

*Vertical: Quality Estimation of Machine Translation from Université Grenoble Alpes*
Mariam Nakhlé, Raheel Qader, Marco Dinarelli and Hervé Blanchon . . . . . 1716

*Post-hoc Correction of Machine Translation Error Span Predictions*
Benjamin Pong . . . . . 1723

*Leveraging Verbalized Confidence in LLM-as-a-Judge for Automated Translation Quality Evaluation*
Richard Servajean, Mohammad Golam Sohrab, Lucie Kunitomo-Jacquin and Matiss Rikters 1730

*Reference-Free Consensus Evaluation of Machine Translation: Ensembling LLM Error-Span Judgments with Neutral Cross-Verification and STAPLE Reliability Fusion*
Assaf Siani . . . . . 1739

*QEbreak at WMT26: A Pre-Registered Audit of Omission and Addition Asymmetry in Machine Translation Quality Metrics*
Maksim Silchenko . . . . . 1745

*SpinPop: A Fast Spin Metric for the WMT26 Metrics Shared Task*
Jia Xu . . . . . 1757

*Beyond Rankings: Insights from ALTAE's PTT-MULTITAN Submission to the WMT 2026 Shared Task on Automated Translation Quality Evaluation Systems*
Lichao Zhu, Maria Zimina-Poirot and Nicolas Froeliger . . . . . 1763

*RWS at WMT26 Terminology Translation Task*
Jon Cambra Guinea and Andrea Alfieri . . . . . 1772

*UniOR-MT: An Agentic Pipeline for Terminology Translation*
Antonio Castaldo, Giulia Speranza, Maria Carmen Staiano, Petra Giommarelli, Johanna Monti and Maria Pia Di Buono . . . . . 1779

*Agenteak: A Multi-Agent Pipeline for Terminology-Constrained Spanish-Basque Translation*
Jurgi Giraud and Andrew Gargett . . . . . 1791

*HW-TSC's Submission to the WMT26 Terminology Translation Shared Task*
Boqi Huang, Daimeng Wei, Jiaxin Guo, Yuanchang Luo, Hengchao Shang, Zongyao Li, Jinlong Yang, Zhanglin Wu, Yu He and Xiaoqing Lan . . . . . 1801

*SalamandraTA at WMT 2026 Terminology Shared Task: Hard Examples Are Better Teachers*
Xixian Liao and Maite Melero . . . . . 1807

*GRIAL-TA participation in the WMT26 Terminology Shared Task*
Gonzalo López-Sánchez, Antoni Oliver, Marta Cozzini, Mercè Vàzquez, Patricia Morales-Hurtado and Sergi Alvarez-Vidal . . . . . 1819

*STaR-MT: Select, Translate, and Revise Pipeline for Terminology Aware Machine Translation*
Guilherme Marchetti, Gil Rocha, Henrique Lopes Cardoso and Rui Sousa-Silva . . . . . 1830

*TARL: A Terminology-Aware Agentic Repair Loop for Language-Agnostic Translation*
Shivam Mhaskar, Vrunda Sukhadia, Anurag Deshmukh, Manan Sharma and Pawan Rajpoot 1840

*CUNI-ÚFAL at the WMT26 Terminology Translation Task*
Aleš Manuel Papáček and Tomáš Sourada . . . . . 1849

*Tilde's Submission for the WMT2026 Shared Task on Terminology Translation*
Marcis Pinnis, Martins Kronis, Emils Grims, Ervins Jakovelis, Roberts Rozis and Toms Bergmanis 1860

*UniVie-HAITrans at WMT26 Terminology Translation Task: Terminology-Guided Data Filtering and Few-Shot Fine-Tuning for Lightweight LLMs*
Miguel Angel Rios Gaona . . . . . 1873

*STRA-MT: Deterministic Terminology Control for Document-Level Machine Translation*
Vania Velda, Yigyu Hwang and Yongho Kim . . . . . 1881

*TaT at WMT26 Terminology Translation Shared Task*
Fan Zhang, Tu Mei, Zhang Mengchao, Jinting Wu and Bowbjut.edu.cnen Zhang . . . . . 1892

*A Monolingual LoRA-Tuned Qwen2.5-3B System for Arabic Context-Based Question Answering*
Hasan Alkhder, Maria Hanini, Imane Hocine, Maher Pasa and Amro Najjar . . . . . 1899

*Laniqo at WMT26 Multilingual Instruction Shared Task (MIST): Full-Parameter Knowledge Distillation with Task-Conditional Pivot Decoding Under a 10B-Parameter Constraint*
Adrian Charkiewicz and Artur Nowakowski . . . . . 1906

*SentinelQA: Task-Level Routing and Output Verification for Multilingual Instruction Following*
Asher Egerton-Idehen . . . . . 1917

*TUM-Heilbronn: WMT26 Multilingual Instruction Shared Task*
Jen-Chien Hou, Tsedeniya Kinfe Temesgen and Alexander Fraser . . . . . 1925

*Probe Before you Answer! Answerability Probing for Abstention in Cross-Lingual Context-Based Question Answering*
Lea Krause, Stefan Schouten, Michiel Van Der Meer and Piek Vossen . . . . . 1933

*CUNI-UFAL at WMT26 Multilingual Instruction Shared Task*
Aleš Manuel Papáček and Patricia Schmidtova . . . . . 1949

*PSK at WMT 2026 MIST: Task-Specialized QLoRA Adapters for Multilingual Summarization and Question Answering*
Srikar Kashyap Pulipaka . . . . . 1959

*Task-Preserving Multilingual Instruction Tuning for Open-Ended QA at WMT 2026 MIST*
Aleix Sant, Jordi Luque Serrano and Carlos Escolano Peinado . . . . . 1965

*COMET Sensitivity-Guided Mixed Precision Quantization for the WMT26 Model Compression Task*
Angad Ripudaman Singh Bajwa . . . . . 1973

*Importance-Guided Structural Pruning of Aya Expanse 8B and Gemma-3-12B for English–Chinese Machine Translation*
Havish Balaga, Anish Racherla, Kolupoti Kiran, Saumitra Yadav and Manish Shrivastava . . 1979

*Pare4Bit: Quantization, Depth Pruning, and Model Selection for the WMT26 Model Compression Task*
Nail Fakhrutdinov . . . . . 1986

*Quantize, Qualify, Rerank: A Recipe for Compressing LLMs Without Losing Quality*
Thamme Gowda . . . . . 1991

*WMT26 Model Compression Task: Quantising and Distilling TildeOpen*
Martins Kronis, Toms Bergmanis, Ingus Pretkalniņš and Marcis Pinnis . . . . . 1999

*ESTS at WMT26: Routing-Informed Expert Pruning for Model Compression*
Liu Martin, Lucas Bandarkar and Nanyun Peng . . . . . 2009

*TMU-onono at WMT26: DiBA-Based Model Compression for Czech-to-German Machine Translation*
Nobutaka Ono . . . . . 2017

*Layer-Aware Native Quantization for Compact Machine Translation: A WMT26 English-to-Chinese Submission*
Alonso Palomino . . . . . 2025

*Tiny Titans at WMT26: Task-Calibrated Quantization and Activation-Aware Low-Rank Compression of Gemma 3 12B*
Vania Raya-Rios, Aleksandr Klimchuk, Nicolas Cuadrado Avila, Ivo Gollini Navarrete, Samuel Horvath and Martin Takác . . . . . 2030

*Vicomtech@WMT 2026: Mask-based Pruning for Model Compression*
David Ponce and Thierry Etchegoyhen . . . . . 2038

*The ILSP/ARC submission to the WMT26 Model Compression Task*
Sokratis Sofianopoulos and Prokopis Prokopidis . . . . . 2051

*FBK's Submission to WMT26 Model Compression Task: Improving Inference Speed for Quantized Models*
Dhairya Suman and Luisa Bentivogli . . . . . 2061

*LTRC_Plural: Better Data and Better Rewards for Low-Resource Indic MT*
Vishnuraj A, Yuvrajsinh Bodana, Heli Hingrajiya, Priyanka Dasari and Parameswari Krishnamurthy . . . . . 2067

*ADI-IITP: Reward-Guided Preference Optimization for Low-Resource English-Assamese Machine Translation*
Aditya Aditya and Asif Ekbal . . . . . 2078

*BVSLP: Enhancing Machine Translation through NMT Fine-Tuning, Back-Translation, and LLM-Assisted Synthetic Data Generation*
Palak Arora, Adhikarimayum Sharma, Mrityunjaya Indoria, Keneiwenuo Lhoungu, Lalthafamkimi Lalthafamkimi, Bharti Nathani and Nisheeth Joshi . . . . . 2086

*EROL: Transformer-Based Multilingual Translation for Northeastern Indian Language Pairs*
Laishram Thoibisana Devi and Grace Lee . . . . . 2094

*NLP-MT_Amrita: A RL-Inspired GRPO based Agentic RAG Framework for Manipuri and Bodo*
Kuruva Divya Sree and Deepa Gupta . . . . . 2101

*gators: BM25-Augmented Many-Shot Translation for Low-Resource North-Eastern Indian Languages*
Aashish Dhawan, Christopher Driggers-Ellis, Dzmitry Kasinets, Christan Grant and Zhe Wang 2111

*AkibaNLP-TUT: Improving Low-Resource Machine Translation via Language-Specific and Length-Adaptive Noise Injection*
Takumi Kachi, Tomoyosi Akiba and Hajime Tsukada . . . . . 2124

*TIP-RBG-AI: Overcoming Orthographic Discrepancies via Algorithmic Translinear Pipelines and Phylogenetic Script Mapping*
Barathi Ganesh Hb, Michal Ptaszynski, Meenakshi Sharma and Jairam R . . . . . 2135

*MTG-LIRA: Scaling Neural Machine Translation for Low-Resource Indian Languages through Multilingual Learning and Synthetic Data*
Vedarth Hede, Neha Gupta, Harish Bapat and Harsh Ekbote . . . . . 2146

*PANINI: Improving Low-Resource English-Manipuri Translation in Two Scripts via rsLoRA and Three-Stream Self-Augmentation*

Rudali Huidrom, Vikas Kumar, Hoomexsun Pangsatabam, Pinaki Das, K. Kabi Khanganba, Nongmaithem Zeno, Nicholas Khumukcham, Mangalton Okram, Justice Konjengbam, Sai Jamalpoor, Alex Khangembam, Anand Konjengbam and Vikram Goyal . . . . . 2154

*ANVITA : Machine Translation System for Low-resource Indian Languages - Khasi, Nagamese and Tagin*
Siva J, Daneshwari Kankanwadi, Abhinav Gugulothu and Biswajit Paul . . . . . 2163

*SCE-KIIT: Fine-Tuning NLLB-200 for English-Nagamese Translation*
Agniva Maiti, Aarsh Muley and Sovan Sahoo . . . . . 2173

*SCE-KIIT: KokLLaMA: Cross-Task Adaptation for Low-Resource English–Kokborok Translation*
Agniva Maiti, Aarsh Muley and Sovan Sahoo . . . . . 2183

*KrenTransV0.1: Multi-Model Routing and Reranking for Low-Resource Northeast Indian Translation*
Badal Nyalang, Riya Tekcham and Biman Debbarma . . . . . 2193

*DELAB-IIITM WMT26: Full Fine-Tuning and LoRA-Based Adaptation for English-to-Low-Resource Indic Translation*
Dingku Oinam and Navanath Saharia . . . . . 2199

*Decepticons-IIITH : Morphology-Aware Lexicon Filtering of Back-Translated Data for Low-Resource English-to-Indic Translation*
Soujanya Rao, Sakhil Taneja, Krishna Chaitanya and Radhika Mamidi . . . . . 2207

*Winterpeg: Do Neural Cellular Automata Help Where Pretraining Ends?*
Sujay Rittikar and Sheela Ramanna . . . . . 2213

*An LLM-Driven Pipeline for Extremely Low-Resource English-to-Indic Translation — From Vocabulary Injection to Post-Training and Decoding*
Lu Ruan, Shaoying Jia, Fan Ning, Wei Wang, Zhengzhen Cai, Fei Hu, Heng Hu and Chenzi Wang 2223

*JH_NLP_APAShreya2: LoRA Fine-Tuning of NLLB-200 for English–Manipuri Machine Translation at WMT 2026*
Aparajita Sinha, Monika Agarwal, Shreya Bhat, Shreya Bonal and Aryan Agrahari . . . . . 2231

*BRS-NK: Bidirectional Finetuning of NLLB-200 for Low-Resource Indic Languages: Assamese-English and Bodo-English Machine Translation*
Bipesh Subedi and Nischal Karki . . . . . 2239

*RozarNLP-cr7 at WMT 2026: LoRA-Fine-Tuned NLLB for Low-Resource Machine Translation in Northeastern Indian Languages*
Suyash Yadav, Utkarsh Chaudhary and Alapan Kuila . . . . . 2247

*FARABI at WMT 2026: Post-Hoc Channel Controllers for Low-Resource Arabic–Asian Machine Translation*
Farizeh Aldabbas, Zyad Altahan, Hossam Elsafty and Rafet Sifa . . . . . 2255

*OpenBracket at WMT 2026: COMET-MBR System Combination over Arabic-Native and Multilingual Models for Low-Resource Arabic-English Translation*
Abrar Alotaibi . . . . . 2266

*BVSLP at WMT 2026: An Empirical Study of Multilingual Transfer for Low-Resource Arabic-Centric Translation*
Palak Arora, Syed Ahmed, Mansi Jangid, Bharti Nathani and Nisheeth Joshi . . . . . 2273

*MAGADIR at WMT 2026: Cross-System QE Re-ranking and Entity-Aware Selection for Low-Resource Arabic-English Translation*
Hossam Boudraa . . . . . 2280

*NCI-MT at WMT 2026: A Quality-Gated Cascade for Low-Resource Arabic-Asian Machine Translation*
Satarupa Deb and Prashanth Nayak . . . . . 2298

*MTG-LIRA at WMT 2026: Data-Centric Arabic-Hindi Machine Translation through Corpus Augmentation, Synthetic Parallel Data Generation and Transformer Models.*
Vedarth Hede, Neha Gupta, Harish Bapat and Harsh Ekbote . . . . . 2304

*IndicMT at WMT 2026: Full Fine-Tuning of NLLB-200-600M with Round-Trip Filtering and Forward Self-Training for Arabic-Asian Translation*
Pramit Jana, Arindam Adhikari, Priyobroto Acharya and Dipankar Das . . . . . 2311

*NERDS-NITS at WMT2026: Pivot-Based and Direct Neural Machine Translation for Arabic–Asian Low-Resource Language Pairs*
Misbahul Karim, Faruk Ahmed, Mishbahul Islam, Sahinur Laskar and Rabul Laskar . . . . . 2318

*NITM AI Lab at WMT 2026 Shared Task: Low-Resource Arabic-Asian Language Translation*
Nabin Koirala, Rhythm Bhetwal and Nurul Choudhury . . . . . 2324

*NLP-IIT Patna at WMT 2026: Corpus-Driven Adaptation of Multilingual MT Models for Low-Resource Arabic–Asian Machine Translation*
Pushkar Sharma, Mo Ahtasam, Kshetrimayum Boynao Singh, Deepak Kumar and Asif Ekbal 2329

*UPES_NLP at WMT 2026 Low-Resource Arabic–Asian Machine Translation Shared Task: Arabic-Centric Machine Translation with NLLB-200-MOE and Prompt-Constrained Entity-Preserving Translation with GPT-5-mini*
Sumit Singh, Anish Vishwakarma, Brijmohan Sahu and Ashwani Kumar . . . . . 2338

*Code & Corpus at WMT 2026: Checkpoint-Pool Minimum Bayes Risk Decoding for Arabic-Hindi and Arabic-Bangla Translation*
Raman Yadav and Alapan Kuila . . . . . 2344

*SLPG_FJWU at WMT 2026: Domain Adapted Augmentation for Low-Resource Arabic-Asian Language Translation*
Shomaiza Zafar, Sadaf Abdul Rauf, Sheema Firdous, Muhammad Munir and Nadeem Fakhar2351

*An LLM-Driven Pipeline for Extremely Low-Resource English-to-Indic Translation — From Vocabulary Injection to Post-Training and Decoding*
Lu Ruan, Shaoying Jia, Fan Ning, Wei Wang, Zhengzhen Cai, Fei Hu, Heng Hu and Chenzi Wang 2360

*ASEAN-8B: A Prompted Qwen3.5-9B System for Chinese–Southeast Asian Web Translation*
Wen Haobin . . . . . 2368

*Jiutian-MT-8B at WMT26: Faithfulness-First Training for Chinese-Southeast Asian Translation*
Meng Su, Jian Liu and Youxuan Fang . . . . . 2374

*Xiaoyu-MT: Kunming University of Science and Technology at WMT 2026 Chinese-Southeast Asian Multilingual MT Task*
Zhenhan Wang, Fengzhao Fan, Yuxin Huang, Kaiwen Tan, Zhengtao Yu, Shengxiang Gao, Cunli Mao, Siqi Zhang and Shuting Jiang . . . . . 2379

*A Direction-Specialized System for WMT26 Chinese-Southeast Asian Multilingual Machine Translation*
Xiaojing Yan and Rile Hu . . . . . 2389

*Hy-MT2-1.8B for WMT26: Staged Multilingual Adaptation for Chinese–Southeast Asian Translation*

*QwenSub-MT Framework for WMT 2026 Video Subtitle Translation*
Palak Arora, Mansi Jangid, Bharti Nathani and Nisheeth Joshi . . . . . 2584

*SubVision@WMT26: QLoRA Fine-Tuning of Hy-MT2-1.8B for Chinese to English Video Subtitle Translation*
Prajwal Ghimire and Aashish Mahato . . . . . 2592

*Laniqo at WMT26 Video Subtitle Translation Shared Task: Multi-Objective Fusion of Pareto-Optimal Candidates*
Kamil Guttmann and Artur Nowakowski . . . . . 2608

*paramanandaAI@WMT26 Video Subtitle Translation: QLoRA Fine-Tuning with Test-Time Metadata Prompting*
Shiv Saud, Sundeep Dawadi and Sunil Regmi . . . . . 2616

*~rupiah at WMT26: Training-Free Context-Aware Subtitle Translation with QE Selection*
Pieter Yudhistira, Sayyidah Azzahra, Dzaki Malik and Tirana Noor Fatyanosa . . . . . 2623

*Full-Video Context and Anonymous Candidate Selection for WMT26 Video Subtitle Translation*
Jianfeng Wu . . . . . 2631

*A Translator–Critic System for Chinese-to-English Subtitle Translation*
Aaryan Yekkisetty . . . . . 2637

*One Model, Five Tasks, Two RTX 3090 GPUs: The HSE System for the Sorbian Track of WMT26 Multitask LLMs with Limited Resources*
Michael Diskin . . . . . 2652

*HeyBusan at WMT26: A System for the Sorbian Track*
Mikhail Khasykov . . . . . 2662

*Getting More from Small LLMs and Limited Data: Fuzzy-Match Retrieval and Candidate Scoring for Multitask Sorbian NLP*
Thomas Moerman and Arda Tezcan . . . . . 2668

*TUMHN@WMT2026: LLMs with Limited Resources for Slavic Languages*
Tsedeniya Kinfe Temesgen, Sinan Kurtyigit and Alexander Fraser . . . . . 2682

*Zolint at WMT 2026: A Multitask LLM Submission for the Low-Resource Ukrainian Track*
Lingchu Yang, Zitong Fu, Hämmerl Kathy and Masaki Ito . . . . . 2689

*HITSZ at WMT 2026: Mixed Continued Pre-training and Supervised Fine-tuning for Low-Resource Sorbian*
Cong Zhang, Yutong Wang, Xuebo Liu and Min Zhang . . . . . 2697

# Program

**Wednesday, October 28, 2026**

08:45 - 09:00 *Opening Remarks*

09:10 - 10:30 *Session 1 - Shared Task Overview Papers I*

*Findings of the WMT26 General Machine Translation Shared Task: Contrastive Dynamic Human Evaluation at Scale*
Tom Kocmi, Ekaterina Artemova, Eleftherios Avramidis, Rachel Bawden, Ondřej Bojar, Sergey Dukanov, Anton Dvorkovich, Mark Fishel, Markus Freitag, Samuel Frontull, Thamme Gowda, Roman Grundkiewicz, Barry Haddow, Stan Kharevich, Philipp Koehn, Zheng Li, Jean Maillard, Christof Monz, Alexander Murauski, Kenton Murray, Masaaki Nagata, Stefano Perrella, Martin Popel, Maja Popović, Lorenzo Proietti, Sara Rajaee, Parker Riley, Mariya Shmatova, Steinthór Steingrímsson, Lisa Yankovskaya and Vilem Zouhar

*Findings of the WMT26 Shared Task on Automated Translation Quality Evaluation Systems: Compact Open Models are Competitive Quality Evaluators*
Alon Lavie, Greg Hanneman, Stefano Perrella, Shuoyang Ding, Eleftherios Avramidis, Lorenzo Proietti, Chi-Kiu Lo, Ammon Shurtz, Chrysoula Zerva, Archchana Sindhujan, Vilem Zouhar, Diptesh Kanojia, Frederic Blain, Brian Thompson, Giorgos Filandrianos, Orfeas Menis Mastromichalakis, Tom Kocmi and Pranav Gupta

*Findings of the WMT26 Multilingual Instruction Shared Task: Small Models Are Not Yet Polyglots*
Patricia Schmidtova, Ekaterina Artemova, Seth Aycock, Niyati Bafna, Shobhit Banga, Manmeet Kaur, Tom Kocmi, Philipp Koehn, Danni Liu, Nam Luu, Sara Papi, Beatrice Savoldi, Mariya Shmatova, Hanuman Sidh, Evfrosiniya Zerminova, Vilem Zouhar, Maike Züfle and Pinzhen Chen

*Findings of the WMT26 Terminology Translation Task: The Hard Part is Finding the Terms, Not Using Them*
Adrian Charkiewicz, Pinzhen Chen, Thierry Etchegoyhen, Harritxu Gete, Kamil Guttmann, Xu Huang, David Ponce, Artur Nowakowski, Frederic Odermatt, Arturo Oncevay, Dawei Zhu, Vilem Zouhar and Kirill Semenov

*Findings of the WMT 2026 Shared Task on Model Compression: No Free Lunch at Extreme Compression*
Thamme Gowda, Marco Gaido, Roman Grundkiewicz and Matteo Negri

10:30 - 11:00 *Coffee Break*

11:00 - 12:00 *Session 2 - Invited Talk by Marta Ruiz Costa-jussa - Towards Omnilinguality in AI - MT as a Starting Point for Language Coverage and Capability Parity*

12:00 - 13:00 *Session 3 - Shared Task Posters I*

12:00 - 13:00 *General Translation Shared Task*

*LiLa at WMT 2026 General MT Task: Exploring Beyond NMT and Learning the Limits of LLM Adaptation for Ligurian and Ladin*
Mirelle Bueno, Lucas Domingues, Samuel Frontull, Jean Maillard and Sushil Garg

*SCIR-TG-MT's Submission for the WMT 2026 General Machine Translation Task*

*GRIAL-TA participation in the WMT26 General Translation Shared Task: SalamandraTA7bFFT*
Marta Cozzini, Antoni Oliver, Gonzalo López-Sánchez, Mercè Vàzquez, Patricia Morales-Hurtado and Sergi Alvarez-Vidal

*Dubformer at WMT26 General MT: Translating the Video, Not the Transcript*
Sergey Dukanov, Maria Tsyurupa and Anton Dvorkovich

*Relay-MT: Multi-agent LLM Ensembling for Machine Translation – Samsung R&D Poland Submission for WMT2026*
Adam Dobrowolski, Paweł Przybysz, Marcin Szymański, Paweł Przewłocki and Artur Janicki

*Grammatist at WMT 2026 General MT Task: An Agentic LLM Framework for Machine Translation with Explicit Linguistic Knowledge*
Samuel Frontull, Jean Maillard, Christopher Haberland, Ruth Videsott and Stefano Lusito

*HW-TSC's Submission to the WMT 2026 General Machine Translation Track*
Yu He, Xiaoqing Lan, Daimeng Wei, Jiaxin Guo, Yuanchang Luo, Hengchao Shang, Zongyao Li, Jinlong Yang, Zhanglin Wu and Boqi Huang

*CUNI-MH and CUNI-EdUKate at the WMT26 General MT Shared Task*
Miroslav Hrabal, Josef Jon and Ondřej Bojar

*CUNI-AR Team at WMT26 General Translation Task for Egyptian Arabic*
Josef Jon, Rawan Bondok, Miroslav Hrabal and Ondřej Bojar

*In the Blind: Building Pseudo-References for MT Evaluation*
Diptesh Kanojia, Chi-Kiu Lo, Archchana Sindhujan, Samuel Larkin, Greg Hanneman and Alon Lavie

*North Small Translate: Advanced Cost-Effective Translation (Cohere CAT+)*
Tom Kocmi, Alexandre Berard, Phil Blunsom, Samuel Cahyawijaya, Shaun Cassini, Ona De Gibert, Aidan Gomez, Nithya Govindarajan, Shun Kiyono, Olivia Lasche, Lawrence Rogers, Kelly Marchisio, Nikita Moghe, Yash More, Camila Moran-Hidalgo, Yiyang Nan, Michael Sachs, Trisha Starostina, Daan Van Stigt, Spencer Rarrick, Sebastian Vincent, Ivan Zhang and Nicholas Frosst

*AdaptiveMT at WMT26: A Controller–Executor–Reducer Agent Harness for Document-Level Translation*
Soyoung Lee

*BSC Submission for WMT26 General Machine Translation Shared Task*
Audrey Mash, Jonathan Ayebakuro, Ella Bohman, Xixian Liao, Francesca De Luca Fornaciari and Maite Melero

*RFMT at WMT 2026 General Translation Task*
Ryosuke Matsuda, Keito Kudo, Ryo Fujii, Takumi Ito, Makoto Morishita and Jun Suzuki

*MakotoAI at WMT26: Per-Pair Model Selection with Deterministic Output Normalization for the General Machine Translation Task*
Chris Nishihama

*ReMova: Fine-tuning LLMs for English to Belarusian translation*
Mikita Pilinka, Aliaksandr Kliuyeu, David Samuel and Yves Scherrer

*Apertium-sme-eng for WMT2026 shared task—creating new pair by crossing dictionaries and translating rules*
Flammie Pirinen

*Yandex at WMT26: Translation Adaptation at 235B and Hard-Label Distillation to 8B*
Dmitrii Popov, Elizaveta Kozlova, Ekaterina Taracheva, Elizaveta Makhotina, Artem Mekhraliev, Miron Baratelia, Ekaterina Enikeeva and Nikolay Karpachev

*Wayfinder: An Agentic Ensemble-and-Postcheck System for WMT26 GenMT*
Liangying Shao, Xinwei Wu, Yichong Huang, Jifang Wang, Ruoxi Xu, Ling Shi, Baosong Yang and Linlong Xu

*What a DRAG (it is being small): The AMI Submission to the WMT 2026 General Translation Shared Task*
Steinthór Steingrímsson, Sveinbjörn Thórdharson and Jón Dadason

*Krosny at WMT26 General Translation Task: Dictionary Augmentation and Iterative Refinement for English–Belarusian Translation*
Oksana Volchek and Vladislav Poritski

*Lumen at WMT2026: Instruction-Specialized Translation via Quality-Aware Training and On-Policy Distillation*
Hao Wang, Yangyang Liu, Xiaohu Zhao, Heng Liu, Zifu Shang, Tianhao Li, Ruize Gao, Jialong Tang, Shiao Shao, Haoran Wei, Baosong Yang, Linlong Xu, Longyue Wang and Weihua Luo

*UvA-MT's Participation in the WMT26 General Translation Shared Task*
Di Wu, Sergey Troshin, Wafaa Mohammed, Seth Aycock, Evgeniia Tokarchuk, Vlad Niculae and Christof Monz

*QINGQIU-MT-9B: An Instruction-Following Multilingual Translation Model*
Tian Xia, Chao Chen, Mengpeng Yang, Jingxu Yang, Yabo Sun and Qiang Liu

*TRIVE: A Tri-Fusion Verified Translation Agent*
Mengpeng Yang, Tian Xia, Jingxu Yang, Chao Chen, Yabo Sun and Qiang Liu

*TransCore: The NewTranx Submission to the Constrained Track of the WMT26 General Machine Translation Shared Task*
Hao Yu, Ziyan Chen, Hongyu Zhao, Yulong Zhang, Xiaogang Wang, Kaiyu Huang and Degen Huang

12:00 - 13:00 *Test Suites*

*KUEST: Korean game Usage Evaluation Suite for LLM Translation*
Minjoo Choi, Jaejun Jung, Gunwoo Han, Junhyeop Kim, Yiji Yoon, Hyemi Kim, Yeonseo Cho and Jinwoo Jang

*Terminology Resources as (MT) Benchmarks: Evaluation of Legal Terminology Challenges in German Language Varieties by EURAC*
Paolo Di Natale, Elena Chiocchetti, Natascia Ralli, Marlies Alber and Egon Stemle

*Mind the Gap: Exposing LLM Translation Blind Spots Using the AlphaMWE Multilingual Parallel Corpus*
Lifeng Han, Jiahui Liang, Anna Latusek, Karim El Haff, Amal Haddad Haddad, Josua Höfgen, Kilian Evang, Min Ma and Maryia Zhyrko

*Lost in Morphology at WMT26: A Korean-English Test Suite for LLM Translation Blind Spots*
Deun Sol Lee, Dae Woong Kim and Yun Ha Seo

*Evaluating Occupational Gender Bias and Male Default in Turkish-to-English Machine Translation*
Yusuf Öztop

*Translating Syntactic Structures: An English-Icelandic Test Suite for Syntactic Divergence*
Einar Sigurdsson, Steinthór Steingrímsson, Bjarki Ármannsson, Atli Jasonarson, Helga Svala Sigurdardottir and Jón Markússon

*I'm Sorry, I Can't Translate That: A Challenge Set for Refusal to Translate, Overgeneration and Hallucination in LLM Translation Systems*
Lisa Vasileva

*Finding the Gaps in LLM Translation with CoST*
Saumitra Yadav, Ananya Mukherjee and Manish Shrivastava

**Wednesday, October 28, 2026 (continued)**

12:00 - 13:00 *Metrics Shared Task*

*Phrase at WMT26 Automated MT Evaluation Task*
Alan Eckhardt, Ondrej Glembek and Craig Stewart

*FECE: A Challenge Set for Evaluating Fine-Grained Translation Error Correction*
Jie Ding and Xiangyu Duan

*Pterodactyl: Pushing the Limits of Efficient Automated Translation Evaluation*
Evelyn Garland and Carola Berger

*AGGREE: An Aggregation-Grounded Challenge Set for Segment-Level MT Metric Evaluation*
Lena Griesbeck and Michaela Geierhos

*CUNI at the WMT26 Automated MT Evaluation Shared Task*
Miroslav Hrabal and Ondřej Bojar

*HUFS-DILAB at WMT 2026 Automated Translation Quality Evaluation Task 1: Language-Pair Prompt Routing for Error Span Annotation*
Jisoo Jang, Haewon Cho and Seungtaek Choi

*FACET at WMT 2026 Automated Translation Quality Evaluation Task*
Ahrii Kim, Chanjun Park and Seong-Heum Kim

*PragmaSpan at WMT26: Taxonomy-Guided Few-Shot Error Span Detection and an Empirical Analysis of MPP*
Soyoung Lee

*Benchmarking Gender Bias in Machine Translation Evaluation Metrics across Occupations*
Orfeas Menis Mastromichalakis, Giorgos Filandrianos, Wafaa Mohammed, Giuseppe Attanasio and Chrysoula Zerva

*Translation Metrics Cannot Judge What Their Tokeniser Deletes: LIGATUR and AEGIS Submissions to the WMT26 Shared Task on Automated Translation Quality Evaluation*
Animesh Mishra, Krishang Sharma and Sonia Khetarpaul

*Algebras FluencyScore at WMT26 Automated Translation Quality Evaluation*
Airana Mongush and Dmitrii Pukhov

*Vertical: Quality Estimation of Machine Translation from Université Grenoble Alpes*
Mariam Nakhlé, Raheel Qader, Marco Dinarelli and Hervé Blanchon

*Post-hoc Correction of Machine Translation Error Span Predictions*
Benjamin Pong

*Leveraging Verbalized Confidence in LLM-as-a-Judge for Automated Translation Quality Evaluation*
Richard Servajean, Mohammad Golam Sohrab, Lucie Kunitomo-Jacquin and Matiss Rikters

*Reference-Free Consensus Evaluation of Machine Translation: Ensembling LLM Error-Span Judgments with Neutral Cross-Verification and STAPLE Reliability Fusion*
Assaf Siani

*QEbreak at WMT26: A Pre-Registered Audit of Omission and Addition Asymmetry in Machine Translation Quality Metrics*
Maksim Silchenko

*SpinPop: A Fast Spin Metric for the WMT26 Metrics Shared Task*
Jia Xu

*Beyond Rankings: Insights from ALTAE's PTT-MULTITAN Submission to the WMT 2026 Shared Task on Automated Translation Quality Evaluation Systems*
Lichao Zhu, Maria Zimina-Poirot and Nicolas Froeliger

12:00 - 13:00 *Terminology Translation Shared Task*

*RWS at WMT26 Terminology Translation Task*
Jon Cambra Guinea and Andrea Alfieri

*UniOR-MT: An Agentic Pipeline for Terminology Translation*
Antonio Castaldo, Giulia Speranza, Maria Carmen Staiano, Petra Giommarelli, Johanna Monti and Maria Pia Di Buono

*Agenteak: A Multi-Agent Pipeline for Terminology-Constrained Spanish-Basque Translation*
Jurgi Giraud and Andrew Gargett

*HW-TSC's Submission to the WMT26 Terminology Translation Shared Task*
Boqi Huang, Daimeng Wei, Jiaxin Guo, Yuanchang Luo, Hengchao Shang, Zongyao Li, Jinlong Yang, Zhanglin Wu, Yu He and Xiaoqing Lan

*SalamandraTA at WMT 2026 Terminology Shared Task: Hard Examples Are Better Teachers*
Xixian Liao and Maite Melero

*GRIAL-TA participation in the WMT26 Terminology Shared Task*
Gonzalo López-Sánchez, Antoni Oliver, Marta Cozzini, Mercè Vàzquez, Patricia Morales-Hurtado and Sergi Alvarez-Vidal

*STaR-MT: Select, Translate, and Revise Pipeline for Terminology Aware Machine Translation*
Guilherme Marchetti, Gil Rocha, Henrique Lopes Cardoso and Rui Sousa-Silva

*TARL: A Terminology-Aware Agentic Repair Loop for Language-Agnostic Translation*
Shivam Mhaskar, Vrunda Sukhadia, Anurag Deshmukh, Manan Sharma and Pawan Rajpoot

*CUNI-ÚFAL at the WMT26 Terminology Translation Task*
Aleš Manuel Papáček and Tomáš Sourada

*Tilde's Submission for the WMT2026 Shared Task on Terminology Translation*
Marcis Pinnis, Martins Kronis, Emils Grims, Ervins Jakovelis, Roberts Rozis and Toms Bergmanis

*UniVie-HAITrans at WMT26 Terminology Translation Task: Terminology-Guided Data Filtering and Few-Shot Fine-Tuning for Lightweight LLMs*
Miguel Angel Rios Gaona

*STRA-MT: Deterministic Terminology Control for Document-Level Machine Translation*
Vania Velda, Yigyu Hwang and Yongho Kim

*TaT at WMT26 Terminology Translation Shared Task*
Fan Zhang, Tu Mei, Zhang Mengchao, Jinting Wu and Bowbjut.edu.cnen Zhang

**Wednesday, October 28, 2026 (continued)**

12:00 - 13:00 *Multilingual Instruction Shared Task*

*A Monolingual LoRA-Tuned Qwen2.5-3B System for Arabic Context-Based Question Answering*
Hasan Alkhder, Maria Hanini, Imane Hocine, Maher Pasa and Amro Najjar

*Laniqo at WMT26 Multilingual Instruction Shared Task (MIST): Full-Parameter Knowledge Distillation with Task-Conditional Pivot Decoding Under a 10B-Parameter Constraint*
Adrian Charkiewicz and Artur Nowakowski

*SentinelQA: Task-Level Routing and Output Verification for Multilingual Instruction Following*
Asher Egerton-Idehen

*TUM-Heilbronn: WMT26 Multilingual Instruction Shared Task*
Jen-Chien Hou, Tsedeniya Kinfe Temesgen and Alexander Fraser

*Probe Before you Answer! Answerability Probing for Abstention in Cross-Lingual Context-Based Question Answering*
Lea Krause, Stefan Schouten, Michiel Van Der Meer and Piek Vossen

*CUNI-UFAL at WMT26 Multilingual Instruction Shared Task*
Aleš Manuel Papáček and Patricia Schmidtova

*PSK at WMT 2026 MIST: Task-Specialized QLoRA Adapters for Multilingual Summarization and Question Answering*
Srikar Kashyap Pulipaka

*Task-Preserving Multilingual Instruction Tuning for Open-Ended QA at WMT 2026 MIST*
Aleix Sant, Jordi Luque Serrano and Carlos Escolano Peinado

12:00 - 13:00 *Model Compression Shared Task*

*COMET Sensitivity-Guided Mixed Precision Quantization for the WMT26 Model Compression Task*
Angad Ripudaman Singh Bajwa

*Importance-Guided Structural Pruning of Aya Expanse 8B and Gemma-3-12B for English–Chinese Machine Translation*
Havish Balaga, Anish Racherla, Kolupoti Kiran, Saumitra Yadav and Manish Shrivastava

*Pare4Bit: Quantization, Depth Pruning, and Model Selection for the WMT26 Model Compression Task*
Nail Fakhrutdinov

*Quantize, Qualify, Rerank: A Recipe for Compressing LLMs Without Losing Quality*
Thamme Gowda

*WMT26 Model Compression Task: Quantising and Distilling TildeOpen*
Martins Kronis, Toms Bergmanis, Ingus Pretkalniņš and Marcis Pinnis

*ESTS at WMT26: Routing-Informed Expert Pruning for Model Compression*
Liu Martin, Lucas Bandarkar and Nanyun Peng

*TMU-onono at WMT26: DiBA-Based Model Compression for Czech-to-German Machine Translation*
Nobutaka Ono

*Layer-Aware Native Quantization for Compact Machine Translation: A WMT26 English-to-Chinese Submission*
Alonso Palomino

*Tiny Titans at WMT26: Task-Calibrated Quantization and Activation-Aware Low-Rank Compression of Gemma 3 12B*
Vania Raya-Rios, Aleksandr Klimchuk, Nicolas Cuadrado Avila, Ivo Gollini Navarrete, Samuel Horvath and Martin Takác

*Vicomtech@WMT 2026: Mask-based Pruning for Model Compression*
David Ponce and Thierry Etchegoyhen

*The ILSP/ARC submission to the WMT26 Model Compression Task*
Sokratis Sofianopoulos and Prokopis Prokopidis

*FBK's Submission to WMT26 Model Compression Task: Improving Inference Speed for Quantized Models*
Dhairya Suman and Luisa Bentivogli

13:00 - 14:00 *Lunch*

**Wednesday, October 28, 2026 (continued)**

14:00 - 15:30 *Session 4 - Research Papers Boaster Talks*

*Efficient Multilingual Neural Machine Translation via Corpus-Driven Vocabulary Pruning: An English-Arabic Case Study.*
Ahmed Amine Aliane, Nasredine Semmar and Hassina Aliane

*TACTICS: Taxonomy-Aware Intelligent Corpus Sampling for Machine Translation*
Prasanth Bathala, Anubhav Shrimal, Sukhdeep Singh Kharbhanda, Pradyumna Lanka and Rohit Dhaipule

*Synthetic Slang Generation for Benchmarking Machine Translation*
Eric Bennett

*The Constitution Speaks Nheengatu: An Open MT System and Reproducible Corpus Pipeline for the Amazonian Língua Geral*
Fabrício Carraro, Rodolfo Zevallos, Rodrigo Gonçalves De Souza, Caio Faustino Da Silva and John E. Ortega

*ChakmaNMT: Machine Translation for a Low-Resource and Endangered Language via Transliteration*
Aunabil Chakma, Aditya Chakma, Masum Hasan, Soham Khisa, Chumui Tripura and Rifat Shahriyar

*TermJudge: A Document-Level Metric Judging, Not Counting, Terminology in Machine Translation Evaluation*
Nicolas Dahan, François Yvon and Rachel Bawden

*BaatCheet: A Multilingual Corpus for Dialogue Translation in Indian Languages*
Priyanka Dasari, Yuvrajsinh Bodana, Vandan Mujadia, Arafat Ahsan, Dipti Sharma and Parameswari Krishnamurthy

*StalePO: Anchored Token-Level Preference Optimization using Legacy Post-Edits in Machine Translation*
Rohit Dhaipule, Sukhdeep Kharbanda, Prasanth Bathala, Pradyumna Lanka and Anubhav Shrimal

*Balancing Global Quality and Pronoun-Specific Feedback for Context-Aware Machine Translation*
Harshit Dhankhar, Baban Gain, Asif Ekbal and Yogesh Tripathi

*Compact Models for Machine Translation in the Bioinformatics Domain: Synthetic Data, Domain Adaptation, and Expert Evaluation*
Jurgi Giraud and Andrew Gargett

*ChainAlign: Cross-Lingual Sentence Alignment via Sparse Co-linear Chaining*
Owen Goldner and Connor Gramazio

*LocQE: Principled Domain Adaptation for Localisation Quality Estimation by Leveraging Post-Edits*
Kathy Haemmerl, Gabriel Bretschner and Joern Wuebker

*Low-resource machine translation using a general-purpose LLM informed by a dedicated NMT model and lexical resources: A case study on Ainu–Japanese translation*
Nagito Hara, Karol Nowakowski, Michal Ptaszynski, Lloyd Overacker and Masahiro Toyoura

*SNAPP: Segment-Level Neural Alignment Post-Processing for Low-Resource Parallel Sentence Mining*
Niklas Hettich, Shu Okabe and Alexander Fraser

*Dynamic Lagging using Stable-Prefix Training for Simultaneous Translation*
Hieu Hoang, Amittai Axelrod and Matt Post

*Evaluating Pragmatic Appropriateness in English–Vietnamese Machine Translation with Dyadic Profiles*
Zheng-Yu Huang and Richard Tzong-han Tsai

*Which Metric for Which Script? A Quantified Meta-Evaluation of Automatic Metrics and LLM Judges for Low-Resource Indic Machine Translation*
Rudali Huidrom, Vikas Kumar, Hoomexsun Pangsatabam, Pinaki Das, Kshetrimayum Boynao Singh and Anand Konjengbam

*Align, Integrate, and Fire: Efficient Token-Level Alignment for Zero-Shot SpeechLLMs*
Abderrahmane Issam, Yusuf Can Semerci, Jan Scholtes and Gerasimos Spanakis

*IndicQE-APE: A Consolidated Benchmark for Quality Estimation and Automatic Post-Editing over Indic Languages*
Diptesh Kanojia, Archchana Sindhujan, Sourabh Deoghare, Daria Sokova, Shenbin Qian, Girish Koushik, Tharindu Ranasinghe, Constantin Orasan, Chrysoula Zerva, Ricardo Rei, Frederic Blain, André Martins, Marco Turchi, Matteo Negri, Anoop Kunchukuttan, Mitesh M. Khapra and Pushpak Bhattacharyya

*Text-Only vs. Image-Aware VLM Judges for Manga Translation Evaluation*
Subaru Kimura and Jun Suzuki

*From Error Detection to Credit Assignment: Do xCOMET Error Spans Provide Useful Policy Credit for Chinese–Malay Translation?*
Zi Chen Koo

*Translationese as a Rational Response to Translation Task Difficulty*
Maria Kunilovskaya

*RT-SFT: Text Style Transfer from Non-Parallel Corpora by Roundtrip Translation*
Ruoxi Liu and Philipp Koehn

*Multilingual Reasoning Cascades Need More Context*
Arnav Mazumder, Dengjia Zhang, Shuyue Stella Li, Yulia Tsvetkov and Niyati Bafna

*Lost in Mimicry: Verified Training-Free Post-Editing for LLM Translationese*
Dongwon Noh, Donghyeok Koh, Yeon-Soo Lim, Seohyeong Jeong, Yunsu Kim, Gyuwan Kim, Soojong Do, Jinyeong Bak, Sugyeong Eo and Cheoneum Park

*MITRA-MT: Continued Pretraining, Parallel Corpus Mining, and Multi-Directional Machine Translation for Sanskrit, Tibetan, and Buddhist Chinese*
Sebastian Nehrdich and Kurt Keutzer

*Mitrasamgraha: A Comprehensive Classical Sanskrit Machine Translation Dataset*
Sebastian Nehrdich, David Allport, Jivnesh Sandhan, Manoj Balaji Jagadeeshan, Sujeet Kumar, Sven Sellmer, Pawan Goyal and Kurt Keutzer

*LAND: Learning an Adaptive Number of Draws for Bayesian Best-of-N Selection*
Koen Oostermeijer and Teryn Jones

*How many raters do we need to recognize a bad translation via perplexity?*
Antonín Otmar and Ondřej Bojar

*Comparing Machine and Human Simultaneous Interpreting*
Dongpeng Pan and Kilian Seeber

*An Analysis of Source-Side Diversity in Machine Translation Evaluation*
Esther Ploeger, Johannes Bjerva, Dong Nguyen and Robert Östling

*TransClean: A Benchmark for Detecting and Extracting Clean Translations from Large Language Model Outputs*
Shenbin Qian and Yves Scherrer

*Unlocking Reasoning Capability on Machine Translation in Large Language Models*
Sara Rajaee, Sebastian Vincent, Alexandre Berard, Marzieh Fadaee, Kelly Marchisio and Tom Kocmi

*DoDS-IITPKD: LoRA Fine-Tuning and LLM Post-Editing for Low-Resource Indic Machine Translation*
G.l. Salvin, Amisha Ramesan, Abigairl Chigwededza, Shrikant Budde and Swapnil Hingmire

*Making COMET Comparable Across Scripts: Diagnosis and Correction of Tokeniser-Induced Script Bias in Indic MT Evaluation*
G.l. Salvin and Swapnil Hingmire

*Fine-Tuning LLMs for Translation: General Forgetting Mitigation Does Not Preserve MT-Specific Instruction Following*
Niklas Scholz, David Thulke, Abdallah Nasir, Will Allred, Evgeny Matusov and Hermann Ney

*AQI: a composite human-calibrated metric for machine translation quality assessment*
Anastasiya Serdioukova and Denis Zhilko

*Mind Which Bird You Favour: Parameterizing Adequacy-Fluency Balance in Meta-Evaluation of Machine Translation*
Behzad Shayegh and Niloofar Kazemi

*In-Context Learning for Upper Sorbian to German Translation: Comparing Lexical and Morpho-Syntactic Information*
Qimin Sheng, Marion Di Marco and Alexander Fraser

*Retrieval-Augmented Terminology Translation for English-Russian: A Multi-Domain Study*
Maria Sukhareva and Ekaterina Enikeeva

*Obligatory Slots: Under Reference-Free Evaluation, Dropping a Distinction the Source Never Made Is Free*
Luxshan Thavarasa, Jubeerathan Thevakumar and Sivasuthan Sukumar

*AmanaMT: Translation Direction Predicts Automatic Metric Reliability*
Isaac Thompson

*ImgMT: Wikipedia-based Dataset For Evaluating Text-in-Image Translation*
Šárka Uramová, Petar Petrov, Josef Jon, Ondřej Bojar and Michal Novák

*Doc2FRC: Length-Consistent Document-Level Machine Translation via Fixed-Range Chunking*
Xiaotian Wang, Youyuan Lin, Zhan Shen and Hitomi Yanaka

*Learning from Many Voices: Literary MT Using Multi-Reference Human and Synthetic Data*
Si Wu, John Wieting and David Smith

*Studying quantization trade-offs for efficient inference deployment in machine translation*
Jim Zhao, Sohir Maskey, Koen Oostermeijer, Douglas Orr and Teryn Jones

*Contrastive ESA: Human Evaluation of Multiple Translations at Once*
Vilem Zouhar, Roman Grundkiewicz, Sara Rajaee, Parker Riley, Rachel Bawden, Philipp Koehn, Marine Carpuat and Tom Kocmi

16:00 - 17:30 *Session 5 - Research Papers Posters*

**Thursday, October 29, 2026**

08:45 - 10:30 *Session 6 - Shared Task Overview Papers II*

*Findings of WMT 2026 shared task on Low-resource Indic Languages Translation*
Partha Pakray, Santanu Pal, Advaitha Vetagiri, Kshetrimayum Boynao Singh, Sandeep Dash, Arnab Maji, Saralin Lyngdoh, Lenin Laitonjam, Anupam Jamatia, Ajit Das, Sunita Warjri, Uzzal Sharma, Koj Sambyo and Riyanka Manna

*Findings of the WMT 2026 Shared Task on Low-Resource Arabic-Asian Language Translation*
Sahinur Rahman Laskar, Firoj Alam, Bishwaraj Paul, Irfan Ahmad, Maya Silvi Lydia and Pankaj Dadure

*Findings of the WMT26 Chinese–Southeast Asian Multilingual MT Shared Task*
Tianyu Dong, Ziyan Chen, Jingsong Liu and Shaolin Zhu

*Findings of the Second Shared Task for Creole Language Machine Translation, at WMT 2026*
Nathaniel Robinson, Ruth-Ann Armstrong, Claire Bizon Monroc, Rasul Dent, Pranav Gupta, Raj Dabre, Andre Coy and Kenton Murray

*Findings of the WMT 2026 Shared Task of the Open Language Data Initiative*
Laurie Burchell, David Dale, Jean Maillard, Idris Abdulmumin, Antonios Anastasopoulos, Isaac Caswell and Philipp Koehn

*Findings of the WMT26 Video Subtitle Translation Shared Task: Context and Candidate Selection Matter*
Zheng Li and Mao Zheng

*Findings of the WMT 2026 Shared Task: Multitask LLMs with Limited Resources*
Shu Okabe, Marion Di Marco, Kathy Haemmerl, Daryna Dementieva, Lukas Edman, Marko Měškank, Anita Hendrichowa and Alexander Fraser

10:30 - 11:00 *Coffee Break*

11:00 - 12:00 *Session 7 - Shared Task Posters II*

11:00 - 12:00 *Indic Translation Shared Task*

*LTRC_Plural: Better Data and Better Rewards for Low-Resource Indic MT*
Vishnuraj A, Yuvrajsinh Bodana, Heli Hingrajiya, Priyanka Dasari and Parameswari Krishnamurthy

*ADI-IITP: Reward-Guided Preference Optimization for Low-Resource English-Assamese Machine Translation*
Aditya Aditya and Asif Ekbal

*BVSLP: Enhancing Machine Translation through NMT Fine-Tuning, Back-Translation, and LLM-Assisted Synthetic Data Generation*
Palak Arora, Adhikarimayum Sharma, Mrityunjaya Indoria, Keneiwenuo Lhoungu, Lalthafamkimi Lalthafamkimi, Bharti Nathani and Nisheeth Joshi

*EROL: Transformer-Based Multilingual Translation for Northeastern Indian Language Pairs*
Laishram Thoibisana Devi and Grace Lee

*NLP-MT_Amrita: A RL-Inspired GRPO based Agentic RAG Framework for Manipuri and Bodo*
Kuruva Divya Sree and Deepa Gupta

*gators: BM25-Augmented Many-Shot Translation for Low-Resource North-Eastern Indian Languages*
Aashish Dhawan, Christopher Driggers-Ellis, Dzmitry Kasinets, Christan Grant and Zhe Wang

*AkibaNLP-TUT: Improving Low-Resource Machine Translation via Language-Specific and Length-Adaptive Noise Injection*
Takumi Kachi, Tomoyosi Akiba and Hajime Tsukada

*TIP-RBG-AI: Overcoming Orthographic Discrepancies via Algorithmic Translinear Pipelines and Phylogenetic Script Mapping*
Barathi Ganesh Hb, Michal Ptaszynski, Meenakshi Sharma and Jairam R

*MTG-LIRA: Scaling Neural Machine Translation for Low-Resource Indian Languages through Multilingual Learning and Synthetic Data*
Vedarth Hede, Neha Gupta, Harish Bapat and Harsh Ekbote

*PANINI: Improving Low-Resource English-Manipuri Translation in Two Scripts via rsLoRA and Three-Stream Self-Augmentation*
Rudali Huidrom, Vikas Kumar, Hoomexsun Pangsatabam, Pinaki Das, K. Kabi Khanganba, Nongmaithem Zeno, Nicholas Khumukcham, Mangalton Okram, Justice Konjengbam, Sai Jamalpoor, Alex Khangembam, Anand Konjengbam and Vikram Goyal

*ANVITA : Machine Translation System for Low-resource Indian Languages - Khasi, Nagamese and Tagin*
Siva J, Daneshwari Kankanwadi, Abhinav Gugulothu and Biswajit Paul

*SCE-KIIT: Fine-Tuning NLLB-200 for English-Nagamese Translation*
Agniva Maiti, Aarsh Muley and Sovan Sahoo

*SCE-KIIT: KokLLaMA: Cross-Task Adaptation for Low-Resource English–Kokborok Translation*
Agniva Maiti, Aarsh Muley and Sovan Sahoo

*KrenTransV0.1: Multi-Model Routing and Reranking for Low-Resource Northeast Indian Translation*
Badal Nyalang, Riya Tekcham and Biman Debbarma

*DELAB-IIITM WMT26: Full Fine-Tuning and LoRA-Based Adaptation for English-to-Low-Resource Indic Translation*
Dingku Oinam and Navanath Saharia

*Decepticons-IIITH : Morphology-Aware Lexicon Filtering of Back-Translated Data for Low-Resource English-to-Indic Translation*
Soujanya Rao, Sakhil Taneja, Krishna Chaitanya and Radhika Mamidi

*Winterpeg: Do Neural Cellular Automata Help Where Pretraining Ends?*
Sujay Rittikar and Sheela Ramanna

*An LLM-Driven Pipeline for Extremely Low-Resource English-to-Indic Translation — From Vocabulary Injection to Post-Training and Decoding*
Lu Ruan, Shaoying Jia, Fan Ning, Wei Wang, Zhengzhen Cai, Fei Hu, Heng Hu and Chenzi Wang

*JH_NLP_APAShreya2: LoRA Fine-Tuning of NLLB-200 for English–Manipuri Machine Translation at WMT 2026*
Aparajita Sinha, Monika Agarwal, Shreya Bhat, Shreya Bonal and Aryan Agrahari

*BRS-NK: Bidirectional Finetuning of NLLB-200 for Low-Resource Indic Languages: Assamese-English and Bodo-English Machine Translation*
Bipesh Subedi and Nischal Karki

*RozarNLP-cr7 at WMT 2026: LoRA-Fine-Tuned NLLB for Low-Resource Machine Translation in Northeastern Indian Languages*
Suyash Yadav, Utkarsh Chaudhary and Alapan Kuila

11:00 - 12:00 *Arabic-Asian Translation Shared Task*

*FARABI at WMT 2026: Post-Hoc Channel Controllers for Low-Resource Arabic–Asian Machine Translation*
Farizeh Aldabbas, Zyad Altahan, Hossam Elsafty and Rafet Sifa

*OpenBracket at WMT 2026: COMET-MBR System Combination over Arabic-Native and Multilingual Models for Low-Resource Arabic-English Translation*
Abrar Alotaibi

*BVSLP at WMT 2026: An Empirical Study of Multilingual Transfer for Low-Resource Arabic-Centric Translation*
Palak Arora, Syed Ahmed, Mansi Jangid, Bharti Nathani and Nisheeth Joshi

*MAGADIR at WMT 2026: Cross-System QE Re-ranking and Entity-Aware Selection for Low-Resource Arabic-English Translation*
Hossam Boudraa

*NCI-MT at WMT 2026: A Quality-Gated Cascade for Low-Resource Arabic-Asian Machine Translation*
Satarupa Deb and Prashanth Nayak

*MTG-LIRA at WMT 2026: Data-Centric Arabic-Hindi Machine Translation through Corpus Augmentation, Synthetic Parallel Data Generation and Transformer Models.*
Vedarth Hede, Neha Gupta, Harish Bapat and Harsh Ekbote

*IndicMT at WMT 2026: Full Fine-Tuning of NLLB-200-600M with Round-Trip Filtering and Forward Self-Training for Arabic-Asian Translation*
Pramit Jana, Arindam Adhikari, Priyobroto Acharya and Dipankar Das

*NERDS-NITS at WMT2026: Pivot-Based and Direct Neural Machine Translation for Arabic–Asian Low-Resource Language Pairs*
Misbahul Karim, Faruk Ahmed, Mishbahul Islam, Sahinur Laskar and Rabul Laskar

*NITM AI Lab at WMT 2026 Shared Task: Low-Resource Arabic-Asian Language Translation*
Nabin Koirala, Rhythm Bhetwal and Nurul Choudhury

*NLP-IIT Patna at WMT 2026: Corpus-Driven Adaptation of Multilingual MT Models for Low-Resource Arabic–Asian Machine Translation*
Pushkar Sharma, Mo Ahtasam, Kshetrimayum Boynao Singh, Deepak Kumar and Asif Ekbal

*UPES_NLP at WMT 2026 Low-Resource Arabic–Asian Machine Translation Shared Task: Arabic-Centric Machine Translation with NLLB-200-MOE and Prompt-Constrained Entity-Preserving Translation with GPT-5-mini*
Sumit Singh, Anish Vishwakarma, Brijmohan Sahu and Ashwani Kumar

*Code & Corpus at WMT 2026: Checkpoint-Pool Minimum Bayes Risk Decoding for Arabic-Hindi and Arabic-Bangla Translation*
Raman Yadav and Alapan Kuila

*SLPG_FJWU at WMT 2026: Domain Adapted Augmentation for Low-Resource Arabic-Asian Language Translation*
Shomaiza Zafar, Sadaf Abdul Rauf, Sheema Firdous, Muhammad Munir and Nadeem Fakhar

## Abstract

The adoption of large pre-trained multilingual models for neural machine translation (MNMT) faces a major challenge: excessive memory and computational consumption due to overly large vocabularies and embedding layers. Although existing compression methods like pruning, quantization and knowledge distillation reduce parameter redundancy, they mainly preserve the structure of the original vocabulary, leaving a major source of inefficiency unresolved. We propose in this paper a general optimization framework combining a vocabulary pruning method with a targeted fine-tuning protocol for MNMT models. We evaluate the proposed framework using three models (M2M100, NLLB-200, mBART-50) on the English-Arabic language pair. Our approach reduces the vocabulary size by 82-87% depending on the architecture, without any loss in performance. Results show that optimized multilingual models can match or exceed the performance of dedicated bilingual baselines. In particular, the pruned and fine-tuned M2M100 model achieves a competitive BLEU score of 42.04 (against 44.59 for the OPUS-MT-en-ar bilingual model) while it significantly outperforms it on the COMET metric (0.8730 vs 0.7911) revealing superior semantic adequacy and fluency.

## 1 Introduction

Large-scale Multilingual Neural Machine Translation models such as Facebook's M2M100 and NLLB-200 have transformed cross-lingual interaction by facilitating translation among hundreds of languages through a single architecture. These models have achieved state-of-the-art performance and significantly advanced zero-shot translation capabilities. However, to achieve high performance, they rely on massive parameter counts and require very large vocabularies (often exceeding 128,000 subword tokens), resulting in prohibitive memory footprints and inference latency, although most vocabulary entries remain inactive for any given language pair. While existing compression techniques such as quantization, and weight pruning have been extensively studied, they primarily focus on reducing model parameters rather than addressing the structural inefficiency introduced by large multilingual vocabularies. Moreover, most adaptation methods preserve the original vocabulary, thereby maintaining a high memory footprint even after compression. In practice, very few studies explicitly target the vocabulary size issue in large-scale MNMT systems, leaving an important gap in efficient multilingual model design.

In this paper, we propose a novel general optimization framework combining vocabulary pruning and targeted fine-tuning for MNMT: pruning retains only tokens relevant to a specific language pair, while fine-tuning allows the model to re-learn the optimal parameters configuration within the new vocabulary space.

We evaluate the proposed framework using three state-of-the-art multilingual models (M2M100, mBART-50, NLLB-200) for English-Arabic machine translation and the dedicated model OPUS-MT-en-ar as a baseline. Furthermore, we trained our models on both formal and hybrid (formal and informal) corpora, to explore the impact of data composition on the stability of pruned models. Our contributions include: (1) a minimalist architecture-agnostic framework for MNMT that is founded on vocabulary pruning, (2) extensive validation on English-Arabic translation using M2M100, mBART-50 and NLLB-200, obtaining scores comparable to or exceeding those obtained with a dedicated bilingual model, while reducing embedding-layer parameters by $\sim 82-87\%$, (3) an analysis of the synergy between vocabulary reduction and fine-tuning, showing that hybrid strategies combining formal and informal text are crucial for

maintaining model robustness after compression, outperforming models trained on single-register corpora.

## 2 Related work

### 2.1 Large-scale Multilingual Neural Machine Translation Models

Multilingual Neural Machine Translation (MNMT) builds on the NMT successes. MNMT's key innovation rests on leveraging a single shared model capable of translating between multiple languages instead of training a specific model for each targeted language pair (Firat et al., 2016; Johnson et al., 2017). The adoption of subword tokenization (Kudo, 2018), which provided an effective means of addressing the rare word problem in neural machine translation (Luong et al., 2015), has subsequently become an essential component of multilingual models by enabling a shared vocabulary across diverse languages and writing systems. The introduction of mBART (Liu et al., 2020) demonstrated the effectiveness of multilingual denoising pretraining for sequence-to-sequence translation for 25 languages. mBART-50 (Tang et al., 2020) extended this capability to a many-to-many setting, handling 50 languages without relying on English as an interlingua. M2M100 (Fan et al., 2021) scaled multilingual translation to 100 languages via a natively trained many-to-many architecture while NLLB-200 (Costa-Jussa et al., 2022) expanded this to 200 languages, achieving state-of-the-art results across diverse language families. These gains in quality and language coverage come at the cost of prohibitive memory requirements and computational overhead.

### 2.2 Model compression and domain adaptation

Extensive research has explored the use of compression techniques and adaptation strategies to improve the efficiency of large-scale multilingual neural translation models. Common approaches, including quantization (Zafrir et al., 2019; Shen et al., 2020; Mohammadshahi et al., 2022; Prato et al., 2020), weight pruning (See et al., 2016; Voita et al., 2019; Behnke and Heafield, 2020; Khan et al., 2021), layer pruning (Fan et al., 2019; Peer et al., 2022; Moslem et al., 2025) and knowledge distillation (Hinton et al., 2015; Kim and Rush, 2016; Tan et al., 2019) have been successfully applied to monolingual and multilingual models. Compressing multilingual models is not language-neutral, pruning and quantization can cause uneven degradation, particularly for low-resource languages (Mohammadshahi et al., 2022; Gaido et al., 2025; Palomino, 2026). Crucially, these methods leave embedding layers largely unchanged, which constitutes a structural bottleneck for multilingual models where shared vocabulary size often exceeds 128,000 tokens, contributing substantially to the memory footprint.

Domain adaptation via targeted fine-tuning is a well-established strategy for specializing multilingual models to specific language pairs, yet it typically preserves the full multilingual vocabulary. Vocabulary pruning, the direct reduction of the model's vocabulary by removing tokens irrelevant to a target language pair, is a less explored avenue in MNMT literature. L'Hostis et al. (2016) explored in earlier work vocabulary selection and pruning strategies for efficient NMT, in bilingual settings, but did not address the challenges introduced by large-scale multilingual models and shared cross-lingual vocabularies. Existing work has mainly investigated vocabulary trimming (Ushio et al., 2023; Dorkin et al., 2024) and the impact of BPE vocabulary trimming on translation quality (Cognetta et al., 2024). More recently (Jiang et al., 2026) proposed re-tokenizing a pruned vocabulary with embedding relearning, improving the performance on low-resource and non-latin scripts languages. Zhang et al.(2026)proposed VocabTailor, a dynamic vocabulary selection method that filters input and language-specific tokens at inference time rather than through a corpus-driven keep-set, achieving aggressive vocabulary reduction while matching or exceeding static pruning baselines on several tasks including machine translation. However, despite these efforts, combining domain adaptation with vocabulary reduction for pretrained multilingual translation models remains underexplored. Other parameter-efficient alternatives such as (Chronopoulou et al., 2023), address a related but distinct axis of efficiency, leaving the vocabulary itself untouched.

## 3 Methodology

Unlike common compression methods, our framework employs a deterministic pruning strategy that preserves weight alignment for non-embedding layers while removing only tokens irrelevant to the target language pair.

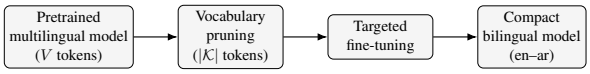

Figure 1: Overview of the proposed optimization framework: corpus-driven vocabulary pruning followed by targeted fine-tuning.

Our approach is motivated by two main observations. First, conventional compression methods target attention and feed-forward weights, leaving the vocabulary-dependent layer unchanged.Thus, substantial memory overhead remains in the input embedding and output projection matrices, whose size grows linearly with the multilingual vocabulary (Fan et al., 2021). However, for language-pair specific translation tasks, only a small portion of this shared vocabulary is actively utilized while the remaining embedding parameters continue to occupy memory throughout both fine-tuning and inference. This argues for vocabulary pruning as an orthogonal direction for compressing multilingual translation models. Second, large multilingual models jointly pretrained on hundreds of languages learn language-agnostic representations that provide stronger initialization for bilingual fine-tuning than training from scratch (Arivazhagan et al., 2019), suggesting that most multilingual knowledge resides in shared parameters rather than the exhaustive joint vocabulary.

Building on these observations, we propose an optimization framework for multilingual NMT articulated around two complementary sequential phases (Figure 1):

1. A corpus-driven vocabulary pruning phase, which reshapes the model's embedding space by retaining only tokens relevant to a given language pair, thus reducing the necessary memory without training from scratch.

2. A targeted fine-tuning protocol that adapts the pruned model to the language pair at hand, by learning an optimal new parameter configuration with the reduced vocabulary space.

This framework allows full exploitation of cross-lingual transfer inherited from massive pretraining, while overcoming hardware limitations. We validate our approach on three model families: M2M100, mBART-50 and NLLB-200, covering different model sizes and tokenization strategies.

### 3.1 Corpus-driven vocabulary pruning

Our approach performs structural compaction of the pretrained model's embedding space by retaining only parameters associated with tokens observed in the target training data. Unlike approaches relying on sparse masks or internal layer modifications, we implement a five-stage pipeline that executes exact row-wise slicing operations. This process transforms the original vocabulary dimension $V$ into a task-relevant subset $|\mathcal{K}|$, starting from corpus-driven token identification to in-place tensor updates and runtime tokenizer remapping.

**Stage 1: Corpus-driven token collection.** We randomly sample $N$ sentence pairs from the training corpus (default $N = 150{,}000$), sized to ensure vocabulary coverage for the target language pair. Both the source and target texts are tokenized using the original pretrained tokenizer. The union of all token IDs appearing in at least one tokenized sentence is collected into a set $\mathcal{C}$:

$$\mathcal{C} \;=\; \bigcup_{i=1}^{N} \Big( \mathrm{tok}(S_i) \,\cup\, \mathrm{tok}(T_i) \Big),$$

where $S_i$ and $T_i$ denote the source and target sentences of pair $i$, respectively. This empirical harvest ensures that the retained vocabulary reflects actual usage patterns rather than predetermined selection thresholds. We validate this empirically in Section 4.5: across 83,000 held-out sentences that the trimmer never saw, at least 99.6% of Arabic tokens survive the pruned vocabulary, and even word types entirely unseen in the pruning corpus, including dialectal ones, decompose into retained productive subwords with at least 98.5% full coverage.

**Stage 2: Mandatory token preservation.** Special tokens that must survive pruning, including padding (PAD), end-of-sentence (EOS), beginning-of-sentence (BOS), and unknown (UNK)— are preserved independently of corpus frequency. Additionally, all language-tag tokens required for proper model routing (e.g. `__ar__`, `arb_Arab`, `ar_AR`) are collected into a set $\mathcal{M}$. The final keep-set $\mathcal{K}$ and its sorted ID mapping are defined as:

$$\mathcal{K} \;=\; \mathcal{C} \cup \mathcal{M}, \qquad \phi : \{0, \ldots, |\mathcal{K}| - 1\} \;\xrightarrow{\sim}\; \mathcal{K}.$$

This guarantees functional integrity after aggressive vocabulary reduction.

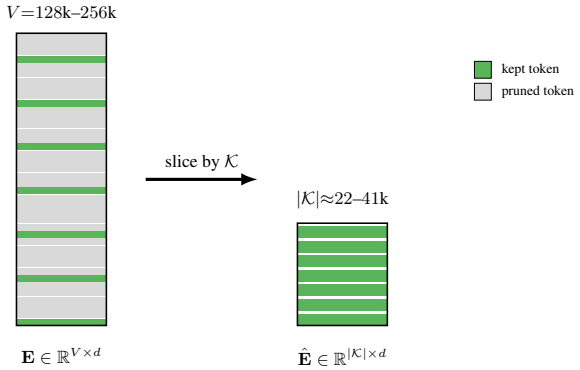

Figure 2: Row-wise slicing of the embedding matrix: only rows corresponding to the corpus-driven keep-set $\mathcal{K}$ (Stages 1–2) are retained when constructing the compacted embedding $\hat{\mathbf{E}}$ (Stages 3–4). The kept set amounts to 13–18% of the original vocabulary ($V = 128{,}104$ for M2M100, $250{,}054$ for mBART-50, $256{,}206$ for NLLB-200 600M; $|\mathcal{K}| = 22{,}535$, $31{,}969$ and $40{,}952$ respectively).

**Stage 3: Weight extraction before resizing.** The embedding matrix $\mathbf{E} \in \mathbb{R}^{V \times d}$ and the language-model head $\mathbf{W} \in \mathbb{R}^{V \times d}$ are indexed by $\mathcal{K}$ *while they are still at their original size* $V$, producing sliced copies

$$\hat{\mathbf{E}},\ \hat{\mathbf{W}} \ \in \ \mathbb{R}^{|\mathcal{K}| \times d}.$$

Extracting weights before resizing is critical: resizing first would invalidate any index $\geq |\mathcal{K}|$, leading to incorrect weight extraction or misaligned embeddings.

**Stage 4: In-place resize and weight injection.** The model's embedding matrices are resized to the new vocabulary cardinality $|\mathcal{K}|$ via `resize_token_embeddings(`$|\mathcal{K}|$`)`. The extracted matrices $\hat{\mathbf{E}}$ and $\hat{\mathbf{W}}$ are then written back to their corresponding positions. Model configuration parameters (`vocab_size`, `pad_token_id`, `eos_token_id`) are updated to reflect the reduced vocabulary, and any weight tying between encoder and decoder embeddings is re-established.

**Stage 5: Remapped tokenizer wrapper.** Since the on-disk SentencePiece vocabulary retains its original cardinality $V$, we construct a lightweight `RemappedTokenizer` wrapper that intercepts the primary tokenization and detokenization entry points (encoding and decoding). The forward map $\phi^{-1}$ converts external token IDs to internal indices during encoding, while the reverse map $\phi$ performs the inverse conversion during decoding. This allows the trimmed model to be used through the standard tokenizer interface for most inference code, though batched tensor-level remapping in performance-sensitive paths accesses the wrapper's internal lookup tensor directly.

The resulting trimmed models retain only tokens observed in the English–Arabic corpus, reducing the embedding layer by approximately 82-87% with a corresponding decrease in GPU memory footprint.

### 3.2 Targeted fine-tuning protocol and adaptation operations

Vocabulary pruning alters the token-ID embedding space by removing discarded token representations. While retained embeddings preserve their local semantics, the language model head and decoder must adapt to the remapped, lower-dimensional categorical distribution. Without adaptation, this induces systemic errors: softmax probabilities become skewed by unchanged weight magnitudes on remaining tokens (logits calibration), and training dynamics shift given the altered gradient flow through smaller embedding matrices (cross-entropy convergence). To address these issues and maintain steady generation outputs, we introduce an immediate targeted fine-tuning phase within our framework. The fine-tuning protocol uses supervised learning on task-specific parallel corpora, enabling the model to re-optimize its parameter configuration within the constrained lexical space while preserving beneficial cross-lingual representations inherited from pretraining.

## 4 Experiments and Discussion

In this section, we validate our proposed optimization framework on the English-Arabic machine translation task. We have chosen this language pair for three key reasons:

1. Arabic morphological richness makes it a stringent test case for compression methods.

2. Both languages are well represented in multilingual pretraining corpora, enabling fair zero-shot comparisons.

3. Existing bilingual baselines provide strong reference points for evaluating pruned model performance.

Below, we detail our experimental configuration, evaluation protocols and results across three state-of-the-art multilingual architectures.

### 4.1 Experimental Setup

**Data.** Two training corpus configurations are evaluated: 200,000 parallel sentence pairs from MultiUN (Eisele and Chen, 2010), representing formal diplomatic discourse and a second configuration augmenting this with heterogeneous OPUS-100 text (Tiedemann, 2012), to expose the pruned vocabulary to higher lexical entropy and informal register. Both configurations pass through a deterministic filtering pipeline removing anomalous pairs, alignment corruptions, and over-length sequences. Evaluation uses a held-out partition of 1,500 MultiUN test segments.

**Training configuration.** All models are fine-tuned for 5 epochs with a linear learning rate decay (500 warm-up steps, peak $\eta = 2 \times 10^{-5}$), an effective batch size of 512 (16 samples/device $\times$ 8 gradient-accumulation steps $\times$ 4 GPUs via Hugging Face Accelerate), and FP16 mixed precision. Gradient checkpointing and an 8-bit quantized AdamW optimizer (Dettmers et al., 2022) keep training within workstation-grade memory constraints, consistent with the $\sim$82-87% embedding-layer reduction from pruning.

**Baselines.** We compare against three reference points:

(a) The original multilingual checkpoints evaluated zero-shot, establishing the pre-fine-tuning ceiling for each architecture.

(b) The trimmed-only variants of each architecture, which serves to isolate the baseline impact of vocabulary reduction before any training occurs.

(c) *OPUS-MT-en-ar*, a dedicated bilingual model serving as a baseline trained exclusively English–Arabic.

### 4.2 Evaluation framework and main translation results

#### 4.2.1 Evaluation framework

Performance is measured on a strictly held-out partition (1,500 segments from the MultiUN test set) using four complementary metrics: **BLEU** (Papineni et al., 2002), **chrF++** (Popović, 2015),**TER** (Snover et al., 2006), and **COMET** (Rei et al., 2020). Using both surface-level (BLEU, chrF++) and meaning-based (COMET) evaluations allows us to distinguish between superficial token matching and genuine translation quality, an essential consideration for morphologically rich targets like Arabic, where BLEU may penalize fluent but lexically divergent outputs.

Table 1: Translation results for English → Arabic. All fine-tuned and trimmed models use the vocabulary pruning framework described in Section 3.1. COMET scores: range 0–1. TER: lower is better (↓).

| Condition | Training Data | System | BLEU | chrF++ | TER ↓ | COMET |
|---|---|---|---|---|---|---|
| FINE-TUNED | MultiUN | M2M100 | 42.04 | **58.81** | **51.55** | 0.8730 |
| | | mBART-50 | 39.84 | 57.47 | 52.88 | **0.8742** |
| | | NLLB-200 600M | 37.70 | 55.79 | 55.04 | 0.8640 |
| | MultiUN + OPUS-100 | M2M100 | 39.55 | 57.23 | 53.27 | 0.8680 |
| | | mBART-50 | 36.73 | 55.09 | 55.02 | 0.8663 |
| | | NLLB-200 600M | 35.51 | 54.26 | 56.82 | 0.8589 |
| | OPUS-100 | M2M100 | 36.98 | 55.34 | 55.25 | 0.8609 |
| TRIMMED | — | NLLB-200 600M | 26.43 | 48.07 | 64.03 | 0.8418 |
| | | M2M100 418M | 24.95 | 46.64 | 65.09 | 0.8371 |
| | | mBART-50 | 13.65 | 31.70 | 80.77 | 0.7477 |
| BASELINE | — | NLLB-200 Distilled 600M | 26.82 | 48.44 | 62.91 | 0.8452 |
| | | M2M100 418M (Original) | 24.86 | 46.62 | 65.16 | 0.8372 |
| | | mBART-50 (Original) | 13.67 | 31.44 | 80.98 | 0.7452 |
| Comparison | Bilingual | *OPUS-MT-en-ar* | **44.59** | 58.77 | 58.59 | 0.7911 |

#### 4.2.2 Main Translation Results

Table 1 reports the translation performance of all evaluated configurations across four metrics. We group results into four conditions: fine-tuned models (pruned then fine-tuned), trimmed-only models, the original unmodified checkpoints as zero-shot baselines, and the dedicated bilingual OPUS-MT-en-ar model.

**Fine-tuned models.** The fine-tuned M2M100 trained on MultiUN achieves the highest BLEU (42.04) and chrF++ (58.81) among all systems, demonstrating that the pruning–fine-tuning pipeline successfully recovers and improves upon the original multilingual capabilities for the English–Arabic pair. The mBART-50 fine-tuned variant achieves the highest COMET score (0.8742), despite a slightly lower BLEU. The hybrid MultiUN + OPUS-100 training data consistently underperforms the MultiUN-only variant on the formal test set, which is expected given that the evaluation domain (MultiUN) matches the formal training data. However, the hybrid strategy is expected to offer better robustness on out-of-domain text, a hypothesis explored further in the error analysis below. NLLB-200 fine-tuned achieves a competitive 37.70 BLEU despite a far larger original vocabulary (256,000 tokens), suggesting pruning is effective across different model scales and tokenizer designs.

**Trimmed-only models.** Trimming alone without subsequent fine-tuning degrades performance sub-

stantially across all architectures. Notably, NLLB-200 trimmed (BLEU 26.43, COMET 0.8418) and M2M100 trimmed (BLEU 24.95, COMET 0.8371) both remain competitive with the zero-shot baseline (BLEU 26.82, COMET 0.8452), demonstrating that vocabulary pruning alone does not catastrophically destroy translation capability. The mBART-50 trimmed variant is the exception, collapsing to BLEU 13.65 and COMET 0.7477, which we attribute to the architecture's stronger coupling between the decoder embedding and the language-model head, a coupling more severely disrupted by the remapping of token IDs.

Results from Table 1 confirm that the combination of vocabulary pruning and fine-tuning is essential. The pruning step reduces embedding-layer size by approximately 82-87% while the fine-tuning step recovers and improves translation quality, with the best system matching or exceeding dedicated bilingual baselines at a fraction of the memory cost. We additionally compare against a few-shot instruction-tuned LLM baseline (Aya-8B); see Appendix D.

Table 2: Out-of-domain translation results for English → Arabic on FLORES-200 devtest ($n = 1{,}012$ segments). All fine-tuned and trimmed models use the vocabulary pruning framework described in Section 3.1. TER: lower is better (↓). COMET not computed.

| Condition | Training Data | System | BLEU | chrF++ | TER ↓ |
|---|---|---|---|---|---|
| FINE-TUNED | MultiUN | M2M100 | 24.79 | 44.62 | 68.12 |
| | | mBART-50 | 22.09 | 42.87 | 67.90 |
| | | NLLB-200 600M | **27.83** | **48.25** | 64.11 |
| | MultiUN + OPUS-100 | M2M100 | **26.02** | 46.27 | 65.58 |
| TRIMMED | — | NLLB-200 600M | **29.47** | **49.81** | **60.19** |
| | | mBART-50 | 21.19 | 42.25 | 67.01 |

**Out-of-domain robustness.** To assess whether the pruning–fine-tuning framework generalizes beyond MultiUN formal register, we re-evaluate a subset of our strongest checkpoints on FLORES-200 devtest (Goyal et al., 2022; Costa-Jussa et al., 2022), a Wikipedia-domain benchmark with no overlap with MultiUN. Table 2 reports these results, read for relative ordering rather than direct comparison with Table 1. As an external reference, the NLLB-200 paper reports English → Arabic spBLEU scores in the low-to-mid 30s on this benchmark for their full-scale, non-pruned production model, averaged across Arabic dialect directions (Costa-Jussa et al., 2022). Our trimmed-only NLLB-200 600M checkpoint (29.47 BLEU) falls within this range despite being smaller with no domain fine-tuning, suggesting that pruning alone preserves most of general-domain competence. The mBART-50 models, our weakest systems (21.19–22.09 BLEU), sit roughly ten points below this reference, indicating greater competence loss for this architecture. The MultiUN + OPUS-100 fine-tuned M2M100 also outperforms its MultiUN-only counterpart here (26.02 vs 24.79 BLEU, 46.27 vs 44.62 chrF++), reversing the in-domain ranking and supporting our hypothesis that informal data exposure improves out-of-domain robustness at an in-domain cost. More strikingly, the trimmed-only NLLB-200 model (no fine-tuning) achieves the best FLORES-200 score overall (29.47 BLEU) surpassing its own fine-tuned counterpart (27.83 BLEU). This suggests that narrow-domain fine-tuning trades cross-domain generalization for in-domain specialization, while pruning alone better preserves pretrained multilingual representations. mBART-50 shows the opposite pattern, with fine-tuning still improving over the trimmed variant (22.09 vs 21.19 BLEU), consistent with its greater sensitivity to vocabulary remapping already noted in Table 1. We emphasize that this out-of-domain evaluation covers a subset of the configurations in Table 1, focused on the strongest MultiUN fine-tuned and trimmed-only systems; a full out-of-domain sweep across all training-data compositions and architectures is left for future work.

### 4.3 Confidence Intervals

Table 3 reports 95% bootstrap confidence intervals for the best fine-tuned system and the dedicated bilingual baseline. Intervals were produced using 1,000 bootstrap resamples over 1,500 test segments. Because BLEU is a non-linear corpus-level metric, bootstrap resampling systematically underestimates its true corpus-level value (Koehn, 2004). We therefore derive interval half-widths from the bootstrap distribution and re-centre them on the corpus-level point estimate. chrF++ and TER, being approximately linear at the segment level, require no such correction: their bootstrap means coincide with the point estimates to within rounding error.

The confidence intervals reveal two important findings. First, the BLEU gap between OPUS-MT-en-ar (44.59) and M2M100 (MultiUN) (42.04) is real but modest: the intervals do not overlap, con-

Table 3: 95% bootstrap confidence intervals (1,000 resamples, $n = 1,500$). Bounds are centred on the corpus-level point estimate; half-widths are taken from the bootstrap distribution. TER: lower is better (↓).

| System | BLEU [95% CI] | chrF++ [95% CI] | TER↓ [95% CI] |
|---|---|---|---|
| M2M100 (MultiUN) | 42.04 [40.87 – 43.22] | 58.81 [57.91 – 59.71] | 51.55 [50.30 – 52.80] |
| OPUS-MT en-ar (baseline) | 44.59 [43.20 – 45.98] | 58.77 [57.79 – 59.75] | 58.59 [57.11 – 60.07] |

firming a statistically significant difference on this metric. Second, the chrF++ scores are statistically indistinguishable (58.81 vs 58.77, with overlapping CIs), and M2M100 (MultiUN) substantially outperforms OPUS-MT-en-ar on TER (51.55 vs 58.59, non-overlapping intervals). Combined with the COMET advantage of M2M100 (MultiUN) (0.8730 vs 0.7911), this suggests that the bilingual model's BLEU lead is driven primarily by surface n-gram alignment with the MultiUN reference style, while the pruned multilingual model produces semantically superior and more fluent translations as captured by the meaning-based metrics.

### 4.4 Segment-Level Error Analysis (M2M100 Models)

To complement the corpus-level metrics reported above, we conduct a fine-grained segment-level analysis on the two M2M100 fine-tuned variants: M2M100 (MultiUN) and M2M100 (MultiUN + OPUS-100). Both models were re-run on 500 held-out test segments and evaluated at the sentence level using chrF++, which we bucket into three quality tiers: *good* ($\geq 50$), *medium* (25–50), and *poor* ($< 25$). We additionally flag empty outputs and token-level repetition, both of which are known failure modes for Arabic NMT. Analyses comparing the two fine-tuned variants use this 500-segment subset throughout; control analyses involving only M2M100 (MultiUN) and the untrimmed baseline use the full 1,500-segment test set.

**Score distribution.** Table 4 summarises the quality distribution for both models. M2M100 (MultiUN) achieves a higher proportion of good segments (69.2% vs 66.4%) and an identical poor rate (3.6%) compared to the hybrid variant. The average segment chrF++ is 59.27 vs 57.56, consistent with the corpus-level gap in Table 1. Critically, neither model produces any empty or repetitive outputs across 500 segments, confirming that the vocabulary pruning procedure does not introduce pathological decoding failures.

Table 4: Segment-level quality distribution for M2M100 fine-tuned variants (500 test segments, chrF++ buckets: good $\geq 50$, medium 25–50, poor $< 25$).

| Model | Avg chrF++ | Good (%) | Medium (%) | Poor (%) | Empty | Repetitive |
|---|---|---|---|---|---|---|
| M2M100 (MultiUN) | 59.27 | 69.2 | 27.2 | 3.6 | 0 | 0 |
| M2M100 (MultiUN + OPUS) | 57.56 | 66.4 | 30.0 | 3.6 | 0 | 0 |

**Length bucket analysis.** Table 5 breaks down performance by source sentence length. Across both models a consistent and counter-intuitive pattern emerges: *long* sentences ($\geq 35$ tokens) attain a lower poor rate than short sentences ($\leq 15$ tokens). This reflects the nature of MultiUN: long diplomatic sentences follow predictable, formula-heavy syntax well covered by training data, while short segments often consist of citations, proper nouns, or abbreviations underrepresented in the vocabulary.

Table 5: Segment performance by source length bucket. Short: $\leq 15$ tokens; medium: 16–34; long: $\geq 35$.

| Model | Length bucket | Count | Avg chrF++ | Poor (%) |
|---|---|---|---|---|
| M2M100 (MultiUN) | Short ($\leq 15$) | 125 | 60.97 | 5.6 |
| | Medium (16–34) | 234 | 58.57 | 3.8 |
| | Long ($\geq 35$) | 141 | 58.94 | 1.4 |
| M2M100 (MultiUN + OPUS) | Short ($\leq 15$) | 125 | 58.77 | 7.2 |
| | Medium (16–34) | 234 | 56.77 | 3.0 |
| | Long ($\geq 35$) | 141 | 57.80 | 1.4 |

The hybrid (MultiUN + OPUS) model shows an elevated poor rate for short segments (7.2% vs 5.6%) but a lower poor rate for medium segments (3.0% vs 3.8%), suggesting that exposure to the stylistically diverse OPUS-100 data slightly destabilises performance on the short formal fragments characteristic of the MultiUN domain while marginally improving fluency on moderately-length sentences.

**Pruning versus corpus effects.** To disentangle pruning from corpus properties, we evaluate the untrimmed M2M100-418M baseline (full 128k vocabulary, no fine-tuning) on the full 1,500-segment test set. It exhibits the same length-dependent pattern, and more strongly: poor rate falls from 13.9% (short) to 3.4% (long) versus 6.0% to 2.9% for the pruned and fine-tuned model. Since the untrimmed model has zero pruning exposure, this reflects contextual redundancy rather than vocabulary removal: source-side type–token ratio falls from 0.97 (short) to 0.78 (long), showing that longer sentences are lexically more repetitive and thus easier to translate correctly, independently of vocabulary size.

**Rare-form parity test.** We further test whether the length effect masks a bias against rare Ara-

bic morphology. Tagging test segments whose reference contains at least one word type from the bottom 5% frequency tail of the fine-tuning corpus (27% of segments overall, rising to 42% of long segments), we find that rare-form segments in the long bucket are not poorer than other long segments (3.5% vs 2.5% poor rate, $z$-test $p = 0.58$). Rare-form segments do show elevated poor rates in the short (14.3% vs 4.4%, $p = 0.003$) and medium (5.9% vs 1.7%, $p = 0.003$) buckets, but the untrimmed baseline shows a comparable medium-bucket penalty (7.1% vs 3.2%, $p = 0.03$), indicating that this penalty reflects inherent task difficulty (consistent with the citation and proper-noun cases identified in our qualitative error taxonomy below) rather than an artefact of vocabulary pruning. In other words, given sufficient context, rare morphology is not a distinct failure mode for either the pruned or the full-vocabulary model.

**Output length ratio and head-to-head comparison.** Neither model exhibits systematic over- or under-generation (average ratios of 0.97 and 0.96 with under 1% of segments showing severe lenght mismatch). Aligning the 500 matched segments across both variants, M2M100(MultiUN) scores higher on 246 segments (49.2%) versus 174 (34.8%) for the hybrid variant, with 80 ties. The formal model's largest wins ($\Delta$chrF++ $> 10$ on 55 segments) concentrate on long institutional passages with direct MultiUN coverage, while the hybrid variant's advantages (23 segments) concentrate on medium-length, informally phrased segments, consistent with OPUS-100 exposure.

**Qualitative error taxonomy.** Inspecting worst-performing segments reveals three recurring error types. First, *bibliographic leakage*: segments consisting of partial citations (e.g. "(3) of the commentary to article 12, p. 126") are frequently transliterated rather than rendered in Arabic script, yielding near-zero chrF++ scores. These segments expose a gap between the multilingual formal register of MultiUN prose and the parenthetical citation style it occasionally embeds. Second, *reference mismatch*: certain references point to text that is substantially different in the Arabic side (e.g. the source discusses one topic while the reference Arabic sentence discusses a completely different subject), inflating the apparent error count for otherwise fluent translations. Third, *domain shift in short proper nouns*: place names, personal names, and institution acronyms (e.g. "Vanuatu", "N.P.D.D.") tend to be transliterated in the hypothesis but transcribed differently in the reference, penalising chrF++ despite producing pragmatically correct output. These findings reinforce two practical recommendations: (i)complement formal-register fine-tuning data with citation- and entity-specific augmentation to close the short-segment gap, and (ii)give COMET significant weight alongside BLEU for Arabic NMT evaluation, as it is less sensitive to the reference-mismatch artefacts described above.

### 4.5 Pruning validity on held-out data

Section 4.4 shows that vocabulary pruning does not, by itself, explain the length-dependent and rare-form error patterns observed on the MultiUN test set. To directly address whether corpus-driven pruning introduces a bias against productive but infrequent Arabic forms, and to explicitly validate the pruning strategy on rare morphology, clitic combinations, dialectal variation, named entities and domain-specific terminology, we conduct a dedicated coverage and challenge-set audit on data that was never used for pruning or fine-tuning.

**Held-out corpora.** We use three held-out sources, none overlapping with pruning or fine-tuning data. The first is the FLORES-200 devtest set ($n$ = 1,012, Section 4.2). The second is a purpose-built 2,000 challenge set spanning eight linguistic categories: `rare_morph` (bottom 5% frequency tail), `clitic` (stacked proclitics/enclitics, regex identified), `ner` (spaCy-tagged named entities), `domain_term` (log-odds distinctive terms vs. MultiUN), and four AraBench-sampled dialects. The third source is the full AraBench test split ($n = 80{,}413$), used only for the coverage audit, full construction details, including decontamination and filtering criteria are given in Appendix A.

**Vocabulary coverage audit.** For each corpus, we tokenize the Arabic references with the original pretrained tokenizer and measure token/type representability after pruning. Coverage is detailed further in Appendix B (Table 6). Retained-token rates reach 99.9%, 99.8% and 99.6% for FLORES, the challenge set and AraBench respectively, with $\sim$96% of sentences per corpus tokenizing with zero pruned tokens. Of the 105,569 removed token IDs, all were hapax or entirely unseen in the pruning corpus, accounting for only 138 occurrences across

FLORES and challenge-set sentences combined, and 3,763 across AraBench.

**Frequency-stratified bias test.** Table 6 (Appendix B) bins held-out Arabic word types by pruning corpus frequency and confirms coverage is essentially flat: every bin with non-zero frequency reaches 100% coverage, and even entirely unseen word types (bin 0) are covered at 98.5–98.8%, including under the maximal distributional shift of dialectal AraBench (57,469 of 70,433 held-out types unseen by construction). This is consistent with the subword solution to the rare-word problem (Luong et al., 2015): rare and unseen word types remain representable because they decompose into retained stems, clitics and affixes, rather than being individually preserved.

**Challenge-set translation results.** Table 7 (Appendix C) reports BLEU, chrF++, TER and COMET for the pruned and fine-tuned M2M100 (MultiUN) model on each challenge category. The three mined formal categories (clitics, `domain-term`, ner), all meet or exceed the FLORES out-of-domain reference (24.79 BLEU); with COMET $\geq 0.78$, indicating no category collapses. The `rare_morph` slice is harder (16.59 BLEU) -expected given its bottom-tail composition- but since these forms remain fully representable in $\mathcal{K}$ (coverage audit above), the gap reflects content unfamiliarity rather than vocabulary removal. The dialectal slices score lowest (BLEU 4.7–8.3), consistent with the model being fine-tuned to produce MSA while the references are dialectal, the same surface-level mismatch any MSA-trained system exhibits against dialectal references. This aligns with human evaluation findings from the WMT 2025 general translation shared task (Kocmi et al., 2025) which reported persistent difficulties in producing Egyptian dialect, with several systems defaulting to MSA-like outputs instead. This BLEU/COMET divergence echoes a broader finding from from the WMT 2025 on automated translation evaluation shared task (Lavie et al., 2025) which found automatic metrics particularly unreliable across linguistically diverse targets, reinforcing our reliance on COMET alongside BLEU for the dialectal categories. COMET nonetheless stays at 0.68–0.74, and the AraBench audit (98.8% coverage of unseen word types) confirms that the pruned vocabulary itself can represent dialectal morphology. Dialect handling therefore appears to be a register mismatch orthogonal to pruning (see Limitations). Taken together, these results confirm that pruning does not systematically penalize infrequent Arabic forms: the two-lowest scoring categories reflect content unfamiliarity and register mismatch, not vocabulary size.

## 5 Conclusion

We have presented in this paper a minimalist, yet powerful, two-stage framework for efficient multilingual NMT that combines corpus-driven vocabulary pruning with targeted fine-tuning. Applied to M2M100, mBART-50, and NLLB-200 on the English–Arabic translation task, our approach achieves approximately 82-87% reduction in embedding-layer size while matching or exceeding the performance of the uncompressed baselines. The best pruned M2M100 fine-tuned on MultiUN, outperforms the zero-shot baseline by more than 15 BLEU points and approaches dedicated bilingual model at a substantially lower memory cost. A dedicated coverage and challenge-set audit further shows that pruning preserves near-total vocabulary coverage across frequency bins, including on rare morphology, clitic combinations, named entities, domain terminology and dialectal Arabic never seen during pruning or fine-tuning. Segment-level analysis shows robust long-sentence performance and no empty or repetitive outputs on M2M100 variant. The main remaining challenge lies in short segments containing bibliographic references, proper nouns, and domain-specific abbreviations, which are failure modes independent of the pruning procedure and call for targeted data augmentation.

Future work will explore extending the pruning framework to larger model variants applying the approach to additional language pairs with non-Latin scripts, and integrating structured knowledge distillation to further reduce the parameter count of the attention layers beyond what vocabulary pruning alone achieves. We also plan to investigate entity-preserving strategies, such as NER-guided vocabulary retention, to mitigate failure modes on proper nouns, citations and domain-specific abbreviations identified in our error analysis.

## Limitations

While our approach is applicable to any language pair, it has been validated on the single English-Arabic pair. We selected this pair due to the Arabic's morphological complexity and non-latin

script, providing a rigorous testbed. Although the methodology is transferable, further evaluation on diverse language families is required to determine whether the reported gains generalize across model architectures and tokenization schemes. Furthermore, the corpus-driven pruning strategy can, in principle, lead to performance degradation on rare entities (e.g. proper nouns, citations) absent from the training data. Our coverage audit (Section 4.5) shows that pruning removes almost exclusively hapax or entirely unseen tokens, with 99.6–99.9% held-out token retention and flat coverage across frequency bins, including 98.8% coverage of 57,000 dialectal word types never seen in the training corpus. The residual degradation we do observe is confined to content that is genuinely absent from training (proper nouns, citations) and to register mismatch (dialectal targets against an MSA-trained model), both of which are orthogonal to vocabulary removal: the full-vocabulary baseline exhibits the same rare-form penalty on medium-length segments (Section 4.4), and the dialect slices of our challenge set show a comparable COMET range (0.68–0.74) to the model's other out-of-domain results despite very low BLEU (4.7–8.3), consistent with an MSA/dialect surface mismatch rather than a vocabulary-coverage failure. Targeted entity-preserving strategies, such as NER-guided vocabulary retention, remain a promising mitigation, and dialect-aware fine-tuning is left to future work. Finally, we observe a trade-off between in-domain specialization and generalization: models fine-tuned exclusively on formal data (MultiUN) showed slight degradation on general domain text (FLORES-200) compared to hybrid (MultiUN and OPUS) variant while the latter exhibited reduced in-domain performance. This suggests that balancing training data composition is essential to maintain cross-domain adaptability alongside memory optimization.

## A Held-Out Corpus Construction

This appendix details the construction of the three held-out sources used in the coverage and challenge-set audit (Section 4.5), none of which overlaps with the pruning or fine-tuning data.

The first source is the FLORES-200 devtest set ($n = 1{,}012$), already introduced in Section 4.2. The second is a purpose-built challenge set of 2,000 segments (250 per category) spanning eight categories chosen to probe specific linguistic phenomena: `rare_morph` (target sentences drawn from the bottom 5% frequency tail of the fine-tuning corpus), `clitic` (target sentences with stacked Arabic proclitics and enclitics, identified with a regex heuristic), `ner` (source sentences containing named entities, tagged with a spaCy NER model), `domain_term` (source sentences whose English terms are lexically distinctive relative to the MultiUN training corpus by a log-odds criterion), and four dialect categories (`dialect_egyptian`, `dialect_gulf`, `dialect_levantine`, `dialect_maghrebi`) sampled from the AraBench test split. The first four categories are mined from the FLORES dev/devtest and OPUS-100 test pools; the dialect categories are drawn from an 80,000-sentence AraBench pool. An exact-match decontamination check against the prepared MultiUN train, development and test partitions removed 15 overlapping candidates, and all mined sentences pass a minimum-length quality filter (at least four words on both sides).

The third source is the full AraBench test split ($n = 80{,}413$), used only for the coverage audit given its size.

Because the challenge set concentrates hard phenomena by construction, its overall score sits below the general out-of-domain FLORES result (21.54 vs 24.79 BLEU). It should therefore be read relatively, as a test of whether any category collapses below what general out-of-domain difficulty alone would predict, rather than as an absolute measure of translation quality.

## B Vocabulary Coverage Details

For each held-out corpus (Appendix A), we tokenize the Arabic references with the original pretrained tokenizer and measure token- and type-

level representability after pruning. Retained-token rates reach 99.9%, 99.8% and 99.6% for FLORES, the challenge set and AraBench respectively, with $\sim$96% of sentences per corpus tokenizing with zero pruned tokens. Table 6 stratifies coverage by word-type frequency in the pruning corpus.

Table 6: Coverage of held-out Arabic word types by the pruned vocabulary, stratified by frequency in the pruning corpus (bin 0 = unseen in the pruning corpus). Coverage is the percentage of word types that decompose entirely into retained subwords.

| | FLORES | | Challenge | | AraBench | |
|---|---|---|---|---|---|---|
| **Corpus-freq bin** | **Types** | **% cov.** | **Types** | **% cov.** | **Types** | **% cov.** |
| 0 (unseen) | 3108 | 98.71 | 5191 | 98.54 | 57 469 | 98.82 |
| 1 | 617 | 100.00 | 907 | 100.00 | 2530 | 100.00 |
| 2–5 | 1048 | 100.00 | 1106 | 100.00 | 3057 | 100.00 |
| 6–20 | 1290 | 100.00 | 1247 | 100.00 | 2681 | 100.00 |
| 21–100 | 1629 | 100.00 | 1620 | 100.00 | 2527 | 100.00 |
| >100 | 1937 | 100.00 | 2077 | 100.00 | 2169 | 100.00 |

## C Challenge-set Translation Results

Table 7 reports BLEU, chrF++, TER and COMET for the pruned and fine-tuned M2M100 (MultiUN) model on each challenge category, together with the overall score on the full 2,000-segment set.

Table 7: Challenge-set translation results for M2M100 (MultiUN, pruned and fine-tuned), 250 segments per category except Overall (2,000). TER: lower is better (↓). Reference points: MultiUN in-domain test BLEU 42.04 / COMET 0.8730 (Table 1); FLORES out-of-domain BLEU 24.79 (Table 2).

| **Category** | **BLEU** | **chrF++** | **TER ↓** | **COMET** |
|---|---|---|---|---|
| **Overall (2,000)** | **21.54** | **40.19** | **79.02** | **0.747** |
| clitic | 28.57 | 49.69 | 70.02 | 0.805 |
| domain_term | 28.69 | 47.89 | 65.14 | 0.792 |
| ner | 26.45 | 45.35 | 67.97 | 0.788 |
| rare_morph | 16.59 | 34.14 | 86.03 | 0.741 |
| dialect_egyptian | 8.18 | 24.96 | 94.15 | 0.744 |
| dialect_gulf | 8.29 | 26.07 | 101.34 | 0.732 |
| dialect_levantine | 4.73 | 20.13 | 113.52 | 0.694 |
| dialect_maghrebi | 5.79 | 20.04 | 103.44 | 0.680 |

## D Comparison with a Few-Shot LLM Baseline

Table 8 reports results for Aya-8B (Üstün et al., 2024), an open-weight multilingual LLM, prompted with 5 fixed in-domain exemplars (seed 42, temperature 0, no fine-tuning or vocabulary pruning), on the same MultiUN test set and metrics as Table 1.

Table 8: Aya-8B (5-shot) versus pruned/fine-tuned and bilingual systems on the MultiUN test set ($n = 1{,}500$). TER: lower is better (↓).

| **System** | **BLEU** | **chrF++** | **TER ↓** | **COMET** |
|---|---|---|---|---|
| Aya-8B (5-shot) | 36.77 | 55.14 | 56.57 | 0.8754 |
| M2M100 (pruned + FT, MultiUN) | 42.04 | 58.81 | 51.55 | 0.8730 |
| NLLB-200 600M (pruned + FT, MultiUN) | 37.70 | 55.79 | 55.04 | 0.8640 |
| OPUS-MT-en-ar (bilingual baseline) | 44.59 | 58.77 | 58.59 | 0.7911 |

M2M100 outperforms Aya-8B on BLEU, chrF++, and TER, with comparable COMET scores. NLLB-200 trails Aya-8B on all four metrics, while OPUS-MT-en-ar shows the same BLEU/COMET divergence noted in Section 4.3.

# TACTICS: Taxonomy-Aware Intelligent Corpus Sampling for Machine Translation

## Abstract

Large-scale machine-translation (MT) systems are typically evaluated on random samples from a corpus whose distributional composition is an artifact of how it was assembled. Such a sample inherits the phenomena the collection happens to contain rather than the full space a system must handle, spanning rule-governed conventions (terminology, punctuation, currency formatting) and context-dependent phenomena (tone, honorifics, document-level coherence), and thus provides no coverage guarantee for assessing robustness. We propose **TACTICS** (**T**axonomy-**A**ware **C**overage-op**T**imized **I**ntelligent **C**orpus **S**ampling), which recasts coverage as an explicit objective. TACTICS induces a hierarchical taxonomy from a locale style guide, classifies segments against it, and selects a fixed-budget subset jointly optimizing coverage of rare categories, document-level coherence, and distributional fidelity to the full corpus. Applied to MT evaluation across four translation directions, TACTICS improves coverage of rare categories over lexical and embedding-based selection. By targeting the phenomena that separate systems, TACTICS makes a fixed evaluation budget go further, recovering the true system ranking from far fewer segments than random sampling wherever a real quality gap exists and never signaling a difference where none exists.

## 1 Introduction

Modern machine translation (MT) systems, including both dedicated neural MT engines and LLM-based translation pipelines, are increasingly deployed at scale across many language pairs and locales (Bahdanau et al., 2015; Vaswani et al., 2017; Brown et al., 2020; Touvron et al., 2023; OpenAI, 2023). At this scale, evaluation is a bottleneck. Human assessment of every translated segment is prohibitively expensive, so systems are typically evaluated on a random sample drawn from a large corpus. The implicit assumption is that such a sample provides a representative picture of system quality. But a representative sample is not the same as a diagnostic one. A random sample reproduces the corpus faithfully, yet provides no guarantee of adequate coverage of the phenomena that discriminate between systems.

The difficulty is that these discriminating phenomena are also the ones a corpus represents least evenly. Most of a translation corpus consists of short, common segments that nearly any system translates correctly, whereas the cases that genuinely stress a system, such as terminology constraints, locale-specific formatting, and date or currency conventions, are comparatively rare. This matters because an evaluation, whether by automatic metric (Sai et al., 2022) or human protocol such as MQM (Lommel et al., 2014), is only as diagnostic as the set on which it is computed. When easy segments dominate that set, the differences concentrated in the harder ones are averaged away, and two systems of unequal quality can appear all but indistinguishable.

Existing selection methods do not close this coverage gap. Most target training-data curation rather than evaluation, whether through quality filtering (Gao et al., 2021; Marion et al., 2023; Tirumala et al., 2023), importance resampling on lexical or n-gram statistics such as DSIR (Xie et al., 2023), or embedding-space diversity such as ClusterCLIP (Shao et al., 2024). These signals capture frequent lexical patterns or broad semantic variation, but none of them explicitly models the prescriptive rules that govern localization, such as whether a brand term is preserved, punctuation follows locale conventions, or currency and dates are formatted correctly. A sample can therefore be lexically or semantically diverse and still fail to cover the phenomena on which systems actually differ.

We propose **TACTICS** (**T**axonomy-**A**ware

*Proceedings of the Eleventh Conference on Machine Translation*, pages 14–32
October 28-29, 2026 ©2026 Association for Computational Linguistics

**C**overage-op**T**imized **I**ntelligent **C**orpus **S**ampling), a data-selection method that constructs compact, stratified evaluation sets by treating coverage as an explicit objective rather than a byproduct of how the corpus was sampled. It formulates evaluation-set construction as a constrained optimization problem over a hierarchical taxonomy induced from prescriptive style guides. We instantiate this for MT, though the approach applies to any evaluation that must cover a structured set of phenomena under a fixed budget. TACTICS balances three properties (Figure 1).

(i) **Coverage.** Every taxonomy category, including rare ones, is adequately represented under a fixed budget, unlike random sampling.

(ii) **Coherence.** Segments are selected with their document neighbors, so each is evaluated in context rather than in isolation.

(iii) **Fidelity.** The sample matches the full corpus in category composition and difficulty.

We evaluate TACTICS on a large-scale localization corpus across four translation directions. At a fixed budget of $B = 5{,}000$, TACTICS raises the average number of taxonomy categories with at least 20 sampled segments from 56.3 to 73.3 relative to random sampling, while preserving high correlation with the full-corpus category distribution (Pearson $r = 0.949$ to $0.982$) and close alignment on edit rate. It also increases the average segments per document from 1.9 to 3.2, yielding less fragmented samples. Most importantly, these subsets are more diagnostic. Where a real quality gap exists, TACTICS recovers the true system ranking from fewer segments than random, with a higher paired $t$-statistic at every budget on en→hi, and raises no false signal on directions where the systems are tied.

Our contributions are:

- We introduce a **style-guide-grounded taxonomy induction pipeline** for representing localization phenomena relevant to MT evaluation.
- We formulate fixed-budget evaluation set construction as a **taxonomy-aware constrained sampling problem** over coverage, coherence, and fidelity.
- We show that TACTICS **covers rare phenomena** and **recovers true system quality differences** more reliably than random, lexical, and embedding-based selection.

## 2 Related Work

### 2.1 MT Evaluation and Test Set Design

MT evaluation relies on automatic metrics such as BLEU (Papineni et al., 2002), TER (Snover et al., 2006), chrF (Popović, 2015), COMET (Rei et al., 2020), and BLEURT (Sellam et al., 2020), whose reliability for ranking systems has been studied at scale (Kocmi et al., 2021), alongside human frameworks such as MQM (Lommel et al., 2014; Freitag et al., 2022). These estimate quality on a test set but not whether the set is diagnostic, that is, whether it contains the phenomena on which systems differ. This depends on how the set is built. The WMT shared task builds its test sets by drawing source texts from a chosen domain, usually online news, and commissioning reference translations for the task, leaving targeted phenomenon evaluation to separately contributed test suites (Barrault et al., 2020). Its composition is therefore fixed by the choice of domain and source rather than by explicit coverage of these phenomena, and reproducing it for a new language pair or domain requires substantial manual effort. Benchmarks like FLORES-101 and FLORES-200 scale instead by sampling their sentences from a corpus such as Wikipedia (Goyal et al., 2022; NLLB Team et al., 2022), but inherit whatever the corpus contains, with no guarantee that the discriminating phenomena are covered. TACTICS addresses both limitations by making coverage of a style-guide-derived taxonomy an explicit objective when sampling a corpus, so those phenomena that discriminate systems are represented by construction rather than by chance or manual curation.

### 2.2 Data Selection and Sampling

Prior data-selection work has largely focused on training data, including quality filtering (Gao et al., 2021; Marion et al., 2023), pruning (Tirumala et al., 2023), importance resampling such as DSIR (Xie et al., 2023), and embedding-based diversity such as ClusterCLIP (Shao et al., 2024). These methods select examples using lexical statistics, embeddings, or training utility.

A separate line of work selects data for *evaluation* rather than training, so that systems can be tested on fewer examples. One group reduces a benchmark to a small subset that still reproduces its system ranking, keeping the examples that mod-

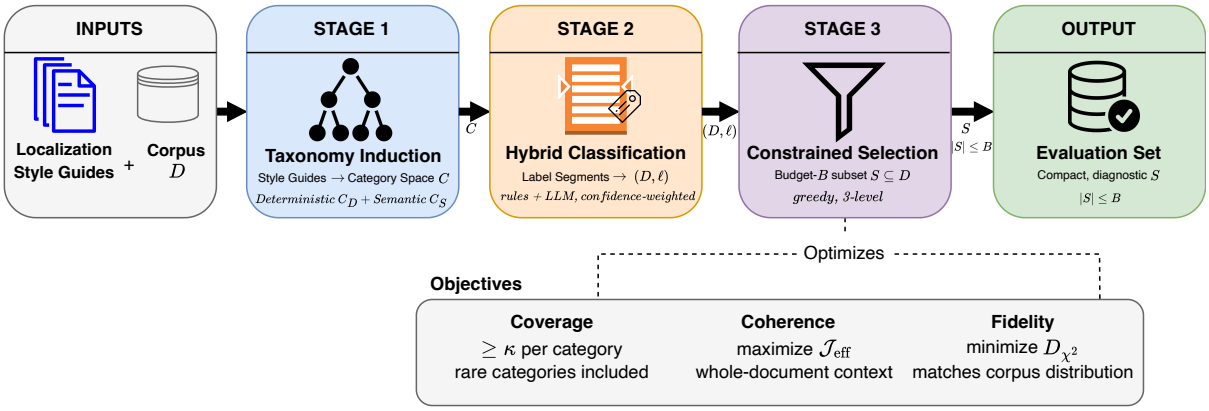

Figure 1: Overview of TACTICS. Stage 1 induces a taxonomy (category space $C$) from style guides; Stage 2 labels segments into $C$, yielding $(D, \ell)$; Stage 3 selects a budget-$B$ subset $S$ jointly optimizing coverage ($\geq \kappa$), coherence ($\mathcal{J}_{\text{eff}}$), and fidelity ($D_{\chi^2}$).

els find hardest or most discriminating (Vivek et al., 2024; Maia Polo et al., 2024; Rodriguez et al., 2021; Vania et al., 2021; Perlitz et al., 2024). Another selects examples adaptively, spending human judgments on the comparisons that best separate systems (Chaganty et al., 2018; Mohankumar and Khapra, 2022; Kossen et al., 2021). More recently, Zouhar et al. (2025) pick segments for human evaluation of NLG systems from metric-score variance, output diversity, and item difficulty. All of these rely on signals read from model outputs. The selection is therefore tied to the systems being evaluated, does not transfer easily to new ones, and cannot ensure that the phenomena a system should handle are covered.

TACTICS inverts this dependence. We cast evaluation-set construction as taxonomy-aware stratified sampling under a fixed budget, with strata drawn from a prescriptive style-guide taxonomy rather than surface metadata, domains, or embedding clusters. The taxonomy is fixed independently of any model, so the resulting evaluation set is reusable across systems, including ones built later. This approach suits MT, where much of localization quality depends not on meaning but on explicit rules, such as preserving brand terms, formatting dates and currencies for the locale, or choosing the correct honorific. These rules are set by style guides, yet selection by lexical or embedding similarity fails to capture them (Section 4.3).

### 2.3 Automated Taxonomy Construction

Recent LLM-based taxonomy induction methods build taxonomies bottom-up from observed data, e.g., TnT-LLM (Wan et al., 2024) and Chain-of-Layer (Zeng et al., 2024). Such methods discover corpus-salient patterns, but localization evaluation also depends on prescriptive rules that may be scarce in a given corpus, such as currency formatting, brand preservation, quotation marks, or date conventions. TACTICS takes a complementary top-down approach. It induces taxonomy structure from localization style guides and grounds it in the corpus through constrained classification and sampling, so evaluation sets cover both common patterns and rare style-guide-defined phenomena that matter for system comparison.

## 3 Methodology

### 3.1 Problem Formulation

Let $D = \{s_i\}_{i=1}^{n}$ denote translation segments, with each segment belonging to a document $J \in \mathcal{J}$. Let $T$ be a hierarchical taxonomy with category set $C = C_D \cup C_S$, where deterministic categories $C_D$ are rule-matchable and semantic categories $C_S$ are LLM-inferred. Each segment has taxonomy labels $\ell(s) \subseteq C$ and a post-edit score $e(s) \in [0, 1]$, the fraction of a machine translation that a human corrected (approximated by TER). The score can come from any MT system and serves only to approximate the segment's difficulty.

Given a budget $B \ll |D|$, we select a stratified evaluation subset $S \subset D$, $|S| \leq B$, by enforcing coverage constraints and optimizing the coherence and fidelity objectives below.

**Coverage (constraint).** For a minimum threshold $\kappa \geq 1$, each category with at least $\kappa$ segments

in the corpus must be represented in the sample:

$$\forall c \in C: \quad |\{s \in S : c \in \ell(s)\}| \geq \kappa. \quad (1)$$

**Coherence (maximize).** Sampling entire documents preserves the context surrounding each segment. Beyond this, we favor samples spread across many documents rather than a few, measured by the effective number of documents:

$$\mathcal{J}_{\text{eff}}(S) = \exp\Big(-\sum_{j=1}^{|\mathcal{J}|} p_j \log p_j\Big), \quad (2)$$

where $p_j = |S \cap J_j|/|S|$ is document $J_j$'s share of the sample. Exponentiating rescales the entropy into an interpretable document count without changing the optimum.

**Fidelity (minimize).** We align the sample $S$ with the corpus $D$ in category composition and difficulty. The category distribution $P_C$ gives the relative frequency of each taxonomy category in $C$, and $P_e$ is a histogram of the post-edit score $e \in [0, 1]$ over fixed bins, both empirical distributions computed on the corpus ($P$) and the sample ($\hat{P}$). We minimize their chi-squared divergence,

$$D_{\chi^2}(\hat{P}_C \,\|\, P_C) + \lambda\, D_{\chi^2}(\hat{P}_e \,\|\, P_e), \quad (3)$$

with $\lambda > 0$ trades off category against difficulty alignment.

### 3.2 Method Overview

TACTICS formulates stratified evaluation-set construction as constrained selection over a taxonomy-induced representation of the full corpus. The framework has three stages (Figure 1): taxonomy induction defines the category space, segment annotation maps the corpus into this space, and constrained sampling selects a fixed-budget subset that balances coverage of rare phenomena, document-level coherence, and fidelity. This yields compact evaluation sets that preserve both the linguistic structure and the key statistical properties of the full corpus.

#### 3.2.1 Taxonomy Extraction (Stage 1)

We induce a hierarchical taxonomy $T$ from locale-specific style guides to define the category space $C$ used for sampling. This is necessary because the corpus does not explicitly annotate linguistic phenomena, and embeddings or metadata alone do not capture prescriptive constraints such as terminology, branding, formatting, or locale-specific

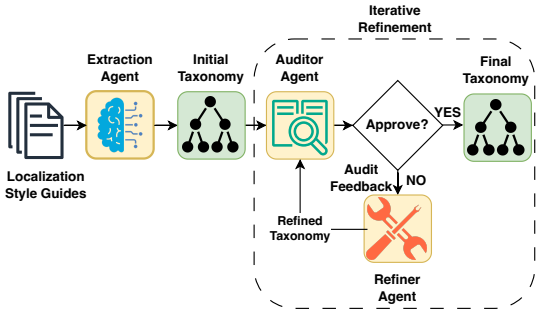

Figure 2: Style-guide-grounded taxonomy induction. An *Extraction Agent* turns style guides into an initial taxonomy; an *Auditor Agent* then checks its coverage, looping through a *Refiner Agent* until it approves or an iteration limit is reached.

conventions. The taxonomy is partitioned into *Deterministic* categories $C_D$, covering high-precision rule-matchable phenomena, and *Semantic* categories $C_S$, covering context-dependent phenomena such as tone, register, or implicit meaning.

We construct $T$ with an agentic extract–audit–refine loop (Figure 2; Appendix I). An Extraction Agent identifies candidate rules from the style guide and organizes them into an initial hierarchy, an Auditor Agent checks coverage against the source, and a Refiner Agent incorporates missing or under-specified rules. The loop terminates when no major gaps remain or an iteration limit is reached, yielding the prescriptive category space used for annotation, coverage constraints, and distributional alignment in later stages.

#### 3.2.2 Hybrid Classification (Stage 2)

Given taxonomy $T$, we define a labeling function $\ell(s) \subseteq C$ that maps each segment $s \in D$ to one or more taxonomy categories, embedding the corpus into the category space from Stage 1. Classification is hybrid. Deterministic categories $C_D$ are assigned by rule-based matchers, such as regular expressions for terminology or formatting patterns, producing high-precision labels with confidence 1.0. Semantic categories $C_S$ are assigned by a context-aware classifier whose outputs are constrained to valid taxonomy paths. Each segment receives a primary category and optional secondary categories to capture co-occurring phenomena. The resulting labeled dataset $(D, \ell)$ supports the coverage constraint and defines the empirical distributions used by the fidelity objective.

#### 3.2.3 Stratified Sampling (Stage 3)

Given labeled data $(D, \ell)$, we greedily select a budgeted subset $S \subset D$, $|S| \leq B$, to approximate the constrained optimization problem of Section 3.1. At each step, we add the segment that most improves the objective while preserving satisfied constraints.

**Level 1: Coverage enforcement.** We first build a seed set that satisfies the minimum coverage constraint (Eq. 1) for each feasible category $c \in C$. Categories are processed from rare to frequent, and segments are selected using a fixed mix of confidence levels. Each selected segment is augmented with a local context window from the same document to preserve translation context. This stage ensures explicit coverage of long-tail categories and initializes $S$ for later optimization.

**Level 2: Coherence optimization.** We next improve coherence by adding documents that contribute diverse taxonomy signals. Directly maximizing $\mathcal{J}_{\text{eff}}(S)$ (Eq. 2) is hard, since each document's contribution depends on its size and the evolving sample. We instead use a category-aware document score analogous to TF–IDF, with taxonomy categories playing the role of terms. For category $c$ and document $j$,

$$\mathrm{CF}(c, j) = \frac{\#\{s \in J_j : c \in \ell(s)\}}{|J_j|}, \tag{4}$$

$$\mathrm{IDF}(c) = \log \frac{|\mathcal{J}|}{\mathrm{df}(c)}, \tag{5}$$

where $\mathrm{df}(c)$ is the number of documents containing $c$, CF is the category's frequency within a document, and IDF downweights categories common across documents. To stop a category repeated within one document from dominating, we saturate CF with hyperparameter $k_1$,

$$\mathrm{CF}_{\text{sat}}(c, j) = \frac{\mathrm{CF}(c, j)(k_1 + 1)}{\mathrm{CF}(c, j) + k_1}, \tag{6}$$

and score each document as

$$\mathrm{score}(j) = w_{\text{conf}}(j)\, w_{\text{size}}(j) \times \sum_{c \in C} \mathrm{CF}_{\text{sat}}(c, j)\, \mathrm{IDF}(c), \tag{7}$$

where $w_{\text{conf}}$ favors reliable assignments and $w_{\text{size}}$ downweights documents that are too small or too large (Appendix A, B). At each step we add the highest-scoring document's remaining segments to $S$.

| Pair | Segments | Docs | Categories | Edit rate (%) |
|---|---|---|---|---|
| en → fr | 57,524 | 13,211 | 149 | 56.6 |
| en → hi | 64,932 | 18,897 | 80 | 53.1 |
| ja → en | 83,522 | 9,379 | 126 | 60.4 |
| ja → zh | 82,578 | 9,659 | 127 | 68.0 |

Table 1: Locale pairs used for baseline comparison analysis. Segments and documents from the classified evaluation pool; categories from the merged taxonomy; edit rate from post-edit annotations.

**Level 3: Fidelity alignment.** With the remaining budget, we reduce the fidelity objective (Eq. 3) to align the sample with the corpus in category distribution and edit-rate profile. Estimating target statistics from $D$, we add segments that close the largest gaps, selecting edited segments to match the target difficulty profile and unedited segments from underrepresented categories. This corrects the distributional drift introduced by coverage and coherence optimization, yielding a sample that faithfully reflects the corpus in both composition and difficulty.

## 4 Experiments

### 4.1 Data and Baselines

We evaluate on four localization translation directions, en→fr, en→hi, ja→en, and ja→zh. Each direction uses a proprietary, in-house localization post-editing corpus in which source segments are machine-translated and then post-edited by professional linguists. Each segment thus carries a source, an MT translation, and a post-edited target, and is linked to its source document. Its post-edit score is the edit rate between the MT output and the post-edit, approximated by TER (Section 3.1). Table 1 summarizes the pools, which range from 57K–84K segments, 9K–19K documents, 80–149 taxonomy categories, and edit rates from 53.1% to 68.0%. We also use target-locale style guides, which specify orthographic, lexical, and formatting constraints not observable from the corpus, to induce the taxonomy (Section 3.2.1, example in Appendix C).

All methods sample $B = 5{,}000$ segments per locale from the same classified evaluation pool. We compare TACTICS against Random uniform sampling, DSIR (Xie et al., 2023) (importance resampling on n-gram statistics), and ClusterCLIP (Shao et al., 2024) (embedding clustering with balanced sampling).

| Locale ($\|C\|$) | Method | $\text{Cov}_{20}\|\text{Cov}_1$ | Gini | Pearson $r$ | $\text{MSE}_C \downarrow$ | $\text{MSE}_{\text{TER}} \downarrow$ | Edit (%) | S/D |
|---|---|---|---|---|---|---|---|---|
| en→fr (149) | Random | 56\|106 | 0.421 | **0.999** | 0.43 | 5.26 | 56.7 | 2.0 |
| | DSIR | 13\|70 | 0.133 | 0.983 | **0.38** | **1.46** | 64.8 | 1.2 |
| | ClusterCLIP | 56\|101 | 0.426 | 0.999 | 1.23 | 24.6 | 58.2 | 2.0 |
| | **TACTICS** | **70\|133** | **0.497** | 0.982 | 6.90 | 95.9 | **56.6** | **3.1** |
| en→hi (80) | Random | 64\|79 | 0.388 | **0.999** | 3.66 | **7.98** | 53.4 | 1.8 |
| | DSIR | 9\|70 | 0.164 | 0.952 | 49.6 | 66.4 | 56.8 | 1.2 |
| | ClusterCLIP | 66\|80 | 0.393 | 0.999 | **1.24** | 14.9 | 55.5 | 1.8 |
| | **TACTICS** | **79\|80** | **0.468** | 0.969 | 46.5 | 133 | **53.1** | **2.4** |
| ja→en (126) | Random | 53\|85 | 0.349 | **1.000** | **0.09** | **11.5** | 59.9 | 1.9 |
| | DSIR | 11\|57 | 0.151 | 0.892 | 49.8 | 843 | 81.0 | 1.2 |
| | ClusterCLIP | 54\|87 | 0.331 | 0.942 | 26.8 | 1090 | 74.0 | 1.8 |
| | **TACTICS** | **85\|102** | **0.491** | 0.972 | 11.8 | 111 | **60.4** | **3.4** |
| ja→zh (127) | Random | 52\|96 | 0.346 | **0.999** | **0.08** | **6.02** | 67.8 | 1.9 |
| | DSIR | 7\|57 | 0.114 | 0.893 | 50.2 | 1510 | 88.1 | 1.1 |
| | ClusterCLIP | 51\|94 | 0.308 | 0.929 | 25.1 | 1690 | 85.7 | 1.7 |
| | **TACTICS** | **59\|113** | **0.550** | 0.949 | 9.17 | 71.6 | **68.0** | **4.0** |

Table 2: Intrinsic sampling quality at $B = 5{,}000$. $\text{Cov}_{20}|\text{Cov}_1$ counts categories with $\geq 20$ and $\geq 1$ samples; $r$ is Pearson correlation with the full-corpus category distribution; $\text{MSE}_C$ and $\text{MSE}_{\text{TER}}$ ($\times 10^{-6}$) are mean squared errors of the sampled vs. full-corpus category and TER distributions; Edit is post-edit rate; S/D is segments per document. Random matches the corpus distributions most closely, while TACTICS trades fidelity to cover rare categories and harder segments. Baselines: DSIR (Xie et al., 2023), ClusterCLIP (Shao et al., 2024).

### 4.2 Evaluation Setup

We select pipeline models by role, as the method is agnostic to the specific LLMs. Taxonomy induction runs once per locale, so we use **Claude Sonnet 4.5** to generate the taxonomy and the more capable **Claude Opus 4.5** to audit it for missing or under-specified rules (Figure 2, Section 3.2.1). Classification runs over the whole corpus, so we label segments with **Kimi K2.5**, constraining its outputs to valid taxonomy paths. From a different family than the taxonomy models, it labels cheaply at scale and independently of the generator. For downstream evaluation we compare $\text{NMT}_{\text{base}}$, a dedicated neural MT system, with $\text{LLM}_{\text{MT}}$, a **Gemma 4-26B-A4B** model prompted to translate, conditioned on summarized style guides.

We report intrinsic metrics aligned with the three objectives of TACTICS. **Coverage** is $\text{Cov}_{20}$ and $\text{Cov}_1$, the number of categories with at least 20 and at least 1 sampled segments. **Coherence** combines the Gini coefficient over per-document segment counts with segments per document (S/D), where higher values mean more multi-segment context. **Fidelity** compares the sample to the full corpus via Pearson correlation ($r$) and category- and TER-distribution MSE (higher $r$, lower MSE better), with edit rate as a difficulty proxy. Downstream, we report TER (Snover et al., 2006), BLEU (Papineni et al., 2002), and chrF (Popović, 2015) against the human post-edited target, together with withholding rate (WH), the fraction of segments passing an automated QA pipeline. The pipeline applies deterministic checks (a translation-memory match against known-good references, and length heuristics that flag implausible target-to-source length ratios or name lengths) together with a learned classifier that predicts translation quality from the source and target sentence. These checks use no style guides, so they are independent of the taxonomy and the $\text{LLM}_{\text{MT}}$ prompt and favor neither system.

### 4.3 Results

We provide taxonomy consistency checks, including inter-model agreement and manual spot checks, in Appendix J.

**Intrinsic sampling quality (Table 2).** TACTICS improves coverage and coherence across all directions. $\text{Cov}_{20}$ rises over Random from 56 to 70, 64 to 79, 53 to 85, and 52 to 59 for en→fr, en→hi, ja→en, and ja→zh. It also attains the highest Gini and segments per document (S/D) everywhere, selecting multiple segments from the same document rather than isolated ones. This matters because translation quality is context-dependent, and a segment like "Click here" is only translatable alongside its neighbors. But covering the tail pulls the sample away from the corpus. Random most closely matches the full-corpus category and TER distributions (lowest MSE), since it simply reproduces the corpus proportions, whereas TACTICS deviates more to represent rare categories

Table 3: Downstream translation performance across sampling strategies. Best value per direction, metric, and system is in **bold**. Lower TER is better, and higher BLEU, chrF, and WH are better. WH is the withholding rate, the percentage of segments passing automated QA checks. Baselines include DSIR (Xie et al., 2023) and ClusterCLIP (Shao et al., 2024).

| Locale | Systems | Segs | True $\Delta$ | Verdict |
|---|---|---|---|---|
| en→fr | NMT / LLM | 3959 | $+0.016$ | not sig. |
| en→hi | NMT / LLM | 4334 | $+0.314$ | significant |
| ja→en | $\text{LLM}^{-\text{SG}}$ / NMT | 3168 | $+1.121$ | significant |
| ja→zh | LLM / NMT | 3062 | $-0.086$ | significant |

Table 4: Full-pool human-audit reference verdicts, the ground truth each subsample aims to reproduce. Systems: NMT ($\text{NMT}_{\text{base}}$), LLM ($\text{LLM}_{\text{MT}}$, style-guided), and $\text{LLM}^{-\text{SG}}$ ($\text{LLM}_{\text{MT}}$ without style guides); ja→en uses $\text{LLM}^{-\text{SG}}$, the only direction it was annotated. Each segment is judged by one linguist with a second-expert QA pass. MQM penalty $= 25\,\text{critical} + 5\,\text{major} + \text{minor}$ (lower is better), so $\Delta = A - B > 0$ means the first-listed system $A$ is worse. Full $t$ and $p$ values in Appendix F.

and harder segments. Even so, TACTICS keeps the corpus category ordering (Pearson $r = 0.949$–$0.982$) and stays far more stable than DSIR and ClusterCLIP, whose MSE swings by orders of magnitude across directions.

**Downstream translation performance (Table 3).** On a random sample, $\text{NMT}_{\text{base}}$ and $\text{LLM}_{\text{MT}}$ score very close across TER, BLEU, chrF, and WH, since it rarely includes the segments that separate them. The TACTICS set covers these rarer and harder cases, and the gap becomes clear. On ja→zh the $\text{LLM}_{\text{MT}}$–$\text{NMT}_{\text{base}}$ WH gap widens from about one point to over twenty, BLEU from 0.788 to 0.865 and chrF from 0.814 to 0.907, and the mean WH gap across directions grows from 1.3 to 17.3 points. Human evaluation shows the same pattern by category. Auditing one NMT system on comparably sized TACTICS and random samples (∼3,000 vs. 2,874 segments), the TACTICS audit covered 18 error categories against 15 for random, including three the random audit missed entirely, `number-format`, `text-truncation`, and `offensive-content`. Several of these carry major errors, three for text-truncation and one for offensive-content, so a random-only audit leaves real, category-specific failures unmeasured. We therefore use the two together, TACTICS to check per-category quality including the long tail, and random to estimate overall quality at the corpus proportion.

**Sample efficiency (Table 4, Figure 3).** Table 4 gives the true system ranking each subsample must recover, and Figure 3 measures how efficiently the samplers reach it. The four selectors are Random (uniform, unstratified), Equal-allocation (flat per-category quota), Low-confidence-first (lowest classifier-confidence segments, TACTICS's hard-example heuristic alone), and TACTICS (the full three-level pipeline). The three category-aware selectors differ only in how they spend the budget, isolating TACTICS's allocation strategy rather than the corpus-level baselines of Section 4.1. The top row is wasted budget, the fraction of a batch that both systems translate cleanly and that reveals nothing about their difference, which TACTICS keeps lowest in most settings. The bottom row is the paired $t$-statistic magnitude $|t|$ per batch, larger when a batch separates the systems more clearly and significant above the dashed line. On en→hi

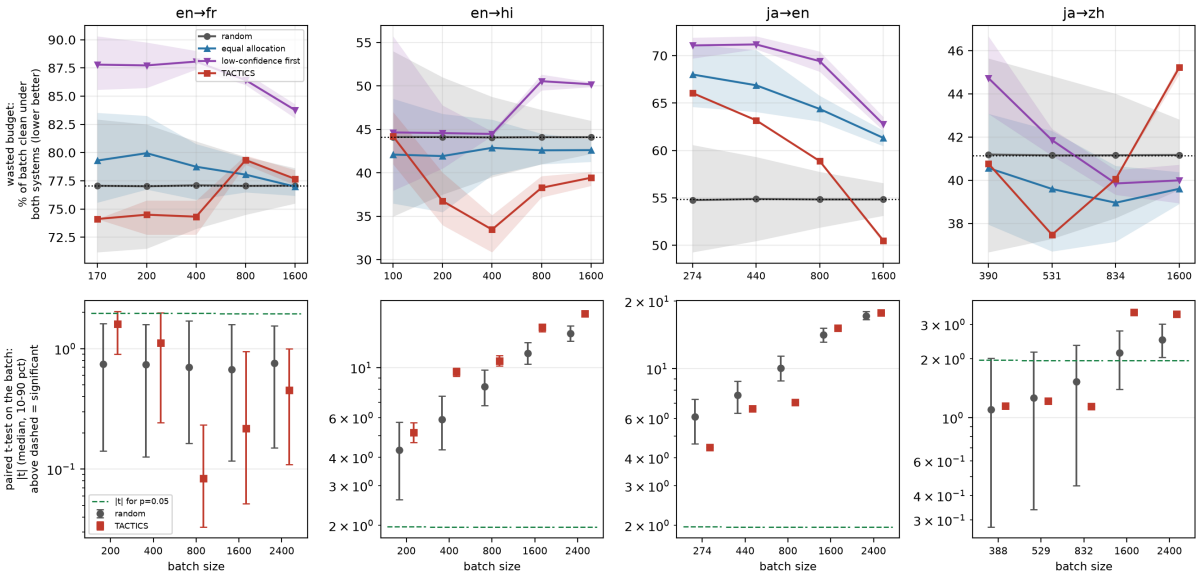

Figure 3: Sample efficiency across four directions. **Top**, wasted budget, the percentage of a batch that is clean under both systems and so cannot separate them (lower is better). **Bottom**, the paired $|t|$ on the batch (median over draws, 10–90 percentile bars). Points above the dashed line are significant at $p$=0.05. TACTICS is compared against random, equal-allocation, and low-confidence-first selection.

TACTICS exceeds random at every budget (ratio 1.19–1.63), and on ja→zh it clears the threshold at 1600 and 2400 segments where random does not. en→fr is a control, where the systems are tied ($\Delta = 0.016$) and both samplers stay below the line, so TACTICS signals a difference only when one is real. Although it estimates the corpus average less accurately (Appendix F), TACTICS detects a real gap from far fewer segments than random.

## 5 Discussion

**A representative sample is not a diagnostic one.** Random sampling reproduces the corpus almost exactly, which is why it struggles to compare systems. Most of a corpus is routine text both systems handle, so a faithful sample is dominated by segments that carry no signal about their difference, while the cases that separate systems, such as rare terminology, date and number formats, or long-context documents, are easily left out. A sample can thus match the corpus yet fail to reveal which system is better.

**Generic selectors miss prescriptive rules.** DSIR and ClusterCLIP rank segments by lexical or embedding similarity, capturing frequent surface patterns but not the prescriptive rules localization depends on, such as terminology, punctuation, and date, currency, and locale-specific formats. They therefore cover fewer taxonomy categories than TACTICS, and their sample statistics vary widely across directions.

**Coverage trades against fidelity by design.** By guaranteeing rare categories and harder segments, TACTICS deviates from the corpus more than random and so has higher distributional error. This is intentional. TACTICS keeps the corpus category ordering while shifting weight to the long tail, making it a weaker estimator of the corpus average but a stronger detector of system differences. Fidelity is a constraint to stay close enough, not the objective to maximize.

**Use both samplers together.** The two roles are complementary. Human evaluation is expensive, so the limited annotation budget is best spent on a TACTICS set, which guarantees that every content type is judged, including the rare and difficult cases random evaluation can miss. A cheaper random sample then estimates overall quality at the corpus proportion. Together they answer whether a system is good everywhere and how it performs on average.

## 6 Conclusion and Future Work

We presented TACTICS, a taxonomy-aware method for building compact, diagnostic MT evaluation sets. By inducing categories from local-

ization style guides and jointly optimizing coverage of rare phenomena, document-level coherence, and distributional fidelity, TACTICS guarantees that evaluation covers the content types that distinguish systems, including the long tail that random sampling misses. Across four directions it improves category coverage over random, lexical, and embedding-based selection, and recovers the true system ranking from fewer segments where a real quality gap exists. It does so by trading corpus-average fidelity for discriminative power, so we recommend pairing a TACTICS set, where costly human evaluation is best spent, with a random sample that estimates overall quality at the corpus proportion.

The core mechanism, taxonomy-aware constrained sampling over coverage, coherence, and fidelity, is not specific to machine translation. Any evaluation setting with a prescriptive taxonomy, long-tail skew over that taxonomy, and a fixed annotation budget could benefit. Future work includes validating TACTICS on public benchmarks and style guides to support reproducibility, extending it to other domains such as content moderation and clinical text, expanding human validation of taxonomy boundaries, and studying adaptive sampling budgets.

## Limitations

Our primary evaluation uses a proprietary localization corpus that we cannot release, which limits direct reproducibility. We therefore plan a public companion study on open style guides and benchmarks. The evaluation is also confined to localization, and generalization to other domains such as news, biomedical, or legal text requires further validation. The taxonomy induction pipeline depends on the availability and quality of prescriptive style guides, which may not exist or may vary in granularity across locales, and the LLM-based classifier reaches only moderate inter-annotator agreement (Cohen's $\kappa = 0.51$), so misclassifications can affect coverage. By design, TACTICS trades fidelity to the corpus distribution for coverage and discriminative power, making it a deliberately biased estimator of corpus-average quality that should be paired with a random sample when an aggregate estimate is needed.

## Acknowledgments

We thank Elijah Smith for automating and containerizing the sampling pipeline, enabling large-scale sampling jobs to be scheduled and run reliably with minimal manual intervention. This infrastructure was instrumental in carrying out the experiments presented in this paper.

# Appendix

## A Level-2 Scoring Ablation

Level-2 scores each document by how much rare-category evidence it concentrates (Eq. (7)). Table 5 ablates the two design choices in that function, *saturation* and *aggregation*, under a fixed budget $B = 5{,}000$ (seed 42) with Level-1 disabled, so the differences reflect Level-2 scoring alone. The score combines two per-category signals. *Category frequency* $\text{CF}(c, j)$ is the fraction of segments in document $j$ assigned to category $c$ and is high when the document gives concentrated evidence for a phenomenon. *Inverse document frequency* $\text{IDF}(c)$ is large for rare categories, so the product $\text{CF} \cdot \text{IDF}$ favors documents rich in rare phenomena rather than documents that only repeat common ones. *Saturation* applies a concave transform $\text{CF}_{\text{sat}}$ so that a category repeated many times within one document cannot dominate its score. *Aggregation* is either *pure*, where each category contributes once as $\text{CF}_{\text{sat}}(c, j)\,\text{IDF}(c)$ (Eq. (7)), or *weighted*, which additionally scales each term by the segment count $n(c, j) = |\{s \in J_j : c \in \ell(s)\}|$ and rewards repeated occurrences. All four variants share the same confidence weight $w_{\text{conf}} \in \{1.2, 1.0, 0.8\}$ (high, medium, low) and size factor $w_{\text{size}}$ (Appendix B). The table shows a sharp split between the two aggregation choices. Weighted variants collapse the budget into 16–17 documents (Gini $\approx$ 0.1, Top-10 $\approx$ 66–69%) and cover only 37/76 categories. Pure variants instead spread selection over hundreds to more than 1,600 documents, raising effective diversity by more than an order of magnitude and lifting coverage to 48–49/76. **Saturated pure** trades a small amount of raw diversity for more balanced within-document evidence, selecting 815 documents at Gini 0.441 and $\text{Cov}_{30} = 48/76$, and is our default Level-2 configuration.

## B Level-2 Weighting Details

The Level-2 document score (Eq. 7) applies two multiplicative weights that favor reliable, moderately sized documents. The confidence weight $w_{\text{conf}}(j)$ is 1.2 for high-confidence documents, 1.0 for medium, and 0.8 for low. For the size weight, let $n_j = |J_j|$ be the number of segments in document $j$, let $Q_1$ be the first quartile of document sizes, and let $n_{\max}$ be a segment cap, and define $r_j = \min\big(\frac{n_j - n_{\max}}{n_{\max}}, 1\big)$. The size weight is

$$w_{\text{size}}(j) = \begin{cases} 0.8 + 0.2 \cdot \frac{n_j}{Q_1}, & n_j \leq Q_1, \\ 1.0, & Q_1 < n_j \leq n_{\max}, \\ \max\big(0.5,\, 1 - 0.3\, r_j\big), & n_j > n_{\max}. \end{cases} \tag{8}$$

This down-weights both highly fragmented samples drawn from very small documents and budget domination by very large ones.

## C Example Style Guide Snippet

**Style Guide Snippet (Illustrative)**

**Currency Format.** The currency symbol should be inserted after the number and preceded by a space. For Canadian dollars, there should be a space between the dollar sign and the currency symbol.
**Examples:** 50,99 / 4 500 EUR / 50 $ CA
As a general rule, use ISO currency codes.

**Common currencies:**

| Country/Region | Currency name | Symbol | ISO code |
|---|---|---|---|
| EU | euro | | EUR |
| Canada | Canadian dollar | CA $ | CAD |
| USA | US dollar | $ | USD |

If currency symbols or ISO codes (e.g., $, , GBP, EUR) appear in the source text, they should be preserved and formatted according to locale-specific rules.

**Date Format.** Dates must follow the French day–month format rather than the US month–day format.

| US English | French | Comments |
|---|---|---|
| 7/14/2013 | 14/07/2013 | N/A |
| July 14, 2013 | 14 juillet 2013 | Extended |

This snippet is a representative portion of a larger localization style guide. It illustrates the type of constraints used to induce the taxonomy in Section 3.2.1.

## D Per-Level Pipeline Breakdown

Each level of TACTICS contributes a distinct sampling property. Table 6 reports per-stage statistics to illustrate how coverage, coherence, and fidelity are introduced incrementally. L1 constructs

the initial coverage-oriented seed set, L2 adds coherent document-level context, and L3 fills the remaining budget to match the full-corpus edit-rate statistics.

**Level contributions.** L1 selects the initial coverage-oriented seed set, ranging from roughly 1.5K to 2.9K segments across locales. L2 then adds coherent document-level context to reach approximately 3.5K segments. At this point coverage is effectively fixed, for example fr-FR reaches 98/105 categories and hi-IN reaches 79/80. L2 also introduces coherent multi-segment documents, with the number of selected documents varying by locale and document-size distribution.

L3 uses the remaining budget to reach $N = 5{,}000$ and align the sample with the full-corpus edit-rate profile. Since L3 only adds segments, coverage does not decrease from L2 to L3. The edit-rate correction can be substantial, with ja-JP decreasing from 75.7% to 61.5% and hi-IN from 74.2% to 53.1%. This happens because L1 and L2 over-sample edited segments, which are more category-diverse, while L3 rebalances the final sample by adding segments that restore distributional fidelity.

## E Cross-Locale Generalization

We evaluate TACTICS across 22 locales spanning seven language families to assess whether the sampling objectives generalize beyond the main baseline-comparison directions. Table 7 reports intrinsic sampling quality for the test split at $N = 5{,}000$. Across locales, TACTICS maintains strong distributional fidelity, with mean Pearson correlation $r = 0.992$ and mean edit-rate deviation of 0.5 percentage points. L1 coverage varies with taxonomy size, where compact taxonomies such as en-AE (48 categories) achieve higher coverage at the $\geq 20$ threshold, while larger taxonomies such as en-AU (177 categories) are harder to cover under the same fixed budget. L2 Gini averages 0.54 across locales, indicating consistent document-level diversity.

## F Corpus-Mean Estimation Error

Table 8 reports the RMSE of the estimated system delta against the full-pool truth for random and TACTICS batches. TACTICS has higher RMSE in most cells, and the error is bias-dominated (bias$^2$/MSE near 100%). This is expected of a deliberately unrepresentative diagnostic batch, where concentrating rare and harder segments makes the sample a poor estimator of the corpus average while making it a stronger detector of the system ranking. This trade-off motivates pairing TACTICS with a separate random sample for aggregate estimation.

## G System-Ranking Recovery

Table 9 reports how reliably a sampled batch recovers the correct system ranking, complementing the corpus-average estimation error of Appendix F. Using the full-pool audit verdict of Table 4 as reference, for each budget we draw many batches and run a paired $t$-test on the per-segment MQM deltas, reporting the median $|t|$ and the *recovery rate* (draws that are significant at $p < 0.05$ and match the verdict sign).

The pattern mirrors the estimation trade-off. Where the true effect is clear (en→hi, ja→en) both samplers recover it almost always. Where it is small (ja→zh, $\Delta = -0.086$) TACTICS recovers the verdict at 1600–2400 segments (100% vs. 62–93%), and on the null control (en→fr, $\Delta = +0.016$) it raises no false verdict (0% vs. random's 4–6%).

## H Fidelity Diagnostics

Figure 4 shows representative Level-3 fidelity diagnostics for the hi-IN test split. The sampled set closely matches the full evaluation pool across taxonomy-category distribution, post-edit distribution, and clean-segment/lock-rate statistics.

## I Taxonomy Generation Pipeline

The taxonomy generation pipeline consists of three LLM-based agents orchestrated in an iterative loop, **Extract** → **Audit** → **Refine** → **Audit** → …, running for up to 5 iterations or until the auditor marks the taxonomy as complete. Each agent can use a different LLM instance. Below we reproduce the full system prompts (DSPy signatures) for each agent.

### I.1 Taxonomy Extraction Agent

The extraction agent operates in two stages, *Feature Extraction* followed by *Synthesis*.

#### I.1.1 Stage 1: Feature Extraction

```
Analyze a translation style guide and
identify SOURCE-TEXT TRIGGERS.

IGNORE THE FOLLOWING:
  Rules that only apply to the target
```

| Locale | Dir | $\|C\|$ | Stage | Seg. | $\text{Cov}_{20}$ | Edit (%) | L2 Docs |
|---|---|---|---|---|---|---|---|
| fr-FR | en→fr | 105 | L1 | 2,882 | – | – | – |
| | | | L1+L2 | 3,503 | 98/105 | 47.6 | 169 |
| | | | L1+L2+L3 | 5,000 | 98/105 | **45.7** | 169 |
| ja-JP | en→ja | 76 | L1 | 1,897 | – | – | – |
| | | | L1+L2 | 3,524 | 75/76 | 75.7 | 302 |
| | | | L1+L2+L3 | 5,000 | 75/76 | **61.5** | 302 |
| ko-KR | en→ko | 86 | L1 | 2,255 | – | – | – |
| | | | L1+L2 | 3,504 | 83/86 | 68.2 | 331 |
| | | | L1+L2+L3 | 5,000 | 83/86 | **55.4** | 331 |
| hi-IN | en→hi | 80 | L1 | 1,510 | – | – | – |
| | | | L1+L2 | 3,506 | 79/80 | 74.2 | 483 |
| | | | L1+L2+L3 | 5,000 | 79/80 | **53.1** | 483 |
| en-US | ja→en | 126 | L1 | 2,913 | – | – | – |
| | | | L1+L2 | 3,510 | 86/126 | 64.6 | 53 |
| | | | L1+L2+L3 | 5,000 | 86/126 | **60.4** | 53 |
| zh-CN | ja→zh | 127 | L1 | 2,530 | – | – | – |
| | | | L1+L2 | 3,507 | 93/127 | 73.3 | 105 |
| | | | L1+L2+L3 | 5,000 | 93/127 | **68.0** | 105 |

Table 6: Per-stage pipeline statistics at $N = 5{,}000$. $\text{Cov}_{20}$ denotes the number of taxonomy categories with at least 20 sampled segments. Bold edit rates indicate the final L3-aligned edit rate, matching the full evaluation pool.

(e.g., 'no double spaces in target')
Team-specific or project-specific instructions (e.g., "Note for X projects", "Exception for Y projects", "Specific instructions for Z")
Rules from other organizations/clients (only extract rules for the specified organization_name)

FOCUS ON:
Universal source attributes that force a specific translation decision
Linguistic markers (e.g., Second-person pronouns)
Content types (e.g., UI labels, Legal names)
Technical constraints (e.g., ICU placeholders)
General rules applicable across all projects for this organization

**Inputs:**
*markdown_content*: The style guide content
*organization_name*: Organization/Client name of the style guide

**Output:**
*source_features*: Structured list of features including categories, names, rules, and pattern hints.

### I.1.2 Stage 2: Taxonomy Synthesis

Consolidates raw features into a source-centric hierarchical TaxonomyStructure.

Logic:
1. PERSPECTIVE SHIFT: Transform target-evaluation rules into source-text triggers. (e.g., Change 'Check for natural translation' to 'Idiomatic/Complex Source').
2. BUCKETING: Group into 'Deterministic' (Regex-ready) vs. 'Semantic' (LLM-required).
3. LABELING: Ensure Semantic labels describe what to LOOK FOR in the Source-Text.
4. DEDUPLICATION: Merge identical source-triggers from different guide sections.

IGNORE DURING SYNTHESIS:
Team-specific or project-specific instructions
Rules that only apply to specific teams, projects, or contexts

**Input:**
*raw_features*: Aggregated features from guide extraction

**Output:**
*organized_taxonomy*: The final nested hierarchy (Deterministic/Semantic) ready for the Classifier.

## I.2 Taxonomy Auditor Agent

Audit taxonomy extraction for structural completeness.

SCOPE CONSTRAINTS:
Be pragmatic, not exhaustive.
Focus on STRUCTURAL completeness, not exhaustive examples or word lists.
A category is complete if it captures the CONCEPT and RULE, not every instance.
Do NOT request specific word pairs, complete tables, or dictionary references.
Maximum 3 5 high-priority structural gaps per audit.

| Locale | Family | $\|C\|$ | $\text{Cov}_{20}$ | Gini | $r$ / Edit $\Delta$ |
|---|---|---|---|---|---|
| es-MX | Romance | 76 | 69/76 | 0.441 | 0.980 / 0.1 |
| zh-TW | Sinitic | 87 | 48/87 | 0.490 | 0.987 / 0.0 |
| en-AE | Germanic | 48 | 35/48 | 0.576 | 0.991 / 1.7 |
| en-AU | Germanic | 177 | 36/177 | 0.626 | 0.997 / 0.3 |
| en-CA | Germanic | 82 | 38/82 | 0.571 | 0.995 / 1.5 |
| en-GB | Germanic | 95 | 32/95 | 0.747 | 0.951 / 0.0 |
| en-IE | Germanic | 128 | 34/128 | 0.610 | 0.994 / 1.9 |
| en-IN | Germanic | 112 | 26/112 | 0.584 | 0.999 / 0.6 |
| en-SG | Germanic | 72 | 40/72 | 0.537 | 0.996 / 1.5 |
| en-US | Germanic | 126 | 34/126 | 0.491 | 0.997 / 0.4 |
| en-ZA | Germanic | 136 | 34/136 | 0.605 | 0.992 / 0.8 |
| nl-BE | Germanic | 89 | 44/89 | 0.517 | 0.994 / 0.2 |
| nl-NL | Germanic | 100 | 47/100 | 0.525 | 0.996 / 0.0 |
| hi-IN | Indic | 80 | 51/80 | 0.468 | 0.996 / 0.0 |
| ja-JP | Japonic | 76 | 48/76 | 0.526 | 0.992 / 0.0 |
| ko-KR | Koreanic | 86 | 42/86 | 0.500 | 0.997 / 0.0 |
| fr-BE | Romance | 77 | 45/77 | 0.511 | 0.994 / 0.0 |
| fr-FR | Romance | 105 | 44/105 | 0.541 | 0.996 / 0.3 |
| it-IT | Romance | 96 | 45/96 | 0.510 | 0.995 / 0.2 |
| pt-BR | Romance | 150 | 42/150 | 0.474 | 0.997 / 0.1 |
| pt-PT | Romance | 92 | 44/92 | 0.516 | 0.991 / 0.2 |
| pl-PL | Slavic | 87 | 37/87 | 0.482 | 0.992 / 0.0 |
| **Mean** | – | **99** | **44.0%** | **0.543** | **0.992 / 0.5** |

Table 7: Cross-locale intrinsic sampling quality at $N = 5{,}000$. $\text{Cov}_{20}$ reports categories with at least 20 samples. Edit $\Delta$ is the absolute edit-rate deviation from the full evaluation pool, in percentage points.

```
  Mark is_complete=True if >80% of major
rule categories are represented.

IGNORE DURING AUDIT:
   Team-specific or project-specific
instructions
  Rules from other organizations/clients
   DO NOT flag team/project-specific
content as “missing” from the taxonomy

MARK COMPLETE (is_complete=True) IF:
  All major GENERAL category TYPES are
represented
   Patterns capture general structure
adequately
  Descriptions explain the rule/concept
sufficiently
   Source document lacks extractable
rules (intro/purpose text only)
   You cannot meaningfully validate
against source content

MARK INCOMPLETE (is_complete=False)
ONLY IF:
  Entire GENERAL rule categories are
clearly missing
     Critical patterns have no
representation at all
  AND source document contains actual
rules to validate against

EDGE CASE AUTOMATIC PASS:
If source document contains only
introductory/purpose statements
with no actual rules, patterns, or
guidelines to extract, you MUST return
is_complete=True. Do not flag items
as “missing” when the source itself
contains nothing to extract.

LOGICAL CONSTRAINT:
“Cannot assess completeness” +
“is_complete=False” is INVALID. If
validation is impossible due to
source content → is_complete=True
automatically. Do NOT waste iterations
on unvalidatable content.

DO NOT REQUEST:
  Exhaustive word lists or substitution
tables
  Specific external reference links or
dictionary citations
  Every example from source document
   Granular details requiring multiple
extraction passes
   Items not present in the source
document
    Team/project-specific rules or
exceptions

Inputs:
markdown_content: The original style
guide text
organization_name: Organization/Client
name
current_taxonomy: Current extracted
TaxonomyStructure

Outputs:
missing_rules: List of specific
```

Table 9: System-ranking recovery on the audited pool. For each direction and budget, each sampler draws batches and we run a paired $t$-test on the per-segment MQM deltas of the two systems in Table 4. The $|t|$ columns give the median over draws, ratio $= |t|_{\text{TAC}}/|t|_{\text{rand}}$ ($> 1$ favors TACTICS), and Rec is the fraction of draws that are significant ($p < 0.05$) *and* match the full-pool verdict sign. en→fr is a null control, where lower Rec is better.

```
rules/structural gaps identified
is_complete: Boolean  True if >80%
covered, False only if major structural
categories are missing
```

### I.3 Taxonomy Refiner Agent

```
Update the existing category taxonomy
structure based on the feedback from the
auditor agent.

INSTRUCTIONS:
1. Review the 'current_taxonomy'.
2.  Incorporate the missing rules
identified in 'audit_report'.
3.  Return the FULL, updated JSON
structure.
4.  Maintain the existing Group →
Subgroup Hierarchy.

IGNORE DURING REFINEMENT:
   Team-specific or project-specific
instructions
  Rules that only apply to specific
teams, projects, or contexts
  DO NOT add project-specific rules
when incorporating missing rules from
audit_report

Inputs:
current_taxonomy:  The  existing
TaxonomyStructure JSON
audit_report:  Specific missing rules or
errors found by the auditor

Output:
revised_taxonomy: The updated version of
the taxonomy
```

### I.4 Orchestration

The three agents are composed in a LangGraph workflow with conditional routing:

1. **Extraction node** (iteration 0): Runs the two-stage Taxonomy Extraction Agent (Feature Extraction → Synthesis) to produce an initial `TaxonomyStructure`.

2. **Audit node**: Runs the Taxonomy Auditor Agent against each style guide document. If >80% of major rule categories are covered, marks `is_complete=True`.

3. **Routing decision**: If complete or `iterations > max_iterations` (default 5), the workflow terminates. Otherwise, it proceeds to refinement.

4. **Refinement node** (iterations $\geq 1$): Runs the Taxonomy Refiner Agent to incorporate the auditor's missing rules into the existing taxonomy, then loops back to the audit node.

Each stage supports a separate LLM instance (`extraction_lm`, `audit_lm`, `refinement_lm`), enabling heterogeneous model configurations (e.g., a stronger model for extraction, a faster model for auditing). All modules use DSPy's `ChainOfThought` wrapper, which elicits step-by-step reasoning before producing the structured output.

## J Taxonomy Validation

We assess taxonomy consistency via cross-family agreement between two independent classifiers from different model families, Kimi K2.5 and Claude Haiku 4.5. Agreement improves after refinement (Cohen's $\kappa$ from 0.27 to 0.51 on a 100-segment pilot), indicating clearer category boundaries. A taxonomy spot checker additionally samples induced categories and verifies that each is grounded in a prescriptive style-guide rule, clearly defined, and distinguishable from its neighbors, and Table 10 shows this mapping for fr-FR.

Taxonomy sizes range from 48 to 177 categories across locales, reflecting variation in style-guide complexity. English variants (e.g., en-AU,

en-IE, en-ZA) are largest (128–177), East Asian locales (ja-JP, ko-KR, zh-TW) most compact (76–87), and Romance locales fall in between (77–150).

## K Example Taxonomy for French (fr-FR)

Figure 5 shows a condensed view of the taxonomy induced for French (fr-FR), separating *Deterministic* categories (detectable with regex-style or rule-based patterns) from *Semantic* categories (requiring context-aware LLM reasoning). The full taxonomy contains 27 deterministic categories (72 sub-categories) and 17 semantic categories (42 sub-categories).

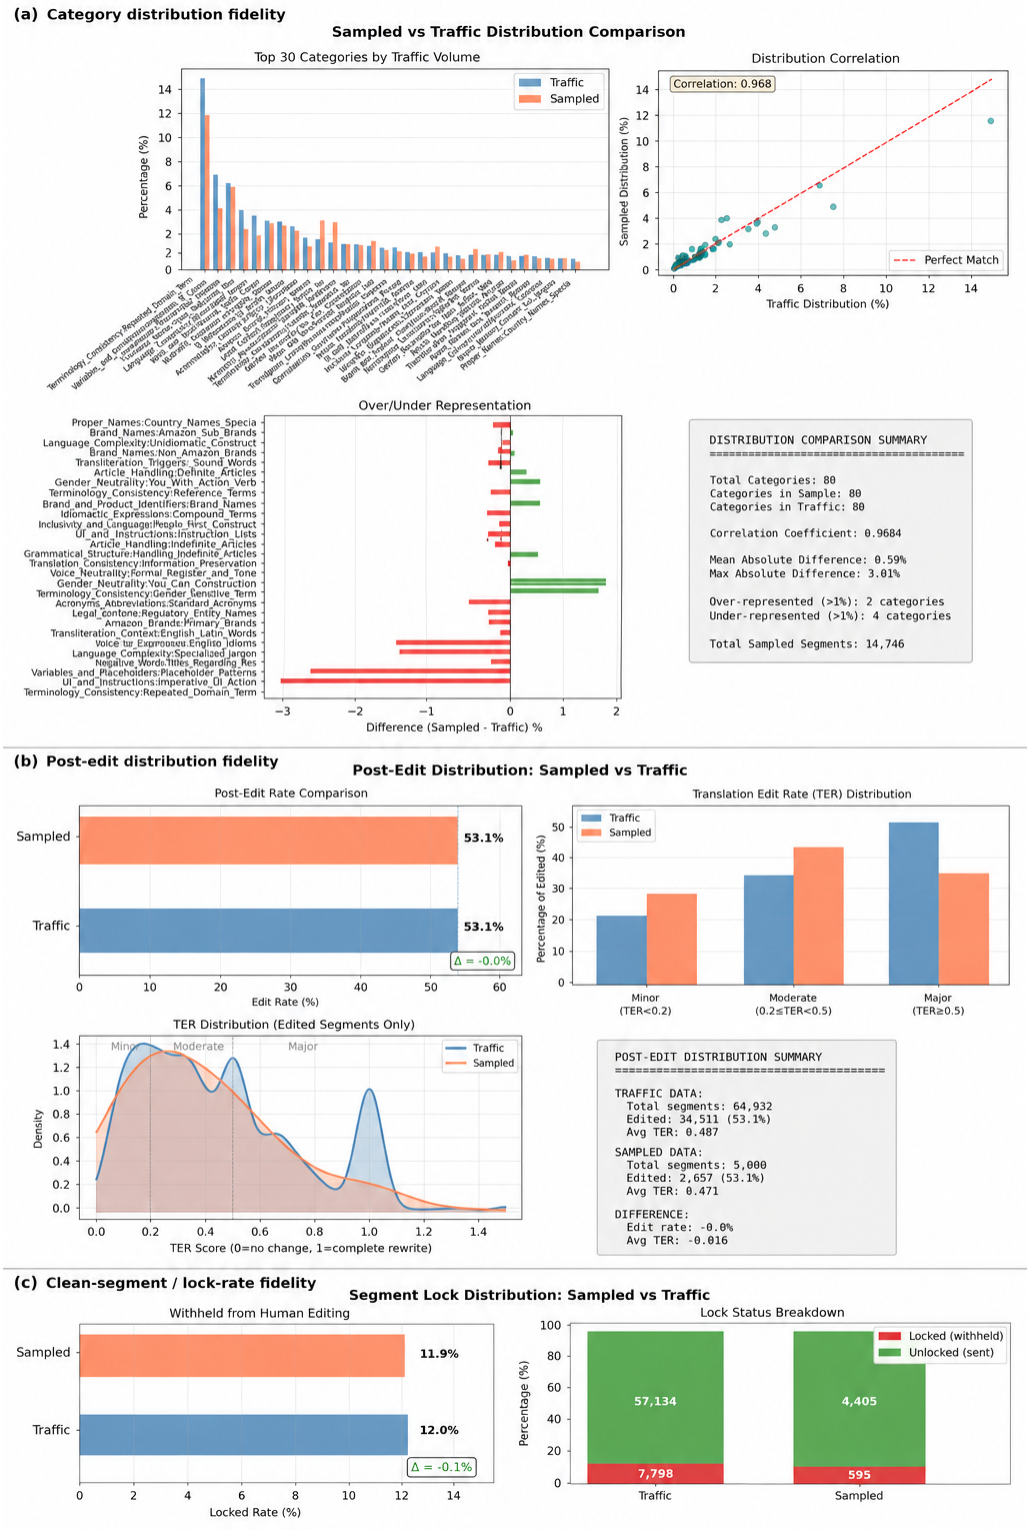

Figure 4: Fidelity diagnostics for the hi-IN test split. (a) Category distribution fidelity compares taxonomy-category frequencies between sampled data and the full evaluation pool. (b) Post-edit distribution fidelity compares edit rate and TER severity distributions. (c) Clean-segment / lock-rate fidelity compares the percentage of segments withheld from human editing. These diagnostics illustrate how Level 3 aligns the final sampled set with the full pool.

| Style Guide Rule | Taxonomy Category | Type | Spot-Check Example |
|---|---|---|---|
| | *Fluency – Grammar & Spelling* | | |
| No plural on acronyms (PDFs → PDF) | Acronyms_Abbrev. / Pluralized_Acronyms | Det. | `\b[A-Z]{2,}s\b` catches "PDFs", "DVDs" |
| Country abbrev. (UK → Royaume-Uni) | Acronyms_Abbrev. / Country_Abbreviations | Det. | `UK\|U.K.` → "Royaume-Uni" |
| Dotted abbrev. (U.S. → États-Unis) | Acronyms_Abbrev. / Dotted_Abbreviations | Det. | `U.S.` matched by `[A-Z]\.([A-Z]\.)+` |
| Tech spelling (Wi-Fi, e-mail) | Technology_Terms / Tech_Spelling | Det. | "WiFi" → "Wi-Fi"; "email" → "e-mail" |
| Web capitalization | Technology_Terms / Web_Capitalization | Det. | "web" → "Web" |
| Proper names invariable (iPads) | Proper_Names / Apple_Products | Det. | "iPads" → "les iPad" (no plural) |
| | *Fluency – Typography* | | |
| Ampersand → "et" | Punctuation_Typo. / Ampersand | Det. | "Shoes & Bags" → "Chaussures et sacs" |
| Hashtag → n$^{o}$ | Punctuation_Typo. / Hashtag_Number | Det. | "#1" → "n$^{o}$ 1" |
| No exclamation in UI | Punctuation_Typo. / Exclamation_in_UI | Det. | "Welcome!" → remove "!" in UI strings |
| | *Locale Convention* | | |
| Currency format (symbol after number) | Currency_Pricing / Currency_Symbols | Det. | "$19.99" → "19,99 $" or "19,99 USD" |
| Date format (MM/DD → DD/MM) | Date_Formats / US_Numeric_Date | Det. | "7/14/2013" → "14/07/2013" |
| Written date reorder | Date_Formats / Written_Month_Date | Det. | "July 14, 2013" → "14 juillet 2013" |
| 12h → 24h time | Time_Formats / Twelve_Hour_Time | Det. | "8:30 pm" → "20 h 30" |
| Thousands sep. (comma → space) | Number_Formats / Thousands_Separator | Det. | "2,935,000" → "2 935 000" |
| Decimal sep. (period → comma) | Number_Formats / Decimal_Numbers | Det. | "11.5" → "11,5" |
| Percent spacing | Number_Formats / Percentage_Values | Det. | "10%" → "10 %" |
| Discount format | Number_Formats / Discount_Expressions | Det. | "40% off" → "- 40 %" |
| Fahrenheit → Celsius | Measurements / Temperature_Fahrenheit | Det. | "72°F" → "22 °C" |
| Imperial → metric | Measurements / Imperial_Units | Det. | "12 inches" → "30,48 cm" |
| Clothing sizes | Measurements / Clothing_Sizes | Det. | "Small" → "Taille S" |
| | *Style* | | |
| Polite "vous" form | Voice_Tone / Second_Person_Address | Sem. | "you" → always "vous" (formal) |
| Imperative in instructions | Instruction_Style / Imperative | Sem. | "Print label" → "Imprimez l'étiquette" |
| Infinitive for buttons | Instruction_Style / Button_Link_Labels | Sem. | "Find a package" → "Trouver un paquet" |
| Gender-neutral roles | Gender_Neutrality / Role_Terms | Sem. | "specialist" → "Spécialiste" (not "Expert(e)") |
| Predicate adj. with "you" | Gender_Neutrality / Predicate_Adj. | Sem. | "you're ready" → rephrase to avoid gendered agreement |
| Long sentences | Language_Complexity / Long_Complex | Sem. | Break up multi-clause sentences for readability |

Table 10: Spot-check mapping between French (fr-FR) localization style guide rules and taxonomy categories. **Type**: Det. = Deterministic (regex-based), Sem. = Semantic (LLM-based). Each row shows a style guide rule, its corresponding taxonomy category, detection type, and a concrete example of how the rule is operationalized.

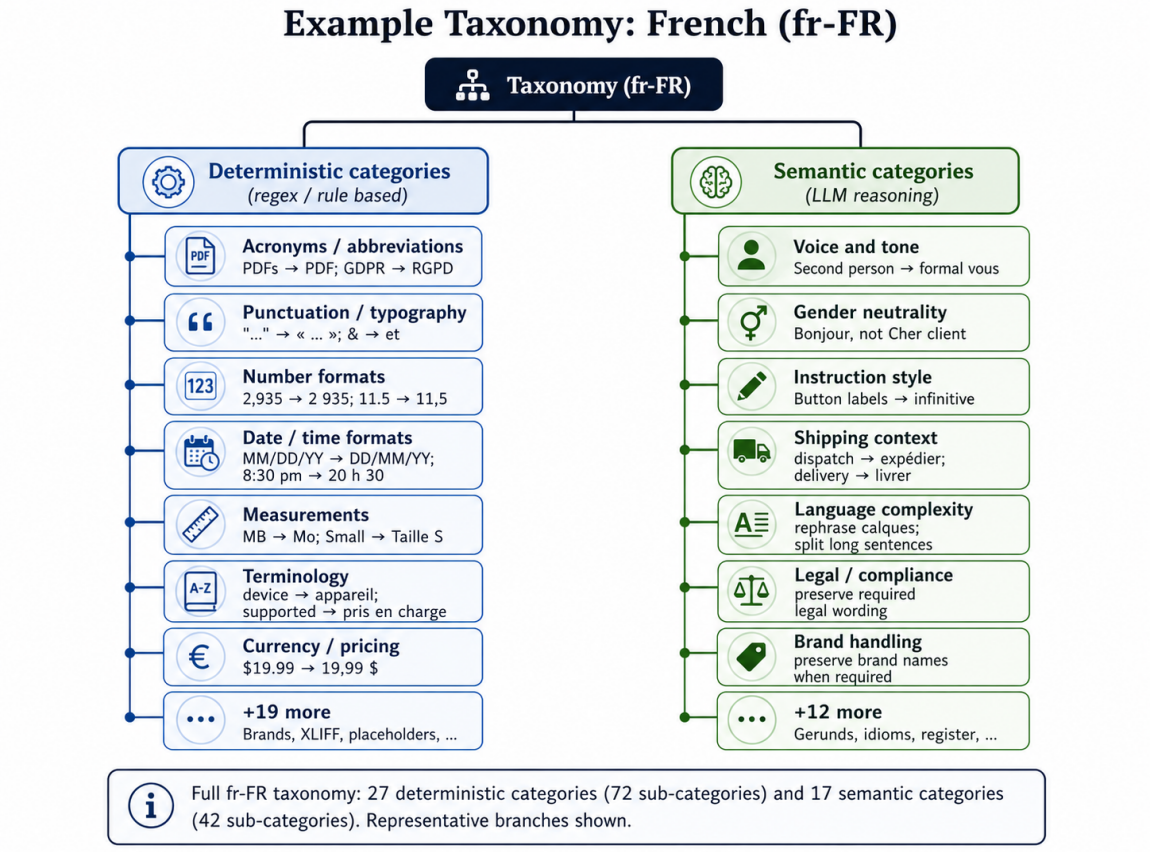

Figure 5: Condensed example taxonomy for French (fr-FR). Deterministic categories capture rule-matchable phenomena such as punctuation, number formats, terminology, and currency conventions. Semantic categories capture context-dependent phenomena such as tone, gender neutrality, instruction style, and shipping context.

# Synthetic Slang Generation for Benchmarking Machine Translation

**Eric Bennett**
Northeastern University
bennett.er@northeastern.edu

## Abstract

Slang presents a persistent challenge in machine translation (MT) because its informal, socially situated meanings can depend heavily on context, especially when a system has not encountered the form or sense in training. We introduce a language-adaptable pipeline for generating and validating realistic synthetic slang, and use it to create a benchmark of 1,087 items across Chinese, Russian, and Farsi. We evaluate ten large language model (LLM)-based MT systems under three conditions: translation from a single usage, translation with an additional example of usage in context, and translation conditioned on a gold definition. We find additional context consistently improves translation quality, especially on slang types which are most difficult without assistance. The benefit of providing the gold definition generally grows as model size shrinks. We also test the ability for models to recover the synthetic slang definition, rising to 99% accuracy with 2 examples in context. These results demonstrate how synthetic slang can provide a controlled stress test of meaning inference from context in MT systems.

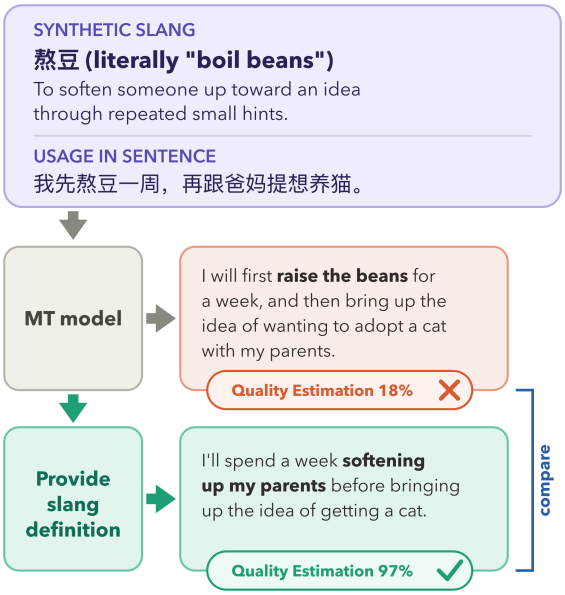

Figure 1: Illustration of the synthetic-slang translation conditions. Given a source sentence containing a synthetic slang term, an MT system translates the sentence with and without access to the term's intended meaning. Translation quality is compared using reference-free quality-estimation metrics.

## 1 Introduction

Slang translation is a uniquely difficult problem in Machine Translation (MT). Slang is constantly changing and highly individualistic – two friends might use specific terms unused anywhere else in the world in that context. Rather than test the ability for an MT system to retrieve existing cross-lingual representations seen in the training data, this type of language requires an ability to extract the meaning of a term from its context alone.

In this paper, we introduce a method for generating synthetic-but-realistic slang to benchmark MT systems[1], and evaluate it on ten LLM-based MT systems for Chinese, Russian, and Farsi. Using the benchmark we report results comparing direct translations of synthetic slang in context to translations conditioned on the ground-truth slang definition, as shown in Figure 1.

### 1.1 Why Slang is Hard to Translate

Slang and informal language show up constantly in realistic material, and standard MT systems and static lexicons often can't keep up with how quickly that vocabulary shifts. A term can fall out of use, narrow, broaden, or pick up a completely new meaning within a matter of months, which means a glossary or MT system trained a year ago may already be missing the terms that matter most in current events. Culture-specific references add another layer of complexity, introduc-

[1]We release code at the following link: https://github.com/softly-undefined/synthslang

*Proceedings of the Eleventh Conference on Machine Translation*, pages 33–46
October 28-29, 2026 ©2026 Association for Computational Linguistics

ing idioms, running jokes, references to current events, regional slang, and in-group shorthand. A word that reads as neutral or even funny in one cultural context can land very differently in another, and there's no way to fix that with lexical accuracy alone; the missing piece is background knowledge, not vocabulary.

The difficulty of translating slang differs depending on the linguistic makeup of a language. In Russian, derivational morphology often contributes meaning beyond simple lexical modification. Affixes may encode evaluation, emotional stance, intensity, familiarity, irony, or informality alongside their grammatical functions. Within a constructionist framework, speakers can interpret novel slang formations because they possess abstract knowledge of productive morphological schemas and the semantic and pragmatic meanings associated with them.

Chinese slang is highly dependent on compounding, semantic extension, homophony, and character-level wordplay, so meaning is often carried by the combination and reinterpretation of existing characters. A novel slang term may combine familiar characters in an unfamiliar way, or exploit phonetic similarity with another word. In the development of our Chinese slang generation taxonomy, we analyzed the internet slang data collected by Zhao et al. (2026) for recurring slang patterns.

Farsi forms much of its slang through the productive compound (light-verb) construction, pairing a nominal or adjectival element with a small set of light verbs to coin new verbs whose meaning exceeds their parts. It also draws on ready assimilation of foreign loanwords, which are re-inflected as native words.

Sociolinguistic factors also contribute to the creation of slang, as new slang often acquires meanings associated with particular communities, identities, generations, or communicative settings. Translation of slang language therefore must encode semantic, morphological, and pragmatic information into a single expression, and artfully reinterpret those layers of meaning in another language.

### 1.2 Slang in Machine Translation

In this work, slang is characterized by informal, socially situated use, and may involve a new form or a new sense. Our synthetic slang spans multiple categories of how slang is developed, including a recently coined form or meaning now in broader use (neologisms), and a word created for a particular occasion without broader circulation (nonce words), as well as overlapping with related linguistic phenomena, including informal language used in everyday settings (colloquial language), and alternation between languages within discourse (code-switching).

Recent benchmarks have begun to evaluate slang in machine translation. SlangDIT tests whether LLMs can infer and translate the meanings of attested slang expressions from context (Liang et al., 2025), and Zhao et al. (2026) evaluates translation of Chinese social-media language that includes naturally occurring internet slang. These resources establish slang interpretation as a meaningful stress test of MT. NEO-BENCH studies the effect of neologisms on LLM robustness, including machine translation, using terms that emerged after the models' knowledge cutoffs (Zheng et al., 2024). This reduces the likelihood that models can rely on encountering test data during pretraining, but defining novelty relative to cutoff dates ties the benchmark to particular models and time periods, and requires new items as language evolves. We pursue the same goal by using realistic but nonexistent slang, creating a fixed benchmark whose novelty does not depend on when a model was trained.

Synthetic words have been used to test whether a model can apply learned linguistic patterns to unfamiliar forms, taking inspiration from Wug tests, where a learner is asked to apply familiar morphological rules to invented words (Berko, 1958). Anh et al. (2024) apply a multilingual Wug Test across six languages and find that LLMs can generalize to novel words, though performance varies with morphological complexity. Pantelidou et al. (2026) use a related test and find that language-community size predicts model accuracy better than grammatical complexity. Ismayilzada et al. (2025) test novel roots in Turkish and Finnish and find that models struggle as morphological complexity increases.

Prior work has also shown that MT systems can benefit from external lexical information supplied at inference time. The WMT 2023 Terminology Shared Task directly compares translation with and without segment-level terminology dictionaries (Semenov et al., 2023). Recent work extends this idea by adding retrieved terminology or broader linguistic descriptions to the prompt (Zhang et al., 2024; Li et al., 2025).

In this work, we bridge the gap between glossary-assisted translation and synthetic language evaluation by generating synthetic slang that remains linguistically and culturally grounded in each source language, using it to test how MT systems translate novel slang meanings and whether added information about a term's meaning at inference time helps preserve it in translation.

## 2 Methodology

Our pipeline has three stages: slang generation, translation, and translation evaluation. We first generate candidate slang terms and filter them through a series of quality and contamination gates; we then translate the surviving items under different context and definition conditions; finally, we evaluate translation quality with validated reference-free metrics and measure definition recovery.

### 2.1 Slang Generation

We use an LLM to generate potential new slang terms, as well as the usage of such term in both a sentence and paragraph setting. Each term is passed through a series of gates to ensure the quality of the proposed term in order to address the potential flaws with LLM generation of the novel slang terms.

Slang is linguistically and culturally grounded, so prompts are individualized per-language. We use a single shared slang type across all languages (Semantic Shift), and propose 2-3 language-specific slang types. Examples of each type can be found in Appendix A.

#### 2.1.1 Shared Types

**Semantic Shift** Take an ordinary word in the source language and assign it a completely new figurative meaning through metaphor or metonymy, unrelated to (or only obliquely connected with) its dictionary definition.

**Morphological Blend** (Shared across Chinese and Russian) Fuse two existing roots, or characters, into a single new word, whose meaning goes beyond either component.

**Affixation** (Shared across Chinese and Farsi) Attach a prefix or suffix to a base to coin a term for a behavior or social group. Focuses on a small group of affixes, individualized by language.

#### 2.1.2 Chinese Slang Taxonomy

**Sentence Compression** A process that forms a novel *chengyu*, a classical four-character idiom. Takes a multi-clause colloquial expression and extracts one key character from each clause to produce a memorable 4-character idiom.

#### 2.1.3 Russian Slang Taxonomy

**Suffixation** Attach a productive colloquial Russian suffix to an existing or invented root to coin an expressive new noun, verb, or adjective for a state, person-type, or behavior.

**Foreign Verb** Take a non-Russian word (English, French, German, etc.) and russify it by adding native verbal or nominal morphology (*-ить*, *-овать*, *-нуть*, *-ировать*, or noun endings) so it sounds and inflects like a native Russian word.

#### 2.1.4 Farsi Slang Taxonomy

**Light Verb** Pair a noun or adjective (native, or an assimilated English/foreign loanword) with a native Persian light verb to coin a new compound verb whose slang meaning goes beyond the literal parts.

### 2.2 Contamination Gates

For each slang type and language we generate 400 examples using OpenAI's GPT-5.4, requesting 20 slang–definition pairs per call[2]. These examples are then passed through a series of contamination gates to ensure the synthetic slang passed to the translation phase is novel and realistic. We set 100 cleaned items per type as a target, so generating 400 examples per category allows us to apply conservative filtering at each gate. The gates run cheapest-first, so that the more expensive checks only run on surviving candidates, and only terms that clear all four are taken forward. The purpose of the gates is to optimize which segments are shown to human reviewers by removing clearly unsuitable segments. Throughout, we write $\phi(\cdot)$ to represent a fixed multilingual sentence encoder[3] that returns an $L_2$-normalized embedding, so that the cosine similarity of two texts is their inner product.

**Gate 1: Deduplication** Because generation only removes string duplicates of slang term, two items may still refer to the same concept. We remove

[2]The generation prompts are provided in Appendix C

[3]sentence-transformers/paraphrase-multilingual-MiniLM-L12-v2

these near-duplicates by embedding each candidate's English definition: a candidate is dropped as a near-duplicate of an earlier representative when its cosine similarity to that representative exceeds a cutoff

$$\tau_{\text{dup}} = \max(f,\ \mu + k\sigma)\,, \tag{1}$$

where $\mu$ and $\sigma$ are the mean and standard deviation of all pairwise similarities in the batch, $f$ is a floor, and $k$ scales the outlier (we use $f$=0.5, $k$=3). The floor ensures that a diverse batch flags nothing, while the relative term adapts the cutoff to each batch.

**Gate 2: Guessability** A term is only useful to test if its meaning cannot be recovered from its surface form alone. Using the same model that generated the item, we generate $n$ independent zero-context guesses $g_1, \ldots, g_n$ of the meaning, showing the term (and, for Russian, its part of speech), and withholding the definition $d$. We score guessability by the mean cosine similarity between each guess and the true definition,

$$\mathrm{G}(t) = \frac{1}{n}\sum_{i=1}^{n} \cos\big(\phi(d),\, \phi(g_i)\big), \tag{2}$$

and discard the term when $\mathrm{G}(t) \geq \tau_g$ (we use $n$=3, and $\tau_g$=0.55). A high score means the form gives the meaning away, and would not be genuinely challenging to translate. The guessability prompt can be found in Appendix C.2.

**Gate 3: Existence Check** This gate removes terms that already exist with their synthetic slang meaning, a common issue in early outputs. Each term is searched by itself, in quotation marks, and through queries that combine it with information from its definition. Each retrieved snippet is then evaluated in two ways. The embedding judge counts a snippet $h$ as using the intended meaning when $\cos(\phi(d), \phi(h)) \geq \tau_s$. GPT-5.4-mini separately checks whether the snippet uses the intended meaning and flags cases where the term already exists as another word or name. Letting $S(t)$ be the number of distinct domains contributing an insense snippet, we remove the term when

$$S(t) \geq N, \tag{3}$$

treating distinct domains as independent attestations (we use $N$=3). In the consensus configuration both judges run off a single retrieval: a term is removed only when both flag existence, and cases where the judges disagree are escalated to human review.

| | | | Remaining at gate | | | |
|---|---|---|---|---|---|---|
| **Lang.** | **Slang Type** | **Gen.** | Dedup | Guess | Exist | **Human** |
| Chinese | Semantic Shift | 400 | 324 | 288 | 281 | 100 (57%) |
| | Morphological Blend | 400 | 322 | 224 | 213 | 100 (65%) |
| | Affixation | 400 | 294 | 123 | 114 | 87 (76%) |
| | Sentence Compression | 400 | 248 | 135 | 132 | 100 (77%) |
| Russian | Semantic Shift | 400 | 329 | 317 | 301 | 100 (60%) |
| | Morphological Blend | 400 | 334 | 244 | 214 | 100 (76%) |
| | Suffixation | 400 | 307 | 276 | 258 | 100 (66%) |
| | Foreign Verb | 400 | 326 | 275 | 256 | 100 (59%) |
| Farsi | Semantic Shift | 400 | 331 | 329 | 324 | 100 (90%) |
| | Affixation | 400 | 321 | 149 | 146 | 100 (89%) |
| | Light Verb | 400 | 329 | 277 | 270 | 100 (89%) |

Table 1: Number of synthetic slang items remaining after each contamination gate, by language and slang type. The Human column reports accepted items, with the percentage of reviewed items accepted in parentheses, rounded to the nearest whole percent.

**Gate 4: Human Validation** Terms that survive the first three gates then have a sentence, and paragraph, of the synthetic slang in context generated by an LLM. The resultant (slang, definition, sentence, paragraph) sets are validated by a speaker of the source language. Annotators were asked to measure two aspects of the synthetic slang with a binary judgement: 1) *Faithful Use*: Does the slang term, as used in the sentence and paragraph, faithfully reflect the ground truth definition? 2) *Existence Check*: Is the slang term, as it is defined in definition, novel in this language?

If either aspect is judged as false, we remove that item from the final set. For each slang type we stop human annotation after validating 100 items of that type[4]. Exact details on how many slang items remained after each gate are found in Table 1.

### 2.3 Slang Translation

We evaluate ten LLM-based MT systems, varying the level of context provided to observe its impact on the translation quality of synthetic slang. All systems used temperature 0 for decoding. The ten evaluated systems are:

- Gemma-3 4B-it, 12B-it, and 27B-it
- Qwen3.5 4B, 9B, and 27B
- GPT-4o-mini
- DeepSeek-V3.2
- Claude Sonnet 4.6
- Gemini 3.5 Flash

[4]For the Chinese Affixation slang type after all validation only 87 terms remained

Reasoning was enabled for Claude Sonnet 4.6, where it was set to high, and Gemini 3.5 Flash, where it was set to medium. Through translation, we examine (1) translation quality and (2) definition recovery. All prompts are provided in Appendix C.3.

**Translation Paths**

- **Direct**: A simple translation prompt from the source language to the target language. Run on both a sentence and a paragraph. The prompt is based on Andrew Ng's translation agent[5].
- **DirectContext**: This prompt only runs on the sentence level. The same prompt as Direct, but the prompt includes the paragraph-level text, without a translation of the text, with a second example of the usage of a term in context.
- **DirectWithHint**: In this prompt method, the model is tasked with translating at both the sentence and paragraph level, conditioned on the slang term and ground-truth definition generated in the Slang Generation phase. This condition mimics that of a retrieval-augmented LLM-based MT system, which has recently become a popular idea.

**Definition-Recovery Paths**

- **SlangDITIdentify**: Given the slang term and its usage in a sentence, the model is prompted to create a definition of the term. The prompt is inspired from the vanilla prompt in Liang et al. (2025).
- **SlangDITIdentifyContext**: Given the slang term, its usage in a sentence, and its usage in a paragraph, the model is prompted to create a definition of the term.

### 2.4 Slang Translation Evaluation

With the absence of a true ground-truth translation of these nonexistent slang terms in context, we rely on Quality Estimation (QE) style metrics which take in a (source, hypothesis) tuple and output a score. We do not synthesize reference translations as such translations would be structurally similar to the DirectWithHint translation path, and would themselves require further human validation. QE metrics require no ground-truth reference, making them well suited to our setting where no such reference exists. However, we acknowledge that these metrics are themselves imperfect proxies for translation quality, and use a human evaluation to select which metrics to report. We consider the following metrics:

1. **CometKiwi**: A reference-free neural QE model (wmt22-cometkiwi-da) that concatenates source and translation and feeds them to a pretrained multilingual encoder (XLM-R/InfoXLM) to regress a single scalar quality score. (Rei et al., 2022)
2. **GEMBA-DA (Direct Assessment)**: An LLM-as-a-judge metric that, given a source and hypothesis translation, produces a score on a 0-100 scale. We use OpenAI's GPT-5.4-mini for scoring. (Kocmi and Federmann, 2023)
3. **GEMBA-DA-Def** (ours): The GEMBA-DA judge conditioned on the synthetic slang term and its gold definition, which is added to the prompt so the model scores against the intended meaning of the novel slang term.

We measure definition-recovery accuracy using a binary LLM judgment of whether the definition generated by SlangDITIdentify or SlangDITIdentifyContext conveys the same core meaning as the gold definition. This metric evaluates semantic equivalence rather than exact wording. Appendix C.4 gives prompts for GEMBA-DA-Def and the binary definition-equivalence judge.

**Metric Validation via Human Judgment** Selecting a metric is unusually difficult in our setting: because every slang term is synthetic, no existing metric has observed these terms, and learned QE models were trained on standard, naturally occurring language, so their quality signals may not transfer to synthetic slang. We conduct a human evaluation on a subset of translations to measure agreement between a human judge and automatic metrics. A native speaker of Russian and two annotators fluent in Chinese and Farsi, respectively, performed a blinded three-way preference evaluation: for each slang term (sentence-level, Gemma-3 4B outputs), the annotator was shown the Direct and DirectWithHint translations in randomized order and selected the better translation, or

[5] https://github.com/andrewyng/translation-agent

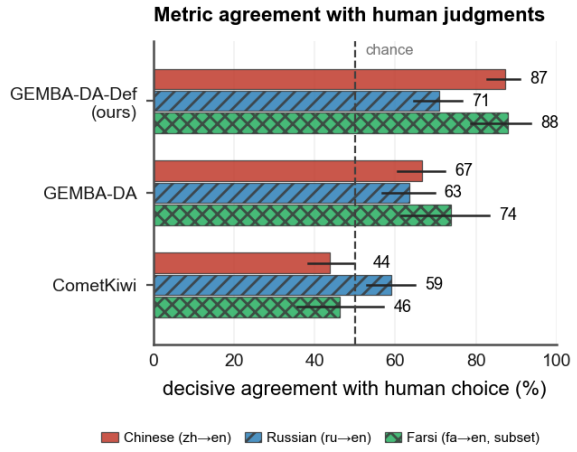

Figure 2: Metric agreement with blinded human judgments across Chinese, Russian, and Farsi. GEMBA-DA conditioned on the gold slang definition (GEMBA-DA-Def) aligns most closely with human preference; Farsi reviews half of all segments, selected randomly.

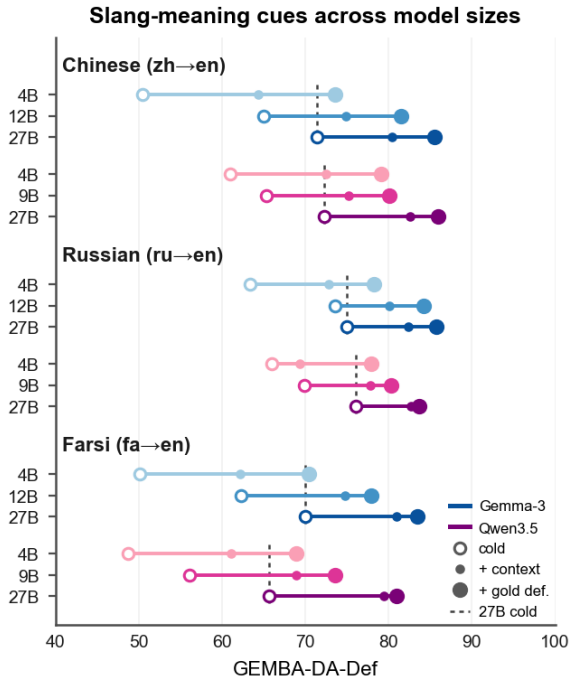

Figure 3: Slang-meaning cues across LLM sizes. Mean GEMBA-DA-Def scores are shown for the Gemma-3 (4B, 12B, and 27B) and Qwen3.5 (4B, 9B, and 27B) size ladders. Translation quality rises with LLM size across both Gemma-3 and Qwen3.5, but the benefit of gold-definition cues shrinks as LLM size grows.

a tie. We score each candidate metric by its concordance with these judgments, the rate at which the metric's preferred translation matches the annotator's choice, reported in Figure 2. Among the metrics tested, GEMBA-DA-Def achieved the highest decisive agreement with human judgments in all three languages: 87.3% for Chinese, 71.0% for Russian, and 88.0% for Farsi. In the Results section we report GEMBA-DA-Def and GEMBA-DA; Appendix B gives a further comparison with two stronger judge variants.

## 3 Results

A full table of translation-quality results across LLM-based MT systems and metrics can be found in Table 2; definition-recovery results across the underlying LLMs can be found in Table 3.

### 3.1 Effect of LLM Size

We report results across Gemma-3 (4B, 12B, 27B) and Qwen3.5 (4B, 9B, 27B) size ladders. Figure 3 shows as LLM size increases, translation quality increases, across all definition conditions. However, as LLM size increases, the benefit of providing the gold definition generally decreases. This suggests larger LLMs are better able to interpret the novel slang's meaning from context alone, and the added information of the hint, or usage in a paragraph, doesn't make as much of an impact. Notably, across model families, a 4-billion-parameter LLM given the gold definition matches or outperforms a 27-billion-parameter LLM without it.

### 3.2 Language Specific Results

Figure 4 shows substantial variation in translation quality across slang types, both within and between languages. The Direct condition, where systems must infer the term's meaning from the sentence-level use alone, shows the most variation. Both assisted conditions produce narrower differences across slang types.

Scores for Semantic Shift differ across languages despite representing the same formation process. For Farsi, additional context brings performance nearly on par with access to the gold definition (74.8 compared with 76.6). One possible explanation is that the mapping between a word's original and synthetic meanings is not equally transferable across languages. For example, Chinese word formation frequently draws on character-level composition, homophony, and culturally specific associations, so a novel sense may compete with several existing interpretations.

The slang types with the lowest Direct scores consistently receive the largest proportional gains from additional context. Across the 11 language–

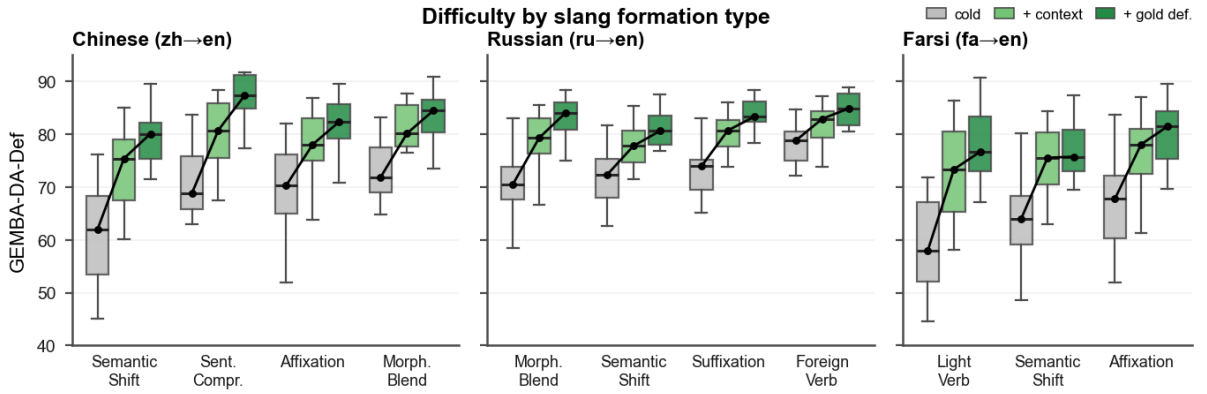

Figure 4: Distribution of per-system mean sentence-level GEMBA-DA-Def scores across ten LLM-based MT systems for the Direct (cold), DirectContext (+context), and DirectWithHint (+gold def.) conditions in Chinese, Russian, and Farsi. Added context produces more consistent translation quality across slang types.

| Condition | Lang. | Metric | Gemma-3 4B | Gemma-3 12B | Gemma-3 27B | Qwen3.5 4B | Qwen3.5 9B | Qwen3.5 27B | GPT-4o -mini | DeepSeek -V3.2 | Claude Sonnet 4.6 | Gemini 3.5 Flash |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Direct | Chinese | GEMBA-DA | 58.4 | 72.8 | 77.6 | 69.0 | 73.8 | 79.2 | 70.5 | 79.2 | 81.5 | **81.9** |
| | | GEMBA-DA-Def | 50.5 | 65.0 | 71.4 | 60.9 | 65.3 | 72.3 | 63.0 | 73.7 | 77.0 | **81.3** |
| | Russian | GEMBA-DA | 72.5 | 82.2 | 84.0 | 73.0 | 78.3 | 83.8 | 78.6 | 83.7 | 84.2 | **87.1** |
| | | GEMBA-DA-Def | 63.3 | 73.6 | 75.0 | 66.0 | 69.9 | 76.1 | 71.4 | 75.3 | 78.5 | **83.2** |
| | Farsi | GEMBA-DA | 60.4 | 74.7 | 80.3 | 60.5 | 68.9 | 77.1 | 72.9 | 77.3 | 82.2 | **85.6** |
| | | GEMBA-DA-Def | 50.2 | 62.3 | 70.0 | 48.7 | 56.1 | 65.7 | 60.5 | 64.8 | 73.8 | **78.6** |
| DirectContext | Chinese | GEMBA-DA | 65.9 | 74.1 | 78.7 | 70.4 | 73.6 | 79.6 | 74.7 | 80.7 | 80.1 | **82.4** |
| | | GEMBA-DA-Def | 64.4 | 74.9 | 80.4 | 72.5 | 75.2 | 82.5 | 74.9 | 82.9 | 86.0 | **87.0** |
| | Russian | GEMBA-DA | 76.7 | 82.9 | 84.5 | 70.9 | 80.7 | 83.9 | 79.7 | 82.9 | 84.9 | **86.4** |
| | | GEMBA-DA-Def | 72.8 | 80.0 | 82.4 | 69.3 | 77.9 | 82.6 | 76.7 | 80.5 | 84.5 | **86.0** |
| | Farsi | GEMBA-DA | 67.6 | 78.2 | 82.3 | 66.4 | 72.3 | 79.3 | 77.4 | 78.6 | 82.1 | **84.8** |
| | | GEMBA-DA-Def | 62.2 | 74.8 | 81.0 | 61.1 | 68.9 | 79.5 | 71.3 | 76.6 | 84.1 | **85.9** |
| DirectWithHint | Chinese | GEMBA-DA | 65.5 | 74.8 | 77.6 | 71.4 | 73.4 | 77.4 | 72.8 | 78.1 | 77.4 | **81.7** |
| | | GEMBA-DA-Def | 73.6 | 81.5 | 85.6 | 79.1 | 80.0 | 86.0 | 80.9 | 85.7 | 89.0 | **89.6** |
| | Russian | GEMBA-DA | 78.5 | 83.3 | **84.9** | 76.8 | 79.7 | 81.8 | 80.7 | 82.1 | 82.9 | **84.9** |
| | | GEMBA-DA-Def | 78.3 | 84.2 | 85.8 | 77.9 | 80.3 | 83.7 | 81.5 | 84.5 | 86.4 | **88.3** |
| | Farsi | GEMBA-DA | 69.8 | 77.2 | 80.8 | 68.2 | 72.3 | 76.8 | 74.2 | 73.1 | 80.7 | **84.3** |
| | | GEMBA-DA-Def | 70.4 | 77.9 | 83.5 | 68.9 | 73.5 | 80.9 | 75.3 | 78.1 | 85.9 | **89.2** |

Table 2: Translation quality across LLM-based MT systems and metrics for Chinese, Russian, and Farsi, by condition (Direct, DirectContext, DirectWithHint), sentence-level. The highest value per metric within each condition block is shown in **bold** and the second-highest underlined. Claude Sonnet 4.6 uses high reasoning, and Gemini 3.5 Flash uses medium reasoning.

type pairs, lower Direct scores coincided with larger proportional gains from added context, suggesting context is especially useful when cold translation is more difficult. Gold definitions also make performance more consistent across slang types. The range between the highest- and lowest-scoring type falls from 11.1 to 7.7 points in Chinese, 7.1 to 3.7 in Russian, and 8.6 to 3.6 in Farsi between Direct and DirectWithHint, reductions of 31%, 48%, and 59%, respectively. Because the performance gap between slang types narrows when the gold definition is provided, the types appear to differ primarily in how difficult their meanings are to infer.

### 3.3 Definition Recovery

Definition-recovery results across models for the Identify and Context conditions can be found in Table 3. Results are strong across models, demonstrating that LLM-based MT systems can recover the meaning of previously unseen slang terms from only one or two examples of their usage in context. Providing a second usage example in the SlangDITIdentifyContext condition improves definition-recovery accuracy for every system and language, reaching 99% according to our LLM judge for Claude Sonnet 4.6 on both Chinese and Farsi. Across all models and languages, providing a second usage example increased definition-recovery accuracy by 26.3 percentage points (95%

| | Chinese | | Russian | | Farsi | |
|---|---|---|---|---|---|---|
| **Model** | Id | Ctx | Id | Ctx | Id | Ctx |

| Gemini 3.5 Flash | 0.77 | 0.97 | 0.77 | 0.91 | 0.81 | 0.96 |

Table 3: Definition-recovery accuracy across models for Chinese, Russian, and Farsi. A prediction is counted as correct when it conveys the same core meaning as the gold definition, as decided by an LLM judge. **Id** = SlangDITIdentify, **Ctx** = SlangDITIdentifyContext. The highest value per column is shown in **bold**. Claude Sonnet 4.6 uses high reasoning, and Gemini 3.5 Flash uses medium reasoning.

CI [24.9, 27.7]). This improvement was statistically significant for every model–language combination.

## 4 Conclusion

We introduce a language-adaptable pipeline for generating and validating synthetic slang and use it to benchmark ten LLM-based MT systems across Chinese, Russian, and Farsi. Across systems, providing an additional usage example or gold definition improves translation quality, with gold-definition gains generally largest among smaller models and gains from either form of assistance largest for slang types that are difficult to translate from a single usage. Systems can also recover the meanings of synthetic slang from context, with a second usage example improving accuracy across every system and language combination evaluated. Together, these results show that synthetic slang can provide a controlled way to test how well MT systems infer unfamiliar meanings from context rather than rely on forms and senses encountered during training.

## 5 Limitations

The benchmark covers three source languages and eleven language–slang type combinations, all translated into English. These slang types are not exhaustive and cannot capture the full complexity and cultural context of how slang develops in the real world. Future work should compare results on synthetic slang to recently-attested naturally occurring slang.

To keep translation evaluation annotation manageable, metric validation focused on sentence-level translations from Gemma-3 4B, with only a random half of the Farsi pairs evaluated. These results provide evidence for selecting GEMBA-DA-Def in the tested setting, although broader annotation would be useful to confirm that its agreement with human judgments holds across annotators, models, and source length.

## 6 Acknowledgments

This work was developed during the Summer Conference on Applied Data Science (SCADS), hosted by the Laboratory for Analytic Sciences at North Carolina State University. Thanks to the language professionals who contributed to human validation and annotation, especially Larysa T.

# A Slang Examples

Table 4 contains representative examples of synthetic slang generated for each language and slang type.

# B Metric Selection Details

To test whether additional compute in the LLM-judge process improves agreement with human judgments, we compare the reported GEMBA-DA-Def against two more expensive variants for the validated Russian slang. All three configurations score the same 400 blinded Direct versus DirectWithHint pairs produced by Gemma-3 4B at the sentence-level. GEMBA-DA-Def-Big uses GPT-5.4 instead of GPT-5.4-mini, while GEMBA-DA-Def-Avg3 samples the GPT-5.4-mini judge three times and averages the resulting scores. Table 5 reports three-way agreement, which treats a match on Tie as agreement, and decisive agreement, which excludes pairs where either the annotator or metric selected Tie. GEMBA-DA-Def-Big produces the highest agreement, reaching 73.8% on decisive pairs compared with 71.0% for GEMBA-DA-Def. Averaging three GPT-5.4-mini judgments does not improve concordance. We identify a single GPT-5.4-mini GEMBA-DA-Def judgment as the best cost–performance tradeoff for the main experiments.

# C Prompt Templates

## C.1 Synthetic Slang Generation

The following are the run-time prompts for the eleven language–formation combinations used in the paper. For space, all few-shot demonstration blocks are omitted throughout this appendix; all other prompt text and formatting are reproduced verbatim.

### Chinese: Semantic Shift

```
Invent fake-but-plausible Chinese internet slang
using SEMANTIC SHIFT: take an ordinary Chinese word
and assign it a completely new figurative meaning
through metaphor or metonymy.

Rules:
- The new meaning must be non-obvious from the
characters alone.
- The meaning should name a recognizable modern
phenomenon, behavior, feeling, or situation.
- Do not use words already known to have slang
meanings.

Generate exactly 20 fake slang terms as a JSON array:

[
  {
    "term": "Chinese characters",
    "base": "literal meaning",
    "definition_tar_lang": "the new slang meaning,
    in English, 1-2 sentences"
  }
]
```

### Chinese: Morphological Blend

```
Invent fake-but-plausible Chinese internet slang
using MORPHOLOGICAL BLEND (混成型): fuse two existing
words or morphemes into a new compound whose meaning
goes beyond either component.

Rules:
- The result should feel like a single new concept,
not just a noun phrase.
- The meaning should not be fully predictable from
the parts — there should be a conceptual leap.
- Aim for 2–3 character compounds.
```

| | Slang Type | Term | Definition | Usage in Sentence |
|---|---|---|---|---|
| **Chinese** | Semantic Shift | 熬豆<br>*áo dòu* | To spend a long time softening up a hesitant friend, parent, or group chat toward an idea through repeated small hints rather than one direct ask. | 我先熬豆一周，再跟爸妈提想养猫。<br>*I'll work on them gradually for a week first, then bring up wanting to adopt a cat to my parents.* |
| | Morphological Blend | 拖嗨<br>*tuō hāi* | The weirdly energized state where, instead of doing the task, you become intensely active about everything around it: organizing files, researching tools, making playlists. Procrastination that feels productive and exciting. | 本来要写方案，结果先把桌面收拾到拖嗨。<br>*I was supposed to write the proposal, but instead I got so dragged-hyped that I ended up tidying my desktop first.* |
| | Affixation | 陪删狗<br>*péi shān gǒu* | A friend called in to witness and support a dramatic cleanup session, whether digital or emotional. Their role is not to solve the problem, but to say 'yes, delete it' at the right moments. | 失恋后找了个陪删狗，聊天记录终于清干净了。<br>*After the breakup, I got a deletion buddy, and finally cleared out the chat history.* |
| | Sentence Compression | 雨停带伞<br>*yǔ tíng dài sǎn* | Used for mildly annoying timing irony: you prepare carefully for bad weather and then the weather immediately stops being a problem. | 早高峰挤地铁还拎把伞，结果一到园区就雨停带伞。<br>*I squeezed onto the subway during rush hour carrying an umbrella, and as soon as I got to the office park, it was a total 'rain-stops-once-you-bring-an-umbrella' moment.* |
| **Russian** | Semantic Shift | распарить<br>*rasparit'* | To wear down someone's resistance to an idea by surrounding them with low-stakes examples, jokes, and repeated exposure until they agree almost passively. It is softening by atmosphere rather than argument. | Он меня так распарил мемами про переезд, что я уже смотрю билеты.<br>*He softened me up so much with memes about moving that I'm already looking at tickets.* |
| | Morphological Blend | срачегория<br>*srachegoriya* | A topic bucket online that reliably stops being discussion and becomes ritualized combat, regardless of how harmless the original post looked. | Стоило упомянуть доставку еды, и тред мгновенно уехал в срачегорию.<br>*I only had to mention food delivery, and the thread instantly derailed into a flame-war zone.* |
| | Suffixation | жмакня<br>*zhmaknya* | The sloppy routine of pressing random interface elements, filters, and reaction buttons without much intent, just to produce movement on screen. It is interaction as idle fidgeting. | Пока ждал созвон, устроил жмакню в настройках и случайно включил тёмную тему.<br>*While waiting for the call, I did some zhmaknya in the settings and accidentally turned on dark mode.* |
| | Foreign Verb | блендануть<br>*blendanut'* | To quietly adapt your style, opinions, or wording to match whatever online crowd you are currently in. It suggests social camouflage so smooth that nobody notices the switch. | Зашёл в новый чат по играм и за вечер так бленданул, будто всегда там сидел.<br>*I joined a new gaming chat and blended in so well over the evening, as if I'd always been there.* |
| **Farsi** | Semantic Shift | تخم‌مرغ<br>*tokhm-e morgh* | An idea or plan everyone treats with extreme caution because it is promising but absurdly easy to ruin with one careless comment, delay, or public exposure. | فعلاً دربارهٔ همکاری جدید چیزی نگو؛ هنوز تخم‌مرغه و زود می‌ترکه.<br>*For now, don't say anything about the new collaboration; it's still an egg and could crack too soon.* |
| | Affixation | پزخور<br>*poz-khor* | A person who is unusually vulnerable to other people's flexing and instantly feels small, provoked, or compelled to answer back. One subtle display of money, taste, or access is enough to ruin their peace. | یه استوری از سفر دبی دید، دوباره پزخوریش زد بالا و شروع کرد کنایه انداختن.<br>*He saw a story from someone's Dubai trip, got triggered by flexing again, and started throwing snide remarks.* |
| | Light Verb | مهتاب بستن<br>*mahtâb bastan* | To give an ordinary moment a soft, cinematic glow in retelling so it sounds deeper, prettier, or more fated than it really was. Often used for romanticizing mediocre nights, weak dates, or basic memories. | قرارمون فقط یه قهوه‌ی معمولی بود، ولی تو استوری‌هاش چنان مهتاب بست انگار فیلم نولان دیده‌ایم.<br>*Our date was just an ordinary coffee, but in her stories she moonlit it so much it looked like we'd watched a Nolan film.* |

Table 4: Representative synthetic slang examples for each language and slang type. Native-script terms are shown with a Latin transliteration beneath. The translations below each sentence are example translations generated by GPT-5.4 and are not considered ground truth.

| Metric | 3-way | $\kappa$ | Non-tie $n$ | Decisive |
|---|---|---|---|---|
| GEMBA-DA-Def | 49.2% | 0.15 | 217 | 71.0% |
| GEMBA-DA-Def-Big | 52.2% | 0.19 | 237 | 73.8% |
| GEMBA-DA-Def-Avg3 | 44.2% | 0.07 | 259 | 67.6% |

Table 5: Agreement between GEMBA-DA-Def judge configurations and blinded human judgments on 400 Russian Direct versus DirectWithHint pairs. Three-way agreement includes matching Tie judgments.

```
- It should name something people recognize but
didn't have a word for.

Generate exactly 20 fake slang terms as a JSON array:

[
  {
    "term": "Chinese characters",
    "components": "Word A (meaning) + Word B
    (meaning) → blend logic",
    "definition_tar_lang": "what the compound means,
    in English, 1-2 sentences"
  }
]
```

## Chinese: Affixation

```
Invent fake-but-plausible Chinese internet slang
using AFFIXATION (派生型): attach a productive suffix
or prefix to a novel base to coin a new term for a
person-type, social group, or behavior.

Affixes (use a mix of all 6 across your 20 examples):
- -族: social tribe defined by a shared situation
- -控: someone obsessively into X
- -狗: self-deprecating in-group label
- -系: a style or aesthetic vibe
- 裸-: doing something stripped-down, without backup
- 被-: passive/"reportedly" — done to you without
consent, often ironic

Rules:
- The coined term must describe something
recognizable but not-yet-named.
- The definition should describe a recognizable kind
of person, group, or behavior.
- Do not reuse existing well-known slang.

Generate exactly 20 fake slang terms as a JSON array:

[
  {
    "term": "Chinese characters",
    "affix": "which affix and its meaning",
    "base": "root and its meaning",
    "definition_tar_lang": "what the term means, in
    English, 2-3 sentences"
  }
]
```

## Chinese: Sentence Compression

```
Invent fake-but-plausible Chinese "internet chengyu"
using SENTENCE COMPRESSION (缩略型): take a
multi-clause colloquial expression and extract one
key character from each clause to produce a
memorable 4-character idiom mimicking the classical
chengyu form.

Construction: start with a natural colloquial
expression (2–4 clauses, 20–50 chars), extract the
most semantically loaded character from each clause,
string them together so they read well aloud.

Rules:
- Source expression must be colloquial modern
Chinese, not literary.
- The 4-char form must be traceable back to the
source.
- The meaning should reflect a recognizable modern
phenomenon, behavior, feeling, or situation.

Generate exactly 20 fake internet chengyu as a JSON
array:

[
  {
    "term": "4 Chinese characters",
    "source": "full source expression",
    "source_gloss": "English translation of source
    expression",
    "compression_map": "char1 from clause 1 + char2
    from clause 2 + ...",
    "definition_tar_lang": "what it means and when
    you'd use it, in English"
  }
]
```

## Russian: Semantic Shift

```
Invent fake-but-plausible Russian internet slang
using SEMANTIC SHIFT: take a real, ordinary Russian
word and assign it a radically new colloquial
meaning through metaphor or metonymy, unrelated to
(or only obliquely connected with) its dictionary
definition.

Rules:
- The base must be a real Russian word, but one with
NO documented slang meaning.
- The new meaning must not be predictable from the
literal meaning alone — there should be a
figurative leap, not a paraphrase.
- The meaning should name a recognizable modern
phenomenon, behavior, feeling, or situation.
- The word should keep its normal Russian inflection
(conjugation/declension) in the new sense.

Generate exactly 20 fake slang terms as a JSON array:

[
  {
    "term": "Cyrillic term",
    "translit": "Latin transliteration of the term",
    "pos": "part of speech",
    "base": "literal/dictionary meaning of the word",
    "definition_tar_lang": "the new slang meaning,
    in English, 1-2 sentences"
  }
]
```

## Russian: Morphological Blend

```
Invent fake-but-plausible Russian internet slang
using MORPHOLOGICAL BLEND: fuse two existing roots
(Russian + Russian, or Russian + assimilated
foreign) into a single new word, portmanteau-style,
whose meaning goes beyond either component.

Rules:
- The result should read as a single new word, not a
noun phrase or hyphenated pair.
- The meaning should not be fully predictable from
the parts — there should be a conceptual leap.
- The blend must be phonologically tight and
pronounceable, and must inflect like a normal
Russian word.
- It should name something people recognize but
didn't have a word for, and must not be an existing
word or known slang.

Generate exactly 20 fake slang terms as a JSON array:

[
  {
    "term": "Cyrillic term",
    "translit": "Latin transliteration of the term",
    "pos": "part of speech",
    "components": "Root A (meaning) + Root B
    (meaning) → blend logic",
    "definition_tar_lang": "what the blend means, in
    English, 1-2 sentences"
  }
]
```

## Russian: Suffixation

```
Invent fake-but-plausible Russian internet slang
using SUFFIXATION: attach a productive colloquial
Russian suffix to an existing or invented root to
coin an expressive new noun, verb, or adjective for
a state, person-type, or behavior.

Suffixes (use a mix across your 20 examples):
- -яга, -ак / -як, -ок: expressive personal/object
nouns
- -няк: a chronic state or condition (cf.
бардак-like expressive nouns)
- -уха: expressive feminine nouns for states or
things
- -ня, -ёж, -лово: collective/process nouns, often
dismissive
- -ота: a quality or atmosphere, with an
unexpectedly warm or ironic tone

Rules:
- The coined word must describe something
recognizable but not-yet-named.
- The suffix's register and the root's meaning must
combine naturally — the word should sound like it
could be real.
- The result must not be an existing word or known
slang, and the meaning must not be transparently
obvious from the root alone.

Generate exactly 20 fake slang terms as a JSON array:

[
  {
    "term": "Cyrillic term",
    "translit": "Latin transliteration of the term",
    "pos": "part of speech",
    "affix": "which suffix and the flavor it adds",
    "base": "root and its meaning (real or
    invented)",
    "definition_tar_lang": "what the term means, in
    English, 1-2 sentences"
  }
]
```

## Russian: Foreign Word Russification

```
Invent fake-but-plausible Russian internet slang
using FOREIGN WORD RUSSIFICATION: take a non-Russian
word (English, French, German, etc.) and russify it
by adding native verbal or nominal morphology (-ить,
-овать, -нуть, -ануть, -ировать, or noun endings) so
it sounds and inflects like a native Russian word.

Rules:
- The foreign source word must NOT already be
established in Russian slang in this form (avoid
well-worn borrowings like чилить, флексить,
кринжовать).
- The russified form must inflect naturally
(conjugate/decline like a native word) and be
phonologically comfortable in Russian.
- Avoid forms that sit close to existing Russian
words — especially vulgar ones — in sound or
spelling.
- The meaning should add a specific twist or
scenario beyond the plain meaning of the source word
— not just a translation of it.
- The meaning should reflect a recognizable modern
phenomenon, behavior, feeling, or situation.

Generate exactly 20 fake slang terms as a JSON array:

[
  {
    "term": "Cyrillic term",
    "translit": "Latin transliteration of the term",
    "pos": "part of speech",
    "source_word": "foreign source word and its
    language",
    "morphology": "which Russian affix/ending was
    added",
    "definition_tar_lang": "what it means, in
    English, 1-2 sentences"
  }
]
```

## Farsi: Light Verb Construction

```
Invent fake-but-plausible Farsi (Persian) slang
using LIGHT VERB CONSTRUCTION: pair a noun or
adjective (native, or an assimilated English/foreign
loanword) with a native Persian light verb to coin a
new compound verb whose slang meaning goes beyond
the literal parts.
Light verbs to draw from (use a mix across your 20
examples): کردن (to do/make), شدن (to become), زدن
(to strike), گرفتن (to take/catch), دادن (to give),
آوردن (to bring), کشیدن (to drag/pull), بستن (to
tie/close), خوردن (to eat).
Rules:
- The compound's meaning must NOT be predictable
from the noun/adjective + verb literally — there
must be a figurative leap.
- The light verb must be one of the native light
verbs above (not an invented verb).
- The meaning should name a recognizable modern
phenomenon, behavior, feeling, or situation.
- The compound must conjugate naturally like a
normal Persian compound verb.
- Do not reuse existing well-known compound-verb
slang (e.g. هم زدن, تیغ زدن, حالی پستن).
Generate exactly 20 fake slang terms as a JSON array:
[
  {
    "term": "Persian term (noun/adjective + light
    verb)",
    "translit": "Latin transliteration of the term",
    "light_verb": "which light verb and its literal
    meaning",
    "base": "the noun/adjective and its literal
    meaning",
    "definition_tar_lang": "the new slang meaning,
    in English, 1-2 sentences"
  }
]
```

## Farsi: Affixation

```
Invent fake-but-plausible Farsi (Persian) slang
using AFFIXATION: attach a productive Persian prefix
or suffix to a novel base (native or an assimilated
loanword) to coin a new term for a person-type,
social group, style, or behavior.
Affixes (use a mix across your 20 examples):
- زاب- (-bâz): someone obsessed with, playing at, or
generating drama around the root
- روخ- (-khor, "eater"): someone who suffers from or
greedily consumes the root
- روط- (-toor): doing something in the manner / vibe
/ style of the root
- مال- (-mâl, "rubber"): one who flatters or sucks
up via the root
- بی- (bi-, "without"): a cutting character judgment
— lacking the root quality
- گندهٔ- (gondeh-, "huge"): a false, inflated sense
of grandeur about the root
- سه- (se-, "three"): doing the root to the utmost /
in a flash
- چهل- (chehel-, "forty"): an abundant, chaotic, or
excessive amount of the root
Rules:
- The coined term must describe something
recognizable but not-yet-named.
- The affix's flavor and the base's meaning must
combine naturally — it should sound like it could be
real.
- The meaning should describe a recognizable kind of
person, group, style, or behavior.
- Do not reuse existing well-known slang (e.g.
دخترباز, غصه‌خور, حال‌ه‌مال, بی‌جنبه).
Generate exactly 20 fake slang terms as a JSON array:
[
  {
    "term": "Persian term",
    "translit": "Latin transliteration of the term",
    "affix": "which affix and the flavor it adds",
    "base": "root and its meaning (native or
    loanword)",
    "definition_tar_lang": "what the term means, in
    English, 2-3 sentences"
  }
]
```

## Farsi: Semantic Shift

```
Invent fake-but-plausible Farsi (Persian) slang
using SEMANTIC SHIFT: take an ordinary, everyday
Persian word and assign it a radically new
colloquial meaning through metaphor, metonymy, or
subversion, unrelated to (or only obliquely
connected with) its normal meaning.
Rules:
- The base must be a real, ordinary Persian word
with NO documented slang meaning.
- The new meaning must not be predictable from the
literal meaning alone — there should be a
figurative leap, not a paraphrase.
- The meaning should name a recognizable modern
phenomenon, behavior, feeling, or situation.
- The word should keep its normal Persian grammar in
the new sense.
Generate exactly 20 fake slang terms as a JSON array:
[
  {
    "term": "Persian word",
    "translit": "Latin transliteration of the term",
    "base": "the ordinary/literal meaning of the
    word",
    "definition_tar_lang": "the new slang meaning,
    in English, 1-2 sentences"
  }
]
```

After the first batch, the code appends the following block, with one list item for every term already seen in the current or resumed run:

```
IMPORTANT — the terms below have ALREADY been
generated. Do NOT repeat any of them, and do NOT
coin new terms that are close to them in form OR in
meaning. Every term you return must be clearly
distinct from all of these:
- {already_generated_term_1}
- {already_generated_term_2}
```

### C.2 Guessability Gate

```
You will be shown a {language} slang term with NO
context. Guess what it most likely means, reasoning
only from its {form_basis} — its form, components,
and sound. Do not search; give your single best
interpretation.

Term: {term}
{optional_part_of_speech}

Return JSON:
{
  "guess": "your best guess at the meaning, in
  English"
}
```

The value of form_basis is "character components" for Chinese, "morphology and root" for Russian, and "morphology, roots, and component words" for Farsi. The optional line is Part of speech: {pos} for Russian and empty otherwise.

### C.3 Translation and Definition-Recovery Inference

For each translation condition below, the first paragraph is the system message and the remainder is the user prompt.

#### Direct

```
You are an expert linguist, specializing in
translation from {src} to {tgt}.

This is an {src} to {tgt} translation, please
provide the {tgt} translation for this text. Do not
provide any explanations or text apart from the
translation.
{src}: {source}

{tgt}:
```

#### DirectWithHint

```
You are an expert linguist, specializing in
translation from {src} to {tgt}.

This is an {src} to {tgt} translation, please
provide the {tgt} translation for this text. Do not
provide any explanations or text apart from the
translation.
{src}: {source}

Note: The text contains the following slang:
"{term}" — {definition}

{tgt}:
```

#### DirectContext

```
You are an expert linguist, specializing in
translation from {src} to {tgt}.

This is an {src} to {tgt} translation, please
provide the {tgt} translation for this text. Do not
provide any explanations or text apart from the
translation.
For reference, here is a {src} paragraph using
similar terminology in context (provided only to
help you understand the usage — do not translate
it):
{context}

{src}: {source}

{tgt}:
```

#### SlangDITIdentify

```
Your task is to analyze the given sentence, which
contains a slang term. Follow the steps below to
provide your answer.

1. Slang Term:

- The sentence contains the slang term: "{term}".

2. Provide Definition:

- Provide a brief definition, in English, of the
slang term's meaning and usage.

3. Output the Results as JSON with the following
keys:
- "slang": the slang term (string)
- "definition": brief definition of the slang term,
in English (string)

Please analyze the following sentence:
Input Sentence: {source}
Slang term: {term}
```

#### SlangDITIdentifyContext

```
Your task is to analyze the given sentence, which
contains a slang term. Follow the steps below to
provide your answer.

1. Slang Term:

- The sentence contains the slang term: "{term}".

2. Provide Definition:

- Provide a brief definition, in English, of the
slang term's meaning and usage.

3. Output the Results as JSON with the following
keys:
- "slang": the slang term (string)
- "definition": brief definition of the slang term,
in English (string)
```

```
For reference, here is a paragraph that uses the
same term in context (provided only to help you
understand its usage):
{context}

Please analyze the following sentence:
Input Sentence: {source}
Slang term: {term}
```

## C.4 Project-Specific Evaluation Prompts

### GEMBA-DA-Def

```
Score the following translation from {src} to {tgt}
on a continuous scale from 0 to 100, where a score
of zero means "no meaning preserved" and score of
one hundred means "perfect meaning and grammar".

Note: the source contains the slang term "{term}",
which means: {definition}

{src} source: "{source}"
{tgt} translation: "{mt_translation}"

Return JSON:
{
  "score": 75
}
```

### Binary Definition-Equivalence Judge

```
Term: "{term}"

Definition A: {reference_definition}
Definition B: {mt_understanding}

Do these two definitions convey the same core
meaning?
- 1 = yes: the essential meaning matches (allow
paraphrase; minor gaps are fine)
- 0 = no: the meaning is wrong, inverted, or a key
component is missing

Return JSON:
{
  "score": 0,
  "reason": "one sentence"
}
```

# The Constitution Speaks Nheengatu: An Open MT System and Reproducible Corpus Pipeline for the Amazonian Língua Geral

**Fabrício Carraro**[1] **Rodolfo Joel Zevallos**[2] **Rodrigo Gonçalves de Souza**[3]
**Caio Henrique Faustino da Silva**[4] **John E. Ortega**[5]
[1]Universidad Internacional Menéndez Pelayo [2]Universitat Pompeu Fabra
[3]Tribunal Regional Federal da 1ª Região [4]PUC-Rio [5]Northeastern University

## Abstract

Nheengatu (yrl), the Amazonian Língua Geral, has 6–10 thousand speakers and is co-official in São Gabriel da Cachoeira (Brazil), yet remains poorly served by evaluated Portuguese–Nheengatu MT resources. We present the largest parallel corpus assembled for the language (14.5k Portuguese–Nheengatu pairs), anchored by the 2023 official translation of the Brazilian Federal Constitution; the first MT evaluation set built from transcribed spontaneous speech; and, to our knowledge, the first open-weight MT models dedicated to bidirectional Portuguese–Nheengatu translation.

Three findings organize the paper. First, translation into Nheengatu on held-out constitutional articles plateaus on development data regardless of training length or model size, and much of the remaining error sits in conventional legal terms that the written sources do not attest consistently; a terminology success rate over a frozen lexicon shows that glossary mechanisms at training time and lexical constraints at decoding each raise term realization, the latter at a cost in repetitive output that chrF++ barely registers. Second, a corpus expansion that adds transcribed conversation raises speech chrF++ by 24–27 points while leaving written domains unchanged, a register gap that written-only benchmarks cannot see. Third, a larger NLLB model helps translation into Portuguese but not into Nheengatu on legal or speech text. For Portuguese-to-Nheengatu translation, our final systems reach 31.7–32.8 chrF++ on article-disjoint constitutional text, 64.1–64.5 on the near-domain set (62.1 after removing items with target-side content overlap), and 45.2–47.5 on speech.

## 1 Introduction

Machine translation nominally covers hundreds of languages, and the most recent effort claims more than sixteen hundred (Omnilingual MT Team, 2026), which is under a quarter of the world's seven thousand (Joshi et al., 2020). However, appearing on a list is not the same as being served. The training signal is typically a few thousand sentences of scripture, the evaluation set is a benchmark the language does not appear in, and speakers are rarely asked whether the output is worth reading.

Nheengatu (yrl) is a sharp case of that gap, and an unusual one. Its ancestor is Tupinambá, the coastal language Europeans met in the sixteenth century. Jesuit missions carried it up the Amazon as the language of catechism, where it nativised into the *Língua Geral Amazônica (Amazonian General Language)* and became the dominant lingua franca of a highly multilingual basin, spoken across ethnic lines by Indigenous and non-Indigenous people alike (Cruz, 2011). It was, for roughly two centuries, the language in which the Amazon conducted its business.

The Directorate of 1757 then imposed Portuguese and banned the general language, and nineteenth-century upheavals (the Cabanagem revolt, the rubber boom, the Paraguayan War) displaced or killed much of the speaking population. Nheengatu survived chiefly in the Upper Rio Negro (Figure 1), with an estimated 6–10 thousand speakers today (Cruz, 2011; Quinto, 2025). Since 2002 it has been co-official in São Gabriel da Cachoeira, a mostly Indigenous municipality of 52,000 where UFAM trains schoolteachers in the language.

Nheengatu is a Tupi-Guarani language (Cruz, 2011). It is typologically SVO, agglutinating, postpositional, with person and number marked on the verb by prefixes and plural by the particle *ita*, which is usually written bound in our sources (*mira-itá* 'people') (Cruz, 2011; de Alencar, 2024). The morphology is concatenative and moderate rather than polysynthetic.

Figure 1: The Upper Rio Negro. Dark: São Gabriel da Cachoeira, where Nheengatu has been co-official since 2002. Boundaries: IBGE; base map: Natural Earth.

The yrl side of our corpus holds 14,888 distinct forms against 12,393 in the matched Portuguese, with 58% occurring exactly once, so word-level $n$-grams rarely recur, which is why we report chrF++ and spBLEU (Goyal et al., 2022) rather than word-level BLEU.

Written Nheengatu has no single settled standard: at least four orthographic traditions circulate in our sources (the academic norm of Navarro and Avila that the UD treebank follows, the missionary orthography of the New Testament, the Rio Negro school norm in which the Constitution was translated, and a convention devised for a smartphone localisation project) and D'Angelis (2023) finds none better founded than the others. Our transcribed speech adds a fifth, marking diacritics differently from all of them. A Nheengatu Language Academy was created in 2021; this paper treats no current tradition or institution as uniquely authoritative.

Ignoring diacritics, 13.9% of yrl word types in our training data have two or more realisations, and those types cover 70.3% of running text; the same measurement on the matched Portuguese side returns 1.7% and 31.8%. That the variation is orthographic and not lexical is visible inside a single document: the Constitution alone writes *istadu-ita* 63 times and *istadu-itá* 23, *deputadu-ita* 10 against *deputadu-itá* 30. Corpus-wide, 1,458 sentences write the plural particle bound, 298 write it free, and 48 do both. A system must emit some orthography, and whichever it emits will be unfamiliar to part of its readership; which norm to produce is therefore a community decision, and our contribution is to build the mechanism that can serve whichever decision is taken.

That co-officiality has no technological counterpart: as of August 2026 the language is absent from NLLB-200, FLORES+, MADLAD, Google Translate and the 1,600-language release of Omnilingual MT Team (2026), and to our knowledge it has no public MT benchmark. The multilingual open-weight release OmniTranslate lists yrl among its languages but reports no yrl-specific evaluation (MihaiPopa-1, 2026). The prior published Portuguese–Nheengatu MT results we discuss come from closed industrial research (Gonçalves et al., 2025).

Two circumstances make this the moment to build one. In 2023 Brazil's Federal Supreme Court and National Council of Justice published the Federal Constitution in Nheengatu, translated over two years by fifteen Indigenous translators under editorial review. It is a contemporary, long, non-religious text of a kind that projects at this resource level almost never have. And enough other material exists (dictionaries, a treebank, school books, transcribed conversation) that a usable corpus can be assembled if provenance is tracked source by source.

**Contributions.** **(1) Corpus** (§3): 14.5k pt–yrl aligned pairs with source provenance and orthographic metadata, twice the closed corpus of Gonçalves et al. (2025), together with article-disjoint legal, pair-deduplicated near-domain, and speech evaluation sets with speakers and sessions held out from training. **(2) Models** (§5.6): to our knowledge, the first open-weight MT models dedicated to bidirectional Portuguese–Nheengatu translation. **(3) Terminology, diagnosed and treated** (§5.2): a terminology success rate (TSR: the share of glossary terms present in the source that the output realizes), scored over a lexicon frozen before the terminology experiments, identifies unstable conventional terminology as an important contributor to the legal plateau; annotation and token-pair augmentation improve term realization; constrained decoding raises surface-form realization at a 3.2–4.8× rise in degeneration (repetitive, runaway output), a cost chrF++ barely registers. **(4) Register vs. model size** (§5.3, §5.4): the corpus expansion strongly improves speech while leaving written-domain scores nearly unchanged; within the tested NLLB family, scaling improves yrl→pt and near-domain pt→yrl but not article-disjoint legal or speech pt→yrl in our runs.

## 2 Related Work

**MT for yrl (closed).** IBM Research Brasil fine-tuned NLLB-600M on ∼6.7k manually cleaned pairs, reporting 69.1/66.9 (pt→yrl / yrl→pt) on a 233-segment test of short dictionary sentences (Gonçalves et al., 2025). Those figures are *sentence-level* chrF, with large reported standard deviations of ±33.8 and ±34.6; they are not corpus-level chrF++, and they are computed on a private test set; we therefore treat them as context, not as a baseline we can measure a gap against (§5.6). Their corpus and models are unpublished, and the same group's human evaluation of those translators found automatic metrics and speaker-judged usefulness to diverge substantially (Pinhanez et al., 2024), one reason we treat our own chrF++ gains as necessary but insufficient evidence.

**Low-resource and Indigenous MT.** No shared task has ever included Nheengatu: neither WMT (Kocmi et al., 2024a, 2025) nor any of the five AmericasNLP editions covers it, and it is absent from the 202 languages of NLLB-200, whose only Tupian language is Guarani. Because no benchmark contains this language, there is no system we can rank against, and we make no ranking claim anywhere in this paper; what counts as a meaningful difference in any case shifts with direction, domain and system proximity (Kocmi et al., 2024b).

**Choice of base model.** Five years of AmericasNLP findings converge on one recipe: fine-tuned NLLB (NLLB Team et al., 2022, 2024) remains the strongest system for translation *into* Indigenous languages (Mager et al., 2021; Ebrahimi et al., 2023, 2024; De Gibert et al., 2025; Stap and Araabi, 2023), to the point where the 2025 edition reports a fine-tuned NLLB baseline that a single team beat, for a single language, by 0.82 chrF++ (De Gibert et al., 2025). Grammar-book prompting works mainly for the reverse direction and for languages with richer descriptive material (Tanzer et al., 2024; Aycock et al., 2025; Pei et al., 2025; Zhang et al., 2024a,b), and post-correction pipelines inherit that asymmetry (Hus et al., 2025); in-context and modular adaptation of large models assume retrieval pools or per-language data far beyond what yrl has (Moslem et al., 2023; Xu et al., 2025). Our own LLM post-editing experiment is a documented null (§5.7), and our same-corpus architecture control is mixed once checkpoint selection is equalized (§5.5).

Table 1: Corpus composition, ordered by yrl words. "yrl w." is running words on the Nheengatu side; "w/s" is the mean number of words per aligned segment; speech units are pause-delimited turns rather than sentences. Religious text is **0.2%** of the corpus (23 pairs), where for most of the world's languages scripture is the only large digital resource; our anchor is instead a contemporary legal text translated under editorial review.

## 3 The Corpus

### 3.1 Constitution pt–yrl (anchor)

In 2023 the Brazilian Supreme Court and the National Justice Council published the Federal Constitution in Nheengatu (Supremo Tribunal Federal and Conselho Nacional de Justiça, 2023), translated over two years by a team of Indigenous translators of the Upper Rio Negro and the Middle Tapajós. It is to our knowledge the largest modern text in the language, and the only one that is simultaneously long, contemporary, and translated by speakers under editorial review. It is also awkward as a corpus: a PDF of a printed book with no sentence alignment, facing an official Portuguese edition that has its own amendment history.

We align the two by *document-structure identity* rather than by length or similarity. Both editions carry the same legal skeleton (article, paragraph, *inciso* and *alínea*: the numbered item and lettered sub-item of Brazilian legal drafting), so we parse each side with a state machine that validates identifier sequences as it walks the document (article 5 must be followed by article 6; item XII by item XIII), and pair units whose full identifier path matches. Structure-based alignment is what makes the result auditable: every pair carries the legal address that produced it, so any error is locatable rather than statistical. Alignment yields 2,496 pairs. The final filtered corpus retains 2,482: 2,031 for training, 233 for development and 218 for testing (Table 1).

We verify the Portuguese side against a third source, the Planalto reference edition (Appendix A). The exercise also surfaced errata in the printed Nheengatu book: mislabeled items, cascade renumberings, and an entire constitutional-amendment block absent from the translation. We detected these precisely because the structural addresses disagreed with the text. Renumberings we repaired by content; six pairs with genuine content errors we excluded from the evaluation splits instead of silently correcting them. Development and test splits hold out *whole articles* (19 and 19), not sentences, so that no article contributes to both training and evaluation, with overlap verified to be zero on both sides.

### 3.2 The aggregate corpus and its versions

Every pair in Table 1 carries its provenance and the orthographic tradition it was written in: a pair's spelling is only interpretable if one knows which of the competing norms produced it, and any later normalization decision must be reversible. Three corpus versions are named in what follows. v1 is the aggregate as first assembled. v2 applies an audited cleaning pass removing dictionary apparatus, ellipsis markers and typographic ALL-CAPS; it changes 170 evaluation pairs, so numbers from the v1 series are never point-compared with later ones. v3 adds 3,408 audited training pairs: (a) **transcribed spontaneous speech**; (b) **dictionary example sentences** (audited against page sources: zero cross-pairings); (c) **school books** from two previously uncovered dialect areas, where length-based alignment *failed* under free translation (one book places translations *before* the source stories) and was replaced by semantic realignment with literal anti-hallucination validation (99.6% pass). Speech evaluation holds out an entire session group: 116/115 content-deduplicated, pause-delimited turns from its two speakers across four elicitation task types, disjoint from the nine speakers in training; the speech test set is single-use. The near-domain sets are exact-pair-deduplicated only (not source- or document-disjoint) and the Limitations quantify what that leaves. Audits of 200 speech pairs and 240 dictionary-example pairs approve 91.5% and 86.7%, respectively. The residual issue classes account for 1.0% and 6.7% of the audited samples. The sampling procedure was not preserved, so these figures do not establish defect rates for the unaudited remainders. These are not one minus the approval rate, because the two non-ok tails have different fates; Appendix A gives the categories and the derivation. Neither residual is mispairing, which is tolerable in training data and would not be in evaluation data.

Training additionally includes 925 FR–yrl pairs (a Nheengatu translation of *Le Petit Prince*, 12,467 yrl words): the Nheengatu side is human, the source side French. They are present in every run reported here. A Portuguese view of the same targets, translated from the French by a frontier LLM (Claude Fable 5), is a separate experiment, reported and rejected in §5.2.

## 4 Experimental Setup

We fine-tune NLLB-200-distilled at 600M and 1.3B (NLLB Team et al., 2022, 2024), using the 600M model for replicated configuration comparisons and the 1.3B model for single-seed scale comparisons. Nheengatu is not explicitly supported by NLLB-200 and has no dedicated language token, so we add `yrl_Latn` and initialize it from the Guarani `grn_Latn` embedding. Training is bidirectional, so a single model serves both directions.

**Training glossary.** Two mechanisms are trained jointly. Inline annotation follows target-lemma annotation (Bergmanis and Pinnis, 2021): a source term is followed by its yrl equivalent in a delimited slot (`term | yrl |`), applied to 30% of matched term occurrences in training and, at *hinted* inference, to every source-side glossary match (the reference is never consulted), capped at two matches per segment. Token pairs follow the lexical-augmentation recipe (Jones et al., 2023): the glossary's 1,027 surface forms injected as standalone training pairs. Both draw on the same audited glossary of 904 entries, mined by Dice association and adjudicated against source evidence. The glossary is built only from training pairs and external lexical resources; evaluation references are never used to construct or adjudicate it.

**Scoring lexicon and Terminology Success Rate.** TSR follows the terminology success rate of the WMT terminology task (Semenov et al., 2023): the proportion of scoring-lexicon term occurrences in a source sentence whose yrl equivalent (or a listed synonym) appears in the output. The scoring lexicon contains the training glossary. We freeze scoring lexicon v1 *before* the terminology experiments by taking the union of the audited training glossary and the base bilingual lexicon. Every TSR value

| | legal (const) | | near-dom. | |
|---|---|---|---|---|
| | pt→yrl | yrl→pt | pt→yrl | yrl→pt |
| 600M (3 seeds) | 31.25 ±0.44 | 35.45 ±0.31 | 64.12 ±0.38 | 56.12 ±0.41 |
| 1.3B (1 seed) | 32.03 | **37.76** | **66.37** | **58.22** |

Table 2: Phase-1 evaluation (v1 series): chrF++ for the 600M (mean±sd over three seeds) and the 1.3B (one run). The 1.3B differences are descriptive: a single run has no seed spread of its own, so the 600M's ±sd does not standardize them.

| training mechanism | unhinted | hinted |
|---|---|---|
| none (baseline) | 51.5 | not run |
| token pairs only | 55.1 | not run |
| annotation only | 51.0 | 63.6 |
| annotation + token pairs | 54.5 | **66.2**±2.7 |

Table 3: TSR on legal development data (198 term occurrences): training mechanism crossed with decode-time hints (v2, 600M). We did not evaluate hints on models trained without annotation; their response to unseen markup would also test robustness to the input format. Single-seed values, except the hinted combination (three-seed mean).

in this paper uses the same frozen scoring lexicon. A hit counts exact, lemma-table, accent-insensitive and fuzzy matches alike, the last at 0.85 and only for forms of five characters or more. Under this protocol the legal dev set carries 198 term occurrences and the legal test set 232. TSR remains conservative: §6 shows by per-case verification that it *understates* our mechanisms, because inflected, respelled and fused realizations still count as misses.

**Metrics.** We report chrF++ as the primary metric and do not use a learned metric as primary evidence, because COMET, CometKiwi and MetricX have not been validated for yrl. We attach no usability label to any absolute chrF++ value.

**Decision discipline.** Configuration decisions use full-dev evaluation and require three seeds; the noise ruler on the legal dev set is ±0.35 chrF++. We adopted the three-seed rule after two single-seed results failed to replicate, and we report both. Test sets are pre-specified and decoded once per model; §5.6 states which are pristine and which are reused holdouts. A 20k-step 600M run costs ≈1.3 GPU-hours, which is what makes three seeds per configuration affordable. Every configuration decision here is reproducible on a single GPU, and only the 1.3B confirmations need a full node. All ± values are sample standard deviations over training seeds.

## 5 Results

### 5.1 Phase 1: configuration and scale effects

Phase 1 settles two configuration choices by ablation: related-language mixing and orthography. Table 2 reports the resulting Phase-1 evaluation on the legal and near-domain holdouts. Mixing Guarani–Spanish data, the obvious transfer candidate given that our new token is initialized from Guarani, costs 0.26 chrF++ and is discarded: the embedding is a starting point, not a related-language signal the model can exploit.

We expected orthographic unification to help, and it did not. Only 29% of the Constitution's *tokens* (5% of its types) appear, by exact surface match, in the vocabulary of the largest modern dictionary (Avila, 2021); ignoring accents raises these to 46% and 8%, which is itself a measure of how much of the divergence is diacritic. Unification nonetheless moved every evaluation set by less than seed noise, with the legal set landing 0.3 chrF++ lower, and it did so with the evaluation references themselves favouring it. We retain a light normalization (punctuation, casing, whitespace) and preserve the original spelling of every pair alongside it. The result is specific to the recipes and data tested here.

Across 8k and 20k training steps and across both model sizes, legal pt→yrl sits at ≈29 chrF++ on dev. Essentially any configuration lands in the same place, while near-domain translation and both yrl→pt directions respond normally to training length and model size. The plateau suggests a data bottleneck specific to article-disjoint legal pt→yrl. §6 identifies unstable conventional terminology as one important contributor, but the present experiments do not establish that it is the sole cause.

### 5.2 Phase 2: terminology-control ablations

The initial mechanism ablations in Table 3 use 600M models on legal development data for pt→yrl with corpus v2. *Hinted* means glossary terms are supplied inline at decoding; *unhinted* means they are not. Table 3 distinguishes the measured training-only comparison from the within-model effect of hints. Relative to the no-mechanism baseline (28.91 chrF++, 51.5 TSR), the combined mechanism alone, decoded without hints, adds 3.0 pp TSR (54.5, single seed) and 0.99±0.17

chrF++ over three seeds. On the one seed decoded in both conditions, supplying hints adds a further 8.6 pp (54.5 to 63.1); across three seeds the hinted system reaches 66.2±2.7 (range 63.1–68.2), 14.7 pp above the unhinted baseline, and brings chrF++ to 1.24±0.32 above it. The no-annotation hinted baseline was not evaluated, so the interaction between annotation training and hints is not estimated. Annotation alone changes chrF++ by 0.29, within seed variation, and token pairs alone add 3.6 pp unhinted TSR. Hints apply to 110 of 233 segments, so the aggregate effect is bounded by glossary coverage.

**Negative results:** the LLM-translated Portuguese view of the 925 literary pairs reduces chrF++ by 0.66 in the unhinted condition and by 1.5 in the hinted condition. Because the Portuguese view is added rather than substituted, the experiment jointly changes duplication, source-language weighting, register, and orthographic composition.

In an exploratory failure-targeted distillation experiment on corpus v3, relative to the annotation-plus-token-pair configuration, we identify 43 terms that fail on legal development data, write 10 legal-register Portuguese sentences for each (leak-guarded against every evaluation set) and translate them with the term forced by constrained decoding, keeping the 233 that survive a length filter. These yield at 600M (2 seeds) **+0.93 chrF++ on legal dev** (30.91±0.25) and **+4.2pp unhinted / +7.2pp hinted TSR** (60.4/72.2), with hint chrF++ turning neutral: the glossary migrates into the parameters. A single 1.3B run with the same distilled pairs shows a similar unhinted TSR gain (+4.6pp, 54.5→59.1; single seed) while *halving* the model's dependence on the hint (hint effect +8.1pp→+4.5pp), though the 600M's chrF++ gain does not transfer (+0.03): at 1.3B the distilled glossary shows up purely as terminology, invisible to chrF++. Term selection is dev-guided (declared).

The mechanisms address different parts of the problem: token pairs expose the model to a term and its spelling, while annotation trains it to condition on a supplied target form and place it in context, which is what makes hinting possible at all (51.0 unhinted to 63.6 hinted). Constrained decoding raises the realization rate at inference, but it is lexical enforcement rather than a guarantee of correct terminology.

| eval | v2 model | v3 model | Δ |
|---|---|---|---|
| speech pt→yrl | 23.06† | **46.77** | +23.7 |
| speech yrl→pt | 22.82† | **49.81** | +27.0 |
| legal pt→yrl | 29.90±0.17 | 29.98±0.13 | +0.1 |
| near-dom. pt→yrl | 60.70±1.01 | 59.99±0.64 | −0.7 |

Table 4: Effect of the v2→v3 expansion (3,408 pairs, 1,156 of them speech) on development chrF++. †The v2 model saw no speech in training, so the speech rows measure the whole expansion, not the speech subset alone; those two rows are single runs without terminology mechanisms, while the written rows are three-seed means of the shared configuration. The expansion also raises unhinted TSR by 3.0 pp, an effect not attributed to any single source.

### 5.3 Phase 2: the speech-register gap

The size of the gap in Table 4 is worth dwelling on, because it is easy to misread as a data-volume result. A model trained on written Nheengatu (legal text, dictionary sentences, school materials) is not merely worse at spontaneous conversation; at 23 chrF++ its similarity to the references falls far below the 30 it reaches on the hardest written set and the 60 on the easiest. Moving from v2 to v3 (an expansion of 3,408 pairs, 1,156 of them speech, under 9% of the resulting 13k-pair training set) improves speech chrF++ by 23.7 to 27.0 points while changing written-domain scores by less than one. The evaluation is speaker-disjoint and session-disjoint, which reduces the risk of speaker memorization. The concentration of the gain on the speech evaluation is consistent with a matched-register effect, but the comparison does not isolate the speech subset from the other v3 additions. We report this because projects on languages that live primarily in speech are routinely evaluated only on written benchmarks, where a 23-point blind spot is invisible.

**What the speech errors look like.** The v2 model's speech outputs were not retained, so we cannot place them beside v3; we characterize the v3 model of Table 4 instead, on its 116 development turns. The lowest-scoring outputs are one- and two-word turns whose reference depends on discourse context the turn does not carry: *Asu* ('I went') rendered as *vou* ('I go'), *amuyatimana* ('I turned') as *ajunto*. Mid-range outputs are adequate paraphrases that chrF++ scores in the forties: reference *mas da nossa região ou de outra*, system *mas da nossa terra ou outro*. Into Nheengatu the dominant residual is orthographic: *siía pixana ta uiku tatá rendá ruaki* against the reference *siyawa*

*pixana uiku tata rẽda ruaki* differs mainly in accent and nasal marking and scores 42. Two adequacy errors recur: a vocative name rendered as a kinship noun (*Dadá* → *Papai*, 'Dad'), and, in the larger and terminology-augmented models we inspected on the same turns, the reportative *disque* inserted into Portuguese where the source carries no evidential marker.

Register-control codes were validated and then rejected for the final system. A `[fala]` tag prepended to conversational sources buys +2.34 chrF++ on speech, a real gain above the noise ruler, but costs a real $-0.74$ on legal text, and the tagged model collapses to 26 on speech when the tag is absent, meaning it has learned to depend on a signal that a deployed system would have to infer. For a single general-purpose model serving mixed traffic, we do not adopt this trade-off. For a dedicated conversational checkpoint, the configuration is promising but requires speaker and user evaluation. Terminology behaviour is unaffected either way, which is itself informative: register control and terminology control behave as largely separate axes in this experiment.

### 5.4 Phase 2: scale at fixed configuration

Phase 1 established that model size does not move legal pt→yrl. With the optimized configuration and the v3 data in place, we can ask a sharper question: is that a property of the legal domain, or of generating Nheengatu at all? Holding the configuration fixed and moving only from 600M to 1.3B, legal pt→yrl lands at 29.67, just below the 600M three-seed spread (29.89–30.12), and spontaneous speech at 46.17, inside the speech spread (45.79–46.70), while translation *into Portuguese* gains 1.3, 3.0 and 2.5 chrF++ on legal, near-domain and spontaneous speech respectively, and near-domain into-yrl gains 3.1.

Within the tested NLLB family, scaling helps all yrl→pt settings and the easier near-domain pt→yrl setting, but does not resolve the harder article-disjoint legal or spontaneous-speech pt→yrl cases in our runs. Because the 1.3B condition uses a single seed, these differences are descriptive.

The direction gap is consistent with NLLB's own ablations, in which translation into English exceeds translation out of English by a larger margin for very-low-resource directions (NLLB Team et al., 2022). Nheengatu is not explicitly supported by NLLB-200 and has no dedicated pretrained language token.

Hinting continues to help at 1.3B on domain text (+0.55 legal) but costs $-0.95$ on conversational input, where dictionary-form hints reduce performance. The operational rule we adopt is to hint domain text but not conversation.

### 5.5 A same-corpus architecture control

We pre-specified a same-corpus control before measuring: full fine-tuning of Qwen3.5-2B (Qwen Team, 2026), a 2B instruction-tuned decoder-only model with a hybrid-attention stack, against our 600M seq2seq, three seeds each, on the development sets. The two sides were not selected alike: the seq2seq kept the checkpoint with the best development chrF++, whereas the decoder-only kept the one with the lowest development loss, which is step 1,000 in all three seeds. Under loss-based selection the seq2seq leads all six cells (Table 7). Because the criteria differ, after submission we also scored the decoder-only's late checkpoints (steps 11–12k, chosen with knowledge of the development scores as a proxy for chrF++-based selection) with the same decoder. The picture changes: the seq2seq still wins conclusively on article-disjoint legal pt→yrl ($+1.90$ chrF++ against a threshold of 1.06 under the pre-specified rule), the decoder-only wins both near-domain cells ($-1.50$ and $-3.23$), and the other three cells are inconclusive. Our declared hypothesis, that the decoder-only would compete into Portuguese, is therefore supported on near-domain yrl→pt once selection is equalized, and not on legal text. Two cautions apply: the late checkpoints are a post-hoc choice, and the near-domain set is where content overlap with training is highest (Limitations), which favours whichever model reproduces training material more readily. This compares *systems*, not architectures (pretraining, size, instruction tuning and checkpoint selection differ together), with one model per side and on development data only, so it does not generalize to decoder-only models as a family. Appendix A gives both selections, the six-cell table and the hyperparameters.

### 5.6 Phase 2: final evaluation

Table 5 reports it, for two systems: the **flagship** (1.3B, light punctuation/casing/whitespace normalization + annotation + token-pair augmentation, 20k steps) and **avg**, the weight average of steps 29k and 30k of a 30k-step extension of that same run. Note also that the two held-out article sets differ in difficulty by ≈2–3 chrF++ (legal test is the

| system | legal | | near-domain | | spontaneous speech | |
|---|---|---|---|---|---|---|
| | pt→yrl | yrl→pt | pt→yrl | yrl→pt | pt→yrl | yrl→pt |
| flagship | 31.70 | 37.39 | 64.11 | 57.10 | 45.24 | **49.67** |
| + hints | 31.13 | — | 64.42 | — | — | — |
| avg | **32.78** | **38.14** | **64.54**† | **58.76** | **47.45** | 49.37 |
| avg, v1 refs | 32.74 | 38.15 | 62.55 | 56.92 | — | — |

Table 5: Phase-2 final test, decoded once. For pt→yrl, paired bootstrap intervals do not resolve the difference between our two systems on legal text (95% CI $[-0.06, +2.26]$) or near-domain text ($[-0.48, +1.44]$); the speech interval excludes zero ($[+0.46, +4.06]$). The same holds against Phase 1 on identical v1 references (32.74 vs. 32.03, $[-0.37, +1.79]$, $p = 0.20$). The 0.71 gap against Phase 1 on v1 references is not resolved by the paired-bootstrap interval on this 218-segment set. †Removing the identified target-side content-overlap items lowers this to 62.09; we report both, and the Limitations give the overlap measurement.

| **ours 1.3B** | Nheengatu | legal (article-disjoint) | **32.8** | **38.1** |
| **ours 1.3B** | Nheengatu | speech | **47.5** | **49.4** |
| **ours 1.3B** | Nheengatu | near-dom. | **64.5** | **58.8** |

Table 6: Context from AmericasNLP, not a ranking: no cell is a like-for-like comparison. All values are chrF++ from fine-tuned NLLB-200-distilled-1.3B models with an extended embedding matrix; our rows are the *avg* system of Table 5. The AmericasNLP pairs use Spanish and translated XNLI test sets; ours use Portuguese and single-step translations (field translation on the speech side, see Limitations).

easier draw), so dev and test numbers are reported separately throughout and never pooled; the Phase-1→Phase-2 comparisons below use the same evaluation split and reference series. Trivial baselines fix the scale: copying the Portuguese source scores 13.8 / 12.2 / 9.3 chrF++ on the legal, near-domain and speech test sets, and shuffled references 13.1 / 9.7 / 11.7. Table 6 fixes the other end: the spread between our own three evaluation sets is larger than the spread between published systems for comparable languages, which is itself the point.

The legal and near-domain sets were first evaluated in Phase 1 and reused in this evaluation, so we treat them as reused holdouts rather than pristine single-use test sets. Each Phase-2 model–test combination was decoded once, with no test-based checkpoint selection. The speech test set remained untouched until this pass. Before decoding we fixed, in writing, which checkpoint would be evaluated, which metric would decide, and what each possible outcome would mean.

First, the ranking flipped between dev and test. On dev the flagship checkpoint beat the checkpoint-averaged system; on test the average won the headline metric by more than a point on the legal set. Had we selected on dev we would have promoted the system test ranked second; had we selected on test we would have been fitting it. We report both, which quantifies the selection risk a 218-segment set carries.

Second, cross-series scoring punishes cleaner models: scored against the *original* v1 references our v3 systems reach 62.6 on near-domain against 66.4 for the v1-trained system, because a model trained not to emit the artefacts those references still contain is penalised for their absence. We therefore never compare across reference series.

Third, the closed baseline (Gonçalves et al., 2025) cannot be compared to ours directly. Rescoring our outputs in *their* protocol gives 64.48 pt→yrl and 60.2 yrl→pt on near-domain against their 69.1 and 66.9. What matters more is that their test set is a random split of the corpus the model was trained on (6,699 training pairs, 233 test pairs, randomly divided); the same paper splits its other language by source instead, and reports 40.2 there. A random split of the training corpus and a held-out test of unseen legal prose measure different things, and only the second probes unseen legal content.

The test also reproduces the terminology dissociation. Without any inference-time intervention, the Phase-2 system scores 47.8 TSR against the Phase-1 system's 44.0 on the same 232 term occurrences (**+3.8pp**): data and training alone internalised part of the glossary. Adding hints then moves TSR from 47.8 to 57.3 (+9.5pp) while costing 0.57 chrF++, the same dissociation observed on development data, reproduced under the pre-specified Phase-2 evaluation. The averaged system, which obtains the highest chrF++ of our two final systems, simultaneously obtains the lower terminology score, at 44.4 TSR.

### 5.7 Decoding without a validated neural metric

Because no learned quality metric is validated for yrl, we do not use neural-metric utility as primary evidence for reranking. We instead evaluate search variants, string-based MBR, terminology reranking, and lexical constraints. Five are null. Three are measured on the near-domain dev set against a

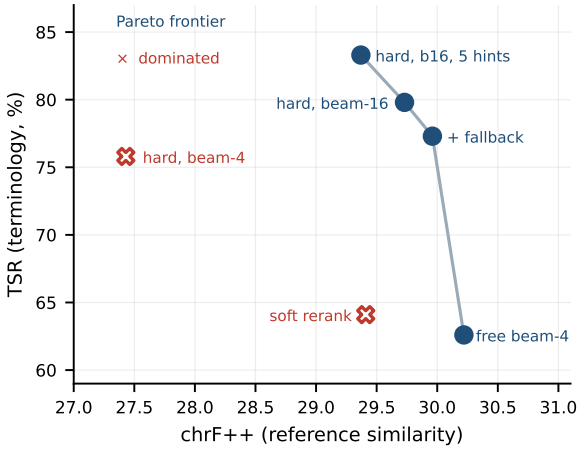

Figure 2: Terminology realization versus chrF++ on hinted legal development data. Free beam-4 gives 30.22 chrF++ at 62.6 TSR; hard constraints with a wide beam and five hints reach **83.3** TSR at 29.37. Two settings are *dominated* in both dimensions at once: soft reranking (29.41/64.1) and hard constraints at beam-4 (27.43/75.8), where narrow constrained search substantially reduces reference similarity and a wider beam recovers part of the loss, as the dynamic-beam-allocation literature predicts (Post and Vilar, 2018). The decoder realizes 164 of 165 requested surface-form insertions, or 99.4%. This measures surface inclusion rather than semantic, morphological, or syntactic correctness. The wide-beam gain is hint-conditional: the argmax drops only when hints are present.

beam-4 reference of 63.1 chrF++: sampled chrF-MBR (61.9–62.6, even with the beam candidate in the pool); MBR reranking of the beam's own n-best (damages the argmax); and wider beams, which saturate unhinted. The other two are conservative LLM post-editing of the Portuguese side ($-0.2$ chrF++; no improvement in reference similarity) and soft terminology reranking, dominated on the legal-dev frontier below. One frontier does validate (Figure 2).

**A cost chrF++ almost hides: constraints multiply degeneration.** Repetition detection over the same 233 outputs (punctuation-normalized $n$-grams; **zero false positives on the 233 human references**, and no source sentence contains list markers) flags 1.7% of free beam-4 outputs and 1.3% of hinted ones, against 6.0%, 7.7% and 8.2% for the three constrained settings (paired uncorrected exact two-sided McNemar $p = .031/.003/.0015$; the ratio holds at 3.2–4.8$\times$ across four detector thresholds). The failure localizes to the constraints themselves: constrained runs consume the *plain* source (terms enter only through `force_words_ids`), and among the 110 sentences that actually receive constraints degeneration rises from 3.6% to 16.4%, while constraint-free sentences under the same decoder stay at 0.8%. Every flagged output is a genuine loop on inspection (median length ratio 3.2, up to 17.8$\times$ the reference, sometimes fabricating enumerations absent from the source).

chrF++ does penalize these sentences ($-7.2$ each against the same sentences decoded freely), but its recall-weighted $F_{\beta=2}$ makes appended repetition cheap: a hypothesis consisting of the reference *tripled* still scores 71.0. Corpus-level the whole pathology is therefore worth only $-0.59$.

A repetition-triggered fallback (detect the loop, re-decode that sentence without constraints) buys it back. It fires on 19 of 233 sentences and gives the fallback point of Figure 2: 29.96 chrF++ (within 0.26 of unconstrained decoding), degeneration down from 8.2% to 0.9%, and TSR at 77.3. That last figure is the honest cost: the fallback trades $-6.0$pp of terminology for $+0.59$ chrF++, because the rescued sentences lose their forced terms by construction. Whether that trade-off suits a community writing assistant must be settled by speaker and user evaluation.

## 6 Analysis

**chrF++$\times$TSR dissociation.** Scale buys chrF++ without terminology (test TSR flat at 600M$\rightarrow$1.3B in Phase 1); annotation + token-pair augmentation buys both; extended training buys chrF++ *and loses* terminology (the avg system). Per-case verification of all 34 hint-induced term flips shows 24/26 gains syntactically integrated and only 1 real regression: the matcher-based TSR *understates* the mechanism.

**Register-conditional orthography switching:** trained on multiple traditions, the model in qualitative inspection sometimes follows the orthographic tradition associated with the input register; we do not quantify this effect, and we propose per-norm control codes as the community-governed mechanism.

**Terminology errors on article-disjoint legal text.** We inspect both model sizes on the same 20 legal-development segments, 40 outputs in all. Outputs generally preserve grammatical frames, legal citations such as *art. 89, VII*, and many numerical expressions, while much of the residual error involves conventional legal terms such as *civil registry*, *death certificate*, and *cruel* (from *penas*

*cruéis*, 'cruel punishments', art. 5, XLVII). The 90 missed term occurrences correspond to 60 distinct glossary forms; only eight occur at most twice in training, and the median training count is 10. Simple token rarity is therefore not the only explanation. Several terms have competing or inconsistent realizations across the written sources we examined. We treat this instability as an important bottleneck, but the present sample does not establish that terminology accounts for the entire legal-performance plateau.

Two further observations from the same samples. First, in $\geq$3/20 legal samples the system is *more faithful to the source than the human reference*: it renders "sixty" where the reference prints "65", and "two rounds" where the reference has "morning or afternoon". chrF++ against such references has a ceiling well below 100, which is why our speaker protocol asks evaluators to judge against the *source*. Second, the hint mechanism's own failure modes are narrow but real: noun hints pasted into verbal slots, and a digit juxtaposed with the hinted native numeral (*"10 ára-ita mukũi pu aára"*, literally "10 days two hands"); conversely, in two cases a hint *cured* a degeneration loop.

## 7 Discussion

Article-disjoint legal pt→yrl plateaus across the tested training lengths and model sizes. Our error analysis points to unstable conventional terminology as an important contributor: the largest modern yrl dictionary (Avila, 2021) provides a usable match for only one of 54 outstanding legal terms, and the tested increase from 600M to 1.3B did not resolve terms that are inconsistently attested in the written resources we examined.

The analysis has a practical implication. For languages whose written resources do not consistently attest specialized terminology, a community-governed control interface can complement the model: a revisable glossary, mechanisms that expose the model to it during training, and an optional lexical-enforcement mode at inference time. The hint budget matters as well: allowing four inline hints per sentence at inference, instead of the two used in training, raises TSR by 1.9$\pm$0.3 pp on the v3 600M models (three seeds) at no chrF++ cost, because sentences that match more than two glossary terms otherwise lose the rest at the cap. The decoding mode increases specified surface-form realization but does not guarantee semantically, morphologically, or syntactically correct use. The components are independently replaceable, allowing the pipeline to incorporate an authoritative terminology list if and when one is established.

Within the tested NLLB family, increasing model size is consistently helpful for yrl→pt and also improves near-domain pt→yrl, but it does not improve article-disjoint legal or speech pt→yrl in our runs. A larger checkpoint is therefore promising for reading support, whereas writing support in the harder registers is likely to require better matched data, terminology governance, and user evaluation in addition to model size.

Finally, the three dissociations we report (chrF++ against terminology, chrF++ against degeneration, dev ranking against test ranking) all point the same way: for languages without a validated learned metric, a single automatic number gives a projection of quality along one axis, unstable at this sample size, and never a summary of it. The next required instrument is speaker-grounded evaluation of adequacy, naturalness, terminology, and usefulness. The planned protocol is described in the Ethics Statement, but no speaker-evaluation result is included in the present version.

## Limitations

**Limited architectural coverage.** Our principal systems are NLLB-200 fine-tunes with an added language token. §5.5 reports a same-corpus control against a 2B decoder-only system, but we did not train an alternative encoder-decoder base such as mBART or M2M-100, and the control itself covers one model and one scale per side, on development data only.

- Small evaluation sets (218–372 per set; speech 115–116). At this size differences of about a point were not resolved by our bootstrap intervals (Table 5).
- No speaker evaluation is included in this version.
- chrF++ penalizes valid cross-orthography outputs.
- TSR synonym coverage is incomplete, and shown to understate.
- The 1.3B models are single-seed.
- Failure-targeted synthetic term selection is development-guided, and no independent test result is included. We therefore treat the distillation result as exploratory.

- Brazilian text-and-data-mining (TDM) legality for third-party research use lacks an explicit exception. Our posture is non-commercial research; one third-party layer is redistributed with its author's written permission and the others remain pending.
- Domain status of the legal evaluation. The legal development and test sets hold out complete constitutional articles, but they come from the same translated Constitution as 2,031 training pairs. They are article-disjoint and segment-disjoint, not domain-disjoint or document-disjoint.
- Terminology governance. The glossary is source-derived and researcher-adjudicated rather than community-authorized. Its forms should be treated as provisional alternatives for experimentation, not as an official Nheengatu terminology standard. Its reach is also bounded: in the legal test set, 8.7% of content tokens (176 word types) never occur in training (by surface form) and none has a glossary entry, so no glossary-based mechanism can act on them.

**Content overlap in the near-domain test set.** Exact-pair deduplication is not sufficient when a language has few sources. Our near-domain test contains no leaked pair (zero identical source sentences, zero identical targets, zero identical pairs against training), but 23 of its 371 targets share an 8-gram with training data, because the same traditional narratives appear in both the dictionary and the treebank, in different renderings. Those 23 items score 80.5 against the set's 64.5, and removing them lowers the set to **62.1**. We report both: 64.5 for the declared set and 62.1 as the conservative reading. The legal and speech sets are practically unaffected (1/218 and 0/115 targets, respectively). The development sets show the same pattern (3/233 legal, 25/372 near-domain, 0/116 speech), which matters because the mechanism and decoding results are measured there. This overlap reflects a structural challenge in low-resource corpus construction, and content-level $n$-gram overlap should be reported alongside exact pair-level deduplication. On the Portuguese source side the same measurement returns 21 of 371 near-domain and 27 of 218 legal segments; the legal figure reflects formulaic legal phrasing recurring across disjoint articles rather than content leakage, and it is the mirror image of the yrl side, where orthographic variation suppresses exact recurrence.

**What our speech numbers are computed over.** Two properties of the time-aligned speech source qualify the speech scores we report. First, its alignment unit is the pause-delimited *turn*, not the sentence (median 1.8 s and 4 words, a third of them two words or fewer; only 10% end in sentence-final punctuation), so most segments are mid-utterance fragments, a unit at once easier than a sentence (short) and harder (fragmentary, context-dependent). Second, its Portuguese side is a field free-translation written by the transcribers: regional Upper Rio Negro and/or L2 Portuguese (sentence-final discourse *nem* in 13.0% of the speech test set, non-standard spelling 9.6%, non-standard agreement 2.6%; the constitutional set scores 0% on all three). Into Portuguese, some model outputs use standard Portuguese forms where the references use regional or non-standard forms, which chrF++ can penalize sentence by sentence: *"Lili, aonde está"* (reference) vs. *"Lili, onde está"* (system) scores 64.3, and 100.0 against a standardized reference. Aggregated the effect vanishes (standardizing unambiguous spellings moves 12 runs by $-0.61$ to $+0.62$, mean $\approx -0.07$), so no headline number needs correcting; we leave the references untouched, which is also the CARE-consistent choice: "correcting" Indigenous speakers' Portuguese is not ours to do. In the pt→yrl direction the same text is *input*; robustness to standardized Portuguese input remains untested.

## Ethics Statement

Our process is informed by the ethical framework of Mager et al. (2023) and by CARE principles. We contacted the Academia da Língua Nheengatu but have not obtained a response, endorsement, or institutional approval; silence is not treated as consent. The glossary and orthographic choices in this work are therefore provisional and source-derived rather than authoritative. Future governance should involve speakers from multiple regions and orthographic traditions. Licensing is layered: official-text layer outside copyright protection under Article 8 of Brazilian Law 9,610/1998; the treebank and speech layers inherit CC BY-NC-SA; the dictionary-example layer (Avila, 2021) is redistributed with the author's written permission; the remaining third-party layers ship as reproducible extraction pipelines pending permission; the three NLLB-derived checkpoints are publicly available

on Hugging Face under CC-BY-NC-4.0; the Qwen-derived checkpoint is released under Apache-2.0. We position the system as writing/reading support, never official translation.

**Speaker evaluation protocol.** No speaker evaluation has been run for this version; the instrument below is built and being fielded, and its results will be reported separately. It presents 75 items in a self-contained offline form: absolute adequacy/naturalness on 30 system outputs balanced across legal, near-domain and speech registers, interleaved with **9 hidden human-reference anchors** (23% of the block, WMT-style) that give a calibration ceiling and an inattentive-rater check; 20 blind pairwise items (free vs. constrained decoding, with preference asked *before* the target term is revealed); 12 blind system-vs-official-translation items; and 4 open language questions. Item counts follow a power analysis. Speech items carry their neighbouring conversational turns as explicitly non-evaluated context, and evaluators are told the Portuguese of those turns is the transcribers' own regional writing, not a translation error. Evaluators are told translations come from undisclosed mixed sources, never that all are machine-made, and are **debriefed within the form** about the hidden human references and why they were concealed; blinding keys never ship with the questionnaire. Evaluation data are anonymous by default. Any option to be acknowledged by name is collected through a separate, explicit opt-in that is not linked to the participant's individual ratings. Participation is voluntary and compensated, with informed consent obtained before rating and the right to withdraw data until analysis. Ratings are stored under pseudonymous identifiers with restricted access. No speaker data have been analysed for this submission.

## Acknowledgments

We thank Marcel Twardowsky Avila for permission to redistribute the dictionary example pairs derived from his thesis; the Revista Leetra Indígena at UFSCar and the authors of its bilingual school books; and the fifteen Indigenous translators of the Upper Rio Negro and Middle Tapajós whose translation of the Constitution, published by the STF and the CNJ, anchors this corpus.

## A Reproducibility

**Hardware and budget.** A 20k-step 600M run takes 72–77 minutes on a single NVIDIA H100 (≈1.3 GPU-h); the 1.3B flagship needs about four hours of wall clock. Jobs killed by a wall-clock limit resume from the last checkpoint, and we note one pitfall we hit: early stopping restarts its patience counter on resume, so patience is not comparable across interrupted and uninterrupted runs.

**Training.** Base checkpoints are NLLB-200-distilled 600M and 1.3B. The new language token `yrl_Latn` is initialized from the `grn_Latn` (Guarani) embedding, a starting point only; mixing Guarani training data was measured and rejected ($-0.26$ chrF++). Hyperparameters follow AmericasNLP submissions in the same line (Gow-Smith and Sánchez Villegas, 2023; Garcia Gilabert et al., 2024): full fine-tuning (no adapters), lr $1 \times 10^{-4}$ with inverse-square-root schedule and 400 warmup steps, weight decay 0.01, no label smoothing, max sequence length 192, effective batch 32 ($16\times2$ accumulation), bf16, 20k steps, evaluation every 1000 steps, best checkpoint selected by dev chrF++ with early-stopping patience 8, beam 4 for the in-training generation.

**The architecture control.** The decoder-only side of §5.5 is `Qwen/Qwen3.5-2B` (Qwen Team, 2026), the instruction-tuned release rather than the pre-trained base, trained on the same v3 data, with the same three seeds, and scored with the same decoding and metrics as the seq2seq runs. The original Qwen checkpoint is a vision–language foundation model whose card counts 2B parameters in the language model; we load it with the text-only `Qwen3_5ForCausalLM` class, which instantiates the language backbone alone (1.882B parameters, the vision tower never constructed) and we use its own tokenizer (248,320 pieces, tied input and output embeddings). Adaptation is full fine-tuning with no adapters: lr $2 \times 10^{-5}$ with cosine schedule and 400 warmup steps, weight decay 0.01, fused AdamW, fp32 master weights under bf16 autocast, gradient checkpointing, maximum sequence length 512 for prompt and target together, effective batch 32 ($8 \times 4$ accumulation), 20k maximum steps, evaluation every 1000 steps on a 600-example development subset, best checkpoint by development loss (the seq2seq side keeps the checkpoint with the best development chrF++; Table 7 scores both selections). Training pairs are rendered with a plain Portuguese instruction template rather than the chat template (*Traduza do <source> para o <target>.*, then the source line and an empty target line), and the reasoning-delimiter tokens are suppressed at decoding so that generation budget cannot be spent on them. In all three seeds the best checkpoint is step 1,000 (1.15 epochs over the 27,900 bidirectional training examples) and the remaining 19k steps never improve development loss. Development chrF++ nonetheless keeps improving well past that point (Table 7): at steps 11–12k the three seeds reach $27.67\pm0.57$ on legal pt→yrl against $25.89\pm0.67$ at step 1,000, and $62.37\pm0.54$ against $52.11\pm0.82$ on near-domain pt→yrl. The conclusiveness threshold is three standard errors of the difference between the two three-seed means, computed separately for each set, direction and metric; across the six cells of the loss-selected comparison it ranges from 0.98 to 3.73 chrF++. Speech yrl→pt clears it by 0.06 chrF++ but falls 0.19 short under spBLEU, which is why the cell is reported and not claimed.

| cell | seq2seq 600M | dec.-only @1k | dec.-only late | Δ late | 3·SE |
|---|---|---|---|---|---|
| legal pt→yrl | 29.57±0.22 | 25.89±0.67 | 27.67±0.57 | +1.90 | 1.06 |
| legal yrl→pt | 34.83±0.29 | 28.14±0.68 | 33.11±1.51 | +1.72 | 2.67 |
| near-dom. pt→yrl | 60.87±0.49 | 52.11±0.82 | 62.37±0.54 | −1.50 | 1.26 |
| near-dom. yrl→pt | 56.68±0.23 | 48.94±0.51 | 59.91±0.05 | −3.23 | 0.41 |
| speech pt→yrl | 46.23±0.48 | 39.96±1.11 | 44.74±0.90 | +1.49 | 1.77 |
| speech yrl→pt | 50.95±1.05 | 47.16±1.88 | 47.88±1.60 | +3.08 | 3.31 |

Table 7: The architecture control under both checkpoint selections (development sets, chrF++, mean±sd over three seeds). "@1k" is the loss-selected checkpoint; "late" is steps 11–12k, scored after submission as a proxy for chrF++ selection. Δ is seq2seq minus late decoder-only (positive favours the seq2seq); 3·SE is three standard errors of the difference, the pre-specified threshold for that comparison, and a cell is conclusive when $|\Delta| \geq 3\cdot\text{SE}$ and $|\Delta| \geq 1.0$: legal pt→yrl (seq2seq) and both near-domain cells (decoder-only).

**Software.** Metrics are computed with sacreBLEU 2.6.0 (`nrefs:1`, `case:mixed`; chrF++ with `nc:6`, `nw:2`, `space:no`; spBLEU with `tok:flores200`); NLLB models are trained with Transformers 4.55.4 and PyTorch 2.6.0, seeds 1–3. The Qwen control uses a separate environment with Transformers 5.14.1. Confidence intervals use paired bootstrap resampling with 1,000 resamples.

**Evaluation.** chrF++ (Popović, 2017) is sacreBLEU's (Post, 2018) `CHRF` with `word_order=2` and the default $\beta = 2$. Table 8 reports the full test results additionally in plain chrF (`word_order=0`) and spBLEU (`tokenize=flores200`), so that they can be read against work using either convention: much of the Indigenous-language literature reports plain chrF, and spBLEU is the severest of the three on a morphologically rich target. We deliberately use *no* neural metric: COMET, CometKiwi and MetricX have not been validated for yrl and provide no dedicated language coverage, so their scores here would be uninterpretable. TSR (§4) is scored over the union of the audited glossary and the base bilingual lexicon, with a yrl lemma table, a fuzzy

| set | dir. | chrF++ | chrF | spBLEU |
|---|---|---|---|---|
| *flagship* | | | | |
| legal | pt→yrl | 31.70 | 35.95 | 12.83 |
| legal | yrl→pt | 37.39 | 39.56 | 19.90 |
| near-dom. | pt→yrl | 64.11 | 65.99 | 54.65 |
| near-dom. | yrl→pt | 57.10 | 57.86 | 41.68 |
| speech | pt→yrl | 45.24 | 49.77 | 27.86 |
| speech | yrl→pt | 49.67 | 50.88 | 31.71 |
| *avg* | | | | |
| legal | pt→yrl | 32.78 | 36.93 | 13.43 |
| legal | yrl→pt | 38.14 | 40.29 | 20.73 |
| near-dom. | pt→yrl | 64.54 | 66.44 | 54.85 |
| near-dom. | yrl→pt | 58.76 | 59.57 | 43.49 |
| speech | pt→yrl | 47.45 | 51.89 | 30.56 |
| speech | yrl→pt | 49.37 | 50.66 | 31.57 |

Table 8: Final test under three metrics. Plain chrF is approximately 0.8–4.5 points above chrF++ in these results; chrF++ additionally incorporates word $n$-grams. spBLEU scores are lower on these sets. The ordering of the two systems within each set and direction is the same under all three metrics; comparisons across directions need not have the same ordering.

threshold of 0.85 applied only to forms of five characters or more, and single-word Portuguese terms under four characters skipped. Each model–test combination was decoded once, under a written protocol fixing the system, the checkpoint and the metric before decoding. The legal and near-domain sets are reused holdouts, first evaluated in Phase 1 and once in Phase 2; `test_fala` was spent in the Phase-2 pass.

**Audit categories and residual estimates.** Two v3 sources were audited on samples of 200 and 240 pairs, with evidence attached to every judgement: 200 speech pairs, scored against the temporal context of neighbouring turns, and 240 dictionary-example pairs, scored against a window of the page's source text.

| | ok | minor | suspect | defective |
|---|---|---|---|---|
| Speech (200) | 183 | 11 | 2 | 4 |
| Dictionary ex. (240) | 208 | 16 | — | 16 |

Table 9: Audit outcomes; the approval rates quoted in §3 are the *ok* column.

The residual estimates are lower than the non-ok mass in Table 9 because the two tails were treated differently. In the speech sample all four defective pairs were code-switch identity pairs, a mechanically detectable class that we then removed population-wide (42 pairs across the full resource); what survives is the suspect category, 2/200 = 1.0% (Wilson 95% CI $[0.3, 3.6]$). In the dictionary sample the 31 corrections returned by the audit were verified against the page sources and applied to the audited pairs only, so the observed defective fraction is 16/240 = 6.7% (Wilson interval $[4.1, 10.6]$). Because the sampling procedure was not preserved, these sample proportions and nominal intervals do not establish population error bounds for the unaudited pairs. Both residual classes are distinct from mispairing: 28 of the 32 dictionary problems are left-edge truncation or bleed on the yrl side, the Portuguese side is correct in 239/240, and cross-pairings are zero.

**The French–yrl pairs.** The 925 FR–yrl pairs are concatenated with the pt–yrl training file before the bidirectional expansion, so both directions are trained: 925 fra→yrl and 925 yrl→fra, 1,850 of the 27,900 training examples, and 12,467 yrl running words, 9.4% of the yrl side the model is fit to. They carry NLLB's own `fra_Latn` and `yrl_Latn` tags and no additional source or register tag. There is no upsampling, downsampling or per-source balancing: the concatenated set is shuffled once, so every source contributes in proportion to its size. Inline terminology annotation is applied only to `por_Latn` sources, so the French pairs are never annotated. yrl→fra is trained and never evaluated; the mirroring is applied uniformly to every training file rather than decided per source.

**Glossary provenance.** The 904 training-glossary entries were mined from the training pairs and from external lexical resources. Evaluation references enter the pipeline only as an exclusion filter, deleting mined candidates that coincide with a development or test pair; they are never a source of entries. Checking every entry against the Portuguese side of both partitions, none has support only in the evaluation references.

**Statistics.** Beyond the $\pm 0.35$ chrF++ ruler of §4, the TSR rulers on the legal dev set are $\pm 1.6$pp unhinted and $\pm 2.7$pp hinted (3 seeds, 600M): a single-run TSR difference below $\sim$3pp is not interpretable, and we mark such comparisons as inconclusive instead of reporting them as effects. Of the two single-seed results that failed to replicate, one was a TSR. Paired comparisons of degeneration rates use McNemar's exact test. The metric values covered by the recorded audit rounds were recomputed from stored hypothesis files independently of the training-time logs. The v2 speech scores are

retained evaluation summaries; their hypotheses were not preserved. The released code includes the terminology matcher and training glossary. The base bilingual lexicon, the scoring lexicon's other component, contains sentence-length entries from sources whose redistribution is still pending.

**Code, data and models.** Four checkpoints are released on Hugging Face: the NLLB 600M annotation-plus-token-pair model (seed 3), the 1.3B flagship and checkpoint average, and the text-only Qwen model (seed 2, step 11,000). The Qwen release has the highest near-domain pt→yrl development chrF++ among the three late checkpoints. Table 7 reports three-seed architecture-control results; its NLLB 600M comparator uses no terminology mechanisms. The final-test results in Table 5 concern the flagship and average. Model cards and weights are linked at `https://huggingface.co/voz-ancestral`. The extraction, alignment, annotation, constrained-decoding and evaluation scripts, and the corpus layers whose licences permit redistribution are at `https://github.com/fabriciocarraro/NheengatuMT`. Third-party layers ship as reproducible extraction pipelines instead of redistributed text where permission is pending; the dictionary-example layer is included with its author's written permission.

# ChakmaNMT: Machine Translation for a Low-Resource and Endangered Language via Transliteration

**Aunabil Chakma[1], Aditya Chakma[5], Masum Hasan[3], Soham Khisa[6], Chumui Tripura[4], Rifat Shahriyar[2]**

## Abstract

We present a systematic study of machine translation for Chakma, an endangered and extremely low-resource Indo-Aryan language, with the goal of supporting language access and preservation. We introduce the first and, to our knowledge, largest Chakma–Bangla MT resource: 15,021 parallel translation pairs comprising 9,548 sentence pairs and 5,473 dictionary word pairs, plus 42,783 Chakma monolingual sentences and a trilingual benchmark with 500 unique sources and 600 Chakma references. To address script mismatch and data scarcity, we propose a character-level transliteration framework designed to preserve pronunciation and lexical identity while enabling transfer from Bangla and multilingual pretrained models. We benchmark from-scratch MT, fine-tuned pretrained models, and large language models via in-context learning. For the tested pretrained models, transliteration is crucial. ICL is strongest for CCP→BN; for BN→CCP, BanglaT5 has the highest BLEU while GPT-4.1 with n-gram retrieval has the highest chrF.

Figure 1: Illustrative Chakma→Bangla translation example comparing our two best-performing approaches: fine-tuned NMT (BanglaT5) and GPT-4.1 with 400 demonstration pairs selected by n-gram similarity, our best-performing ICL variant. Despite similar automatic scores, the outputs differ in lexical choice and interpretation.

## 1 Introduction

The Chakma language is spoken by the indigenous Chakma people across Bangladesh, the easternmost regions of India, and western Myanmar, and belongs to the Indo-Aryan language family (Mohsin, 2013). It is spoken by over 700,000 people across the region (Office of the Registrar General & Census Commissioner, India, 2011; Bangladesh Bureau of Statistics, 2022). Despite this population, Chakma remains predominantly oral, with limited use of its writing system, leaving the language critically under-resourced in digital form. As noted by Saikia and Haokip (2023), Chakma is classified as “Definitely Endangered,” and continued language loss poses risks to cultural identity and community continuity. Although revitalization efforts exist-such as pre-primary materials produced by the National Curriculum and Textbook Board of Bangladesh (National Curriculum and Textbook Board, 2019) and limited school textbooks in India (Chakma Autonomous District Council, 2024)-they remain largely confined to education, while everyday communication and public discourse increasingly rely on dominant regional languages such as Bangla, underscoring the lack of computational support for Chakma in broader communication settings.

Chakma remains underrepresented in NLP, although prior and recent work includes character recognition and handwriting data (Podder et al., 2023; Ferdeous et al., 2026), speech language identification (Pratap et al., 2023), and parallel-corpus MT (Rahman et al., 2025). Although commercial LLMs can recognize Chakma script, preliminary inspection suggests that their Chakma outputs can be semantically unreliable; our experiments use

*Proceedings of the Eleventh Conference on Machine Translation*, pages 64–81
October 28-29, 2026 ©2026 Association for Computational Linguistics

GPT-4.1 variants through the API (Section 7). As a result, foundational text-based capabilities-most notably machine translation (MT), which is critical for cross-lingual communication and access to public resources-remain largely unexplored.

Motivated by the remaining gap, we present a systematic study of machine translation for Chakma, an extremely low-resource and endangered language. We investigate how different modeling paradigms, including classical machine translation, neural models, and large language models via in-context learning, behave under severe data scarcity and cross-script conditions. Our goal is to establish practical baselines for Chakma MT while highlighting challenges that arise in extremely low-resource and non-standardized languages. Figure 1 illustrates qualitative differences between our best-performing systems. A fine-tuned BanglaT5 model produces higher-scoring translations with limited parallel data. A GPT-based in-context learning approach, using 400 demonstration examples, produces outputs that appear more faithful in the inspected examples.

Our contributions are summarized as follows:

(1) **First and largest Chakma–Bangla MT resource to date.** Originally released in 2024, ours was the first Chakma–Bangla MT dataset and remains, to our knowledge, the largest documented Chakma MT corpus, with 15,021 parallel translation pairs comprising 9,548 sentence pairs and 5,473 dictionary word pairs. Of the sentence pairs, 8,647 additionally include aligned English; we also provide 42,783 Chakma monolingual sentences and a trilingual benchmark with 500 unique sources and 600 Chakma references. These resources provide a foundation for machine translation and downstream NLP research on Chakma.

(2) **Script-bridging transliteration framework.** We propose a simple, rule-based character-level transliteration system that leverages Chakma–Bangla script similarity to provide near one-to-one mappings designed to preserve pronunciation and lexical identity. This enables effective cross-script transfer and allows pretrained and large language models to be applied in this extremely low-resource setting.

(3) **Comprehensive benchmarking in an extremely low-resource setting.** We systematically benchmark statistical and neural MT, fine-tuned pretrained models (e.g., BanglaT5, mT5), and GPT-based in-context learning, establishing initial baselines for Chakma–Bangla translation.

(4) **Analysis of orthographic variability.** We analyze orthographic inconsistencies in Chakma arising from non-standardized spelling and script usage. We examine how this variability may affect automatic evaluation, particularly BLEU, when multiple valid spellings occur.

## 2 Related Work

Machine translation has historically relied on abundant parallel data, from statistical systems to neural encoder–decoders (Koehn et al., 2003; Bahdanau et al., 2014; Koehn and Knowles, 2017), leaving languages with scarce digital resources underserved.

Work on low-resource NMT has explored a range of strategies to mitigate data scarcity, including semi-supervised learning with monolingual data (Gulcehre et al., 2015), back-translation (Sennrich et al., 2016), multilingual neural machine translation for cross-lingual transfer (Kocmi and Bojar, 2018), and transliteration for closely related languages with different scripts (Durrani et al., 2010). In extremely low-resource settings, prior work reports very low translation quality overall (often obtaining BLEU scores below 10) (Guzmán et al., 2019), with several MT approaches yielding BLEU scores in the low single digits or around 1–2 under out-of-domain evaluation, highlighting the difficulty of generalization (Zhang et al., 2020).

Following the initial 2024 release of this work, recent Chakma resources include ChakmaBridge, a complementary 807-sentence five-way corpus with MT baselines (Rahman et al., 2025); MELD, which represents Chakma, Garo, and Marma in Bengali script with English and standard Bengali translations (Mahi et al., 2025); a Bangla-transliterated Chakma corpus for studying cross-lingual transfer through MLM fine-tuning (Khisa et al., 2025); and a Chakma handwriting dataset (Ferdeous et al., 2026). LLMs also offer in-context learning (ICL) as an alternative to fine-tuning (Brown et al., 2020), but its direction-dependent performance motivates our study of extremely low-resource, cross-script translation.

## 3 ChakmaNMT Dataset

Table 1 summarizes the parallel, monolingual, and evaluation data collected in this work, with details discussed below.

| Category | Source | Samples | Avg #Tok | Total |
|---|---|---|---|---|
| Parallel | UN-Disabilities (BN-CCP) | 610 | 16.86 | 15,021 |
| | UN-Child Rights (BN-CCP) | 291 | 37.66 | |
| | Dictionary (word pairs) | 5,473 | 1.14 | |
| | Crowdsourced (BN-EN-CCP) | 3,444 | 4.51 | |
| | Community translation + expert review (BN-EN-CCP) | 5,203 | 3.60 | |
| Monolingual | Local Chakma sources (CCP) | 42,783 | 5.81 | 42,783 |
| Evaluation | RisingNews Benchmark Extension (BN-EN-CCP) | 500/600 | 14.8 | 500/600 |

Table 1: Overview of the Chakma–Bangla datasets introduced in this work. The parallel total comprises 9,548 sentence pairs and 5,473 dictionary word pairs. Evaluation contains 500 unique source sentences and 600 Chakma references. Avg #Tok counts space-separated Chakma (CCP) tokens; BN and EN denote Bangla and English.

### 3.1 Parallel Corpus

**Parallel Documents** After extensive searching, we identified two publicly available documents that contain aligned Bangla (BN) and Chakma (CCP) translations: *UN Convention on the Rights of Persons with Disabilities* (United Nations, 2007) and *UN Convention on the Rights of the Child* (United Nations General Assembly, 1989). The Bangla versions of these documents were available only as scanned PDF files containing images of the original printed documents. We applied Tesseract OCR[1] to extract Bangla text from these scans.

Automatic sentence alignment methods such as Hualign (Varga et al., 2005) were not applicable in our setting due to the lack of a sufficiently rich Chakma lexicon. Consequently, all sentence alignments were performed manually. This process resulted in 610 and 291 CCP-BN sentence pairs from the two documents, respectively. In addition, we incorporated word-level translation pairs from the only available Chakma dictionary, provided to us in JSON format.[2] This yielded 5,473 additional parallel samples.

**Community Translation with Expert Review** To obtain high-quality sentence-level translations, we organized a manual data collection effort involving native Chakma speakers with strong literacy skills. We prepared paper-based forms containing 10,000 Bangla sentences randomly sampled from the BN-EN corpus of Hasan et al. (2020). A three-day voluntary translation program was conducted in Dighinala, Khagrachari (Bangladesh). Between 7 and 10 proficient Chakma speakers participated each day.

All collected translations were subsequently reviewed by senior community-recognized Chakma writers or teachers for linguistic quality and consistency. After filtering, this process produced a final set of 5,203 reviewed CCP-BN-EN parallel sentence triples. Further details of this collection process are provided in Appendix A.1.

**Manual Translation via Crowdsourcing** To further expand the dataset, we collected additional translations through a crowdsourcing approach involving non-expert Chakma speakers. We developed a web-based platform that displayed Bangla sentences and allowed users to submit their Chakma translations. The platform link was distributed through social media channels.

The source sentences primarily consisted of common conversational expressions collected from publicly available resources[3]. Contributors translated only the displayed Bangla sentences into Chakma; English was retained when already available as an aligned reference. Since most contributors were unfamiliar with the Chakma script, they were instructed to write Chakma using Bangla characters. We later converted these submissions into Chakma script using a custom transliteration system (see Section 4.2) developed for CCP-BN conversion. After manual verification and filtering by Chakma language experts, this effort yielded 3,444 additional CCP-BN-EN sentence triples.

Overall, we collected 15,021 BN-CCP parallel translation pairs, comprising 9,548 sentence pairs and 5,473 dictionary word pairs. Of the sentence pairs, 8,647 additionally include aligned English translations.

### 3.2 Monolingual Data

Figure 2 shows the distribution of the collected Chakma monolingual data by content type. We collected a substantial amount of Chakma monolingual data relative to the available parallel resources. Due to the scarcity of digitally available Chakma texts,[4] we conducted in-person visits to Chakma language scholars to obtain soft copies of Chakma script materials. These materials primarily consist of poems, articles, short stories, and a small number of national-level textbooks. In addition, we collected Indian Chakma textbooks and a Chakma folktale mobile application, and we reused the Chakma dictionary introduced in the parallel data collection, which contains numerous high-quality example sentences accompanying lexical entries and is therefore well suited for monolingual data extraction.

To process these sources, all materials were first transcribed into separate `.docx` files, which preserved the original Chakma fonts used in the documents. However, these were legacy fonts that mapped Chakma glyphs onto ASCII code points using distinct encodings. To address this, we developed a conversion program that maps all source fonts to RibengUni, a Unicode Chakma font. This enabled consistent normalization across heterogeneous sources.

Finally, we applied a simple rule-based segmentation procedure, splitting text at sentence boundaries defined by three punctuation markers: '?', '!', and 'l' (full stop). After preprocessing and normalization, we obtained a total of 42,783 Chakma monolingual samples. Tables 3 and 4 provide detailed descriptions of the monolingual data sources, while the font conversion code is available in our normalization repository[5] and the list of supported ASCII fonts is provided in Appendix Table 5.

### 3.3 Evaluation Data

To evaluate our models, we constructed a carefully curated benchmark dataset (see Table 1). We randomly selected 500 unique Bangla–English sentence pairs from the RisingNews Benchmark of online news articles (Hasan et al., 2020). We gave only the Bangla sentences to three Chakma language researchers for translation into Chakma; English remained an aligned reference. Each annotator translated 200 sentences, including a common subset of 50 sentences translated by all three annotators. The shared subset was included to allow analysis of translation variability and orthographic inconsistency across gold references, which we further discuss in Section 7. This produced 600 Chakma reference translations corresponding to 500 unique source sentences. All 600 references are retained as separate evaluation rows, so each shared source occurs once per annotator/reference. The resulting *RisingNewsChakma* benchmark is used exclusively for evaluation and differs in domain from the UN documents, dictionary entries, conversational expressions, and short general-domain sentences used for training.

## 4 Machine Translation Approaches

**Machine Translation Task** This task is formulated as a sequence-to-sequence learning problem at the sentence level. Given a source sentence, the model generates a target sentence token by token. The objective is to learn this mapping from limited parallel data. We study machine translation between Chakma and Bangla.

We compare three complementary approaches to establish strong baselines and understand what works best for this language pair. Our methods differ primarily in how they leverage prior knowledge and handle the script mismatch between Chakma and Bangla. First, we train conventional MT systems from scratch using only our parallel data, which are limited by data scarcity. Second, we fine-tune pretrained sequence-to-sequence models by transferring knowledge from Bangla via script-bridging transliteration and monolingual augmentation. Third, we evaluate large language models using few-shot in-context learning, adapting them to Chakma translation without parameter updates.

### 4.1 From-Scratch MT Baselines

We train both statistical and neural baselines from scratch on our parallel corpus. We use phrase-based SMT (Koehn et al., 2003) as a classical baseline that remains competitive in low-resource scenarios (Koehn and Knowles, 2017). We also train a GRU-based RNN with attention (Bahdanau et al., 2014; Luong et al., 2015) as a lightweight neural model. Finally, we train a Transformer (Vaswani et al., 2017) as a stronger but more data-demanding neural baseline.

[4] Chakma digital texts and scripts are rarely available online, and most existing materials are accessible only through local scholars or printed sources.

[5] https://github.com/Aunabil4602/chakma-nmt-normalizer

### 4.2 Script-Bridging Transliteration

To enable the use of pretrained sequence-to-sequence and large language models, we develop a rule-based, character-level transliteration system that bridges the Chakma and Bangla scripts in a near one-to-one manner.[6] The mapping is designed to preserve pronunciation and lexical identity while mapping Chakma text into the Bangla Unicode range, allowing Chakma data to be processed by Bangla-pretrained models. This transliteration step serves as a core foundation for both fine-tuning pretrained models and in-context learning experiments.

**Exploiting the close relationship between Chakma and Bangla.** Chakma and Bangla exhibit an unusually high degree of phonetic and orthographic similarity among Indo-Aryan languages, making transliteration a natural and low-effort strategy to bridge script mismatch and enable effective transfer from Bangla-pretrained models. Beyond script, the languages share a largely similar subject–object–verb (SOV) word order, although Chakma has systematic morphosyntactic differences (e.g., placing negation before the verb) that may introduce local reordering effects. The transliteration is largely based on straightforward one-to-one character mappings in both directions, with a small number of deterministic phonetic substitutions where exact script-level equivalence is unavailable. The mapping is not bijective and may neutralize some orthographic distinctions; thus, round-trip BLEU and chrF measure surface-form retention and convergence rather than independently establishing semantic preservation (Section 7).

In practice, transliteration is used exclusively as preprocessing and postprocessing: if Chakma is the source, input is transliterated into Bangla before translation; if Chakma is the target, Bangla-script model output is transliterated back into Chakma for evaluation. All pretrained sequence-to-sequence models described in the following subsection are trained and evaluated using this transliterated input–output representation.

We provide full mapping statistics, handling of non-direct characters, and a summary of all non-direct rules (Figure 3) in Appendix A.3.

[6] https://github.com/Aunabil4602/chakma-nmt-normalizer

### 4.3 Fine-Tuning Pretrained Sequence-to-Sequence Models

We fine-tune pretrained text-to-text models on transliterated Chakma–Bangla parallel data. We experiment with BanglaT5 (Bhattacharjee et al., 2023), mT5-small (Xue et al., 2021), and mBART (Liu et al., 2020). These models allow us to transfer linguistic knowledge from Bangla and multilingual pretraining into the Chakma setting.

We further evaluate two data-centric extensions to improve robustness under scarcity. We apply iterative back-translation (IBT) (Hoang et al., 2018) to generate synthetic parallel data from monolingual corpora. In IBT, we start with the forward direction CCP→BN trained on the original parallel data, the backward direction (BN→CCP) is trained with synthetic data, and in later iterations both directional models are trained with additional synthetic data. We also evaluate multilingual training (MNMT) following Johnson et al. (2017). For MNMT, we add 10k Bangla–English sentence pairs from Hasan et al. (2020) to the training data to encourage cross-lingual transfer across Bangla, Chakma, and English.

### 4.4 Large Language Models via In-Context Learning

We evaluate few-shot in-context learning as an alternative to fine-tuning using state-of-the-art large language models. Specifically, we test GPT-4.1, GPT-4.1-mini, and o4-mini with a fixed prompting template and a limited number of demonstration translation pairs. This setting assesses their ability to perform Chakma translation using only in-context examples. The full prompting template and example format are shown in Figure 4.

**Example Selection** Demonstration examples are selected using two retrieval strategies: uniform random sampling from the parallel data and character-level n-gram similarity with each 20-sentence query batch. We use character-level matching to handle orthographic variation in Chakma, where multiple valid spellings make word-level retrieval unreliable. Comparing these strategies allows us to examine how retrieval strategy and demonstration count affect in-context translation quality.

## 5 Experimental Setup

**Data Splits and Evaluation** We split the parallel Chakma–Bangla corpus into training and develop-

ment sets.[7] The training set contains 12,016 parallel pairs and the development set contains 3,005 parallel pairs. We evaluate all models on the held-out RisingNewsChakma online-news benchmark. We report BLEU (Post, 2018) and chrF (Popović, 2015) as our primary automatic metrics; following common practice, BLEU is used for model selection on the development set, and chrF is reported alongside BLEU for all experimental results.

**From-Scratch SMT and NMT** We use the Moses toolkit[8] for phrase-based SMT and PyTorch for neural models. All neural models are trained on Google Colab using NVIDIA V100/A100 GPUs[9]. Data preprocessing follows the normalization scheme of Hasan et al. (2020) with minor language-specific adjustments.[10] We apply SentencePiece (Kudo and Richardson, 2018) for tokenization across SMT and NMT systems. Decoding uses beam search with width 5 and a maximum sequence length of 128 tokens; coverage statistics are reported in Appendix A.4. We train the GRU-based and Transformer models described in Section 4.1.

**Fine-Tuning and In-Context Learning** We fine-tune BanglaT5, mT5-small, and mBART for Chakma–Bangla translation. For iterative back-translation, we use the full Chakma monolingual corpus and 50k Bangla monolingual sentences.

We also evaluate large language models using few-shot in-context learning without parameter updates, including GPT-4.1, GPT-4.1-mini, and o4-mini. We retained the default temperature setting and did not tune decoding parameters because of API-budget constraints. Each prompt contains 100–400 demonstration pairs and batches 20 query sentences to reduce API cost; we did not compare single-query prompting. One demonstration set is selected for the full 20-query batch and held fixed across the three repeated generations, so reported variation reflects decoding rather than demonstration-selection variability. Demonstrations are drawn from the training split either randomly or by Jaccard similarity over character 6-grams; Appendix A.4 gives the full retrieval procedure.

We additionally conduct ablation experiments by (i) removing transliteration for fine-tuned and in-context models, and (ii) evaluating a zero-shot in-context learning configuration without demonstrations.

Additional experimental details necessary for replication, including normalization, training hyperparameters, model architectures and initialization, multilingual data formatting and oversampling, in-context learning prompt construction, and multiple runs and randomness, are provided in Appendix A.4. The complete experimental code is available on GitHub.[11]

## 6 Results

**Transliteration is crucial for the tested pretrained models** Removing transliteration causes near-zero BLEU and chrF for the selected pretrained and in-context models under our experimental setup (Table 6). Thus, these models cannot effectively use native Chakma-script data in this configuration; the metrics do not isolate whether the cause is tokenization, representation, or another model-specific factor.

**The relative advantage of ICL is direction- and metric-dependent** ICL is strongest for CCP→BN. For BN→CCP, BanglaT5 achieves the highest BLEU, whereas GPT-4.1 with n-gram retrieval achieves the highest chrF (Tables 2 and 8). Thus, the relative advantage of ICL and fine-tuning depends on translation direction and evaluation metric.

**From-scratch models generalize poorly under extreme data scarcity** From-scratch SMT, RNN, and Transformer models achieve modest development performance but near-zero test BLEU in both directions (Table 2). This large development–test gap is consistent with distributional differences between the training sources and the RisingNewsChakma benchmark, although our results do not isolate domain shift from other causes.

**Back-translation effects depend on model and direction** The effect of iterative back-translation is model- and direction-dependent. It consistently benefits mT5-small, while the largest improvements occur for CCP→BN after two iterations (Table 2). For BanglaT5 BN→CCP, iterative back-translation does not improve over ordinary bilingual fine-tuning. Notably, CCP→BN scores for

Table 2: Translation performance on BN↔CCP across development and test sets. We report mean ± standard deviation for BLEU and chrF. Results are shown for from-scratch models, fine-tuned pretrained models (including iterative back-translation (IBT), up to two iterations, and multilingual fine-tuning (MNMT)), and GPT-based in-context learning (ICL) with 400 examples using random (R) or n-gram (N) similarity-based sampling. ICL is strongest for CCP→BN. For BN→CCP, BanglaT5 has the highest BLEU, while GPT-4.1 with n-gram retrieval has the highest chrF. Dashes denote unavailable ICL development results or unreported SMT standard deviations, as applicable.

BanglaT5 and mT5 remain unchanged after the first IBT iteration, since the backward model is initially trained on the same parallel data.

**Multilingual training generally underperforms bilingual fine-tuning** Adding MNMT reduces test BLEU and chrF for both directions with mT5-small and for BN→CCP with BanglaT5 (Table 2). However, BanglaT5 shows a modest improvement for CCP→BN, from 11.7 BLEU / 37.9 chrF to 12.8 BLEU / 38.5 chrF. Thus, the effect of multilingual training is model- and direction-dependent. Table 9 additionally reports EN↔CCP and BN↔CCP performance under the MNMT setup.

**ICL retrieval and scaling effects are non-uniform** N-gram retrieval generally benefits GPT-4.1, but improvements are not consistent across all model variants or demonstration counts (Table 8). Performance is also non-monotonic as the number of demonstrations increases.

**Performance-cost trade-offs between ICL and fine-tuning** ICL achieves strong CCP→BN performance on both BLEU and chrF with minimal data, but requires large commercial models and costly prompts. Fine-tuning may be more economical under repeated use, although we do not perform a formal cost analysis. The preferred approach therefore depends on translation direction, evaluation metric, and deployment frequency.

## 7 Qualitative Analysis

**BN→CCP translation is substantially harder than CCP→BN** Across all systems, BN→CCP performance is substantially lower than CCP→BN on both BLEU and chrF (Table 2). Even the best BN→CCP results reach only about 2–3 BLEU, while CCP→BN attains 13–18 depending on the method. We hypothesize that this asymmetry arises because pretrained models encode Bangla more effectively, making translation into Bangla easier

than into Chakma. The chrF gap suggests that the difficulty extends beyond a BLEU-specific artifact. Figure 5 provides representative BN→CCP outputs across model families.

**BLEU and lexical or orthographic variation in Chakma** The BLEU–chrF divergence is consistent with lexical and orthographic variation, although without exhaustive variant annotation or human evaluation we cannot isolate its contribution from semantic errors. BLEU is particularly sensitive to re-transliterated Chakma outputs, where spelling differences introduced by script conversion lower n-gram overlap. This is evident in inter-annotator agreement on 50 shared benchmark sentences (Section 3.3), which is only 4.48 BLEU but 38.82 chrF, indicating stable character overlap despite differing word forms. Figure 6 further illustrates multiple valid spellings for common words, strongly penalizing BLEU. These patterns, driven by the lack of standardized Chakma orthography, motivate treating chrF as a co-primary metric alongside BLEU.

**Round-trip transliteration measures surface-form retention** The transliteration mapping is designed to preserve pronunciation and lexical identity, but it is not bijective and may neutralize some orthographic distinctions. After one cycle, scores are 41.55 BLEU / 79.32 chrF for BN→CCP→BN and 38.37 BLEU / 79.69 chrF for CCP→BN→CCP, showing substantial character overlap alongside nontrivial word-form differences. Later rounds converge because the deterministic substitutions have stabilized (Table 10). These round-trip metrics measure surface-form retention and convergence; they do not independently establish semantic preservation.

**Zero-shot ICL ablation highlights the need for demonstrations** As an ablation, we evaluate zero-shot ICL without any demonstrations. For BN→CCP, BLEU remains below 1 across models (Table 11), indicating that zero-shot ICL is ineffective in this direction. CCP→BN performs better even without examples, but still lags behind few-shot ICL. For the tested models and prompts, these results show that demonstrations are important for generating Chakma outputs in this extremely low-resource setting. chrF is similarly low in zero-shot BN→CCP, underscoring that models fail to recover even partial character overlaps without examples.

**LLM variants show different effectiveness under ICL** Under identical in-context learning (ICL) setups, GPT-4.1 achieves the strongest overall performance, while o4-mini often outperforms GPT-4.1-mini in BLEU and chrF (Table 8). As these models differ in architecture, capacity, and intended design, we do not attribute the observed differences to any single factor. Instead, we report them as an empirical comparison of LLM variants under the same ICL conditions. The chrF ranking matches BLEU, suggesting that model differences affect both token-level and character-level fidelity.

## 8 Conclusion

This work introduces new Chakma–Bangla resources and evaluates transliteration-based transfer across several machine translation paradigms. Pretrained models and in-context learning substantially outperform from-scratch systems, but performance remains strongly direction-dependent. ICL performs best for CCP→BN, while BN→CCP remains difficult and shows metric-dependent differences between fine-tuning and ICL. The results provide initial baselines rather than deployment-ready systems.

## Ethics

This work involves data collection for an endangered and low-resource language with the goal of supporting language preservation and accessibility. All human-generated data were collected with informed consent from contributors, who voluntarily participated and expressed support for this research. No personally identifiable information about dataset contributors is included in the released data. Potential risks include linguistic misrepresentation, reinforcement of contested orthographic conventions, and reuse outside the intended community context. We mitigate these risks through community review and explicit documentation of orthographic variation. Third-party materials retain their original rights; we will redistribute processed text only where permission or source licenses allow, and otherwise provide metadata, document identifiers, conversion code, and access instructions.

## Limitations

This work is constrained by the extremely low-resource nature of the Chakma language, which limits the size and diversity of available training

data and leads to relatively low automatic evaluation scores, a common challenge in low-resource machine translation. Our rule-based transliteration framework enables effective cross-script transfer for the tested models, but relies on manually designed mappings and is not character-bijective; round-trip metrics do not independently establish semantic preservation. Automatic metrics such as BLEU may further underestimate translation quality due to orthographic variation and multiple valid spellings in Chakma. Our contribution is resource- and evidence-oriented rather than a new MT architecture, and the findings most directly apply to cross-script pairs with a related higher-resource language. The benchmark contains 500 unique sources and 600 Chakma references, and the low absolute scores make these initial baselines rather than deployment-ready systems. Ultimately, the primary bottleneck remains data scarcity: future work could benefit substantially from automated web-based data crawling and collection systems to expand Chakma textual resources, as well as from more data-driven transliteration and translation approaches tailored to extremely low-resource and non-standardized languages.

## Acknowledgments

Our work would not have been possible without the help of several individuals and organizations. Particularly, we would like to thank Injeb Chakma, who assisted us with any issues related to the Chakma language. We are thankful to Arjya Mitra Chakma, Shanti Chakma, and The Zabarang Foundation for providing important documents. We would also like to express our gratitude to Bivuti Chakma for helping us with the RibengUni font and additional documents. For translating the benchmark data, we are highly grateful to Sujan Chakma, Shanti Chakma, and Binoy Bikash Talukdar. Moreover, we extend our sincere thanks to all the people who supported our work and voluntarily participated in the translation process both online and offline.

"Beyond the Hill" group assisted us in data collection and enabled us to compete in a competition hosted by the ICT Division of Bangladesh, where we won 10,000 BDT.

# A Appendix

## A.1 Additional Details on Community Translation with Expert Review

Prior to data collection, we conducted a pre-assessment to evaluate the feasibility of manual translation by volunteer Chakma speakers. The assessment revealed that participation and translation quality were highly sensitive to task complexity and time requirements. In particular, longer sentences significantly increased cognitive load and annotation time, frequently resulting in incomplete or inaccurate translations. These difficulties were exacerbated by the fact that many Bangla or English lexical items are either rarely used in Chakma or lack direct lexical equivalents, often requiring paraphrasing or explanatory reformulation. Based on these findings, we constrained source sentences to a length of 2 to 8 words to reduce annotation burden while maintaining sufficient linguistic content.

To mitigate these challenges and reduce annotator fatigue, we deliberately selected short sentences, with the probability of sentence selection peaking at 4-5 words and gradually decreasing toward both extremes. This distribution reflects an optimal trade-off between linguistic informativeness and annotation feasibility. Very short sentences (e.g., one word) were avoided due to limited contextual value, while longer sentences were excluded to minimize translation difficulty and error propagation.

The participants were predominantly young native Chakma speakers with functional bilingual proficiency in Bangla and English but limited formal training in translation. Senior reviewers were community-recognized Chakma writers or teachers, and translators were instructed to produce natural translations faithful to the Bangla source. Despite their linguistic competence, many participants reported difficulty translating abstract or institutional terms, as Chakma remains primarily an oral language with limited standardized written usage. Some experienced contributors provided handwritten translations, which were later digitized by trained typists due to limited familiarity with Chakma script typing.

## A.2 Origins of Orthographic Variation in Chakma

Chakma lacks a widely accepted standardized grammar, resulting in substantial variation in spelling and syntactic structure across written sources. Historically, language experts and local shamans have documented the language using personal conventions without publishing formal grammatical guidelines. As a result, the same lexical items are often written using multiple valid spellings, leading to pervasive orthographic inconsistency. Disagreements among scholars have further hindered consensus on standard grammatical rules. These disagreements are also reflected in dif-

ferences between Indian and Bangladeshi Chakma scholarly traditions. Such variability complicates data normalization and automatic evaluation in downstream NLP tasks.

### A.3 Script-Bridging Transliteration: Mapping Coverage and Non-Direct Rules

This appendix provides the full mapping statistics and the handling rules for characters that do not admit an exact one-to-one correspondence between Chakma (CCP) and Bangla (BN). A summary of all non-direct substitutions in both directions is shown in Figure 3.

**CCP→BN coverage.** In the CCP→BN direction, all 10 Chakma digits have direct mappings. Among the core Chakma letters (vowels and consonants), 36 out of 37 characters map directly to Bangla equivalents. For diacritics, 18 out of 21 Chakma diacritical marks have direct mappings. The remaining Chakma characters correspond to prosodic or orthographic distinctions that do not have explicit representations in Bangla. Notably, one such character functions as a lengthening/extension marker: it modifies the pronunciation of an adjacent letter rather than introducing independent lexical content. Since Bangla lacks an equivalent graphemic mechanism for this feature, we normalize it during transliteration by retaining the base character without adding a distinct symbol in the Bangla rendering. The four Chakma characters without direct Bangla equivalents are rare in the collected data, but their semantic effect is not independently evaluated.

**BN→CCP coverage.** In the reverse BN→CCP direction, all 10 Bangla digits have direct mappings. Out of 50 Bangla letters, 44 map directly to Chakma characters. Similarly, 10 out of 11 Bangla diacritics have corresponding Chakma equivalents. The remaining Bangla characters are mapped to the closest Chakma counterparts according to pronunciation and lexical identity.

**Deterministic handling of non-direct characters.** For characters without direct one-to-one correspondences in either direction, we apply deterministic substitutions based on closest phonetic similarity in the target script (Figure 3). Consequently, the transliteration system is not strictly reversible and may neutralize some orthographic distinctions. Round-trip metrics quantify surface-form retention rather than semantic preservation (Section 7). Overall, the system remains predominantly a straightforward character mapping scheme, with a small number of rule-based phonetic normalizations applied only when exact script-level equivalence is unavailable.

### A.4 Additional Experimental Details

**Multiple Runs and Randomness** To assess robustness to training stochasticity, we run all experiments three times with different random seeds (affecting initialization and minibatch order) and report mean and standard deviation. For in-context learning, we fix the demonstration set and repeat generation three times to quantify decoding variability. Therefore, reruns under the same configuration are expected to yield scores consistent with the reported mean ± standard deviation.

**Normalization details** On top of the normalization described by (Hasan et al., 2020), we apply a minimal and conservative normalization step uniformly to all text, including training data, model inputs, and output labels, across all experiments. For Chakma script, we merge a small number of rarely used, phonetically similar vowel variants into a common representation to reduce superficial spelling variation. This is analogous to collapsing long and short vowel variants in low-resource settings and is intended to simplify orthographic variation. We also normalize all bracket symbols to parentheses in order to reduce sparsity in the data. These normalization steps are applied symmetrically; their semantic effect is not independently evaluated.

**Additional details on metrics** We report BLEU and chrF scores using `sacreBLEU` via the Hugging Face `evaluate` library with default settings: BLEU uses a maximum word n-gram order of 4 (BLEU-4), and chrF uses character n-grams of order 6.

**Sequence length and augmentation overlap** Table 1 reports space-separated words rather than model subwords; in the tokenized training data, 3.04% of sequences exceed 32 tokens, 0.73% exceed 64, and 0.02% exceed 128, so the 128-token limit covers over 99.9% of samples. Monolingual augmentation samples were kept disjoint from the parallel splits to avoid overlap and add new content.

**SentencePiece Vocabulary Search** We use SentencePiece (Kudo and Richardson, 2018) both for (i) vocabulary building and (ii) tokenization for

SMT and NMT. As part of hyper-parameter optimization, we evaluate vocabulary sizes of 1,000, 2,000, 5,000, 10,000, and 20,000.

**Training Hyper-Parameters and Optimization Settings** We apply gradient clipping with max norm 1.0. We tune learning rates in {0.001, 0.005, 0.0001, 0.0005}, batch sizes in {8, 16, 32}, and training steps in {10,000, 15,000, 20,000}. Warmup steps are varied in {0, 2000, 4000}. We use linear learning-rate decay after warmup. We also tune label smoothing over {0.1, 0.2, 0.3, 0.4, 0.5}. The final tuned hyper-parameter configurations are reported in Table 7.

**RNN with Attention: Architecture and Initialization** For the RNN baseline, we use a public PyTorch seq2seq implementation.[12] The model incorporates Luong-style attention (Luong et al., 2015). We experiment with 1, 2, and 4 stacked recurrent layers, and consider hidden size and embedding size in {512, 1024}. Dropout is tuned in {0.1, 0.2, 0.3}. All RNN parameters are initialized from a normal distribution with mean 0 and standard deviation 0.1.

**Transformer: Model Variants and Initialization** For Transformer training, we follow the standard Transformer formulation (Vaswani et al., 2017). We explore MarianNMT-style Transformer[13] configurations available through HuggingFace implementations, and initialize weights with Glorot initialization (Glorot and Bengio, 2010). We vary the number of layers in {1, 2, 6}, attention heads in {1, 2, 6}, dropout in {0.1, 0.2, 0.3}, and feed-forward hidden dimensions in {512, 1024}.

**Multilingual Formatting, and Oversampling** In multilingual training (MNMT), we prepend a target-language prefix tag to each input sentence: <BN> for Bangla, <EN> for English, and <CCP> for Chakma. To mitigate imbalance, we oversample Chakma-involving parallel pairs to better balance all translation directions, following practices shown to improve multilingual performance (Johnson et al., 2017).

**In-Context Learning Prompt Construction** For in-context learning (ICL), each prompt contains one batch of 20 query sentences and one shared demonstration set. Random retrieval samples from the training pairs without replacement. For n-gram retrieval, we form the union of character 6-grams across all 20 queries and rank each training source by Jaccard similarity to that union. Equal scores retain the original training-data order. We apply no additional deduplication, so duplicated training rows, if present, can yield repeated demonstrations. The prompt requests 20 numbered outputs aligned by index to the 20 inputs. The selected demonstration set is fixed across the three repeated generations, so the reported variation reflects decoding variability rather than demonstration selection. Character-level matching is used instead of word-level matching due to the absence of standardized spelling. The $n$-gram size was selected through limited manual experimentation using a small subset of the development data, due to computational budget constraints. This subset was used only for preliminary testing of retrieval behavior, and not for model selection or final evaluation. We evaluated a narrow range of values and fixed $n = 6$, which provided the most stable retrieval behavior in these tests.

**mBART: Additional Details** We do not apply iterative back-translation (IBT) or multilingual fine-tuning (MNMT) to mBART, as its plain fine-tuning performance is substantially lower than other models (Table 2, Section 6), making these extensions unlikely to provide meaningful improvements.

### A.5 Interviews with Chakma Language Experts

We interviewed several scholars in Bangladesh to discuss the variants, for example, the number of characters, diacritics, rules, spelling patterns, etc. The scholars include Arjya Mitra, Injeb Chakma, Ananda Mohon Chakma, and Sugata Chakma. However, almost all of them suggested following the rules maintained by the members of the National Curriculum and Textbook Board of Bangladesh involved in writing the Chakma books for the pre-primary levels because their rules will be followed eventually. The most important rule from them that we followed in our transliteration codes from Bangla to Chakma, is that the core grapheme cannot have more than one diacritic attached to a consonant or a vowel. However, in India, this restriction is not maintained, rather more than one diacritic is seen frequently in their documents.

Table 6: Ablation study comparing models evaluated *with* and *without* transliteration on BN→CCP and CCP→BN translation. Rows marked with † indicate evaluation **without transliteration** (native Chakma script as input and output). Comparison includes BanglaT5 and mT5-small fine-tuned models, as well as GPT-based in-context learning (ICL) models with random sampling of 400 examples. Metrics report mean ± std for BLEU and chrF on the development and test sets. Removing transliteration yields near-zero performance for the selected pretrained and ICL models under this experimental setup.

| ওআ | ← | 𑄃 |

Figure 3: Nearest-character substitutions used in the Chakma–Bangla transliteration system for characters without direct one-to-one mappings. These substitutions approximate pronunciation and lexical identity while potentially neutralizing orthographic distinctions. The only entry marked with a dash (–) in the Bangla column corresponds to a rare Chakma prosodic lengthening marker that lacks an explicit Bangla graphemic equivalent and is normalized during transliteration. All four Chakma characters without direct Bangla counterparts are rare in the collected data; their semantic effect is not independently evaluated.

You are given translation examples from Chakma to Bangla below:

Chakma Example 1: মরে নুয়া গরি পিজোর্ ন গরিবে
Bangla Example 1: আমাকে পুনরায় জিজ্ঞাসা করবে না ।

Chakma Example 2: গিগির্রানা
Bangla Example 2: কাঁপা

## Abstract

Existing automatic metrics for evaluating terminological use in machine translation (MT) penalise any divergence from a fixed reference, conflating translation errors with the valid terminological variation that human translators routinely produce. We introduce TERMJUDGE, a document-level terminology metric that assigns an interpretable verdict to every term occurrence: glossary-conforming occurrences are settled deterministically, while divergences are assessed under a two-step LLM-as-a-judge procedure using the full document context: the first detects and labels terminology errors; the second sorts valid document-level variations from inconsistencies. Validated against expert error annotations and document-level human MQM scores, TERMJUDGE ranks first in both system- and segment-level meta-evaluation, ahead of glossary-conformity and quality-estimation baselines. When applied to eight systems translating academic documents, under two prompting conditions, we observe that glossary injection improves terminology translation in all paired comparisons, by removing genuine errors rather than valid variation. TERMJUDGE is released as open-source code.[1]

## 1 Introduction

Evaluating machine translation (MT) at the document level in specialised settings requires assessing how systems translate the technical vocabulary of those documents. In most documents, technical concepts can be split into two main groups: rare concepts that only occur once or twice, usually under the same surface form; and frequent concepts, which may appear under multiple guises. For example, in a research paper on MT, a concept such as `machine translation` may occur repeatedly, as the preferred form (*machine translation*), an acronym (*MT*), a reduction (*translation*), a lexical substitution (*automatic translation*), or a morphosyntactic reformulation (*machine translated (text)*) (Daille, 2017); translators may amplify this variation and introduce further alternations for stylistic or discourse reasons (Bowker, 1998; Fernández-Silva and Kerremans, 2011).

Existing automatic metrics for evaluating the translation of terms decide whether a target form is acceptable through *matching*: against a term-annotated reference (Farajian et al., 2018), against a bilingual glossary entry (ibn Alam et al., 2021; Semenov et al., 2025), against the document's other occurrences of the same concept (Itagaki et al., 2007; Semenov and Bojar, 2022), or against source-side variation patterns (Dahan et al., 2026b). None of them asks whether a mismatch is a translation error or a valid translation choice (e.g., target-language amplification, polysemy disambiguation, acronym introduction at first mention, stylistic alternation), so they may conflate acceptable translations with errors. General-purpose neural metrics offer no remedy, losing correlation with human judgement precisely on the specialised domains where terminology errors concentrate (Zouhar et al., 2024). The question we address is therefore whether an automatic metric can decide, for each occurrence of a concept, whether the output form is acceptable rather than merely identical to a predetermined reference. We propose to address this gap with TERMJUDGE, an automatic document-level terminology metric that not only counts *divergences* (translations that depart from the expected form of a term) but judges each one, and returns interpretable verdicts alongside an aggregate score. Our contributions are:

- A concept-aware document-level terminology metric, built on an LLM-as-a-judge approach comprising several steps (reference validation, then error classification and document-consistency qualification), grounded in established translation studies, which discriminates

[1] https://github.com/nicolasdahan/termjudge

*Proceedings of the Eleventh Conference on Machine Translation*, pages 82–115
October 28-29, 2026 ©2026 Association for Computational Linguistics

errors from valid variation and produces an *interpretable verdict profile* for each system rather than a single opaque score.

- BioMQM-Terms, a terminology-evaluation resource derived from bio-MQM (Zouhar et al., 2024), a corpus containing MT outputs in the biomedical domain, with error annotations. To this we add a bilingual glossary of 729 English–French biomedical concepts and 13,200 aligned term–translation pairs for ten MT systems, released with our code.
- A series of empirical validations: per-occurrence agreement with a fine-grained human error typology on a geoscience corpus (STEP; Cornejo Cárcamo et al., 2026), a document-level meta-evaluation on BioMQM-Terms, where TERMJUDGE ranks first under every aggregation of its score, ahead of ten alternative metrics, and a reevaluation of the use of glossaries to guide LLM-based MT: on two NLP test corpora, we find that glossary-guided prompting improves term translation.

## 2 Related Work

For the global evaluation of MT quality, some of the most widely used automatic metrics (alongside traditional surface-based metrics such as BLEU (Papineni et al., 2002) and chrF (Popović, 2015)) are fine-tuned neural models such as COMET (Rei et al., 2020) and METRICX (Juraska et al., 2024), together with their reference-free counterparts (Rei et al., 2022). They are trained and mostly used at the sentence level. Despite proposals to extend them to longer spans (Vernikos et al., 2022; Deutsch et al., 2023b), their document-level application remains questionable (Dahan et al., 2026a). Two further properties limit their use for terminology. First, fine-tuned metrics lose substantial correlation with human judgements on unseen specialised domains, precisely where terminology errors concentrate (Zouhar et al., 2024). Second, such metrics summarise all aspects of translation quality in a single scalar score, failing to distinguish terminology errors from other types of mistranslations.

Evaluation practice is therefore increasingly dominated by LLM-as-a-judge approaches. GEMBA involves eliciting direct quality scores (Kocmi and Federmann, 2023b), and GEMBA-MQM annotating error spans within the generic MQM typology (Lommel et al., 2013; Kocmi and Federmann, 2023a); Minder et al. (2025) test how reliably LLMs annotate specialised translations with such error typologies: error detection reaches satisfactory levels, but accurate categorisation requires injecting the error definitions in the prompt. LLM-as-a-judge approaches bring the flexibility that qualitative judgements require, but they carry documented biases (order of presentation, verbosity preference, instability across rephrased queries; Zheng et al., 2023), making careful meta-evaluation against human judgements indispensable (Mathur et al., 2020; Deutsch et al., 2023a). Whether applied to isolated segments or to whole documents, they annotate general error categories and do not track how consistently a concept is rendered across a document.

Dedicated terminology evaluation has mostly relied on matching the output against expected target forms. Given a term-annotated reference translation, Farajian et al. (2018) compute a term hit rate, a BLEU-like clipped count of the reference terms retrieved in the output, which TermEval (Haque et al., 2023) extends by also accepting the lexical and inflectional variations of each reference term listed in its termbank. Given a bilingual glossary entry, metrics count how often the expected target term appears in the output, from exact surface matching (ibn Alam et al., 2021) to lemma-aware matching (Alam et al., 2021), as adopted in the WMT terminology shared tasks (Alam et al., 2021; Semenov et al., 2023), whose 2025 edition extends the exercise to document-level translation with one-to-many dictionaries (Semenov et al., 2025). Whatever the matching strategy, these metrics remain anchored to an inventory of expected forms: unlisted reductions, context-dependent acronyms and lexical variants are counted as failures irrespective of their adequacy in context.

When no glossary is available, consistency metrics score the target side against itself. Semenov and Bojar (2022) match each occurrence against a pseudo-reference derived from the system's own dominant translation, concentration indices such as the Herfindahl–Hirschman index (Itagaki et al., 2007; Gašpar et al., 2022) and the Lexical Translation Consistency Ratio (Lyu et al., 2021; Wang et al., 2025) reward the reuse of a single form, and cross-term coherence extends the family to the source side, counting how many variation relationships survive translation (Dahan et al., 2026b). All share one assumption: a term is well translated when every occurrence receives the same translation. That assumption keeps them cheap and

reference-free, but blind to the difference between undue changes and motivated alternations. It is also only warranted for prescriptive terminologies: terminology standards themselves recognise a scale of acceptability from preferred to merely admitted forms (ISO, 2019).

That difference is precisely what studies of specialised discourse document. Denominative variation is a constitutive property of terminology in running text (Daille, 2017), refined into graphical, morphosyntactic, reduction, expansion and lexical variants by Cornejo Cárcamo et al. (2025). Translators preserve or even accentuate source-side variation (Fernández-Silva and Kerremans, 2011), alternate between several translations for discourse and stylistic reasons (Vinay and Darbelnet, 1972; Bowker, 1998; Pecman, 2014), introduce pragmatic and explicitness shifts (Chesterman, 2016; Blum-Kulka, 1986), and resist the over-standardisation that erases author-intended distinctions (Bowker and Hawkins, 2006). MT systems, by contrast, produce less variation than humans (Čulo and Nitzke, 2016). These findings have not reached automatic evaluation: no existing terminology metric asks whether a divergence from the expected form is one of these motivated variations or an error.

## 3 The TERMJUDGE Metric

TERMJUDGE evaluates the terminological adequacy and consistency of a translated document by assigning a verdict to the translation of every term occurrence, and by aggregating these verdicts into a document-level score that can rank systems on terminological quality. A preprocessing stage turns a terminology and a translated corpus into aligned term occurrences (§3.1); TERMJUDGE itself is a five-step pipeline (§3.2) whose decision flow is displayed in Figure 1. Appendix A (Figure 2) gives a graphical overview of both stages. TERMJUDGE shares its starting point with the consistency tradition (§2): each source form is *evaluated separately*, through the set of translations it receives across the document. The variation being adjudicated is therefore target-side only, source-side variation being factored out by construction. For this, TERMJUDGE first computes a reference translation for each source form, and flags as *divergence* any translation that departs from it. It then submits each divergence to an LLM judge in two steps: a first question, Q1, asks whether the divergence is an error and of which kind. When no error

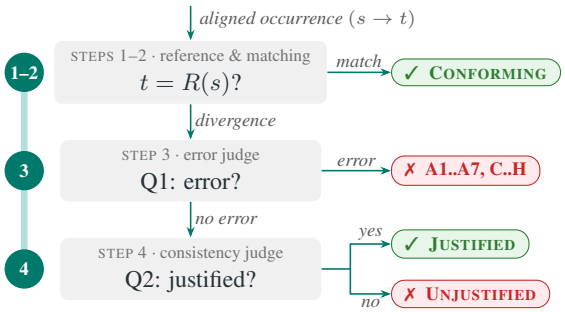

Figure 1: The TERMJUDGE decision flow (§3.2): a match with $R(s)$ is considered CONFORMING without any LLM call; a divergence is classified by the error judge (Q1) then, if error-free, by the consistency judge (Q2), as JUSTIFIED or UNJUSTIFIED.

is found, a second question, Q2, asks whether the variation is a valid choice justified by its context. Both questions are answered by the same model using different prompts, called the *error judge* and the *consistency judge* in what follows. The decomposition is deliberate. The two questions do not judge the same object: Q1 assesses the translation itself, so its answer is independent of the occurrence's position and can be shared across identical translations (§3.2), and Q2 assesses the consistency of a choice with the concept's other translations in the document, and is asked per occurrence. This reflects a key distinction in our error typology: between errors in a translation taken on its own and inconsistencies between the translations of a concept within a document (Appendix C). Merging the two questions into a single LLM call would make every judgement positional, at the occurrence level. It would also imply a much larger label set, possibly degrading the judge's decisions (Appendix C.1). Answering Q1 at the form-level does not mean judging it in isolation: like for Q2, the judge also receives the corresponding concept's glossary entry and the translations of its other source forms.

### 3.1 Data Requirements and Preprocessing

TERMJUDGE relies on a single external resource, a bilingual terminology of the domain structured as a SKOS glossary:[2] each entry pairs a *concept* with one *preferred term* (or *head term*) per language, and a list of *alternative terms*, or *variants*. The object of the evaluation is a collection of source documents together with their translations by one or more MT systems, with aligned source and target segments; no human reference translation is needed.

[2]Simple Knowledge Organization System, https://www.w3.org/TR/skos-reference/.

A glossary, however large, cannot delimit the forms under which concepts surface: beyond *glossary variants* listed as alternative terms, running texts also introduce *non-glossary variants* (reorderings, reductions, context-dependent acronyms). Term occurrences are therefore identified with the CONCORDANCER,[3] an in-house tool that takes the glossary as input and detects, in each source document, the occurrences of every concept. This raises coverage beyond exact-form and lemma matching by also recognising variants derived from glossary entries or detected in context: on PARANLP and IWSLT23, lemma matching alone would miss about 15% of the occurrences the CONCORDANCER detects (Dahan et al., 2026b).

Each attested source form is then labelled automatically with its variation category relative to the head term (procedure and validation in Appendix A), following the typology of §2: *no variation*, *graphical*, *morphosyntactic*, *reduction*, *expansion*, *lexical* or *combined* (Cornejo Cárcamo et al., 2025) (one example per category in Table 8, Appendix A). Each occurrence is then aligned with the target-side span that corresponds to its translation, identified by an LLM call within the aligned target segment rather than the whole document;[4] both sides are normalised for case, punctuation and whitespace, and lemmatised identically.

TERMJUDGE starts from the concept and isolates every distinct source form attested in the document; the head term itself need not appear. The set of occurrences of one source form is a *chain*, and a chain of size one is a *hapax*. Within a chain, occurrences share the source form and differ by their position in the document, hence by their context, and by the translation the system produced for each of them. TERMJUDGE returns one verdict per occurrence (Table 1); Appendix A (Tables 11 and 9) illustrates the setting on occurrences from real evaluation runs.

### 3.2 Evaluation Pipeline

**Step 1: Reference selection.** For each source form $s$ of a concept in a document, TERMJUDGE fixes the expected reference translation $R(s)$: the glossary translation when the source form has one, considered as authoritative, and otherwise the translation that the evaluated system itself produces most often in the document (on lemmas, ties broken by first appearance), a *pseudo-reference* generalising those of consistency metrics (Semenov and Bojar, 2022). A pseudo-reference is first validated by the error judge of Step 3 on source-side evidence only;[5] if judged erroneous, it is replaced by a reference generated by an LLM from the concept entry and source-side contexts, never from the systems' outputs. Each reference is recorded with its provenance (glossary, validated or generated).

| Verdict | Description | Penalty |
|---|---|---|
| CONFORMING | target matches $R(s)$ (Step 1), or judged error-free | 0 |
| JUSTIFIED | variation, consistent with document usage | 0 |
| UNJUSTIFIED | variation, inconsistent (incl. neutralisation) | 0.5 |
| **A1** | attested term of a neighbouring concept | 1 |
| **A2** | paraphrase instead of term | 1 |
| **A3** | invented literal calque | 3 |
| **A4** | left untranslated | 4 |
| **A5** | do-not-translate item translated | 4 |
| **A6** | wrong internal constituent | 4 |
| **A7** | general-language word instead of term | 3 |
| **C** | mis-parsed term structure | 4 |
| **D** | wrong semantic relations between constituents | 3 |
| **E** | failed transposition / syntactic calque | 1 |
| **F** | grammar / phraseology around the term | 1 |
| **G** | content altered (addition, omission, hallucination) | 1 |
| **H** | defective target-language expression / register | 1 |

Table 1: The sixteen verdicts of TERMJUDGE and their penalties. **A1**–**A7** follow level A of the error typology (Cornejo Cárcamo et al., 2026); **C**–**H** group its remaining families, each scored at its most lenient sub-code (benefit of the doubt). Appendix F explains the weights; Appendix C gives the full typology.

**Step 2: Divergence detection.** Each translation is compared with $R(s)$ by exact string matching on lemmas, ignoring case, articles, hyphens and diacritics. A match is labelled CONFORMING without any LLM call: the metric evaluates the choice of term, not its written form. A mismatch is a *divergence* in the sense defined above, and in this case we proceed to Step 3.

**Step 3: Q1, error judgement.** Each divergence's correctness is evaluated by an LLM call that receives the aligned pair, the current segment, the concept's glossary entry when available, the preceding aligned segments, and the concept's prior translations grouped by source form. The question is *absolute*: is the target a valid, contextually-appropriate translation of the source term? The candidate error labels come from a simplified version of a typology developed for the human annotation of terminology errors in specialised MT (Cornejo Cárcamo et al., 2026), with a severity scale following Bénard et al. (2024): wrong equivalent selection uses fine-grained labels (**A1**–**A7**),

[5] Being borrowed from the very output under evaluation, it cannot be taken at face value; the circularity is made explicit to the judges.

the six other error families are collapsed into one code each (**C–H**, Table 1), and the in-document inconsistency family (B) is excluded, being exactly the question delegated to the consistency judge of Step 4 (details in Appendix C). The judge answers with `no_error` or one of the 13 labels, whose gravity fixes the penalty. An error label is the occurrence's final verdict, while `no_error` routes the occurrence to Step 4. Hapax forms skip the matching shortcut of Step 2 and are always submitted to Q1: when a form occurs once, its pseudo-reference is derived from that very occurrence, so a match would be circular. Since consistency is undefined for a single occurrence, an error-free hapax is directly labelled CONFORMING.

**Step 4: Q2, consistency judgement.** Divergences judged error-free by Q1 are passed to the consistency judge, which decides whether the translation is coherent given how the concept is rendered elsewhere in the document. It sees the concept's translations grouped by source form, with the dominant translation and first mentions marked. It answers with one of ten labels, grounded in terminology and translation studies (Vinay and Darbelnet, 1972; Bowker, 1998; Pecman, 2014) as detailed in Appendix I. Seven name a reason that makes the variation coherent ('first mention', 'explicitation', 'avoid repetition', 'document usage', 'register', 'facet', 'synonym merge') and yield JUSTIFIED. Three name an inconsistency and yield UNJUSTIFIED: 'synonym inconsistency' and 'gratuitous divergence' when one source form receives divergent translations, 'neutralisation' when distinct source forms collapse onto one translation; together they operationalise family B of the typology, cases combining an incorrect translation with instability being caught upstream by Q1. Neutralisation, the reproduction of the translation established for *another* source form of the same concept, erases a distinction made by the author (Bowker and Hawkins, 2006), for example the case of a document alternating *percutaneous nephrolithotomy* and its acronym *PNL* where both are rendered as *néphrolithotomie percutanée*.

**Step 5: Propagation and scoring.** Q1 is called once for each distinct divergent translation of a source form within a document, and its verdict is propagated to the group's other occurrences; keeping the translation unlemmatised in the grouping key preserves number and gender errors. Q2, whose answer depends on the occurrence's position, is called once per occurrence of a correct form. Together with the matching shortcut of Step 2, this propagation divides the number of LLM calls by 2.55 on IWSLT23 while leaving the system ranking nearly unchanged (25 of 28 pairwise orderings; Appendix H). Each verdict maps to a penalty (Table 1), and the score of a document for a system is the mean penalty over all its scored occurrences, including those labelled CONFORMING or JUSTIFIED (penalty 0); lower is better, and scores are negated when correlated with human quality scores. System scores macro-average document scores, occurrences can equally be macro-averaged per source form or per concept, and the meta-evaluation of §4.3 reports all three aggregations.

### 3.3 Metric Configuration

All experiments use a single configuration. The judges run on `gpt-4.1-mini`, chosen for its low cost (Appendix J) and because it belongs to a different family from every evaluated system, which limits the self-preference bias of LLM judges (Zheng et al., 2023; Panickssery et al., 2024); its judgements are validated against human annotations in §5. References are selected as in Step 1; the prompts, their context and the decoding settings are detailed in Appendix K.

## 4 Experimental Setup

### 4.1 Datasets

We use two human-annotated corpora to validate TERMJUDGE at two complementary granularities: STEP (Cornejo Cárcamo et al., 2026), in the geoscience domain, provides per-occurrence gold error labels, enabling us to test whether judges classify individual occurrences as human annotators would. bio-MQM (Zouhar et al., 2024), which provides document-level MQM annotations for ten systems, allows us to test how well aggregated document scores match human quality assessments. Two scientific NLP corpora, PARANLP (Peng et al., 2026) and IWSLT23 (Salesky et al., 2023), serve as additional test beds on which we rank contemporary LLM-based MT systems. Each corpus is paired with a terminology (§3.1). Statistics are in Table 2.

**STEP (occurrence-level validation).** STEP (Cornejo Cárcamo et al., 2026) contains 10 geoscience research articles translated from English into French by a document-level MT system fine-tuned on scientific abstracts of that domain

| Corpus | Role | Domain | Docs | Segments | Src words | Systems | Term occ. | Glossary |
|---|---|---|---|---|---|---|---|---|
| bio-MQM | validation (document) | biomedical | 50 | 384 | 7,536 | 10 | 1,320 | 729 |
| STEP | validation (occurrence) | geoscience | 10 | 4,432 | 124,285 | 1 | 3,377 | 17,035 |
| PARANLP | test | NLP (written) | 34 | 7,095 | 137,123 | 8 | 11,122 | 1,722 |
| IWSLT23 | test | NLP (spoken) | 10 | 884 | 15,360 | 8 | 1,356 | 1,722 |

Table 2: Corpus statistics. Term occurrences are aligned term pairs per system for bio-MQM, PARANLP and IWSLT23, and human-annotated occurrences for STEP. All corpora are English–French.

(Peng et al., 2025), and exhaustively annotated for terminology. The associated resource is a 17,035-entry SKOS terminology compiled for the project from the Loterre thesauri[6] and the ARTES database (Pecman and Kübler, 2011). Each occurrence of a known concept was extracted, aligned with its translation, and labelled with the fine-grained error typology of Cornejo Cárcamo et al. (2026), the same typology our error judge instantiates (§3.2), resulting in 3,377 gold-labelled occurrences (Appendix B). 27.7% of occurrences are found as is in the glossary, and 55.4% are source-side variants of their concept's head term. After projecting multi-label annotations onto the metric's label space, 69.8% of occurrences are error-free, 11.0% carry a family-A error, 16.2% another error (C–H), and 3.0% a sole in-document inconsistency label (B).

**bio-MQM (document-level validation).** bio-MQM (Zouhar et al., 2024) is a multilingual biomedical benchmark annotated at the segment level with MQM error labels by professional translators. We use the English–French portion, 50 documents translated by 8 MT systems plus two human references. All MQM categories are retained when computing the human ground truth, because terminology-related problems are annotated under many categories, not only the Terminology label (below). Errors of other kinds, however, only count when they overlap with an aligned term occurrence (§4.3). The biomedical domain moreover exhibits a markedly higher rate of terminology errors than general news (Zouhar et al., 2024).

MQM is a general error typology: bio-MQM includes no term inventory, no occurrences and no source–target term alignments. Turning it into a terminology evaluation benchmark, BioMQM-Terms, is a contribution of this work. We manually extracted the biomedical terms of the 50 source documents by exhaustive reading, obtaining 729 concepts (26% with at least one variant); French labels come from the bilingual MeSH thesaurus (Lipscomb, 2000) where possible and from manual translation otherwise (construction details in Appendix B). The resulting glossary feeds the pipeline of §3.1: 1,320 aligned occurrences per system, i.e. 13,200 term–translation pairs. 21.7% of them are touched by at least one MQM error, of which only a fifth carry the Terminology label, confirming that terminology-related problems spill over into Accuracy, Linguistic and Style categories. BioMQM-Terms comprises the SKOS glossary and, for each system, the aligned pairs with their variation categories and MQM correspondences.

**PARANLP and IWSLT23 (test).** We re-use the two corpora, the MT outputs and the term alignments released by Dahan et al. (2026b). We refer the reader to their detailed description. PARANLP (Peng et al., 2026) is a corpus of NLP research papers published in *ACL venues and their comparable French versions. IWSLT23 (Salesky et al., 2023) comprises manually revised transcripts and translations of 10 presentations delivered at ACL 2022, from the IWSLT 2023 shared task. Both corpora share the INIST/Loterre NLP glossary of 1,722 EN–FR concepts.[7] MT outputs are generated by four open-weight LLMs, each producing two translations of every document: one from plain translation instructions (*baseline*) and one with the glossary-preferred terms in the segment and their French translations injected into the prompt (*base+terms*), yielding eight outputs per corpus.

### 4.2 Occurrence-Level Validation on STEP

For STEP, TERMJUDGE is run on the gold-aligned occurrences, and its verdicts are compared with the human labels occurrence by occurrence. Since the human annotation uses the full 23-code typology while the judge uses its simplified version (§3.2), the gold codes are grouped in the same way, so that both sides share 15 classes: **A1**–**A7**, **C**–**H** (Table 1), **B** (unjustified in-document variation) and no-error. As human annotations are multi-label (25.6% of occurrences carry at least two codes),

[6] https://www.loterre.fr

[7] https://skosmos.loterre.fr/8LP/fr/

they are reduced to one label with a fixed precedence (the most severe A code, then the C–H code, then B, pure inconsistency, then no-error). Consistency notes on locally correct translations (B1/B2) reduce to no-error at the occurrence level, and 4 occurrences with missing annotations are excluded, leaving 3,373 scored occurrences. We report per-class precision, recall and F1, macro-F1, accuracy and balanced accuracy, together with a binary error-detection view in which all error types collapse to a single error class. On the metric side, UNJUSTIFIED maps to B (both denote in-document inconsistency) while CONFORMING and JUSTIFIED map to no-error, the conformity/variation distinction being absent from the human annotation.

### 4.3 Document-Level Meta-Evaluation with BioMQM-Terms

**Human ground truth per (document, system).** Human terminology quality is derived from the MQM annotations at the level of aligned term pairs, not at the level of full segments. For each alignment produced by our pipeline, we aggregate the severity weights of all MQM errors overlapping the target span, using the standard WMT weighting (Critical: 25, Major: 5, Minor: 1, Neutral: 0). When a segment is seen by multiple annotators, the penalty is averaged at the annotator level (annotators who saw the segment but flagged no error contribute 0). The document-level human score is the negated mean alignment penalty (higher is better).

**Meta-evaluation measures.** We evaluate the metrics against human scores at three levels using the `mt-metrics-eval` package.[8] At the system level, Soft Pairwise Accuracy (SPA) (Thompson et al., 2024) checks, for each of the 45 system pairs, whether the metric separates the two systems with the same confidence as the human scores (p-values of paired permutation tests over documents, 1,000 permutations), and averages this agreement over the pairs. At the segment level, the group-by-item pairwise accuracy with tie calibration of Deutsch et al. (2023a), $\mathbf{acc}^{*}_{\mathbf{eq}}$, treats each of the 373 source segments carrying at least one aligned pair (out of the corpus's 384) as an item (a 10-system $\times$ 373-segment score matrix); ties matter at this level, as for 29% of the segments all ten systems receive the same human score. At the document level, the same measure over the 50 documents (a $10 \times 50$ matrix) is reported for completeness: human document scores, averaged over about 26 occurrences, are practically never tied, so the measure reduces to plain pairwise accuracy over 50 items.

**Score aggregation and comparison scope.** Because TERMJUDGE assigns a judgement to every occurrence (§3.2), its document score can be aggregated in three ways: *micro-averaged* over occurrences, and *macro-averaged* per lemmatised source form or per concept; we report all three. Comparison metrics score what they are designed for: the glossary-conformity and divergence-based baselines score the same aligned occurrences as TERMJUDGE, while the terminology-filtered and general QE baselines score every segment of the document. In a *no-hapax* variant, only chains with at least two occurrences are evaluated, for both the metrics and the human scores. This leaves 48 documents; the segment-level QE baselines, which do not depend on term occurrences, keep the full 50 documents. The results of this no-hapax variant are given in Appendix G (Tables 17–19).

**Comparing systems.** TERMJUDGE is compared against four metric families, ordered from most to least terminology-aware. (i) *Divergence QE*: the same pipeline through divergence detection, with typed judges replaced by a quality-estimation model scoring each divergent term pair (the source term and its aligned translation, without the surrounding sentence) (CometKiwi (Rei et al., 2022), MetricX-24 (Juraska et al., 2024) and GEMBA-MQM (Kocmi and Federmann, 2023a); subscripted *div*), which isolates the judges' contribution from that of the divergence architecture. (ii) *Glossary conformity* in the consistency tradition (ibn Alam et al., 2021; Semenov and Bojar, 2022): the head term is matched against its glossary label, and the remaining forms, those without an official reference, against a document-level *pseudo-reference* (first or majority translation), on lemmas. (iii) *Terminology-filtered QE*, a naive LLM judge: GEMBA-MQM restricted to the errors flagged as terminological (by category, or by any mention of terminology). (iv) *General QE*: the same backbones scoring every sentence in the document with no notion of term (subscripted *gen*), averaged over the document, as a generic baseline.

### 4.4 System Ranking on the Test Corpora

On PARANLP and IWSLT23, TERMJUDGE runs in the configuration of §3.3 with the domain set to NLP, and scores the eight MT outputs distributed with the corpora: four open-weight LLMs (Llama-

[8] https://github.com/google-research/mt-metrics-eval

| | TERMJUDGE |
|---|---|
| *15-class agreement* | |
| Macro-F1 | 0.196 |
| Accuracy / Balanced accuracy | 0.644 / 0.230 |
| A-error detection | 0.590 |
| Exact A-code (among detected) | 0.521 |
| *Binary error detection* | |
| F1 / Precision / Recall (error class) | 0.620 / 0.632 / 0.609 |
| Accuracy / Balanced accuracy | 0.775 / 0.728 |
| *Binary accuracy by hapax status* | |
| Hapax ($n$=339) | 0.664 |
| Non-hapax ($n$=3,034) | 0.787 |

Table 3: Agreement between TERMJUDGE and human gold labels on STEP, all occurrences judged via the exhaustive path (§5.1): 3,373 scored occurrences, including 1,019 errors (371 with a family-A label) and 2,354 non-errors.

3.1-8B-Instruct (Grattafiori et al., 2024), Qwen3-8B (Yang et al., 2025), EuroLLM-9B-Instruct (Martins et al., 2025) and EuroLLM-22B-Instruct (Ramos et al., 2026)), each under the two zero-shot conditions of §4.1, *baseline* and *base+terms*. Decoding is greedy except for Qwen3-8B, run in its recommended non-thinking sampling mode.

## 5 Results and Analyses

### 5.1 Occurrence-Level Agreement on STEP

Table 3 reports agreement with the gold labels for 3,373 STEP occurrences under the *exhaustive judging path* (Appendix H). The deterministic matching shortcut is disabled: every occurrence, including matches and hapaxes, is submitted to Q1 and, if error-free, Q2, allowing every gold class to be predicted.

TERMJUDGE detects errors well above the majority-class baseline (balanced accuracy 0.728). Fine-grained code assignment remains hard: 59% of the gold family-A occurrences are flagged with some A code but only about half receive the correct code, with a 15-class macro-F1 close to 0.20. For hapax occurrences (339), binary accuracy drops by about 12 points relative to non-hapax occurrences (0.664 vs. 0.787, Table 3), quantifying the difficulty of judging terms without document-internal evidence. Three patterns dominate the confusion matrix (Appendix D, Table 14). First, the missed errors are mostly not terminological errors proper: of the 398 gold errors judged correct, 159 belong to family F (grammar around the term: agreement, determiners, prepositions) and 82 to pure in-document inconsistency (B), two families that concern the term's surroundings or its consistency rather than the choice of equivalent. Among wrong-equivalent errors (family A), the weak point is A3, the invented calque, accepted as correct in 40 of 65 cases (one is shown in Table 5): the judge takes a literal translation for an attested term. Second, content-altering translations (G: omissions, additions, unintelligible output) are almost always caught (215 out of 227 are tagged erroneous) but mostly with a wrong label (126 as A1): the judge detects that a translation is wrong more reliably than it identifies the mechanism, and this family-level confusion explains the gap between binary balanced accuracy (0.728) and low 15-class macro-F1 (0.196). Third, the gold and judged notions of unjustified variation barely overlap: only 4 of the 101 pure-inconsistency cases are flagged UNJUSTIFIED, while 104 of the 149 UNJUSTIFIED verdicts were not tagged by the annotator. This reflects a difference of status. In the human guidelines, variation between individually correct translations is recorded (family B) but not counted as an error and carries no severity (Appendix C); TERMJUDGE, by contrast, penalises such variation when the consistency judge finds it unjustified (UNJUSTIFIED, Table 1). The human B labels thus describe variation without judging whether it is justified, whereas UNJUSTIFIED asserts that it is not, so the two capture different cases. The LLM judge and the human annotator therefore disagree most on the consistency axis, not on error detection.

### 5.2 Document-Level Meta-Evaluation

Table 4 reports the meta-evaluation on BioMQM-Terms under the micro-average over occurrences defined in §3.2. Macro-averaging per source form or concept yields the same conclusions (Appendix E). TERMJUDGE ranks first in SPA (0.844) and in segment-level $\text{acc}^*_{\text{eq}}$ (0.606). On segment-level $\text{acc}^*_{\text{eq}}$, its lead is significant over every other metric ($p \leq 0.01$, paired permutation tests). On SPA, it is significant for eight of the ten metrics ($p < 0.05$, $k$=2,000), with ties for the Divergence-QE variants $\text{GEMBA}_{\text{div}}$ and $\text{CometKiwi}_{\text{div}}$. The Divergence-QE variants form the second-best family; the remaining families follow within a narrow band (SPA 0.69–0.78).

The document-level $\text{acc}^*_{\text{eq}}$ column, where the measure reduces to plain pairwise accuracy over 50 items (§4.3), is reported for completeness only. Excluding hapax chains removes occurrences lacking another rendering in the document; unless the term

| Metric | SPA | $\text{acc}^*_{\text{eq}}$ (seg) | $\text{acc}^*_{\text{eq}}$ (doc) |
|---|---|---|---|
| *Judged divergences (this work)* | | | |
| **TERMJUDGE** | **0.844** | **0.606** | **0.557** |
| *Divergence QE* | | | |
| $\text{GEMBA}_{\text{div}}$ | 0.803 | 0.597* | 0.516 |
| $\text{MetricX-24}_{\text{div}}$ | 0.769* | 0.593* | 0.526 |
| $\text{CometKiwi}_{\text{div}}$ | 0.786 | 0.599* | 0.543 |
| *Glossary conformity* | | | |
| first-translation fallback | 0.730* | 0.595* | 0.449 |
| majority fallback | 0.723* | 0.598* | 0.445 |
| *Terminology-filtered QE* | | | |
| GEMBA-MQM (any mention) | 0.775* | 0.586* | 0.219 |
| GEMBA-MQM (category) | 0.689* | 0.583* | 0.193 |
| *General QE* | | | |
| $\text{GEMBA}_{\text{gen}}$ | 0.736* | 0.583* | 0.533 |
| $\text{MetricX-24}_{\text{gen}}$ | 0.736* | 0.586* | 0.566 |
| $\text{CometKiwi}_{\text{gen}}$ | 0.729* | 0.591* | 0.552 |

Table 4: Meta-evaluation on BioMQM-Terms, **micro-average** occurrence aggregation (10 systems, 50 documents, 373 segments; human ground truth from all MQM categories). Empirical SPA chance level: $0.592 \pm 0.089$. *: TERMJUDGE is significantly better (paired permutation tests, $p < 0.05$); unmarked values are ties.

is in the glossary, only a judgement of the translation itself, by an LLM or a human, can evaluate them. In that reduced variant, no SPA difference between TERMJUDGE and the remaining metrics is statistically significant ($p \geq 0.17$), while TERMJUDGE stays significantly ahead of general QE on segment-level $\text{acc}^*_{\text{eq}}$ (Appendix G).

Like any typology-based metric, the document score relies on a penalty scale, which follows the gravities assigned by the typology's authors, each grouped family C–H being scored at its most lenient sub-code (benefit of the doubt, Table 1). Varying C, D and E weights from 1 to 4 with $F{=}G{=}H{=}1$ leaves TERMJUDGE ahead of all comparison metrics under occurrence and source-form aggregation (Appendix F).

### 5.3 System Ranking on PARANLP and IWSLT23

Table 6 ranks the eight systems of §4.1 on both corpora with TERMJUDGE and with two of the comparison families of §4.3. With TERMJUDGE, for all four models the *base+terms* run scores better than its *baseline* run, on both corpora, with the largest gains on IWSLT23. Where Dahan et al. (2026b) observed a tension they could not arbitrate (glossary injection improves accuracy and consistency counts while reducing the transfer of source variation), TERMJUDGE returns a clearer verdict, and its verdict distribution (Table 7) shows why: under *base+terms*, exact conformity rises by 6 points on PARANLP and 12 on IWSLT23, wrong-equivalent (A) error rates drop sharply (11.7% to 8.4% of occurrences on PARANLP, 18.6% to 9.3% on IWSLT23), while justified and unjustified variation both recede moderately; the variation that glossary injection suppresses is mostly not valid, so *base+terms* yields a net gain on these corpora. The two comparison metrics behave on these corpora as they did in the meta-evaluation. General QE is blind to the terminological gain: $\text{CometKiwi}_{\text{gen}}$ orders the systems by general quality, is nearly insensitive to the prompting condition, prefers the *baseline* run in most pairs of one *baseline* and one *base+terms* run (eleven of sixteen on IWSLT23, ten on PARANLP with one tie), and its best run for each corpus is a *baseline* run. Glossary conformity ranks every *base+terms* run above every *baseline* run (all sixteen pairs on each corpus), as it counts exactly the glossary terms that the *base+terms* prompt injects, but disagrees with TERMJUDGE within each condition: on IWSLT23 it ranks Qwen3-8B first among the *baseline* runs, where TERMJUDGE ranks it last. Conformity only checks whether the glossary term appears in the output; judges also recognise justified variation and detect errors that matching approaches cannot.

### 5.4 What Judging Adds over Counting

**The comparison metrics as an ablation of TERMJUDGE.** Read from the bottom of Table 4 upwards, the comparison families of §4.3 add one component of TERMJUDGE at a time, so the table can be viewed as an ablation study. General QE is the baseline (SPA 0.729–0.736), restricting it to terminology-mentioning error spans changes little and can even hurt (0.775 for the permissive filter, 0.689 for the strict one), and counting glossary conformity instead of judging results in similar scores (0.723–0.730). The first substantial step is architectural: keeping the document-level divergence detection but scoring the divergence points with an off-the-shelf QE metric increases the score to 0.769–0.803; the divergence architecture already carries part of the signal. The second step is the judgement itself: replacing the generic score at those points with the typed Q1/Q2 judges adds the rest (0.844), and it is the only step that also provides interpretable labels.

**What consistency labels reveal.** Beyond the binary JUSTIFIED/UNJUSTIFIED outcome, the labels returned by the Q2 judge also say why a divergence is judged coherent or not (Appendix I, Table 21). Their distribution is stable across systems: about

| Source form | MT output | Judgement | Verdict | Judge's reason (abridged) |
|---|---|---|---|---|
| *annotation*⋆ | annotation humaine | explicitation | JUSTIFIED | first mention, expands the term with a clarifying adjective |
| *dataset* | jeu de données | synonym inconsistency | UNJUSTIFIED | document established *ensemble de données*; switch without visible reason |
| *attention* | auto-attention | neutralisation | UNJUSTIFIED | reproduces the translation reserved for another source form of the concept |
| *word embedding* | incorporation de mots | invented calque | **A3** | expected *plongement lexical*; calque not attested in the domain |
| *retrieval* | récupération | general word | **A7** | expected *recherche*; general word, not the specialised term |
| *rate and state friction*⋆ | friction à taux et état | first mention | JUSTIFIED (gold: **A3**) | the calque is an established French term, attested in the domain |

Table 5: Five judgements on one system output (EuroLLM-22B-Instruct, *baseline*, IWSLT23) and, below the rule, a documented judgement error from STEP (human gold: **A3**). The last column is the explanation the judge returns with each verdict, abridged. ⋆: first mention.

| | *baseline* | | | | *base+terms* | | | |
|---|---|---|---|---|---|---|---|---|

Table 6: System comparison on the two NLP test corpora with TERMJUDGE (mean per-document penalty, lower is better), glossary conformity and CometKiwi general QE (families (ii) and (iv) of §4.3); best value per metric and corpus in bold. Ll.: Llama, Qw.: Qwen, E9/E22: EuroLLM-9B/22B.

| Corpus | Condition | Conf. | Just. | Unjust. | A | C–H |
|---|---|---|---|---|---|---|
| PARANLP | baseline | 72.2 | 11.6 | 1.6 | 11.7 | 2.9 |
| | base+terms | 78.5 | 9.2 | 1.3 | 8.4 | 2.6 |
| IWSLT23 | baseline | 67.5 | 9.2 | 2.2 | 18.6 | 2.5 |
| | base+terms | 79.2 | 7.5 | 2.1 | 9.3 | 1.9 |

Table 7: Distribution of verdicts by prompting condition (percentage of occurrences, four models pooled): conformity, justified and unjustified variation, wrong-equivalent errors (A) and other error families (C–H).

four divergences out of five follow the document's established usage (e.g., *treatment* rendered *traitement* throughout while the glossary reference is *thérapeutique*: divergent at every occurrence, yet error-free and tagged as 'document usage', JUSTIFIED); 'first mention' accounts for another 6–7%.

The two prompting conditions differ where it matters. Under *base+terms*, 'synonym inconsistency' goes down for every model (3.0–3.7% to 2.0–2.9%) while 'neutralisation' goes up slightly (0.8–1.8% to 1.5–2.1%): glossary injection eliminates unmotivated switching between synonyms, but slightly more often erases a source distinction between a term and one of its variants. This is the loss of source-side variation already observed in §5.3, and it remains far smaller than the reduction of genuine errors (Table 7; the same pattern holds on IWSLT23, where small counts call for caution).

**Example Judgements.** Table 5 displays five real judgements from a single system output. The same situation, a translation that differs from the document's dominant one, is judged in four different ways depending on whether it erases a source distinction, switches designation without purpose, expands the term at its first mention, or is simply a wrong term. The judge also returns an explanation, which makes each decision interpretable. The last row, from STEP, is a judge error of the kind quantified in §5.1 (40 of 65 invented calques accepted): the judge does not merely accept the invented calque, it asserts that it is attested.

## 6 Conclusion

TERMJUDGE starts from a simple observation: terminology metrics that count divergences from a fixed reference conflate translation errors with valid variations that translators routinely produce. It therefore judges instead of counting: matches with the expected translation are settled deterministically, divergences go, in document context, to an error judge and then to a consistency judge, and the interpretable verdicts aggregate into a document-level score. On STEP, error detection agrees with a per-occurrence expert gold (binary balanced accuracy 0.728); on BioMQM-Terms, TERMJUDGE ranks first in SPA under all three aggregations and in segment-level acc$^{*}_{eq}$, significantly ahead of every comparison metric at that level. On two NLP test corpora, it settles a question counting could not: glossary injection helps every model because it removes genuine errors, not legitimate variation. The pipeline is language- and domain-agnostic given a glossary and aligned occurrences; testing open-weight judges, and the stability of the verdicts across judge models and prompts, are natural next steps.

## Limitations

TERMJUDGE inherits the limitations of LLM-as-a-judge evaluation. Verdicts depend on a single proprietary judge model (`gpt-4.1-mini`, chosen as explained in §3.3); decoding is deterministic and all prompts are versioned, but the stability of the verdicts across judge models and prompt paraphrases was not measured and no open-weight judge was tested, although the conclusions hold across judging paths, penalty scales and aggregations (Appendices H, F and E), and exposing the full 23-code typology instead of the compact one moves binary error detection by under three points (Appendix C.1). Pseudo-references are derived from the very output under evaluation; the validation by the error judge and the LLM generation of Step 1 mitigate this circularity but do not eliminate it. Out-of-glossary hapaxes remain the hardest case, with binary agreement about 12 points below non-hapax occurrences on STEP. Ignoring diacritics and hyphens in Step 2 can also conflate distinct words offered for the same term (*élevé* vs *élève*).

The validation supports the metric at the granularities at which it is used, binary error detection and aggregated document scores; per-code agreement is substantially lower (15-class macro-F1 0.196), mostly because the judge detects that a translation is wrong more reliably than it identifies the mechanism (§5.1). Fine-grained codes are therefore reported for diagnosis and should be read as indicative; the document score, for its part, is robust to the weights assigned to the grouped families (Appendix F). Occurrence-level validation relies on a single expert annotator and a single MT system on STEP, so annotator bias cannot be separated from metric error, and document-level validation is limited to one language pair (EN–FR) and ten systems on bio-MQM; the judges' accuracy may differ for other language pairs and domains.

Finally, TERMJUDGE requires a domain glossary and an upstream pipeline (term spotting, variant detection, alignment) whose errors propagate to the verdicts. This propagation was not measured directly, but the two validations bracket it: STEP evaluates the judges alone on gold occurrences and alignments, whereas BioMQM-Terms is processed end-to-end by the pipeline, and TERMJUDGE still ranks first there; the upstream steps themselves were validated on samples (Appendix A). Document scores are also relative to the terminology provided, so comparisons are meaningful across systems evaluated on the same corpus and terminology, not across corpora. Evaluating a full corpus incurs a non-trivial LLM cost (Appendix J).

## Acknowledgments

This work was supported by the French National Agency (ANR) as part of the MaTOS project under reference ANR-22-CE23-0033.[9] The authors are also grateful to the anonymous reviewers for their insightful comments and suggestions, and to Natalie Kübler, Alexandra Mestivier and José Cornejo Cárcamo for early discussions on term variation and evaluation of term translation, to Éric de la Clergerie for his help on the CONCORDANCER and to the MaTOS project team for their feedback on preliminary versions of this work.

## A Pipeline Overview and a Worked Example

Figure 2 situates TERMJUDGE within the full evaluation pipeline: the upstream stages produce the aligned term occurrences defined in §3.1, and the metric proper begins at reference selection.

Table 8 illustrates the variation categories with which each attested source form is labelled relative to the head term of its concept. The label depends on how the form was detected: forms listed in the glossary (head term or variant) are classified by few-shot prompting `gpt-4.1-mini`, and forms derived by the CONCORDANCER take the category of

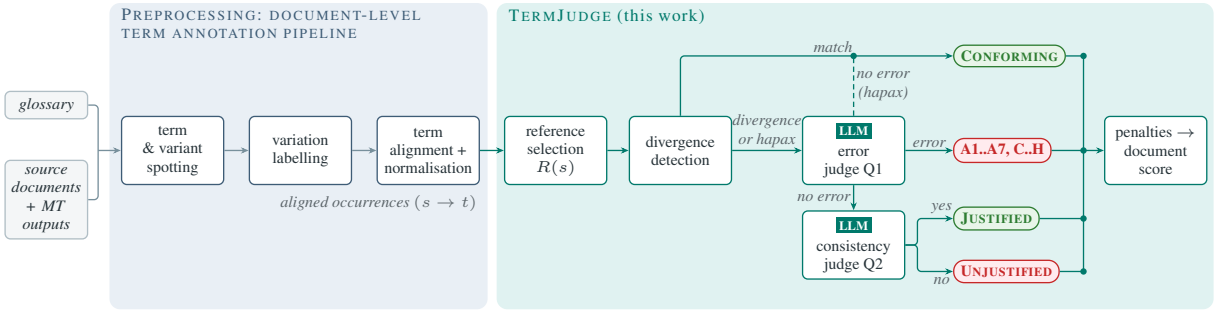

Figure 2: Overview of the evaluation pipeline (every data-side notion is defined in §3.1). Upstream: the CONCORDANCER spots the occurrences of glossary concepts and of their variants in the source documents; each source form is labelled with a variation category; each occurrence is aligned with its translation, normalised into a canonical form and a lemma. TERMJUDGE (this work): a reference $R(s)$ is fixed per source form and document; a translation matching $R(s)$ is CONFORMING without any LLM call; a divergent translation is classified by the LLM error judge (Q1), which either assigns an error label (**A1**–**A7**, **C**–**H**) or passes it to the LLM consistency judge (Q2), which returns JUSTIFIED or UNJUSTIFIED; hapax occurrences are always submitted to Q1 and, if error-free, labelled CONFORMING without the consistency stage; individual penalties aggregate into a document-level score.

| Category | Head term | Attested source form |
|---|---|---|
| no variation | machine translation system | machine translation system |
| graphical | machine translation system | MT system |
| morphosyntactic | machine translation system | system for machine translation |
| reduction | machine translation system | translation system |
| expansion | machine translation system | automatic machine translation system |
| lexical | machine translation system | automatic translation system |
| combined | machine translation system | MT model |

Table 8: Source-side variation categories (Cornejo Cárcamo et al., 2025), illustrated on the running example of the introduction: each attested form is labelled relative to the head term of its concept.

| Seg | Source form | MT output | Judgement | Verdict |
|---|---|---|---|---|
| *slab* (in glossary; variant *downgoing slab* → *plaque plongeante*) | | | | |
| 6 | slab (1st mention) | plaque plongeante | first mention | JUSTIFIED |
| 74 | slab | plaque plongeante | document usage | JUSTIFIED |
| 495 | slab | plaque plongeante | neutralisation | UNJUSTIFIED |
| *subduction initiation* (out of glossary; expected translation *initiation de la subduction*) | | | | |
| 598 | subduction initiation | début de la subduction | paraphrase | **A2** |

Table 9: Real occurrences from a STEP validation document. The source alternates the head term *slab* and its variant *downgoing slab*; the system renders the variant consistently as *plaque plongeante*. Rendering the head term the same way is judged legitimate at 'first mention' and while it follows the 'document usage' (JUSTIFIED), but flagged once *plaque plongeante* is the form reserved for the variant: the source distinction is erased ('neutralisation', UNJUSTIFIED). For the out-of-glossary concept *subduction initiation*, whose reference is established from document usage, the paraphrase *début de la subduction* is a terminological error (**A2**).

the formation pattern that produced them; a form derived from a glossary variant combines both (an acronym of an expansion is *combined*). Dahan et al. (2026b) validated this labelling on 50 sampled forms annotated by a computational linguist: 84% agreement on the category, near-perfect on single-category variants, with *combined* variants under-detected (recall 11%) but accounting for under 2% of occurrences. The same study checked 100 sampled term alignments on PARANLP and IWSLT23 and found 96 correct.

Table 11 follows one concept of an PARANLP document from its glossary entry to the verdicts; Table 9 then illustrates the consistency judge on real occurrences of a STEP validation document.

## B Dataset Construction Details

The manual extraction behind the BioMQM-Terms glossary (§4.1), performed independently of the terms' involvement in any translation error, produced 819 raw entries, deduplicated into 729 unique concepts. Crossing them with the bilingual MeSH thesaurus (30,915 concepts) covers 15.2% of the terms by exact matching, and 31.7% once alternative labels, inflected forms and graphical normalisation are admitted; the remaining 68.3%, too specific or too compositional for MeSH, were translated manually. A complementary error-driven pass over the MQM Terminology error spans examined 132 candidate terms, of which 110 were retained. On STEP, the 3,377 gold-labelled occurrences cover 261 concepts and 793 distinct source forms.

## C A Typology of Terminological Errors

The error typology instantiated by the Q1 judge was developed for the human annotation of terminology errors in specialised machine translation (Cornejo Cárcamo et al., 2026). It builds on the

MeLLANGE error typology (Kübler, 2008) and on subsequent work on the translation of complex noun phrases in specialised texts (Kübler et al., 2022), and its severity scale follows Bénard et al. (2024).

The typology is organised on three levels: a macro-category, a family (A to J), and a fine-grained code. Seven families describe errors in the translation of the term itself, independently of its other occurrences in the document, and yield the 23 fine-grained error codes of Table 12: incorrect equivalent selection (A1–A7), constituent structure of complex terms (C1–C3), semantic relations between constituents (D1–D2), transposition (E1–E2), context-bound grammar and phraseology (F1–F4), content alteration (G1–G3), and target-language expression (H1–H2). Each fine-grained code carries a severity on the scale of Bénard et al. (2024) (neutral, minor, major, critical; only 1–3 are attested in the typology table). Three families carry no severity: family B (B1–B7) describes in-document terminological *(in)consistency*: B1–B4 cover consistency facts about translations that are individually correct (the annotation guidelines stress that these cases « ne représentent pas vraiment une erreur » (*do not really correspond to errors*)), B5–B7 combine incorrectness with instability, and its labels are never assigned alone, since consistency is only assessed at the document level; family I marks the absence of error; family J is an annotator-workflow tag.

TERMJUDGE applies a fixed transformation to this typology before exposing it to the Q1 judge (Table 10). Family A is kept fine-grained; each of the families C to H is collapsed into a single grouped code carrying the gravity of its worst member; family B is excluded from Q1, since in-document inconsistency is exactly the question delegated to Q2 and keeping it in Q1 would count the same phenomenon twice; family I becomes the `no_error` answer; family J is dropped as meaningless for an LLM judge. The 13 remaining codes are exposed to the judge as natural-language labels rather than opaque codes, which reduces reporting errors (mistyping `A6` for `A7` has no surface cue; `wrong_component` vs `general_word_not_term` does); the answer is remapped to the canonical code in post-processing, and any label outside the registry falls back to `no_error`. The natural-language definitions and examples exposed to the judge for each of the 13 labels are those of the Q1 prompt, reproduced verbatim in Appendix K.1. The same transformation is applied to the human annotations of STEP when validating the metric (§4.2), so that metric and human judgements live in the same 15-class space (the 13 codes, plus B reached through Q2, plus no-error).

| Prompt label | Code | Covers |
|---|---|---|
| `wrong_related_term` | **A1** | A1 |
| `paraphrase_not_term` | **A2** | A2 |
| `invented_calque` | **A3** | A3 |
| `left_untranslated` | **A4** | A4 |
| `dnt_violated` | **A5** | A5 |
| `wrong_component` | **A6** | A6 |
| `general_word_not_term` | **A7** | A7 |
| `misparsed_structure` | **C** | C1–C3 |
| `wrong_constituent_relation` | **D** | D1–D2 |
| `failed_transposition` | **E** | E1–E2 |
| `grammar_phraseology` | **F** | F1–F4 |
| `content_altered` | **G** | G1–G3 |
| `defective_register_form` | **H** | H1–H2 |
| `no_error` | – | I |

Table 10: Transformation of the error typology for the Q1 judge: family A stays fine-grained, families C–H are collapsed into one grouped code each, family B is delegated to Q2, family J is dropped. The judge answers with the natural-language label; the canonical code is restored in post-processing.

**Glossary entry**: *semantic similarity* → *similarité sémantique*; English variant *semantic relatedness*; no French variant

| Source form (CONCORDANCER) | Variation category | In glossary | Occ. | Reference $R(s)$ (Step 1) | How the reference was fixed |
|---|---|---|---|---|---|
| semantic similarity | no variation | head term | 2 | similarité sémantique | glossary translation, taken as authoritative |
| similarity (incl. plural) | reduction | no | 14 | similarité | system's most frequent translation, validated by the error judge |
| semantic relatedness | lexical | English variant only | 1 | parenté sémantique | system's only translation, validated by the error judge |

| Seg | Source form → MT output | Step 2: match? | Step 3: Q1 | Step 4: Q2 | Verdict |
|---|---|---|---|---|---|
| 30, 42 | semantic similarity → similarité sémantique | yes | not called | not called | CONFORMING (×2) |
| 33, 46, 47, 85, 87, 90†, 91, 93, 98, 103 (×2), 110 | similarity → similarité(s) | yes | not called | not called | CONFORMING (×12) |
| 79 | semantic relatedness → parenté sémantique | skipped (hapax) | no error, judged in absolute terms | not called (hapax) | CONFORMING |
| 90, 92 | similarity → similitudes | no: divergence | no error (one call, propagated) | gratuitous divergence | UNJUSTIFIED (×2) |

| Seg | **Source** (detected span in bold) | **MT output** (aligned span in bold) |
|---|---|---|
| 30 | … strong link with the notion of **semantic similarity**. | … lien étroit avec la notion de **similarité sémantique**. |

Table 11: Worked example on one concept of an PARANLP document translated by EuroLLM-22B-Instruct (*baseline*). Top: the glossary entry, the forms detected by the CONCORDANCER with their variation category, and the reference translation fixed for each form in Step 1 of §3.2; the glossary provides a French translation for the head term only, so the two other forms receive a pseudo-reference, the system's own translation validated by the error judge. Middle: the path of each occurrence through Steps 2 to 4 and the resulting verdict. Bottom: every segment involved. A match with the reference is labelled CONFORMING without any LLM call. The hapax *semantic relatedness* skips the match and is judged in absolute terms by the error judge, which accepts *parenté sémantique*. The two occurrences rendered *similitudes* diverge from the reference: the error judge finds no error (one call, its answer propagated to the identical translation), and the consistency judge classifies the switch as a 'gratuitous divergence' from the document's usage (UNJUSTIFIED); segment 90 even keeps *similarité* for *Hellinger similarity* in the same sentence. †The CONCORDANCER detected only *similarity* in *Hellinger similarity*; the whole expression should have been identified as an expansion of the term and aligned to *similarité de Hellinger*. In segment 79, the misspelt *semantic simlarity* was not detected.

| Code | Definition | Example (source → *MT → expected) | Penalty | Support |
|---|---|---|---|---|
| *A. Wrong equivalent selection* | | | | |
| A1 | The translation is an attested term of the domain, but the equivalent of another term or concept: an inexact neighbour of the expected equivalent, which can also create spurious repetitions when the two concepts are close. | *tremor* → *tremblement de terre → trémor | 1 | 111 |
| A2 | The terminological unit is replaced by a descriptive, general-language paraphrase, losing the precision of the established term. | *lithospheric mantle* → *couche profonde sous la croûte terrestre → manteau lithosphérique | 1 | 20 |
| A3 | The system produces a formulation that is neither a recognised term of the domain nor a general-language expression: a literal creation. | *earthquake swarm* → *sillage sismique → essaim sismique | 3 | 65 |
| A4 | The term is left in the source language although an established target-language equivalent exists. | *megathrusts* → *megathrusts → mégachevauchements | 4 | 34 |
| A5 | A unit conventionally kept in the source language (proper name, acronym, nomenclature symbol) is translated; for acronyms, the letters may also be reworked or reordered. | *MORB* → *BDRM → MORB | 4 | 23 |
| A6 | Some constituents of a complex term are translated correctly but others are not, yielding a partially correct hybrid term. | *fault patches* → *taches de faille → zones de faille | 4 | 95 |
| A7 | A single general-language word replaces the specialised term; unlike A2, one lexical unit rather than a paraphrase, creating referential ambiguity in specialised discourse. | *repeaters* → *répétiteurs → séismes répétitifs | 3 | 23 |
| *B. In-document terminological (in)consistency (no severity; delegated to the consistency judge)* | | | | |
| B1 | The same base term receives different, individually correct translations across the document. | *earthquake rupture* → rupture sismique / ruptures de séismes | – | – |
| B2 | The same variant receives different, individually correct translations across the document. | *fault creep* → fluage asismique / fluage de la faille / fluage de faille | – | – |
| B3 | A base term and one of its variants receive the same translation, erasing the distinction between them. | *seismic hazard* (variant) / *earthquake hazard* (base term) → risque sismique | – | – |
| B4 | Different variants of the same base term receive the same translation, erasing their nuances. | *dynamic fault slip* / *dynamic slip* → glissement dynamique | – | – |
| B5 | The base term is translated both incorrectly and inconsistently from one occurrence to the next. | *continental forearc* → *marge continentale / *zone de subduction / *zone de l'avant-arc continental | – | – |
| B6 | A variant is translated both incorrectly and inconsistently from one occurrence to the next. | *down-dip* → *encaissée / *en profondeur / *dans la direction aval | – | – |
| B7 | The base term and its variant both receive the same incorrect translation, combining neutralisation with incorrectness. | *Zapotal Formation* / *Zapotal Fm* → *Formation de Zapotal | – | – |
| *C. Structure of complex terms* | | | | |
| C1 | The head noun of the complex term or noun phrase is misidentified; the head fixing the base category of the concept, the designated concept changes. | *subduction-zone serpentinites* → *zones de subduction constituées de serpentinite → serpentinites en zone de subduction | 4 | 10 |
| C2 | An adjective or other modifier is attached to the wrong constituent, altering the qualification relations within the term or phrase. | *fast earthquake rupture* → *rupture rapide de séisme → rupture sismique rapide | 4 | 11 |
| C3 | The constituents are ordered against the conventions of the target language, yielding a structure alien to domain usage. | *slow earthquake* → *lent séisme → séisme lent | 4 | 9 |
| *D. Semantic relations* | | | | |
| D1 | The semantic relations between constituents, often implicit in scientific English, are rendered incorrectly where the target language requires them to be explicit (preposition or paraphrase). | *fast and slow events* → *événements à la fois rapides et lents → événements rapides et lents | 4 | 3 |
| D2 | An element shared (factorised) across coordinated constituents in the source is not distributed to all conjuncts in the target. | *pressure-solution and dislocation creep* → *pression-solution et le glissement par dislocation → fluage par dissolution-précipitation et par dislocation | 4 | 0 |
| *E. Transposition* | | | | |

*Table 12 (continued)*

| Code | Definition | Example (source → *MT → expected) | Penalty | Support |
|---|---|---|---|---|
| E1 | The compact, synthetic source structure is kept as is, without the explicitation (preposition, article, unfolding) that the analytic target structure requires. | *strike-slip and subduction thrust faults* → *failles de décrochement et de chevauchement de subduction → failles de décrochement et de chevauchement dans les zones de subduction | 3 | 13 |
| E2 | The source syntax is calqued although the words themselves are attested, producing unnatural target text (e.g., an English plural mark kept on an acronym, French acronyms being invariable). | *SSEs* → *SSEs → SSE | 1 | 39 |
| *F. Grammar / phraseology in context* | | | | |
| F1 | Inappropriate determiner, or incorrect gender or number agreement, within the term or between the term and its context. | *alkaline basalt* → *la basalte alcalin → le basalte alcalin | 1 | 132 |
| F2 | A preposition required by the target syntactic structure is missing or wrong. | *slip behavior* → *comportement en glissement → comportement de glissement | 3 | 71 |
| F3 | A grammatically correct combination that does not match the established phraseology of the domain. | *magma rises up the conduit* → *le magma monte vers le haut dans le conduit → le magma remonte par le conduit | 3 | 0 |
| F4 | An incorrect spelling, notably in terms borrowed or adapted from the source language. | *aseismic slip* → *glissement aseismique → glissement asismique | 3 | 16 |
| *G. Content alteration* | | | | |
| G1 | Constituents absent from the source term are added, potentially altering the meaning or introducing unintended nuances. | *fault creep* → *glissement lent de la faille → fluage de faille | 4 | 10 |
| G2 | Constituents of the term, or the term entirely, are omitted, losing information that affects the meaning. | *seismicity bursts* → *séismes → vagues de séismes | 4 | 56 |
| G3 | The output bears no relation to the source content or is incoherent with the term to be translated: an unintelligible translation or hallucination. | *earthquake ruptures* → *ruptures d'éruptions → ruptures sismiques | 4 | 161 |
| *H. Target-language expression* | | | | |
| H1 | The relative weight and hierarchy of the constituents, notably their punctuation, is not respected in the target text. | – | 3 | 0 |
| H2 | A semantically correct formulation whose register or style is inappropriate for specialised discourse. | *earthquake ruptures* → *ruptures de tremblements de terre → ruptures sismiques | 1 | 16 |

Table 12: The fine-grained codes of the typology (Cornejo Cárcamo et al., 2026) as implemented in TERMJUDGE: the 23 error codes and the seven consistency codes of family B, with definitions adapted from the annotation guidelines and a geoscience example each (*: erroneous MT output; for error codes, the last element is the expected form). The default penalty follows the fixed 1/3/4 mapping of the gravities assigned by the typology's authors on the scale of Bénard et al. (2024); support is the number of gold occurrences carrying the code among the 3,373 evaluated STEP occurrences (precedence-reduced labels). Family B carries no severity and is never assigned alone: it is the question delegated to the consistency judge (Q2), and the precedence reduction of §4.2 collapses pure-consistency annotations into a single B class (101 occurrences), so no per-code support is reported.

### C.1 Why the Compact Typology

The choice of the compact typology over the full 23-code version rests on a controlled comparison on STEP: two runs of the metric identical in every respect, including references verified identical occurrence by occurrence, except the typology exposed to the Q1 judge, with every occurrence routed through the exhaustive judging path. The unbiased comparison between the two is binary error detection, since the binarised gold is the same for both runs (1,019 erroneous and 2,354 error-free occurrences); Table 13 shows that the compact typology dominates on every measure, with 2.8 points more accuracy, 5.3 points more error precision, 78 fewer false positives and 17 fewer false negatives. Over-segmenting the answer space does not only degrade category choice: it degrades the binary decision itself, pushing the judge out of `no_error` more often and wrongly. The multi-class views live in different label spaces and are not directly comparable, but two observations are robust: the full typology leaves seven attested categories at exactly zero F1 (A5, C1, C2, D1, E1, F2, G1), and the family-A diagnostics, computed identically in both spaces, are of the same order (detection of some A code on gold-A occurrences at 0.590 for the compact typology against 0.563; exact A code among those detected at 0.521 against 0.536), so the compaction costs nothing on the fine-grained terminological core. The full prompt is also about twice as expensive (about 6,700 input tokens per Q1 call against 3,100) and overruns the output budget where the compact prompt never does.

The compaction is deliberately asymmetric. Family A keeps its seven fine codes because distinguishing the mechanisms of wrong equivalent selection is precisely what the metric must explain; families C to H describe errors that affect terms without being terminology errors proper, so the metric only needs to know which family an occurrence fails under. The distributional picture supports the same asymmetry: taken together, families C to H account for 547 of the 1,019 erroneous occurrences and are in no way marginal, but their sixteen fine codes are individually rare (median support 12; eleven of the sixteen at 16 occurrences or fewer; D2, F3 and H1 unattested; only F1 and G3 above one hundred; Table 12), too rare for the judge to be evaluated reliably on them or for the gold to discriminate them, whereas the grouped families recover workable supports (C 30, E 52, F 219, G 227). This observation is consistent with prior findings that fine-grained MQM annotation is much harder for LLMs than coarser quality judgements (Fernandes et al., 2023), that in-context classification degrades over large label spaces (Milios et al., 2023), and with the practice of predicting spans and severities rather than the full MQM taxonomy (Guerreiro et al., 2024); to our knowledge, no prior study quantifies the effect of typology size on an LLM judge all else being equal, which this controlled comparison provides. Its limits are those of the setting: one corpus, one MT output, one judge model, and a single-annotator gold reduced from multi-label annotations by a fixed precedence.

| **Binary error detection** | **Compact** | **Full** |
|---|---|---|
| Accuracy | **0.775** | 0.747 |
| Macro-F1 | **0.730** | 0.701 |
| Balanced accuracy | **0.728** | 0.703 |
| Precision (error class) | **0.632** | 0.579 |
| Recall (error class) | **0.609** | 0.593 |
| F1 (error class) | **0.620** | 0.586 |
| False positives | **362** | 440 |
| False negatives | **398** | 415 |

Table 13: Controlled comparison of the compact (13-code) and full (23-code) typologies on STEP: binary error detection against the same binarised gold (3,373 occurrences; 1,019 error, 2,354 no-error). The two runs differ only in the typology exposed to the Q1 judge.

## D STEP Confusion Matrix

Table 14 gives the full confusion matrix behind the agreement figures of §5.1, with every occurrence judged through the exhaustive Q1→Q2 path.

## E Macro Aggregation Levels

Tables 15 and 16 complete Table 4, reported under the micro-average (occurrence) aggregation, with the two macro-aggregations of §3.2, per source form and per concept. The conclusions are unchanged: TERMJUDGE ranks first in SPA at both levels, ahead of every comparison family.

## F Penalty Scale and Sensitivity

This appendix details the penalty scale behind the document score of §5.2 and its sensitivity analysis.

Like any typology-based metric, e.g. the Critical/Major/Minor weighting of MQM, (§4.3), the document score rests on a penalty scale. The fine-grained penalties are not tuned: they follow the gravities assigned to each code by the typology's authors, through the fixed mapping of gravities

| **Gold \ verdict** | A1 | A2 | A3 | A4 | A5 | A6 | A7 | C | D | E | F | G | H | no-error | B | total |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|

Table 16: Meta-evaluation on BioMQM-Terms, **concept** (macro) aggregation.

1/2/3 to weights 1/3/4 (Appendix C). The 1/3/4 spacing compresses the Minor/Major/Critical scale of MQM penalties (1/5/10): the decisive gap separates near-misses from established errors, while gravities 2 and 3 both signal an unusable translation of the term; the compression also bounds the dynamic range, preventing a few critical codes from dominating a document score. A grouped verdict asserts an error of the family but does not identify which sub-code applies, and the sub-codes of a family differ in gravity; each grouped family, C through H, is therefore scored at its most lenient sub-code, a single benefit-of-the-doubt rule applied uniformly, in favour of the evaluated translation. The uncertainty lies in the judge's granularity, not in the translation, so the rule is a conservative bound rather

than an indulgence: the penalty never exceeds what the verdict certainly establishes. D, with only 31 of the 13,200 occurrences, is too rare for its weight to have any measurable effect.

The six grouped-family penalties (C–H) are the only quantities this rule sets. To test how sensitive the meta-evaluation is to them, we re-scored the saved verdicts under every assignment of weights 1–4 to these six families ($4^6 = 4{,}096$ configurations; A weights and the UNJUSTIFIED penalty at their defaults; macro-average per lemmatised source form), at no LLM cost, since the judges emit labels and the score is a pure function of the penalties applied to them. The meta-evaluation responds in a single, interpretable direction: averaged over the grid, raising the weight of family F (grammar around the term) costs six SPA points (0.833 to 0.774), G (content alteration) three and a half, H (target-language expression) one and a half, E half a point, while C and D (term structure, semantic relations) have no measurable effect. These are the same peripheral families that the confusion analysis of §5.1 shows that the judge handles least reliably; inflating their weight adds non-terminological noise into the score. The minimum rule, adopted on benefit-of-the-doubt grounds alone, thus receives independent support: it places the scale (Table 1) in the $F{=}G{=}H{=}1$ region, whose 64 configurations keep SPA within 2.5 points of one another (0.846–0.871) and above every comparison metric at that aggregation (Table 15), whatever the C, D and E weights, and re-scoring the same 64 scales at the micro aggregation of Table 4 keeps every one of them above every comparison metric as well; the UNJUSTIFIED penalty is second-order (varying it from 0.5 to 1.2 moves mean SPA by a tenth of a point on the development configuration).

## G Meta-Evaluation without Hapax

Tables 17, 18 and 19 repeat the meta-evaluation of §5.2 with single-occurrence chains excluded from both the metrics and the human scores (48 documents, 275 segments). Two caveats: the sentence-level rows, being term-agnostic, keep their full-document scores against the complete human ground truth (50 documents), and are repeated unchanged; and the variant removes exactly the occurrences that only a judge can evaluate, so it is not comparable to the main tables. On this reduced support the SPA differences between systems are all within statistical noise (paired permutation tests, $p \geq 0.17$ for every pair involving TERMJUDGE, $k{=}2{,}000$): the apparent reordering, with the glossary-conformity baselines nominally ahead, is not significant. TERMJUDGE remains significantly better than the five sentence-level rows on segment-level $\text{acc}^*_{\text{eq}}$ ($p < 0.05$) and keeps the best document-level $\text{acc}^*_{\text{eq}}$ of the terminology-aware families.

| $\text{GEMBA}_{\text{div}}$ | 0.717 | 0.384 |
| $\text{MetricX-24}_{\text{div}}$ | 0.754 | 0.450 |
| $\text{CometKiwi}_{\text{div}}$ | 0.744 | 0.450 |
| *Glossary conformity* | | |
| first-translation fallback | **0.794** | 0.401 |
| majority fallback | 0.785 | 0.398 |
| *Terminology-filtered QE (50 docs)* | | |
| GEMBA-MQM (any mention) | 0.725 | 0.204 |
| GEMBA-MQM (category) | 0.641 | 0.178 |
| *General QE (50 docs)* | | |
| $\text{GEMBA}_{\text{gen}}$ | 0.736 | 0.527 |
| $\text{MetricX-24}_{\text{gen}}$ | 0.744 | 0.566 |
| $\text{CometKiwi}_{\text{gen}}$ | 0.766 | 0.556 |

Table 19: No-hapax meta-evaluation, concept-level aggregation.

| | Default | Exhaustive |
|---|---|---|
| Unique LLM judgements | 6,525 | 16,612 |
| Approximate cost (USD) | 6.8 | 15.6 |
| Kendall $\tau$ between rankings | 0.786 (25/28 pairs) | |
| *base+terms* ahead of *baseline* | 16/16 | 16/16 |

Table 20: Default configuration (deterministic shortcuts, Q1 propagation) vs. exhaustive judging path on the eight IWSLT23 outputs, same judge and prompts. The three discordant pairs all involve near-ties (score gap $\leq 0.006$ in one of the two configurations).

duced (Kendall $\tau = 0.786$; 25 of 28 system pairs concordant, the three discordances all involving near-ties, and every *base+terms* system still ahead of every *baseline* one) while requiring 2.55 times more unique LLM calls. The deterministic shortcuts and the Q1 propagation thus buy a substantial cost reduction without affecting the conclusions.

## I Consistency Labels: Grounding and Distribution

The ten labels of the consistency judge operationalise motivations for terminological variation documented in terminology and translation studies. Among the seven coherent labels, 'first mention' is the base case: no translation is established yet, so none can be inconsistent. 'Explicitation' follows the translation procedure of that name (Vinay and Darbelnet, 1972) and the cognitive function of variation, by which writers vary a term to explain a concept better (Pecman, 2014). 'Avoid repetition' reflects the stylistic avoidance of repetition, marked in French (Vinay and Darbelnet, 1972). 'Register' and 'facet' follow Bowker (1998), who shows that variation in expert discourse is motivated by the audience and purpose of the text and by the dimension of the concept that the context foregrounds, a cognitive function also described by Pecman (2014). 'Document usage' and 'synonym merge' encode the consistency norm itself: repeating the rendering established in the document is coherent, and two source forms that differ only by syntactic reordering (*colour flatbed scanner* vs *flatbed colour scanner* in Bowker, 1998; morphosyntactic variants in Cornejo Cárcamo et al., 2025) may share one translation. The three inconsistency labels mirror the consistency tradition of §2: 'synonym inconsistency' and 'gratuitous divergence' penalise a switch away from an established rendering without such a motivation, and 'neutralisation' the erasure of a source-side distinction (Bowker and Hawkins, 2006).

| | *baseline* | | | | *base+terms* | | | |
|---|---|---|---|---|---|---|---|---|
| **Q2 label (%)** | Ll. | Qw. | E9 | E22 | Ll. | Qw. | E9 | E22 |
| Document usage | 79.5 | 76.5 | 79.2 | 80.1 | 78.8 | 77.2 | 79.8 | 81.0 |
| First mention | 6.0 | 6.7 | 6.6 | 6.1 | 6.6 | 7.0 | 7.3 | 6.0 |
| Synonym merge | 2.2 | 3.0 | 2.0 | 2.1 | 1.7 | 1.8 | 1.8 | 1.4 |
| Other coherent | 0.1 | 0.2 | 0.3 | 0.3 | 0.3 | 0.2 | 0.2 | 0.4 |
| Neutralisation | 0.8 | 1.8 | 1.2 | 1.6 | 2.1 | 1.8 | 1.5 | 1.6 |
| Synonym inconsist. | 3.7 | 3.3 | 3.0 | 3.2 | 2.0 | 2.4 | 2.9 | 2.3 |
| Grat. divergence | 7.8 | 8.4 | 7.7 | 6.6 | 8.6 | 9.6 | 6.5 | 7.2 |
| Judgements (count) | 1393 | 1471 | 1537 | 1481 | 1127 | 1057 | 1300 | 1179 |

Table 21: Distribution of the consistency-judge labels on PARANLP, per system (Ll.: Llama, Qw.: Qwen, E9/E22: Euro9/Euro22) and prompting condition (percentage of that system's Q2 judgements; last row: absolute counts). The first four labels are coherent (JUSTIFIED), the last three inconsistent (UNJUSTIFIED). 'register' was never chosen; 'facet' and 'avoid repetition' are grouped under "Other coherent"; rare out-of-registry answers are counted with gratuitous divergence.

Table 21 details, per system and prompting condition, the distribution of the consistency-judge labels on PARANLP behind the analysis of §5.4.

## J Judgement Counts and Cost

A *unique judgement* is one judge prompt actually sent to the LLM. Three mechanisms keep this number low: deterministic shortcuts skip cases that need no judge, Q1 propagation lets identical translations of the same source form share one judgement, and a cache serves identical prompts, so repeated runs add no calls. With `gpt-4.1-mini` at list price, evaluating BioMQM-Terms took about 12,000 judgements (about $6),

the eight IWSLT23 outputs about 6,500 (about $7) and the eight PARANLP outputs about 46,000 (about $50). STEP is the exception: for the validation of §4.2 it deliberately runs the exhaustive path with no shortcut, so its 3,377 occurrences (one system) yield about 3,700 judgements. For comparison, glossary-conformity metrics issue no LLM call, neural QE needs one GPU inference per segment, and GEMBA-MQM issued about 4,500 calls to `gpt-4o-mini` on BioMQM-Terms, for about $2.

## K LLM Prompts

All prompts are templated with Python `str.format` placeholders (in braces) populated at runtime. The domain name is injected per corpus through the {domain} placeholder, which presents the term under judgement as belonging to that domain (e.g., "in the biomedical domain"); the context blocks ({concept_block}, {preceding_segments}, {prior_renderings}, {discourse_context}, {concept_renderings}) are built per occurrence, the preceding-segment block holding the five preceding aligned segment pairs. Each judge receives a fixed system message identifying its role, and answers with a JSON object whose `justification` field precedes the label, so that the label must follow from the stated reasoning. Decoding is at temperature 0 with a content-addressed cache, so runs are deterministic for a given model version and prompts. The hapax judgements reuse the Q1 prompt verbatim (§3.2).

### K.1 Q1: Error Judgement

```
You are judging how a machine-translation system rendered ONE specialised source term, from English
    into French in the {domain} domain. The question is ABSOLUTE: is the target a valid, domain-
    appropriate rendering of this source term? Decide whether it is an ERROR (one label below) or
    acceptable (no_error).

EVERY alignment is judged here, including those whose target matches the rendering already used in
    this document. Such a match is not by itself proof of correctness  it may simply repeat the
    system's own output. Judge the target itself.

Error typology  answer with exactly ONE label. The first seven labels distinguish fine-grained
    mechanisms of wrong equivalent selection; the following six each group several related
    mechanisms.
- wrong_related_term : the target is a term that exists in the {domain} domain but denotes a
    neighbouring concept, not the one named by the English term (e.g. for "tremor" the MT output "
    tremblement de terre" names a different concept, the earthquake; expected: "trémor"). Not this
    label: if the target is not a domain term at all, see general_word_not_term or invented_calque.
- paraphrase_not_term : the target replaces the established term with a descriptive multi-word
    paraphrase in general language (e.g. for "lithospheric mantle" the MT output "couche profonde
    sous la croûte terrestre" is a description, not the term; expected: "manteau lithosphérique").
- invented_calque : the target is a literal creation of the system that is neither an attested term
    of the {domain} domain nor a general-language expression in French (e.g. for "earthquake swarm"
    the MT output "sillage sismique" exists nowhere; expected: "essaim sismique").
- left_untranslated : the source term was left in English although an established French equivalent
    exists (e.g. for "megathrusts" the MT output "megathrusts" is untranslated; expected: "mé
    gachevauchements").
- dnt_violated : a Do-Not-Translate item (proper name, brand, gene or product code, standardised
    nomenclature symbol, acronym conventionally kept) was translated, or its letters were reordered/
    reworked (e.g. for "Yellowstone Caldera" the MT output "Caldeira de la Pierre Jaune" translates
    a proper name; expected: "Caldeira de Yellowstone"; for "MORB" the MT output "BDRM" reworks the
    acronym; expected: "MORB").
- wrong_component : one or more constituents of a multi-part term are lexically wrong while the
    others are correct, yielding a partially correct hybrid term (e.g. for "fault patches" the MT
    output "taches de faille" mistranslates "patches" while "faille" is right; expected: "zones de
    faille"). Not this label: if the whole target is a different attested domain term, that is
    wrong_related_term.
- general_word_not_term : a single general-language word used instead of the specialised term  unlike
     paraphrase_not_term, one lexical unit rather than a descriptive phrase (e.g. for "repeaters"
    the MT output "répétiteurs" is a general-language word with no terminological value; expected: "
    séismes répétitifs").
- misparsed_structure : the internal structure of the complex term or noun phrase is mis-analysed
    the head noun is misidentified (the head fixes the base category of the concept), a modifier is
    attached to the wrong constituent, or the constituents are ordered against French conventions (e.
    g. for "subduction-zone serpentinites" the MT output "zones de subduction constituées de
    serpentinite" makes the wrong noun the head; expected: "serpentinites en zone de subduction";
    for "slow earthquake" the MT output "lent séisme" has the wrong order; expected: "séisme lent").
- wrong_constituent_relation: the semantic relation between the term's constituents (often implicit
    in English) is rendered wrongly  a wrong linking relation or unfolding, a coordination misread,
    or a shared (factorised) constituent not distributed to all conjuncts (e.g. for "fast and slow
    events" the MT output "événements àla fois rapides et lents" misreads two distinct event types
    as simultaneous properties; expected: "événements rapides et lents"; for "pressure-solution and
    dislocation creep" the MT output "pression-solution et le glissement par dislocation" fails to
    distribute "creep" to both conjuncts; expected: "fluage par dissolution-précipitation et par
    dislocation").
```

```
- failed_transposition : the synthetic English structure is not transposed to the analytic French one
      a necessary explicitation (preposition, article, unfolding) is missing, or the English syntax
    is calqued although the words are attested (e.g. for "strike-slip and subduction thrust faults"
    the MT output "failles de décrochement et de chevauchement de subduction" lacks the needed
    explicitation; expected: "failles de décrochement et de chevauchement dans les zones de
    subduction"; for "SSEs" the MT output "SSEs" erroneously keeps the English plural mark; expected:
     "SSE", French sigles are invariable).
- grammar_phraseology : the term choice is right but the grammar or phraseology around it is wrong
    determiner or gender/number agreement, a missing or wrong preposition, a non-idiomatic
    collocation for the domain, or a spelling error (e.g. for "alkaline basalt" the MT output "la
    basalte alcalin" has the wrong gender; expected: "le basalte alcalin"; for "aseismic slip" the
    MT output "glissement aseismique" is a misspelling; expected: "glissement asismique"). Not this
    label: for "aseismic slip" the MT output "glissement asismique" is the correctly spelled
    attested term  that is no_error.
- content_altered : the content is altered  an element absent from the source term is added, one or
    more constituents (or the whole term) are omitted, or the output is unintelligible or unrelated
    to the source (e.g. for "fault creep" the MT output "glissement lent de la faille" adds "lent",
    absent from the source; expected: "fluage de faille"; for "earthquake ruptures" the MT output "
    ruptures d'éruptions" hallucinates an unrelated word; expected: "ruptures sismiques"). If the
    aligned target is (empty), the term was omitted, so use content_altered  unless the concept is
    conveyed elsewhere in the French segment, in which case no_error.
- defective_register_form : the meaning is right but the target-language expression is defective  the
     weighting or punctuation hierarchy of the constituents is mishandled, or the register is
    inappropriate for specialised discourse (e.g. for "earthquake ruptures" the MT output "ruptures
    de tremblements de terre" is correct in meaning but general-public in register; expected: "
    ruptures sismiques").
- no_error : the target conveys the same specialised concept correctly and idiomatically  the exact
    established term, an attested terminological synonym, a standard abbreviation or acronym, an
    accepted orthographic variant, a grammatical inflection, or an established domain loanword.
    Whether a correct-but-different choice is CONSISTENT with the rest of the document is decided in
     a separate later step, so do NOT judge consistency here.

How to decide (reason in this order, then output exactly one label):
1. Establish the expected French term yourself: the form attested for this concept in specialised {
    domain} usage (domain corpora, terminology databases, the field's literature). There is not
    necessarily a single mandatory form. Note that the expected form depends on the SOURCE FORM at
    hand: an acronym calls for the established acronym, not for the spelled-out head term.
2. Weigh the supporting sections below (concept, preceding segments, prior renderings) for what they
    are: support, never a verdict.
3. If the target conveys the concept correctly AND is itself an attested, idiomatic form of it, the
    answer is no_error  whether or not it coincides with the expected form.
4. Otherwise, locate where the defect lies and assign the SINGLE most specific label for it:
   - a wrong terminological equivalent was selected -> wrong_related_term / paraphrase_not_term /
       invented_calque / left_untranslated / dnt_violated / wrong_component / general_word_not_term;
   - the equivalents are right but the complex term / noun phrase is mis-structured (head, modifier
       attachment, constituent order) -> misparsed_structure;
   - the constituents are right but their semantic relation is wrong (linking, factorisation) ->
       wrong_constituent_relation;
   - the English structure is not transposed to French (missing explicitation, syntactic calque) ->
       failed_transposition;
   - the term is right but its grammar or phraseology in context is wrong (agreement, preposition,
       collocation, spelling) -> grammar_phraseology;
   - content is added, omitted, or hallucinated -> content_altered;
   - the meaning is right but the target-language expression or register is inappropriate ->
       defective_register_form.
   When a preposition or an unfolding is involved, separate the three by mechanism:
       wrong_constituent_relation = the semantic relation between constituents was misread;
       failed_transposition = the relation is understood but the compact English structure is kept
       untransposed; grammar_phraseology = the analysis is right and only the grammatical marking (
       agreement, preposition choice, spelling) is wrong.

{concept_block}{preceding_segments}{prior_renderings}Current segment (the one containing the pair
    under evaluation):
EN: {src_segment}
FR: {tgt_segment}

Aligned pair under evaluation:
- English term as it appears in the segment: "{src_form_raw}"
- French translation aligned by the system: "{tgt_aligned_raw}"
```

```
Return ONLY a JSON object with this exact schema, keys in this order, with no code fences and no text
      before or after  "justification" is your reasoning, and "label" must follow from it:
{{
  "justification": "<one short sentence: name the expected French form and locate the defect, or
       state why the target is a valid attested form>",
  "label": "<wrong_related_term|paraphrase_not_term|invented_calque|left_untranslated|dnt_violated|
       wrong_component|general_word_not_term|misparsed_structure|wrong_constituent_relation|
       failed_transposition|grammar_phraseology|content_altered|defective_register_form|no_error>"
}}
```

## K.2 Q2: Consistency Judgement

```
You are judging ONE occurrence of a specialised term in an English-to-French translation in the {
    domain} domain. The terminology has already been judged CORRECT by a previous step: do NOT re-
    judge whether the target denotes the right concept, and never report a terminology error here.

Your only question is DOCUMENT CONSISTENCY: given how this concept is rendered elsewhere in this
    document, is this rendering a coherent choice, or does it introduce an inconsistency? Answer
    from the document evidence below  no external reference is required, and none may be available.

Three things make a rendering NOT coherent:
1. NEUTRALISATION  the target erases a distinction the author made. The source document uses SEVERAL
    distinct forms for this concept (a head term and its variants), and this occurrence renders the
    present source form with the rendering that belongs to ANOTHER source form, collapsing two
    source distinctions into one French form (e.g. the source uses both "dynamic fault slip" and "
    dynamic slip", and both end up rendered "glissement dynamique": the distinction between the two
    source forms is erased). Check each source form's renderings in the evidence below. Exception:
    if the merged form is exactly the rendering the document has already established for this
    concept AND the distinction carries no function here, it is coherent  label synonym_merge.
2. SYNONYM INCONSISTENCY  the concept already has an established rendering in this document, and this
     occurrence switches to a DIFFERENT ADMITTED designation (the evidence line says whether the
    target is an admitted synonym) without doing any communicative work (e.g. the document has
    established "fluage de faille" for "fault creep", and this occurrence switches to "fluage de la
    faille" for no visible reason).
3. GRATUITOUS DIVERGENCE  same switch, but the divergent rendering is NOT an admitted synonym of the
    concept (it was judged a valid attested form in the previous step, yet it departs from both the
    document's established usage and the admitted designations) and no communicative work justifies
    the departure.

A rendering IS coherent when it repeats the document's established form, or when the divergence does
    genuine communicative work from this closed list  the need must be visible in the current
    segment itself; do not use these labels as default excuses:
- introduction : first mention of the concept in the document; no rendering is established yet, so
    there is nothing to be inconsistent with.
- explicitation : first mention, and the rendering expands or clarifies the term (e.g. unfolds an
    acronym, adds the head noun).
- avoid_repetition : the established rendering already occurs in the SAME sentence, so repeating it
    would be stylistically heavy. Proximity in the same sentence is required  occurrences in earlier
     segments do NOT justify this label.
- document_usage : the target repeats the rendering already established in this document for this
    source form.
- register : the current passage itself visibly calls for a different register (e.g. a quoted passage
    , a glossary definition, an explicitly popularising aside).
- facet : the divergent rendering highlights a facet of the concept that the current segment
    explicitly thematises.
- synonym_merge : the neutralisation exception defined above  in particular when the source forms
    differ only by a syntactic reordering or trivial variation that French cannot reproduce (e.g. "
    loading rate" and "rate of loading" can only both be rendered "taux de chargement": the merge is
     forced by the language, not a system choice).
Length or fluency alone is NOT communicative work.

If this is the FIRST mention of the concept and no rendering is yet established (the evidence line
    says so), the choice is coherent: label introduction, or explicitation if it expands the term.

How to decide (reason in this order, then output exactly one label):
1. If this is the first mention -> introduction or explicitation. Stop.
2. Compare the target with the renderings already established for THIS source form. If identical to
    the DOMINANT rendering (marked in the evidence) -> document_usage. Stop. If identical only to a
    MINORITY prior rendering, this is not self-justifying  an inconsistency repeated is still an
    inconsistency; continue to steps 3-4.
3. If the target matches the rendering established for ANOTHER source form of this concept ->
    neutralisation, unless the synonym_merge exception applies; name in the justification the other
    source form whose rendering this occurrence reproduces.
4. Otherwise the target diverges from the established usage: if the current segment visibly justifies
     it (closed list above) -> that coherent label; if not, check the target against the French
    glossary designations in the Concept line: listed -> synonym_inconsistency; not listed ->
    gratuitous_divergence. If the Concept line says the concept has no glossary entry, the admitted/
    gratuitous distinction cannot be made: use synonym_inconsistency  the previous step already
    validated the rendering as an attested designation of this concept.
```

```
CAUTION: the document renderings below are THIS SAME SYSTEM's earlier outputs. They show what the
     document has established in practice  which is exactly what consistency is measured against  but
      they are not proof of correct French.

{discourse_context}{concept_renderings}Current segment (the one containing the occurrence under
     evaluation):
EN: {src_segment}
FR: {tgt_segment}

Occurrence under evaluation:
- English source form as it appears: "{src_form_raw}"
- Is this source form the concept's head term or a variant? {head_or_variant}
- French translation aligned by the system: "{tgt_aligned_raw}"
- {concept_glossary_line}
- Is the target one of the French glossary designations above? {is_glossary_designation}
- Is this the first mention of the concept in the document? {is_first_mention}

Return ONLY a JSON object with this exact schema, keys in this order, with no code fences and no text
      before or after  "justification" is your reasoning, and "label" must follow from it:
{{
  "justification": "<one short sentence: name the document's established rendering and state why this
       occurrence is coherent with it or diverges from it; for neutralisation, name the other source
       form whose rendering is reproduced>",
  "label": "<introduction|explicitation|avoid_repetition|document_usage|register|facet|synonym_merge|
      neutralisation|synonym_inconsistency|gratuitous_divergence>"
}}
```

### K.3 Reference Selection

Used by the `validated` cascade when an LLM must select among observed candidate translations (§3.2).

```
You are given one English specialised source term in the {domain} domain and the French translations
    observed for it across several machine-translation systems in a single document. Pick the best
    reference translation: the single French form a professional translator of this domain would use
     consistently for this term in this document. It becomes the anchor against which every system's
     translation of this term is judged.

Selection rules, in order:
1. Prefer the glossary candidate (the line tagged "glossary:") when there is one, unless it clearly
    renders a different sense of the term than the sense used in this document. A glossary candidate
     is shown only for a head term; a variant source form has none.
2. Otherwise prefer the most idiomatic, terminologically appropriate French form. An established
    concise term beats a longer explanatory paraphrase; never prefer a form merely because it is
    longer.
3. Tie-break: higher observed count; if still tied, the one appearing first (candidate list first,
    then observed translations top to bottom).

The chosen reference MUST be one of the French forms displayed below. Never invent, correct,
    translate back, or rephrase a form. Copy it exactly, WITHOUT the surrounding quotes and WITHOUT
    the strategy tag.

In the two lists below, each form is wrapped in quotes; a candidate line is additionally prefixed by
    a strategy tag ("glossary", "frequency" or "first"). The quotes and the tag are display
    formatting and must not be copied into your answer; the tag only tells you where a candidate
    came from (Rule 1 uses it to spot the glossary candidate). A prefLabel shown as "(unknown)", or
    a list shown as "(none)", is unavailable.

<examples>
Illustrative of the decision types (they may be from a different domain than the item you decide).
    Each example shows the same fields as the item you will decide. Base each decision only on the
    fields shown.

<example>
Term and document:
- English source term: seismic hazard
- Glossary concept (English prefLabel): seismic hazard
- Document: doc3
Candidate references (each line: "- <strategy>: <French form in quotes>"):
  - glossary: "aléa sismique"
  - frequency: "risque sismique"
  - first: "risque sismique"
Observed French translations in this document (each line: "- <French form in quotes> ×<count>"):
  - "risque sismique" ×2
  - "aléa sismique" ×1
{{
  "reference": "aléa sismique",
  "justification": "Rule 1 prefers the glossary candidate 'aléa sismique', the domain-standard term,
      over the more frequent 'risque sismique'."
}}
</example>

<example>
Term and document:
- English source term: stress
- Glossary concept (English prefLabel): stress
- Document: doc9
Candidate references (each line: "- <strategy>: <French form in quotes>"):
  - glossary: "stress"
  - frequency: "contrainte"
  - first: "contrainte"
Observed French translations in this document (each line: "- <French form in quotes> ×<count>"):
  - "contrainte" ×4
  - "stress" ×1
{{
  "reference": "contrainte",
  "justification": "Rule 1 exception: the glossary form 'stress' fits the psychological sense, but
      this document uses the mechanical sense, whose established term is 'contrainte'."
}}
```

```
</example>

<example>
Term and document:
- English source term: crust-mantle boundary
- Glossary concept (English prefLabel): Moho
- Document: doc5
Candidate references (each line: "- <strategy>: <French form in quotes>"):
  - frequency: "limite entre la croûte et le manteau"
  - first: "limite entre la croûte et le manteau"
Observed French translations in this document (each line: "- <French form in quotes> ×<count>"):
  - "limite entre la croûte et le manteau" ×3
  - "limite croûte-manteau" ×2
{{
  "reference": "limite croûte-manteau",
  "justification": "No glossary candidate; rule 2 prefers the concise compound term 'limite croûte-
      manteau' over the longer paraphrase, even though the paraphrase is more frequent."
}}
</example>

<example>
Term and document:
- English source term: very-low-frequency earthquakes
- Glossary concept (English prefLabel): (unknown)
- Document: doc1
Candidate references (each line: "- <strategy>: <French form in quotes>"):
  - frequency: "séismes de très basse fréquence"
  - first: "séismes de très basse fréquence"
Observed French translations in this document (each line: "- <French form in quotes> ×<count>"):
  - "séismes de très basse fréquence" ×2
  - "séismes àtrès basse fréquence" ×2
{{
  "reference": "séismes de très basse fréquence",
  "justification": "'de' and 'à' are both attested and equally idiomatic here and the two forms tie
      on count, so rule 3 keeps the one appearing first."
}}
</example>

<example>
Term and document:
- English source term: SEM
- Glossary concept (English prefLabel): scanning electron microscope
- Document: doc8
Candidate references (each line: "- <strategy>: <French form in quotes>"):
  - frequency: "microscopie électronique àbalayage"
  - first: "microscopie électronique àbalayage"
Observed French translations in this document (each line: "- <French form in quotes> ×<count>"):
  - "microscopie électronique àbalayage" ×2
  - "MEB" ×1
{{
  "reference": "MEB",
  "justification": "No glossary candidate; rule 2 prefers the established concise acronym 'MEB' over
      its longer spelled-out form, even though the spelled-out form is more frequent."
}}
</example>
</examples>

Term and document:

  "reference": "<the chosen French form, copied exactly, no surrounding quotes, no strategy tag>",
  "justification": "<one short sentence giving the decisive reason>"
```

```
}}
```

### K.4 Reference Generation

Used by the `validated` cascade when a vetted heuristic reference is rejected and a reference must be produced from source-side evidence only (§3.2).

```
You are given a specialised concept in the {domain} domain and ONE English source term that
    designates it. Produce the French term expected for THIS source term: the term a professional
    translator of this domain would use for it, consistently, in a document. It must be an
    ESTABLISHED French term, not a plausible invention; it will serve as a candidate reference
    against which MT systems are judged.

# Source variation category

The "Source variation category" tells you how the source term relates to the concept's HEAD TERM: it
    is the variation that turns the head term into this source form (both in English). If the source
     term IS the head term, the category is "none". Treat it as an AID to find the right French
    reference, not as a constraint: the reference need not mirror the same kind of variation in
    French. It hints at what the source term is (an acronym, a reduction, a synonym...) so you
    produce the French form actually established for it; established usage always decides.

- none : the source term is the head term itself.
- graphical variation : same content, different written form  acronym or abbreviation (World Health
    Organization / WHO), symbol (lead / Pb), spelling or hyphenation (trademark / trade mark).
- reduction : a shortened form  element deleted (airborne dust particle / airborne dust) or an
    extension dropped (post-authorisation safety study / post-authorisation study).
- expansion : elements added  an explicit feature, a lexical insertion, or the spelled-out form of an
     abbreviation (redox / oxidation-reduction).
- lexical variation : a different lexical designation of the same concept  synonym, quasi-synonym, or
     attested translation (stress / constraint).
- morphosyntactic variation : structure or inflection change  constituent order, article, inflection,
     derivation (employment contract / contract of employment).
- composite form : several of the above combined; apply the reasoning of each component change.

# Rules

1. Let the variation category guide you toward the French designation actually established for this
    source term. Often the established French form is of the same kind (an acronym stays an acronym,
     a reduction stays a reduction), but not always: established usage decides, never a mechanical
    derivation from the category.

2. Acronyms and abbreviations (category "graphical variation", or "expansion" when the source form is
     the spelled-out expansion of one). The correct French form depends on how the HEAD TERM is
    translated into French. Decide among three moves:
   (a) Invert the acronym  when the concept is translated into French and that French term has an
       established French acronym, give the FRENCH acronym. E.g. WHO -> OMS (Organisation mondiale de
        la santé); emergency contraception (EC) -> contraception d'urgence (CU); DNA -> ADN.
   (b) Keep the source acronym as-is  when the field uses the English acronym unchanged in French. E.
       g. PCR, BERT, GPT, LLM.
   (c) Spell it out (rare)  when neither a French acronym nor the borrowed source acronym is used,
       give the developed French form. E.g. ASAP -> dès que possible.
   Do NOT assume French spells the term out by default. Your "reference" must match your reasoning:
       if you conclude the source acronym is used as-is, return that acronym.

3. Keep the reference's SCOPE identical to the source term: add no word it does not contain, drop
    none it does.

4. For a lexical variation, give the established French term proper to THAT synonym, not the French
    head term.

5. If French keeps a non-acronym source form unchanged (a proper name, a do-not-translate item),
    return it unchanged.

6. Do NOT invent. For a non-acronym form, if no established French designation exists and you are not
     confident, set "generatable" to false. For an acronym, keep the source acronym (rule 2b)
    instead of declining.

7. Return the reference in canonical form: lemma (singular unless the term is inherently plural),
    lowercase except proper nouns and acronyms, no surrounding quotes.

# Examples
```

```
Each example shows the same fields as the Data block below, then the expected JSON. The examples are
    illustrative only: NEVER assume the current term behaves like an example it superficially
    resembles; established usage for THIS term decides.

Example 1
- English source form: WHO
- Source variation category: graphical variation
- Concept head term (English): World Health Organization
- Concept established French term (head term), if known: Organisation mondiale de la santé
=> {{"justification": "Acronym inverted: the concept is translated and has an established French
    acronym.", "generatable": true, "reference": "OMS", "confidence": "high"}}

Example 2
- English source form: PCR
- Source variation category: graphical variation
- Concept head term (English): polymerase chain reaction
- Concept established French term (head term), if known: réaction en chaîne par polymérase
=> {{"justification": "Acronym kept as-is: standard French usage borrows PCR unchanged.", "
    generatable": true, "reference": "PCR", "confidence": "high"}}

Example 3
- English source form: oxidation-reduction
- Source variation category: expansion
- Concept head term (English): redox
- Concept established French term (head term), if known: redox
=> {{"justification": "Expansion of an abbreviation: the spelled-out French form of «redox ».", "
    generatable": true, "reference": "oxydoréduction", "confidence": "high"}}

Example 4
- English source form: abiotic constraint
- Source variation category: lexical variation
- Concept head term (English): abiotic stress
- Concept established French term (head term), if known: stress abiotique
=> {{"justification": "Lexical variation: French equivalent of the synonym, not of the head term.", "
    generatable": true, "reference": "contrainte abiotique", "confidence": "medium"}}

Example 5
- English source form: post-authorisation study
- Source variation category: reduction
- Concept head term (English): post-authorisation safety study
- Concept established French term (head term), if known: étude de sécurité post-autorisation
=> {{"justification": "Reduction: the French head term with the dropped element ('sécurité') removed
    .", "generatable": true, "reference": "étude post-autorisation", "confidence": "medium"}}

# Data

- English source form: {src_form}

# *BaatCheet:* A Multilingual Corpus for Dialogue Translation in Indian Languages

**Priyanka Dasari***, **Yuvrajsinh D. Bodana***, **Vandan Mujadia**, **Arafat Ahsan**, **Dipti Misra Sharma**, **Parameswari Krishnamurthy**

*Language Technologies Research Centre, IIIT Hyderabad, India*

{dasari.priyanka,yuvrajsinh.bodana}@research.iiit.ac.in, vmujadia@gmail.com, {arafat.ahsan,dipti,param.krishna}@iiit.ac.in

## Abstract

Existing translation models are typically trained on sentence-level and formal text, limiting their ability to capture everyday conversational dialogue phenomena such as informality, speaker interaction, and discourse coherence. Most existing Indic translation resources and evaluation benchmarks focus on sentence-level or formal text, making it difficult to assess translation quality of the dialogue phenomena. In this work, we introduce *BaatCheet*, a multilingual dialogue corpus named after the Hindi term for *conversation* or *chitchat*, containing approximately 49,000 dialogues for dialogue translation across five translation directions. We fine-tune five open-source LLMs across seven training data configurations and find that fine-tuning yields substantial gains over zero- and few-shot baselines. To comprehensively evaluate dialogue translation quality, we employ multiple evaluation strategies, including automatic metrics, LLM-as-judge, and human assessments using an SQM-guided Direct Assessment (DA) Protocol. The dataset is available here[1].

## 1 Introduction

*Dialogue* is a fundamental mode of human communication through which individuals express emotions, intentions, and maintain social relationships (Gumperz, 1982; Halliday, 1987). In the sociolinguistic context of the Indian subcontinent, these interactions are predominantly multi-turn and informal, often involving dynamic code-mixing between regional and global languages. Such dialogues diverge from formal written text, which exhibits fragmented syntax, elliptical structures, and heavy use of colloquial expressions that reflect the spontaneity of natural speech. With the growing need for cross-lingual communication in multilingual societies like India, machine translation (MT) has become pivotal in bridging language barriers. Most existing MT systems are primarily trained on formal, sentence-level parallel corpora derived from news and governance domains (Koehn, 2005; Mujadia and Sharma, 2025). Such systems often struggle to preserve the pragmatic and contextual nuances inherent in natural conversation (Sung et al., 2024) and this gap persists even for LLM-based translation systems (Choudhary et al., 2025), a trend our own baseline evaluation reaffirms for informal Indic dialogue (§3.2).

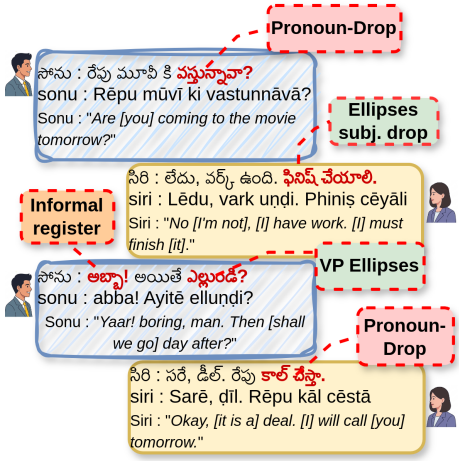

Figure 1: Highlighting Linguistic phenomena in informal Telugu dialogue. Dashed boxes highlight examples of pro-drop, ellipses, and register-specific informal expressions in a sample conversation.

To illustrate these challenges, we present a sample dialogue in Telugu, a major Dravidian language[2], in Figure 1. Unlike the formal datasets commonly used in MT research, this spontaneous conversation is replete with code-mix, pro-drop (where both subjects and objects are null) and contextual ellipsis, where utterances like 'No' (lēdu) and 'Then day after?' (ayitē elluṇḍi?) carry a

*Authors contributed equally.

[1]https://huggingface.co/datasets/HimangY/BaatCheet-Corpus

[2]Throughout this paper we use *Indic* as an umbrella term for the languages of the Indian subcontinent covered in our corpus, spanning both the Indo-Aryan (e.g., Hindi, Gujarati) and Dravidian (e.g., Tamil, Telugu) language families; we use *Dravidian* specifically when referring to that family.

*Proceedings of the Eleventh Conference on Machine Translation*, pages 116–145

high semantic load that is only recoverable through multi-turn reasoning.

For example, a major challenge in dialogue translation is the encoding of social relationships through honorific pronouns. Unlike English, which uses a single second-person pronoun *you* across all social contexts, Indian languages grammaticalize social distance and respect, directly distinguishing formal and informal pronouns. These distinctions carry pragmatic weight that MT systems routinely collapse (Hingrajiya et al., 2026). This limitation is highly consequential in high-stakes applications (e.g., healthcare, customer support, and travel assistance), where misinterpreting register or speaker intent can degrade communication. To evaluate these phenomena, sentence-level parallel test sets exist for Indic languages (Team et al., 2022), but no dialogue-level test set is available for evaluating informal dialogue translation.

We address this gap by introducing **BaatCheet**, named after the Hindi term for *conversation* or *chitchat*, a multilingual corpus for informal dialogue translation spanning English, Hindi, Tamil, and Telugu. It is built from combining existing dialogue resources and synthetically generated dialogues, as illustrated in Figure 2. The dataset consists of two primary components: (i) **BaatCheet_Gold**, containing gold-standard human translations split into *BaatCheet_Human_Train* and a *BaatCheet_Test*; and (ii) **BaatCheet_Synthetic**, comprising two training subsets: *BaatCheet_Syn_X2IL*- a set whose monolingual dialogue data was collected and created in source languages and translated into target languages and *BaatCheet_Syn_IL2X* whose monolingual dialogue data was collected and created in target languages and those were translated into source languages and column swapped to make it source to target parallel data for fine-tuning purpose.

Using this corpus, we fine-tune five open-source LLMs across seven training data configurations spanning synthetic-only, human-only, and hybrid compositions to study how data provenance, scale, and quality interact with model capacity. To evaluate translation quality beyond automatic metrics, we conduct human and LLM-as-a-judge evaluations using the SQM-guided DA framework (Bojar et al., 2017; Perrella et al., 2024).

The primary contributions of this work are as follows:

1. ***BaatCheet***: A multilingual dialogue corpus for English → {Hindi, Telugu, Tamil} and Hindi → {Telugu, Tamil} featuring human translations and synthetically generated dialogues.
2. ***BaatCheet_Gold***: A curated gold-standard testset for evaluating informal dialogue machine translation in Indic languages.
3. A structured data creation pipeline employing automatic metric-guided quality selection for high-quality synthetic training corpus curation.
4. A fine-tuning study of five open-source LLMs across multiple data configurations, tailored for informal dialogue translation.
5. A large-scale human and LLM-as-judge evaluation using SQM-guided DA establishing the reliability of automatic and LLM-based assessment for this task.

Specifically, our work addresses the following key research questions:

- **RQ1:** How well do existing open-source LLMs, dedicated MT systems, and proprietary LLMs translate informal dialogues into Indic languages?
- **RQ2:** How do the two synthetic data axes, *BaatCheet_Syn_X2IL* and *BaatCheet_Syn_IL2X*, differ in their effect on fine-tuned dialogue translation quality?
- **RQ3:** How well do automatic metrics, and LLM-based judges agree with human assessment of informal dialogue translation?

## 2 Related work

Early research on document and dialogue-level machine translation focused on incorporating broader discourse history to improve translation coherence (Maruf et al., 2021). Traditional approaches leveraged source and target-side conversational history to model multi-speaker dynamics (Maruf et al., 2018), or integrated extra-textual speaker identity cues to improve personalized translation (Vincent, 2021). The emergence of multilingual Large Language Models (LLMs) has further advanced this domain by enabling zero-shot context handling (Zhang et al., 2023) and generating high-quality synthetic parallel text to address low-resource gaps (Jiao et al., 2023).

Another line of work focuses on constructing dialogue datasets to support conversational machine translation research. The DailyDialog dataset (Li et al., 2017) provides a widely used multi-turn conversational dataset containing human-written ev-

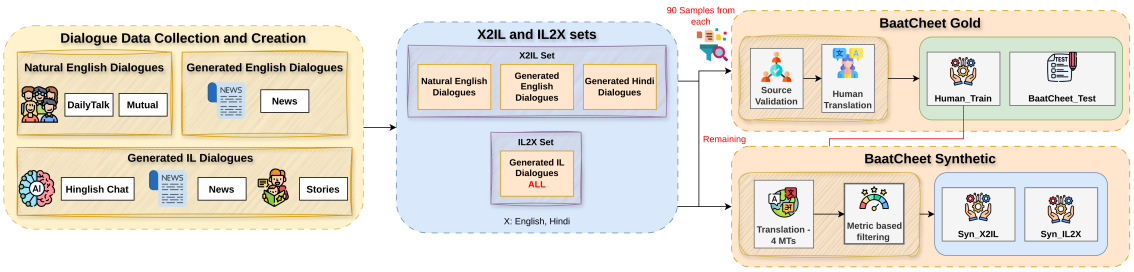

Figure 2: A flowchart of the BaatCheet Corpora preparation process for training and evaluation. The Metric-based methodology for selecting high-quality synthetic is detailed in Section 3.3.

eryday dialogues. Subtitle-based resources such as OpenSubtitles (Lison and Tiedemann, 2016) have also been used extensively for training conversational translation systems. (Wang et al., 2016) proposed methods to automatically construct parallel dialogue corpora by aligning subtitle data with monolingual scripts while preserving speaker and discourse information. More recently, (Majewska et al., 2023) introduced an outline-based approach for generating multilingual dialogue datasets, while (Bawden et al., 2021) developed the *DiaBLa* English–French corpus of informal written dialogues specifically designed, for evaluating context-aware machine translation systems. Additionally, IndicDialogue (Arnob et al., 2024) provides subtitle-based dialogue corpora across multiple Indic languages.

For Indic languages, benchmarks like FLORES-200 (Team et al., 2022) and the conversational subset IN22-Conv (Gala et al., 2023) evaluate translation across standard formal registers.

However, many of these datasets focus primarily on sentence-level translation or subtitle-style dialogues and often lack the informal conversational structures, and code-mixed characteristics that are common in real-world multilingual conversations across Indian languages. Standard reference-based metrics like BLEU and sentence-level COMET (Rei et al., 2022) often fail to capture dialogue-level coherence and register fidelity. Recent advances introduce context-aware metrics like DOC-COMET (Vernikos et al., 2022) alongside LLM-as-a-Judge frameworks for qualitative assessment (Zheng et al., 2023).

## 3 Building BaatCheet Corpora

*BaatCheet Corpora* is a multilingual dialogue corpus spanning English, Hindi, Tamil, and Telugu, designed to support training and evaluation of LLMs and MT systems for informal dialogue. In total, the corpus comprises approximately 49,000 dialogues, 383,000 utterances, and 690,500 sentences, organized into two major components: (i) *BaatCheet_Synthetic*, a large-scale machine-translated corpus subdivided into *BaatCheet_Syn_X2IL* and *BaatCheet_Syn_IL2X*; and (ii) *BaatCheet_Gold*, a human-translated set subdivided into *BaatCheet_Human_Train* and *BaatCheet_Test*.

**Data Sources.** The corpus draws on three categories of dialogue sources spanning all four languages: **(i) Natural English Dialogues:** *DailyTalk* (Lee et al., 2022), and *MuTual* (Cui et al., 2020) are human-authored two-speaker daily conversational corpora. **(ii) Generated English Dialogues:** *News-Eng**[3], informal dialogues generated using GPT-4o-mini from English news articles. **(iii) Generated IL Dialogues:** *Hinglish-Chat* (Khatri, 2024), an existing LLM-generated dialogue dataset subsequently refined via prompting to reduce robotic phrasing and improve conversational fluency; and *News-Hin**, dialogues generated from Hindi news articles, *News-Tam**, *News-Tel** and *Story-Tam**, *Story-Tel** dialogues generated from Tamil and Telugu news articles and short stories, respectively. A full description of each data source, including generation prompts and language coverage, is provided in Table 5 (Appendix C).

**Human Validation of Generated Dialogues.** Large Language Models often generate synthetically fluent text that may suffer from contextual pronoun mismatches, rigid/overly formal phrasing, or awkward code-mixing. To address this, native speakers validated and edited a small sample of LLM-generated dialogues, which comprise both BaatCheet_Gold source dialogues (Eng-src: News-Eng and Hin-src: Hinglish, News-Hin) and other generated dialogue sources across all lan-

[3]All * datasources are generated dialogues with GPT-4o-mini

guages. Across 344 dialogues containing 4,487 turns, 71.80% of dialogues required at least one human intervention, with 37.24% of overall individual turns modified. Table 6 (Appendix C.1) detailed analysis along with TER and CER.

### 3.1 BaatCheet_Gold

**Dialogue Sampling.** For English source dialogues, we stratify a sample 90 dialogues each from *DailyTalk*, *MuTual*, and *News-Eng**. For Hindi, 90 dialogues each are sampled from *Hinglish-Chat* and *News-Hin**. From each source, dialogues are partitioned into *BaatCheet_Human_Train* and *BaatCheet_Test*.

1. ***BaatCheet_Human_Train***: Used both as the reference set for Automatic metric-guided quality selection to identify the highest-quality translations for curating the synthetic training corpus, i.e., *BaatCheet_Synthetic* (detailed in section 3.3), and as gold training data for fine-tuning our selected translation models.
2. ***BaatCheet_Test***: Reserved exclusively as a held-out evaluation set for all translation experiments.

These validated BaatCheet_Gold source dialogues are human-translated by our inhouse translators. Translation guidelines, quality review processes, and detailed source validation metrics are described in Appendix C.4.

### 3.2 Baselines Evaluation on BaatCheet_Human_Train

With our established human-translated *BaatCheet_Human_Train* reference set, we conduct a systematic evaluation of existing MT systems and open-source and proprietary LLMs on informal Indic dialogue translation across our target directions (Eng → IL and Hin → IL). This evaluation serves a dual purpose: to test current models' capability on informal dialogue, and to identify which systems produce translations of sufficient quality to serve as candidate MT engines for large-scale synthetic data generation.

We evaluate nine systems on *BaatCheet_Human_Train* using reference-based COMET and reference-free COMET-QE across three categories: (i) five open-source LLMs (*Llama-3.1-8B-Instruct*[4] (Meta, 2024), *Llama-3.2-3B-Instruct*[5], *Qwen3-4B-Instruct*[6] (Team, 2025), *Gemma3-4B-IT*[7] (Team et al., 2025), and *Sarvam-Translate* [8].); (ii) three dedicated MT systems (*Google Translate* (GMT)[9], *IndicTrans2* (Gala et al., 2023), and *BhashaVerse*(Mujadia and Sharma, 2025) [10]); and (iii) one proprietary LLM (*GPT-4o-mini* (Jiao et al., 2023)).

Figure 3 reports scores across all five language directions. The three dedicated MT systems alongside *GPT-4o-mini* consistently outperform among all models under both metrics (ref-based avg. 0.803–0.848; ref-free avg. 0.823–0.857). Among open-sourced LLMs, *Gemma3-4B* and *Sarvam-Translate* are the strongest, while *Qwen3-4B* and *Llama-3.2-3B* score lowest (avg. below 0.54 and 0.59 respectively). These results reveal a clear quality gap between established MT systems and open-source LLMs for informal Indic dialogue translation, motivating our approach of using the four top-performing systems to generate large-scale synthetic training data, and subsequently fine-tuning the five open-source LLMs on this curated corpus to evaluate whether the gap can be closed.

### 3.3 BaatCheet_Synthetic Curation Pipeline

**Synthetic Dialogue Sources.** To enrich training data diversity and mitigate MT-bias on the Indic target side, we curate synthetic dialogues along two translation axes, as illustrated in Figure 2.

1. **Syn_X2IL:** Comprises English source dialogues *DailyTalk*, *MuTual*) and *News-Eng** machine-translated into Hindi, Tamil, and Telugu; and Hindi source dialogues *Hinglish-Chat*, *News-Hin** are machine-translated into Tamil and Telugu.
2. **Syn_IL2X:** Comprises Tamil dialogues (*News-Tam**, *Story-Tam**) and Telugu dialogues (*News-Tel**, *Story-Tel**), machine-translated into English and Hindi; and Hindi dialogues (*Hinglish-Chat*, *News-Hin**) machine-translated into English. All resulting pairs are column-swapped to align with our target language pair direction X→IL (English, Hindi to IL) training direction while fine-tuning our selected open-sourced LLMs, ensuring that the Indic target side in

[10]https://ssmt.iiit.ac.in/translatev3

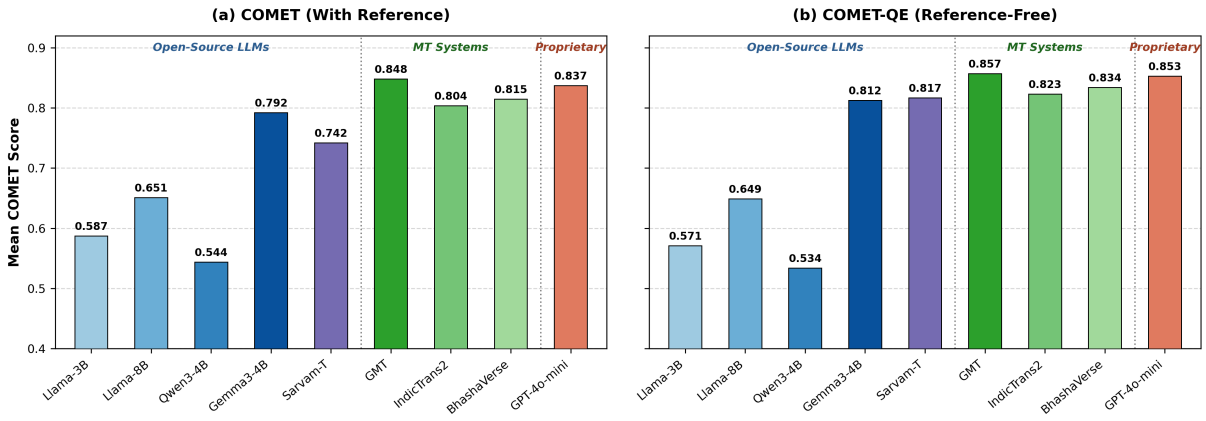

Figure 3: Baseline performance comparison across nine candidate systems on *BaatCheet_Human_Train* using (a)reference-based COMET and (b)reference-free COMET-QE. Dedicated MT systems (*GMT*, *IndicTrans2*, *BhashaVerse*) and *GPT-4o-mini* consistently outperform open-source LLMs across all language directions.

Syn_IL2X comprises dialogues generated natively in Indic style, preserving informal dialogue characteristics rather than just MT-biased output.

**Selecting Candidate MT Systems.** Based on our baseline evaluation on BaatCheet_Human_Train (Section 3.2, Figure 3), the four top-performing systems, *Google Translate* (GMT), *GPT-4o-mini*, *IndicTrans2*, and *BhashaVerse* are selected as candidate MT outputs.

Each system independently translates all *BaatCheet_Human_Train* dialogues, producing four parallel candidate translations per source utterance across both directions, forming *Human_Train_X2IL* and *Human_Train_IL2X* candidate sets. Language-pair disaggregated COMET scores of all four MT engines on these candidate sets are provided in Appendix D.1.

**Automatic Metric Guided Quality Selection.** We apply utterance-level reference-based (COMET) and reference-free (COMET-QE) scoring on *Human_Train_X2IL* and *Human_Train_IL2X* candidate sets to select the highest-quality translation per utterance from the four candidates, comparing two selection strategies:

1. ***Utt-Avg* (Utterance-Average):** Selects the single MT system that achieves the highest average utterance score across an entire dialogue.
2. ***Utt-High* (Utterance-Highest):** Selects the highest-scoring candidate translation independently for every individual utterance within a dialogue.

Analysis of MT candidate selection counts (Appendix D.2) reveals that *GMT* and *GPT-4o-mini* are the most frequently selected engines under both strategies across all language directions.

**Validation of Selection Strategies and Human Alignment.** To determine which filtering strategy yields higher-quality translations on BaatCheet_Human_Train candidates, we compare Utt-Avg and Utt-High using DOC-COMET (Vernikos et al., 2022) and COMTAIL (Ahsan et al., 2025), plus a human binary preference study on 510 dialogues (255 per direction, X2IL and IL2X), where annotators chose between COMET-QE-curated Utt-Avg and Utt-High outputs. Both automatic metrics consistently favor Utt-High (Appendix D.3), while humans preferred Utt-Avg in 58% of dialogues (304/510) versus 42% for Utt-High. This divergence is smaller than it appears: in over 90% of dialogues, a single MT system contributes most utterances, so the two strategies select highly similar data. For example, in a 13-utterance dialogue (Appendix D.4), Utt-High independently picks GMT for 8 turns, and GMT is also the top engine under Utt-Avg's dialogue-level average (0.8697). The two strategies converge on the same dominant engine even though candidate scoring is done turn-by-turn versus dialogue-wide. Disagreement concentrates in the remaining $\sim$10%, where a dialogue-level average can be inflated by a few strong utterances that mask weaker ones (Appendix D.4). Since our downstream goal is SFT data where turn-level accuracy directly shapes model output, we prioritize Utt-High's guaranteed per-utterance quality

| BaatCheet Corpus | #Dialogues | #Utterances | #Sentences | | Avg Dlg Len | Avg Utt Len | | Avg Sent Len | |
|---|---|---|---|---|---|---|---|---|---|
| | | | Src | Tgt | | Src | Tgt | Src | Tgt |

| **TOTAL** | **49,412** | **392,253** | **702,264** | **702,705** | **13.0** | **16.0** | **13.0** | **8.8** | **7.2** |

Table 1: Overall statistics of the *BaatCheet* corpus across 4 splits.

floor over Utt-Avg's holistic stylistic consistency. We therefore adopt *Utt-High* for selecting the best-scoring translation at each turn via COMET-QE to construct *BaatCheet_Synthetic*.

**BaatCheet Corpus Overview.** Based on these findings, we curate the final *BaatCheet_Synthetic* dataset using reference-free COMET-QE under the *Utt-High* strategy. Table 1 summarizes *BaatCheet* across its four splits, comprising 49,412 dialogues, 392,253 utterances, and ∼702k sentences. Large-scale synthetic data includes Syn_X2IL (42.1k dialogues) and Syn_IL2X (6.1k dialogues) with native Indic targets to reduce MT bias for our target direction X → IL fine-tuning of models. Human-translated dialogue splits contain 510 dialogues in Human_Train and 658 held-out dialogues in BaatCheet_Test. Full breakdown appears in Table 7, Appendix C.2.

**Linguistics Properties.** Automatic language-ID tagging (Madhani et al., 2023) measures an average code-mixing rate of ∼20% across language pairs, although this is likely an underestimate because it relies on Roman-script detection and misses the pervasive practice of transliterating English words into native Indic scripts. The corpus also preserves *pro-drop* (null subjects/objects) and syntactic *ellipsis*, especially Tamil and Telugu permit subjects and objects to be omitted when recoverable from the discourse context, as illustrated in Figure 1. The translation challenge is not pro-drop itself, but correctly recovering omitted arguments when the target language requires explicit realization. Statistically evaluating this recovery is, however, not straightforward, as the Auto Pronoun Translation metric (APT (Miculicich Werlen and Popescu-Belis, 2017)) is designed for pro-drop-scarce European languages and is unreliable in conversational Indic settings where omission is grammatical rather than exceptional(Hingrajiya et al., 2026).

## 4 BaatCheet Experimental Setup

We select a structurally diverse suite of decoder-only instruction-tuned models: *Llama-3.1-8B-Instruct* (Meta, 2024), *Llama-3.2-3B-Instruct*, *Qwen3-4B-Instruct* (Team, 2025), *Gemma3-4B-IT* (Team et al., 2025), and *Sarvam-Translate* [11]. These models are chosen for their pre-training exposure to Indic languages, multilingual baselines, and optimized tokenizers for low-resource scripts.

To establish strong baselines for comparing zero-shot and few-shot translation performance against supervised fine-tuning, we evaluate all models on *BaatCheet_Test* under two settings:

- **Zero-Shot Baseline:** Models translate dialogue prompts directly without in-context examples.
- **Few-Shot Baseline:** Implemented an adaptive retrieval strategy to dynamically select the most contextually relevant in-context examples. Specifically, we generate dense embeddings for all dialogues in the *Human_Train* set using the `all-MiniLM-L6-v2` model, which are indexed using FAISS. For each test dialogue, we retrieve the top-$k$ mathematically closest context examples.

**Fine-Tuning Setup.** Models are loaded in 4-bit NormalFloat (NF4) quantized format using *bitsandbytes* (Dettmers et al., 2022) and trained using bfloat16 precision for numerical stability. The absolute context length is constrained to 4096 tokens. To prevent truncation of long, multi-turn dialogue contexts, we implement a *length-aware chunking* protocol: dialogues exceeding the maximum token budget are segmented into contiguous sub-dialogues, with each segment prefixed by a custom control token, `<splitted_dialogue>`, to preserve contextual and structural continuity. This chunking mechanism is applied identically during both training and inference. The training prompt template is shown in Appendix section E.2.

Table 2: Performance comparison of five open-source LLMs across fine-tuning configurations on *BaatCheet_Test*, evaluated using (a) COMET DA, (b) DOC-COMET, and (c) COMTAIL DA. `Syn_Both` denotes Syn_[X2IL+IL2X] and `HT` denotes Human_Train. Bold values indicate the best-performing data configuration for each respective model.

**Parameter-Efficient Fine-tuning.** We employ Parameter-Efficient Fine-Tuning (PEFT) leveraging QLoRA combined with Rank-Stabilized LoRA (rsLoRA) (Kalajdzievski, 2023). Specifically, rsLoRA enhances training stability across linguistically distinct target vocabularies by scaling the adapter updates with a factor proportional to $\alpha/\sqrt{r}$ (where $r$ denotes the LoRA rank and $\alpha$ is the scaling factor), rather than the traditional $\alpha/r$ scaling. LoRA adapter weights, particularly matrix A is Gaussian-initialized to encourage diverse feature representations and matrix B is initialized to zeros. The complete set of training hyperparameters is detailed Table 13 in the Appendix.

### 4.1 Training Data Configurations

To systematically investigate the effect of dataset composition on informal dialogue translation quality, we define seven configurations spanning five categories:

1. **Baselines:** The zero-shot and few-shot baseline performance of each model.
2. **Synthetic-Only:** Fine-tuning exclusively on each synthetic split (`Synt_X2IL` vs. `Synt_IL2X`) in isolation, to evaluate whether training on target-side machine translations (`Synt_X2IL`) versus column-swapped native Indic target text (`Synt_IL2X`) more effectively boosts fine-tuned translation performance.
3. **Human-Only:** Fine-tuning strictly on gold standard translation set- *Human_Train*.
4. **Dual-Hybrid:** Blending a single synthetic dialogue set with human gold standard - *Syn_X2IL +HT* and *Syn_IL2X +HT* to evaluate the complementary gain from combining machine-translated scale with human-translated dialogues.
5. **Multi-Hybrid:** Blending all synthetic dialogue sets - *Syn_X2IL* and *Syn_IL2X* with human translation sets at two scaling ratios: *Syn_Both +HT* and *Syn_Both + 3×HT* to assess whether increasing the proportion of human-translated data further improves translation quality at scale.

## 5 Results and Discussion

We evaluate five fine-tuned LLMs across all dataset configurations on *BaatCheet_Test* using three automatic metrics (Table 2). Detailed results across all five LLMs on all configurations are provided in the Appendix Section E.3.

### 5.1 Metric Behaviour.

**COMET** (Rei et al., 2022) scores are consistently the highest across all configurations (ranging 0.49–0.86). Being a sentence-level metric, COMET rewards local lexical and semantic adequacy per utterance independently, without modelling cross-turn discourse coherence.

**DOC-COMET** (Vernikos et al., 2022) scores are systematically lower (0.35–0.79), as it incorpo-

rates up to three preceding utterances as additional context signal. While this enables coarse dialogue-level coherence scoring, its limited context window is insufficient to capture long-range dependencies in multi-turn conversations. Consequently, translations that are locally fluent but contextually incoherent are penalized, resulting in lower overall scores compared to sentence-level COMET.

**COMTAIL** (Ahsan et al., 2025) produces the lowest scores overall (0.25–0.77). As an Indic- specialized metric, COMTAIL may be more sensitive to Indic language-specific imperfections in lexical choice, morphology, and domain register. However, since COMTAIL is primarily fine-tuned on formal sentence-level parallel data, it may lack calibration for informal dialogue registers, resulting in conservatively lower scores.

### 5.2 Training Data Configuration Observations

**Baselines.** Few-shot performance is consistently lower than zero-shot for most models (e.g., *Sarvam-T*: 0.6168 → 0.4859 COMET; *Gemma*: 0.4145 → 0.3755 DOC-COMET). We attribute this to two compounding issues: (i) retrieved in-context examples from *BaatCheet_Human_Train* may not align well in topic or register with test dialogues, introducing distributional noise into the prompt; and (ii) multi-turn dialogue examples significantly expand input length, leading to context window saturation and truncation of earlier dialogue history, forcing the model to translate with incomplete context.

**Synthetic-Only.** Fine-tuning on Syn_X2IL consistently outperforms Syn_IL2X across all models and metrics. In Syn_X2IL, the source side largely comprises naturally occurring dialogues (*DailyTalk*, *MuTual*, *Hinglish-Chat*) with machine-translated Indic targets (Section 3.3). In contrast, Syn_IL2X is entirely synthetic on both sides: its source (English/Hindi) is machine-translated output, while its Indic targets are *GPT-4o-mini*-generated dialogues which, despite being prompted for informal code-mixed style, lack the naturalistic register variation inherent in human-produced dialogues. Combined with its substantially smaller scale (6.1k vs. 42.1k dialogues), this fully synthetic construction limits the quality and diversity of the SFT signal in Syn_IL2X.

**Human-Only.** Despite comprising only 510 dialogues, *BaatCheet_Human_Train* alone achieves the highest COMET score for *Gemma3-4B* (0.832) and competitive results for *Sarvam* (0.832). Models with strong multilingual pre-training appear capable of efficiently leveraging small but high-quality human-translated corpora.

**Dual-Hybrid.** Syn_X2IL + Human_Train yields peak performance for three of five models: *Llama-3.2-3B* (0.765 COMET), *Sarvam* (0.857), and *Qwen* (0.806). Syn_IL2X + Human_Train, by contrast, consistently underperforms its counterpart across all models. Beyond the fully synthetic nature of Syn_IL2X, its substantially smaller volume fails to add meaningful linguistic diversity to *Human_Train* during SFT.

**Multi-Hybrid.** Syn_Both + 3 × Human_Train delivers peak scores for *Llama-3.1-8B* (COMET: 0.846, DOC-COMET: 0.793, COMTAIL: 0.756) and strong gains for *Qwen3-4B* (COMET: 0.829 vs. 0.770 with 1 × Human_Train). However, Syn_Both + 1 × Human_Train noticeably underperforms noticeably *hurts* these models relative to their Syn_X2IL + Human_Train dual-hybrid performance in Gemma, which we attribute to a *gold dilution effect*: the ∼48k combined synthetic volume overwhelms the 510-dialogue *Human_Train* set, exposing the model disproportionately to noisier synthetic signal. Tripling *Human_Train* (3×) restores the quality-to-volume ratio, providing sufficient human-translated exposure for larger-capacity models to calibrate towards authentic informal dialogue quality.

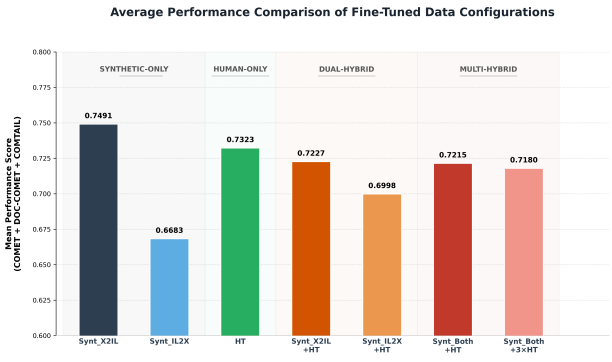

Figure 4: Average translation performance (mean score across all five fine-tuned models and three evaluation metrics: COMET, DOC-COMET, and COMTAIL) for each fine-tuned training configuration.

### 5.3 Comparative Analysis of Training Data Configurations

Table 3: Qualitative SQM-DA evaluation scores ($z$-score normalized and scaled) disaggregated by **Utterance-Level Accuracy** (Utt-level) and **Dialogue-Level Factors** (Dia-level): Naturalness (**Nat**), Informality (**Inf**), and Cohesion & Coherence (**Coh**). Evaluated across top-two data configurations per model by GPT-4o-mini, Gemini-Flash-Lite-preview, and Human Judges. Syn_Both denotes Syn_[X2IL+IL2X]. Bold text indicates the higher score per model setup.

compares the mean scores across all fine-tuning configurations (averaged across all models and evaluation metrics). Among all configurations, Synt_X2IL achieves the highest overall average score (**0.7491**), closely followed by the human-only baseline Gold (**0.7323**). Conversely, Synt_IL2X in isolation yields the lowest overall performance (**0.6683**), and incorporating it into hybrid setups consistently degrades overall translation quality compared to Synt_X2IL alone. Crucially, the responsiveness of each model to these data configurations is strongly governed by base architectural factors like model parameter capacity and pre-trained Indic linguistic knowledge.

### 5.4 Limitations of Automatic Metrics

While automatic metrics confirm substantial and consistent gains from our curated corpus, they do not fully capture pragmatic dimensions critical to informal dialogue translation, including honorific pronoun usage, pro-drop nature, and code-mixed naturalness.

## 6 LLM-as-Judge and Human Assessment

We conduct a qualitative evaluation using both human judges and LLM judges under a Scalar Quality Metric (SQM)-guided Direct Assessment (DA) protocol.

**Experimental Setup and Sampling.** For each of the five fine-tuned models, we select its top-two performing training configurations based on DOC-COMET scores, yielding 10 unique model-configuration setups. From each setup, we sample test dialogues across all language directions: 30 dialogues for each English-source pair (Eng → Hin/Tam/Tel) and 20 dialogues for the Hindi-source pair (Hin → Tel). In total, 1,100 dialogues (900 English-source and 200 Hindi-source) are independently evaluated by expert native-speaking linguists and two SOTA LLM judges: *GPT-5-mini* and *Gemini-3.1-flash-lite-preview*.

**Scoring Granularity.** Evaluations are conducted at two distinct levels: **Dialogue Level:** The judge assesses the full context on three dimensions: *Naturalness*, *Informality*, and *Cohesion & Coherence*. **Utterance Level:** Each sentence pair is independently scored to capture fine-grained translation accuracy. The detailed prompt templates and guidelines are given in section F in the Appendix.

### 6.1 Qualitative Assessment and Analysis

**Cross-Judge Agreement.** Table 3 reveals strong directional consistency across all three evaluators, GPT, Gemini, and Human, with judges largely agreeing on both the relative ranking of models and the preferred training configuration per model. This concordance validates the reliability of LLM judges as proxies for human assessment in the informal Indic dialogue translation setting.

**Model-Specific Qualitative Trends.** Disaggregating scores by model architecture reveals distinct qualitative behaviors:

- For *Gemma3-4B* and *Sarvam-T*, the `Human_Train` configuration consistently yields higher scores than `Syn_X2IL + HT` across all judges and all four evaluation dimensions: utterance accuracy, naturalness, informality, and cohesion. This is consistent with their automatic metric results (Section 5).
- *Llama-3.2-3B* records the lowest qualitative scores across all judges and dimensions, mirroring its modest gains under automatic metrics. This consistent under-performance across both evaluation paradigms confirms that its 3B parameter capacity remains the primary bottleneck, limiting its ability to capture discourse structure regardless of the training data configuration.
- For *Llama-3.1-8B* and *Qwen3-4B*, both evaluated configurations produce closely competitive qualitative scores across all judges, with neither configuration showing a decisive advantage over the other in dialogue-level factors. Notably, for these two models, Gemini and Human judgements exhibit stronger mutual agreement compared to GPT, suggesting that Gemini's evaluation tendencies better align with human preferences for dialogue-level naturalness and coherence assessment in this setting.

**Overall SQM-guided DA Analysis.** Across all models and judges, *Sarvam-T* under `Human_Train` achieves the highest qualitative scores on all three dialogue-level factors, particularly Naturalness (GPT: 60.55; Gemini: 60.59; Human: 58.04) and Cohesion (GPT: 58.66; Gemini: 59.20; Human: 57.18). This is fully consistent with its consistently strong performance in automatic evaluation (Section 5).

**Granular Rubric Distribution for Sarvam-T.** At the dialogue level, 85/130 instances were rated as *Grammatical and somewhat natural*, while 64/130 were classified as *Slightly Informal*. Regarding discourse flow, 66/130 dialogues were deemed *Somewhat coherent and cohesive*, with 52/130 achieving *Strong Coherence and Cohesion*. At the utterance level, over 90% of dialogues achieved high accuracy and naturalness (scores $\geq 61$). A detailed, granular analysis per language pair, along with a sample dialogue error analysis, is provided in Table 17 and Figure 11 in Appendix F.2.

### 6.2 Inter-Judge Correlation Analysis

Table 4 reports average inter-judge correlations across all five models. Utterance-level accuracy achieves the strongest agreement across all judge pairs, confirming that fine-grained translation accuracy is consistently assessable by both human and LLM evaluators. However, when evaluating holistic dialogue-level factors, correlation drops noticeably across all evaluators, while Informality records the lowest correlations. This reveals a fundamental evaluation gap: while judges reliably agree on local-context utterance-level factors, evaluating on dialogue-level factors introduces subjectivity and the cultural-sensitive nature of Judges. This shows that holistic dialogue quality is far more challenging to standardize than utterance-level accuracy. Full per-model breakdowns are provided in Appendix G.

| | GPT vs H | | Ge vs Hu | | GPT vs Ge | |
|---|---|---|---|---|---|---|
| **Factor** | $r$ | $\tau$ | $r$ | $\tau$ | $r$ | $\tau$ |
| Nat | 0.552 | 0.370 | 0.625 | 0.428 | 0.738 | 0.540 |

## 7 Conclusion

We introduce ***BaatCheet***, a multi-turn parallel dialogue corpus for informal Indic translation across five language directions. Our evaluation reveals that while dedicated MT engines and *GPT-4o-mini* lead zero-shot baselines, fine-tuning open-source LLMs—particularly Indic-specialized models like *Sarvam-T* significantly bridges this gap. We demonstrate that synthetic data curated from natural source dialogues (`Synt_X2IL`) provides a far superior training signal compared to synthetic Indic sources (`Synt_IL2X`). Through our evaluations, we show that LLMs can be employed as judges for evaluating dialogue translations as proxies. Future extensions of this study will expand the size of BaatCheet_Human dialogues also to include Bengali, Gujarati, Kannada, and Marathi, maintaining the current source language pairs. Additionally, we aim to develop domain-specific datasets to further refine model performance for specialized downstream applications like healthcare.

## Limitations

Synthetic target generation and MT translation may introduce subtle structural artifacts, lacking the spontaneous code-mixing and deep cultural nuances of organic human conversations. Human-translated gold data, while highly effective for fine-tuning, is limited in volume due to annotation costs, making dataset expansion a key priority. Systemic scoring differences between LLM judges (e.g., Gemini vs. GPT) require calibration against human baselines, and budget constraints limited human Direct Assessment to a sampled subset of 1,100 dialogues.

## Acknowledgments

This work is supported by HIMANGY (HIndustani Machini ANuvaad TechnoloGY), a consortium-based initiative under BHASHINI, funded by the Ministry of Electronics and Information Technology (MeitY), Government of India. We gratefully acknowledge their support in funding in creating the BaatCheet Corpus.

# A Appendix

# B Formal vs Informal Translation

Formal language relies on rigid grammatical structures and standardized vocabulary, whereas informal "BaatCheet" prioritizes social flow and spontaneity through pro-drop (omitted subjects) and code-mixing. For instance, in given example Figure 5, the formal translation uses explicit pronouns and literary metaphors like paheliyan sulajhana (solving riddles), which feel robotic in a casual setting. Conversely, the informal translation naturalizes the dialogue by adding social markers like

"Bhai" and utilizing common urban slang like "life set" instead of a literal translation for "figured out." This shift demonstrates that informal translation is a process of pragmatic transcreation, capturing the "vibe" and cultural nuances that formal, sentence-level MT systems often miss.

## C BaatCheet Corpora Building

Table 5 presents the overview of dialogue data sources used for constructing BaatCheet Corpora across English, Hindi, Tamil, and Telugu.

### C.1 Guidelines for Generated Dialogue Validation

Language experts are provided with the following standardized instructions to validate LLM-generated dialogues:

**Validation Guidelines**

1. Grammatical correctness and semantic coherence.
2. Contextual pronoun consistency across dialogue turns.
3. Gender agreement and awkward phrasing remediation.
4. Converting grammatically sound yet robotic or overly formal expressions into natural, colloquial style.
5. Refining code-mixed phrasing to ensure conversational naturalness.

**Metric Calculation**

**Dialogue Edit Rate (%):** The percentage of dialogues where at least one Utterance was modified by human:

$$\text{Dialogue Edit Rate} = \frac{N_{\text{edited dialogues}}}{N_{\text{total dialogues}}} \times 100$$

**Utterance Edit Rate (%):** The proportion of individual dialogue Utterances altered during validation:

$$\text{Utterance Edit Rate} = \frac{T_{\text{edited}}}{T_{\text{total}}} \times 100$$

**Token Edit Rate (TER %):** Corpus-level word-level Levenshtein edit distance (insertions, deletions, substitutions) normalized by total source word count:

$$\text{TER} = \frac{\sum_{i=1}^{T} \text{Levenshtein}_{\text{word}}(\text{Source}_i, \text{Target}i)}{\sum i = 1^{T} \text{WordCount}(\text{Source}_i)} \times 100$$

**Character Edit Rate (CER %):** Corpus-level character-level Levenshtein edit distance normalized by total source character length:

$$\text{CER} = \frac{\sum_{i=1}^{T} \text{Levenshtein}_{\text{char}}(\text{Source}_i, \text{Target}i)}{\sum i = 1^{T} \text{CharCount}(\text{Source}_i)} \times 100$$

### C.2 Detailed BaatCheet Corpus Statistics

The entire *BaatCheet* corpus aggregates to 49,412 dialogues, 392,253 utterances, and over 702,000 parallel sentences as shown in Table 7.

- **Synthetic Volume (Syn_X2IL & Syn_IL2X):** The synthetic component provides the core scale necessary for LLM fine-tuning. BaatCheet_Syn_X2IL accounts for 42,148 dialogues (301,278 utterances), representing standard X $\rightarrow$ IL translations. BaatCheet_Syn_IL2X contributes 6,096 dialogues (73,666 utterances), which are column-swapped to provide natively generated Indic targets and eliminate machine translation bias on the target side.
- **Human Gold Standards (Human_Train & BaatCheet_Test):** The professionally translated human sets consist of 510 dialogues (8,405 utterances) in BaatCheet_Human_Train and 658 dialogues (8,904 utterances) in BaatCheet_Test. Human_Train acts as both a high-fidelity fine-tuning set and the quality-filtering reference for synthetic curation, while BaatCheet_Test is strictly held out for evaluation.

**Diversity in Linguistic Properties** Comparing Source vs. Target utterance lengths (in words) and sentence lengths reveals fundamental linguistic properties across language families:

**Agglutination (Tamil & Telugu).** In X $\rightarrow$ IL directions (Eng $\rightarrow$ Tam and Eng $\rightarrow$ Tel), English source utterances average 14.97–17.37 words, whereas Tamil and Telugu target utterances average only 11.18–12.76 words. Similarly, in IL $\rightarrow$ X directions (Tam $\rightarrow$ Eng and Tel $\rightarrow$ Eng), Tamil and Telugu source utterances (9.59–12.12 words) expand significantly when translated into English targets (11.86–16.50 words).

> *Linguistic Cause:* Tamil and Telugu are highly agglutinative Dravidian languages. Case markers, postpositions, tense inflections, and pronominal suffixes are morphologically bound into single word forms, resulting in systemat-

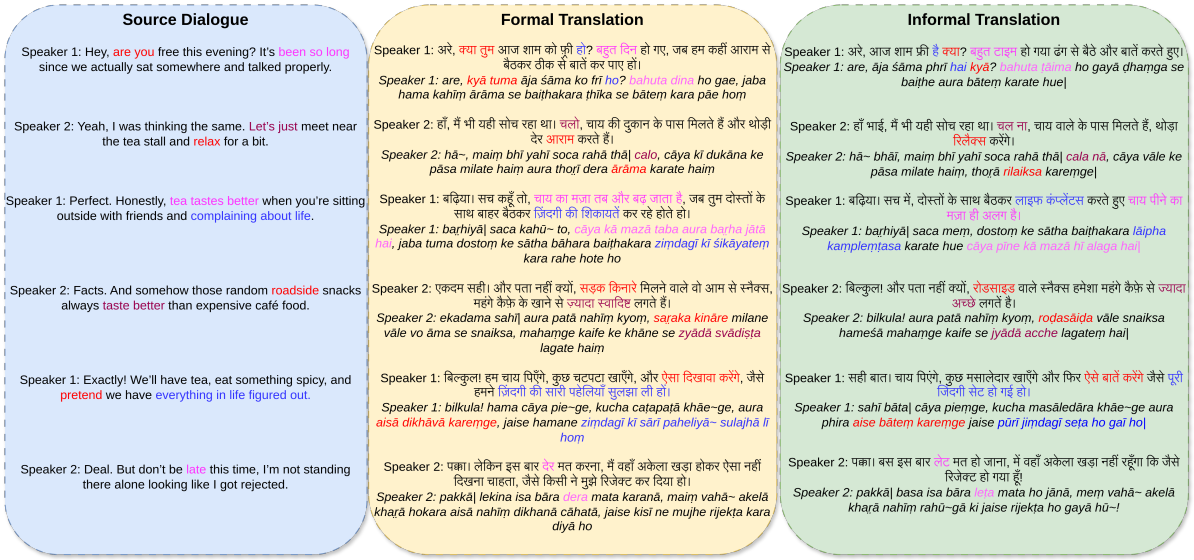

Figure 5: An example of Formal and Informal Translation from English to Hindi along with translitration in IAST format. All the differences are highlited with colors.

ically lower word counts compared to analytic English.

**Domain Diversity** By combining daily speech (*DailyTalk*), multi-turn reasoning (*MuTual*), code-mixed chat (*Hinglish-Chat*), generated news conversations (*News*), and fictional narratives (*Stories*), *BaatCheet* covers a broad spectrum of registers from task-oriented information exchange to informal chitchat.

### C.3 Linguistic Properties: Code-Mixing & Pronoun Ellipsis of BaatCheet Corpus

**Code-Mixing.** To evaluate the prevalence of code-mixing in our corpus, we processed the datasets using the *Indic ILD* (Madhani et al., 2023) language detection tool. The tool identifies an average code-mixing rate of approximately 20% across our language pairs. However, we note that this baseline is a significant underestimate due to a crucial limitation of current automatic tools: Indic ILD relies primarily on the presence of the Roman script (English characters) to identify code-mixed tokens. In contrast, real-world colloquial Indic speech features extensive code-mixing using English words transliterated directly into native Indic scripts. Consequently, although the corpus exhibits a high density of conversational code-mixing, its true frequency cannot be precisely quantified by script-dependent automatic tools.

**Pronoun-Drop and Ellipsis.** Prior work in discourse-aware MT has proposed the Auto Pronoun Translation (APT (Miculicich Werlen and Popescu-Belis, 2017), which is specific for European Languages) metric to evaluate pronoun translation quality. We argue that adapting APT as a primary evaluation metric is highly unreliable in conversational Indic settings. Tamil and Telugu, like other pro-drop languages, permit subjects and objects to be omitted when they are recoverable from grammatical or discourse context. In dialogue translation, the challenge is therefore not the presence of pro-drop itself, but correctly recovering omitted information when translating into a language that requires or prefers its explicit realization as shown in the figure 1.

### C.4 BaatCheet_Gold Translation Protocal

Prior to human translation, synthetically generated source dialogues of *BaatCheet_Gold* underwent expert editing to ensure naturalness, formality, and coherence, and the edit metrics are shown in Table 6 in section C.1.

**Translation Protocol.** Validated source dialogues were assigned to professional human translators with native-level proficiency in the target language and at least three years of translation experience. Per language pair, 2–4 translators independently produced target-language translations following strict informal dialogue guidelines.

1. manual translation only (no MT post-editing);
2. use of colloquial vocabulary; avoidance of formal or Sanskritized registers;

| Data Source – Src.Lang | Description |
|---|---|
| **Hinglish-Chat** – Hin | A synthetically generated Hinglish conversational dataset (Khatri, 2024) featuring everyday life dialogues. The dataset is modified by LLM prompting to *"Remove unnatural nouns and pronouns usage from this dialogue, but it still has to make sense and write it in Hindi (devanagri) script"* |
| **MuTual** (Multi-Turn Dialogue Reasoning) – Eng | A Chinese high school English listening comprehension dataset (Cui et al., 2020), adapted, preprocessed, and manually annotated to create a multi-turn dialogue reasoning corpus aimed at evaluating dialogue models' contextual understanding and reasoning capabilities. |
| **DailyTalk – Eng** | A conversational speech dataset for TTS systems developed by sampling and modifying dialogues from the open-domain DailyDialog corpus (Li et al., 2017). Dialogues from DailyTalk (Lee et al., 2022) are used here, annotated with speaker identifiers to capture natural conversational flow. |
| **News Articles** – Eng, Hin, Tam, Tel | News articles (Mujadia and Sharma, 2025) from diverse domains is used to generate informal dialogues using LLM prompting: *"Generate 10 informal dialogues between two friends on this topic. Keep them short, natural, conversational and direct that concludes meaningfully."* |
| **Short Stories** – Tam, Tel | Short stories from online sources such as `tamil_stories`[12] for Tamil and the `Chandamama Kathalu Dataset`[13] for Telugu are used. Each story is prompted as: *"You are given a language story text. Generate one informal dialogue between two language friends discussing the story in detail in a natural, code-mixed (with English) tone in language. The dialogue should be conversational and informal like spoken language. Reach an opinion about the story."* |

Table 5: Overview of dialogue data sources used for constructing BaatCheet Corpora across English, Hindi, Tamil, and Telugu.

| Datasource | Total Dialogues | Edited Dialogues | Dialogue Edit Rate (%)↓ | Total Utts | Edited Utts | Utt Edit Rate(%)↓ | TER↓ (%) | CER↓ (%) |
|---|---|---|---|---|---|---|---|---|
| News-Eng† | 50 | 4 | 8.00 | 516 | 4 | 0.78 | 0.31 | 0.25 |
| Hinglish† | 49 | 49 | 100.00 | 967 | 638 | 65.98 | 21.99 | 19.60 |
| News-Hin† | 49 | 34 | 69.39 | 492 | 139 | 28.25 | 3.96 | 2.77 |
| News-Tam | 48 | 27 | 56.25 | 344 | 61 | 17.73 | 4.81 | 2.94 |
| News-Tel | 48 | 38 | 79.17 | 361 | 167 | 46.26 | 17.87 | 11.91 |
| Stories-Tam | 50 | 48 | 96.00 | 777 | 330 | 42.47 | 9.68 | 6.21 |
| Stories-Tel | 50 | 47 | 94.00 | 1,030 | 332 | 32.23 | 6.88 | 4.43 |
| **TOTAL** | **344** | **247** | **71.80** | **4,487** | **1,671** | **37.24** | **10.47** | **7.63** |

Table 6: Edit metrics of Human Validation across all data sources. †Indicates BaatCheet_Gold source dialogues; remaining splits are sampled from trainset splits. We report Dialogue Edit Rate, Utterance(Utt) Edit Rate, Token Edit Rate (TER), and Character Edit Rate (CER). Lower is better.

3. contextual adaptation of pronouns and honorifics based on speaker relationships; and
4. preservation of natural turn-taking flow and discourse coherence.

Completed translations underwent an expert review by senior linguists (distinct from the transla-

tors) in the first pass; expert reviewers flagged translations violating any guideline; flagged segments were returned to the translator for revision for targeted revision. This iterative process ensures that *BaatCheet_Gold* constitutes a high-quality gold standard for informal dialogue MT evaluation.

## D Baseline Candidate System Evaluation: Disaggregated Results

Table 8 presents the complete language-pair disaggregated evaluation of all nine candidate systems on *BaatCheet_Human_Train*, comparing reference-based COMET and reference-free COMET-QE scores across all five language directions (Eng → Hin, Eng → Tam, Eng → Tel, Hin → Tam, and Hin → Tel).

**LLM Translation Prompt Template.** For zero-shot baseline evaluation of open-source LLMs (*Llama-3B*, *Llama-8B*, *Qwen3-4B*, *Gemma3-4B*, *Sarvam-Translate*) and *GPT-4o-mini*, we use a simple, direct instruction prompt without in-context examples:

**Baseline Evaluation Prompt Template**

Translate the following from {source_language} to {target_language}: {source_text}

This simple template ensures that baseline evaluations measure pure zero-shot translation capabilities without prompt-engineering artifacts.

**High-Resource Alignment (Eng → Hin).** Eng → Hin exhibits the highest scores across all open-source LLMs under both reference-based COMET (0.699–0.804) and reference-free COMET-QE (0.751–0.846). This superior baseline stems from the abundance of English-Hindi parallel training data in open-source LLM pre-training mixtures, enabling stronger zero-shot cross-lingual transfer even for informal dialogue registers.

**Dravidian Language Challenge (Eng/Hin → Tam/Tel).** For Dravidian target languages (Tamil and Telugu), open-source LLMs experience a sharp performance drop, particularly for Hindi-source directions (Hin → Tam and Hin → Tel). For instance, *Llama-3.2-3B* drops from 0.728 on Eng → Hin to 0.505 on Hin → Tam, while *Qwen3-4B* drops from 0.699 to 0.508. This drop is attributed to morphological complexity (agglutination) and lower representation of Dravidian script in general open-source LLM pre-training.

**Robustness of Dedicated MT Systems and GPT-4o-mini.** In contrast to open-source LLMs, dedicated MT engines (*Google Translate*, *IndicTrans2*, *BhashaVerse*) and *GPT-4o-mini* demonstrate remarkable stability across all language pairs, maintaining high COMET scores ($> 0.80$) even for Dravidian targets. *Google Translate* (GMT) achieves peak overall average performance under both reference-based COMET (0.848) and COMET-QE (0.857), followed closely by *GPT-4o-mini* (0.837 and 0.853). This cross-lingual stability justifies using these top four engines as candidate translation generators in our synthetic curation pipeline.

### D.1 Candidate MT Evaluation: Disaggregated Results

Table 9 presents the complete language-pair and source-disaggregated evaluation of the four candidate MT engines (*Google Translate*, *GPT-4o-mini*, *IndicTrans2*, and *BhashaVerse*) on *Human_Train_X2IL* and *Human_Train_IL2X* candidate sets.

**Engine Performance Trends.** *Google Translate* (GMT) and *GPT-4o-mini* consistently emerge as the top-two performing engines across both translation axes. On X2IL directions (X → IL), GMT achieves peak average scores on English-source pairs (Eng → Tam COMET-QE: 0.8704), while *GPT-4o-mini* leads on Hindi-source Indic pairs (Hin → Tel COMET: 0.8659). On IL2X reverse directions (IL → X), *GPT-4o-mini* displays exceptional translation strength into English targets (Tel → Eng COMET: 0.8711).

**Source-Level Insights.** Conversational corpora (*DailyTalk*, *MuTual*) and news dialogues (*Newsgen*) maintain high translation quality across engines ($> 0.80$ COMET). Conversely, code-mixed dialogues (*Hinglish-Chat*) present greater cross-lingual difficulty when translating into Dravidian targets (Tam → Hin IndicTrans2 COMET: 0.6911), reflecting the morphological and syntactic challenges of informal code-mixed translation. These disaggregated results validate our selection of GMT and *GPT-4o-mini* as the primary translation generators for synthetic corpus curation.

### D.2 Candidate MT Selection Counts Across Filtering Strategies

Table 10 presents the distribution of candidate MT system selections on *BaatCheet_Human_Train* under both filtering strategies: (a) *Utt-Avg* (dialogue-level engine selection across 510 dialogues) and (b) *Utt-High* (turn-by-turn optimal candidate selection across 8,427 utterances).

**Engine Selection Trends.** Two primary patterns emerge from the selection distribution:

- **Dominance of GMT and GPT-4o-mini:** Across both filtering strategies and directions, *Google Translate* (GMT) and *GPT-4o-mini* collectively account for over 80% of all selected dialogues and utterances, confirming their status as the highest-quality translation engines in our pool.
- **Directional Asymmetry:** On X2IL directions (X $\rightarrow$ IL), GMT is the single most selected engine (accounting for 320/510 dialogues in *Utt-Avg* and 3,506/8,427 turns in *Utt-High* under COMET-QE). Conversely, on IL2X reverse directions (IL $\rightarrow$ X), *GPT-4o-mini* becomes the dominant engine (up to 431/510 dialogues in *Utt-Avg* and 4,725/8,427 turns in *Utt-High*), reflecting GPT-4o-mini's strength in generating fluent English and Hindi target outputs.

### D.3 Validation of Filtering Strategies: DOC-COMET and COMTAIL Analysis

Table 11 reports the detailed validation of candidate filtering strategies (*Utt-Avg* vs *Utt-High*) evaluated on *BaatCheet_Human_Train* candidate outputs using context-aware DOC-COMET and Indic-specialized COMTAIL metrics across all language directions.

When candidate selection is guided by reference-free COMET-QE, *Utt-High* consistently outperforms *Utt-Avg* across both evaluation metrics and all language directions:

- **DOC-COMET Alignment:** *Utt-High* achieves higher overall average dialogue scores across both X2IL (0.8854 vs 0.8803) and IL2X (0.8435 vs 0.8392), confirming that selecting the best-scoring candidate translation per turn improves multi-turn discourse consistency.

**Conclusion.** These results confirm that turn-by-turn COMET-QE selection (*Utt-High*) prevents individual low-quality utterances from degrading dialogue quality, ensuring that no utterance falls below the quality ceiling set by the evaluator. This empirical validation justifies adopting **Utt-High** as the primary filtering strategy for scaling up the construction of *BaatCheet_Synthetic*.

### D.4 Human Binary Preference Evaluation of Curation Strategies

To evaluate human perception of dialogue curation strategies, native expert linguists conducted a binary preference study comparing *Utt-Avg* (dialogue-level engine selection) against *Utt-High* (turn-by-turn optimal selection) on 510 sampled dialogues (255 per translation direction). Annotators evaluated pairwise dialogue outputs on overall naturalness, register consistency, and translation accuracy. Table 12 reports the preference counts across both translation axes.

**Key Observations.**

- **Perceived Naturalness Preference:** Human annotators preferred *Utt-Avg* in 54% of evaluated dialogues (276/510) compared to 37% for *Utt-High* (196/510), primarily due to the single-engine stylistic consistency preserved across dialogue turns under *Utt-Avg*.
- **Translation Axis Consistency:** The preference distribution remains highly consistent across both X2IL (55.9% *Utt-Avg* vs 40.9% *Utt-High*) and IL2X (58.2% *Utt-Avg* vs 36.8% *Utt-High*) directions.
- **Strategic Selection:** As analyzed in Section 3.3, while human evaluators favor *Utt-Avg* for surface naturalness, *Utt-High* guarantees strict turn-level translation accuracy, which is the primary criterion for SFT dataset construction.

Figure 6 provides a concrete illustration of *Utt-High* selection on an English$\rightarrow$Telugu dialogue, showing how different MT engines are selected at different turns based on per-utterance COMET-QE scores.

| Translation Direction | Utt-Avg | Utt-High |
|---|---|---|
| X2IL Direction (X $\rightarrow$ IL) | 123 (55.9%) | 90 (40.9%) |
| IL2X Direction (IL $\rightarrow$ X) | 128 (58.2%) | 81 (36.8%) |
| **Total** | **251 (57.0%)** | **171 (38.9%)** |

Table 12: Human binary preference study results comparing *Utt-Avg* and *Utt-High* filtering strategies across 510 sampled dialogues.

| Source from X->IL (Eng-> Tel) | Highest Comet scored Target outputs from 4 MTs | COMET-QE | Picked MT System |
|---|---|---|---|
| Amit :: Bro, did you check out the new draft guidelines for retired government employees? | అమిత్ :: బ్రో, రిటైర్డ్ ప్రభుత్వ ఉద్యోగుల కోసం కొత్త డ్రాఫ్ట్ మార్గదర్శకాలను చూశావా? | 0.84593 | GMT |
| Sanjay :: Yeah, I saw that. They're planning to regulate the salaries for those re-hired on contract, right? | సంజయ్ :: అవును, చూశాను. కాంట్రాక్ట్‌పై తిరిగి నియమించబడిన వారి జీతాలను నియంత్రించడానికి వారు ప్రణాళికలు రూపొందిస్తున్నారు కదా? | 0.876668 | GPT |
| Amit :: Correct. They want to keep the nomination-based appointments minimal. | అమిత్ :: నిజమే. నామినేషన్ ఆధారిత నియామకాలను తక్కువగా ఉంచాలని వారు కోరుకుంటున్నారు. | 0.881104 | GMT |
| Sanjay :: That's good. It should be more about merit than just past connections. | సంజయ్ :: అది బాగుంది. ఇది గత సంబంధాల గురించి కాకుండా యోగ్యత గురించి ఎక్కువగా ఉండాలి. | 0.867858 | GMT |
| Amit :: Absolutely. They're also fixing the salary by deducting the basic pension from the last salary. | అమిత్ :: ఖచ్చితంగా. వారు చివరి జీతం నుండి ప్రాథమిక పెన్షన్ ను తీసివేయడం ద్వారా జీతాన్ని కూడా నిర్ణయిస్తున్నారు. | 0.868421 | BV |
| Sanjay :: So, no increments during the contract? | సంజయ్ :: అయితే, కాంట్రాక్టు సమయంలో ఇంక్రిమెంట్లు లేవా? | 0.874282 | GMT |
| Amit :: Nope, the salary remains unchanged for the contract term. | అమిత్ :: లేదు, కాంట్రాక్ట్ కాలానికి జీతం మారదు. | 0.881761 | GMT |
| Sanjay :: And what about the contract duration? | సంజయ్ :: మరి కాంట్రాక్ట్ వ్యవధి సంగతి ఏమిటి? | 0.878356 | GMT |
| Amit :: Initially up to one year, extendable up to two more years, but not beyond five years post-retirement age. | అమిత్ :: ప్రారంభంలో ఒక సంవత్సరం వరకు, మరో రెండు సంవత్సరాల వరకు పొడిగించవచ్చు, కానీ రిటైర్మెంట్ వయస్సు తర్వాత ఐదు సంవత్సరాలకు మించి కాదు. | 0.866749 | BV |
| Sanjay :: Sounds fair. It'll prevent unnecessary extensions. | సంజయ్ :: ఇది న్యాయంగా అనిపిస్తుంది. ఇది అనవసరమైన పొడిగింపులను నివారిస్తుంది. | 0.874613 | GMT |
| Amit :: Exactly. It's all about maintaining efficiency and fairness. | అమిత్: సరిగ్గా. ఇదంతా సమర్థత మరియు న్యాయాన్ని కాపాడుకోవడం గురించి. | 0.882973 | INT2 |
| Sanjay :: Hope it works out well. | సంజయ్: ఇది బాగా పనిచేస్తుందని ఆశిస్తున్నాను. | 0.879691 | INT2 |
| Amit :: Let's see how it unfolds. | అమిత్ :: అది ఎలా జరుగుతుందో చూద్దాం. | 0.882759 | GMT |

Figure 6: An example English→Telugu dialogue from *BaatCheet_Human_Train* illustrating the *Utt-High* COMET-QE selection strategy. Each utterance's Telugu translation is independently selected from four candidate MT engines (GMT = Google Translate, GPT = GPT-4o-mini, BV = BhashaVerse, INT2 = IndicTrans2), with the corresponding COMET-QE score shown per turn. This shows that GMT dominance is higher, and the same is reflected in the utt-avg highest score; GMT is 0.869 in the same dialogue.

# E The Fine-Tuning Open-Source LLMs

## E.1 Finetuning Parameters

The table 13 shows the hyperparameters used to fine-tune the selected models. BaatCheet_Human_Train configuration we have used 3 epochs to fine-tune the model, and for BaatCheet_[Syn_X2IL+HT] configuration we have fine-tuned the model on BaatCheet_Syn_X2IL first for 1 epoch and then on BaatCheet_Human_Train for 3 epochs.

| Hyperparameter | Value |
|---|---|
| Number of epochs | 1 |
| Batch size | 2 |
| Gradient accumulation step | 4 |
| Learning rate | 1e-4 |
| Maximum sequence length | 4096 |
| LoRA rank | 32 |
| LoRA alpha | 64 |
| LoRA dropout | 0.05 |
| init_lora_weights | gaussian |
| Target Modules | q,k,v,o,gate, up,down proj. |
| Modules to save | lm_head |

Table 13: Training Hyperparameters.

## E.2 Prompt Used for Finetuning the LLMS

The prompt explicitly instructs the model to produce informal and conversational translations, ensuring that the generated outputs better reflect natural spoken dialogue.

**Training Prompt Template**

You are an expert in an informal dialogue machine translation assistant. Translate the following dialogue from source_language to target_language into a natural, informal, and colloquial conversational style in target_language.
Source: source_dialogue
Target: target_dialogue

## E.3 Detailed Automatic Evaluation Results

The fine-tuned model's performance results for each dataset configuration and detailed language-pairwise scores are provided in Table 14 for COMET, Table 15 for DOC-COMET, and Table 16 for COMTAIL.

## F SQM Guided DA Evaluation

We conduct a fine-grained evaluation on these top two configurations of Sarvam-Translate using a Scalar Quality Metric (SQM)-guided Direct Assessment (DA) protocol on a continuous 0 to 100 scale. From each setup, we sample test dialogues across all language directions: 30 dialogues for each English-source pair (Eng $\rightarrow$ Hin/Tam/Tel) and 20 dialogues for the Hindi-source pair (Hin $\rightarrow$ Tel). In total, 1,100 dialogues (900 English-source and 200 Hindi-source) are independently evaluated by expert native-speaking linguists and two SOTA LLM judges:

### F.1 LLM Prompting and Rubrics

The LLM judges were provided with a 7-point rating rubric injected into the system prompt to calibrate the 0–100 scale. We utilized few-shot examples to align the scoring distribution. The full prompt used for both dialogue level and utterance-level evaluation is detailed in Figure 7 and Figure 8.

### F.2 Human Direct Assessment

**Annotator Selection and Screening** To ensure high-fidelity annotations, we implemented a strict crowd-annotator screening protocol. Prospective bilingual candidates completed a 12-item source comprehension test with multiple-choice questions evaluating grammar, colloquial register, and translation accuracy. Only candidates scoring greater than or equal to 9/12 were selected for the evaluation task. Human evaluation was conducted on the *posteditme* platform[14]. Annotations were performed over three iterations by professional linguists. Annotation tool samples are shown in Figures 9 and 10

**Score Aggregation** To eliminate evaluator-specific rating leniency and scale biases, raw scores are standard-normalized ($Z$-scored) per specific evaluator-language pair group, clipped to $[-3.0, 3.0]$ to suppress extreme outlier variance, and linearly rescaled to an intuitive positive 0–100 range.

## G Inter-Judge Correlation Analysis: Per-Model Breakdown

**Metrics.** We report **Pearson** $r$ (linear magnitude agreement between continuous SQM scores) and **Kendall's** $\tau$ (rank-order concordance across all pairwise dialogue comparisons). Together they provide complementary views: $r$ captures score-level agreement while $\tau$ captures ordinal consistency under non-normal distributions.

**Utterance-Level.** The strongest inter-judge agreement is observed at the utterance level (AVG: GPT–Human $r$=0.702, Gemini–Human $r$=0.697), confirming that sentence-level translation accuracy provides a more objective and consistently assessable criterion than holistic dialogue-level factors.

**Naturalness and Cohesion & Coherence.** Both factors achieve moderate-to-good correlations (Naturalness AVG $r$: 0.55–0.74; Cohesion AVG $r$: 0.56–0.74 across judge pairs). Gemini–Human correlations consistently exceed GPT–Human across both dimensions, indicating that Gemini's evaluation tendencies better approximate human quality perception for informal Indic dialogue.

**Informality.** Informality yields the weakest agreement across all models and judge pairs (AVG $r$<0.40), with Kendall's $\tau$ values as low as 0.17. This reflects the inherent subjectivity of register assessment across code-mixed Dravidian languages, where dialectal variation, honorific calibration, and pragmatic code-switching resist standardization within a fixed rubric.

**Overall Patterns.** Three consistent trends emerge across all factors: (i) GPT–Gemini yields the highest correlations, reflecting shared LLM tendencies in rubric interpretation; (ii) Gemini–Human consistently exceeds GPT–Human, suggesting Gemini is a closer proxy for human judgement in this setting; and (iii) Informality is universally the most disagreed-upon dimension, confirming it as the hardest qualitative factor to standardize across evaluators in multilingual informal dialogue assessment.

## Dialogue Level DA+SQM-based Scoring Prompt Template for LLM-as-Judge fonttitle

**System Prompt**

*You are an expert evaluator for dialogue translation and have the ability to evaluate the translated dialogues on the basis of naturalness, informality and cohesion and coherence. You will evaluate the provided Target Dialogue (translated from the Source Dialogue). You need to evaluate the entire Target Dialogue on three factors: Naturalness, Informality, and Cohesion & Coherence by understanding the context of the dialogue.*

**Few-shot Injection**

```
You have been provided with some examples of human evaluations below... Do not copy the scores
and patterns from given example.
```

**Evaluation Rubrics**

| Naturalness | Informality | Cohesion & Coherence |
|---|---|---|
| **00-15:** Ungrammatical/Unnatural | **00-15:** Highly Formal | **00-15:** Incoherent/Incohesive |
| **16-30:** Ungram. but natural-ish | **16-30:** Very Formal | **16-30:** Coherent but Incohesive |
| **31-45:** Minor errors, natural-ish | **31-45:** Moderately Formal | **31-45:** Somew. coherent/cohesive |
| **46-60:** Grammatical but unnatural | **46-60:** Neutral | **46-60:** Coherent/partially cohesive |
| **61-75:** Grammatical/somew. natural | **61-75:** Slightly Informal | **61-75:** Somew. coherent/cohesive |
| **76-90:** Grammatical/natural (minor flaws) | **76-90:** Very Informal | **76-90:** Strong Coherence/Cohesion |
| **91-100:** Grammatical and Natural | **91-100:** Extremely Casual | **91-100:** Fully Coherent/Cohesive |

**Constraint:** *DA Score should be on a continuous scale of 0 to 100 representing the overall quality for that factor. Provide precise, granular scores. Do not round to the nearest 5 or 10.*

**User Input**

| Source Dialogue | Target Dialogue (MT) |
|---|---|
| `{source_text}` | `{mt_text}` |

**Response Instruction:** `Please evaluate the Target Dialogue. Don't provide any other explanations. Give output in the required format.`

## Utterance-Level DA+SQM-based Scoring Prompt Template for LLM-as-Judge fonttitle

**System Prompt**

*You are an expert evaluator for dialogue translation. You have the ability to evaluate the translated utterances. You will evaluate the provided Target utterances corresponding to Source utterances. You need to evaluate MULTIPLE utterances simultaneously. For each utterance, provide a single DA score (0-100) based on the rubric.*

**Few-shot Injection (Optional)**

```
You have been provided with some examples of human evaluations below... Use this understanding
to calibrate your own scoring for the new utterances.
```

**Utterance-Level Scoring Rubric (0-100)**

| Score Range | Evaluation Criteria |
|---|---|
| **00–15** | **Completely unusable:** Nonsensical/total mistranslation; broken grammar; literal word-for-word translation; original meaning cannot be recovered. |
| **16–30** | **Very poor translation:** Major errors in meaning/structure; important info added/omitted; extremely awkward word order; general topic only guessable. |
| **31–45** | **Meaning partially preserved:** Recognizable source meaning but several errors remain; grammatical/lexical issues affect clarity; intent may be distorted. |
| **46–60** | **Meaning correct but unnatural:** Core meaning preserved; grammatically acceptable but sounds literal/stiff; uses formal words in conversational context. |
| **61–75** | **Mostly accurate/somewhat natural:** Message correct; minor awkward phrasing or slightly stiff word order; tone and intent generally preserved. |
| **76–90** | **Accurate and natural:** Core message/tone clearly preserved; sounds natural and conversational; minor stylistic imperfections that do not affect fluency. |
| **91–100** | **Accurate and fully Natural:** Meaning, tone, and intent perfectly preserved; native-like phrasing and word order; correct honorifics and conversational markers. |

**Constraints:** *DA Score should be on a continuous scale of 0 to 100. Provide precise, granular scores. Do not round to the nearest 5 or 10. Provide exactly the same number of scores as the number of utterances provided.*

**User Input Prompt**

```
Here are {num_utterances} utterances to evaluate:
{paired_utterances_text}
Please evaluate the Target utterances and return a list of scores.
```

Figure 8: The prompt used for utterance-level evaluation. The dynamic variable `{paired_utterances_text}` contains the list of source and target sentence pairs.

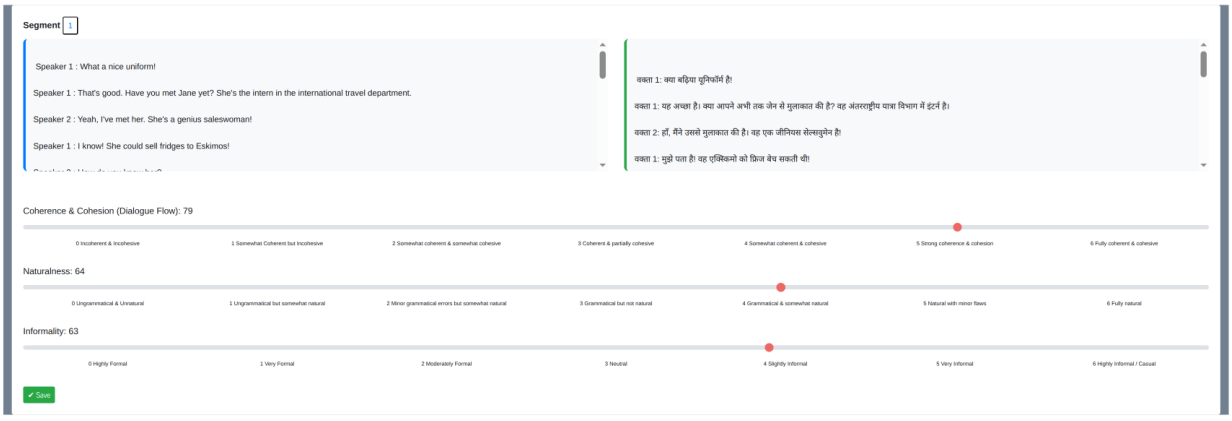

Figure 9: Dialogue-Level Annotation Platform

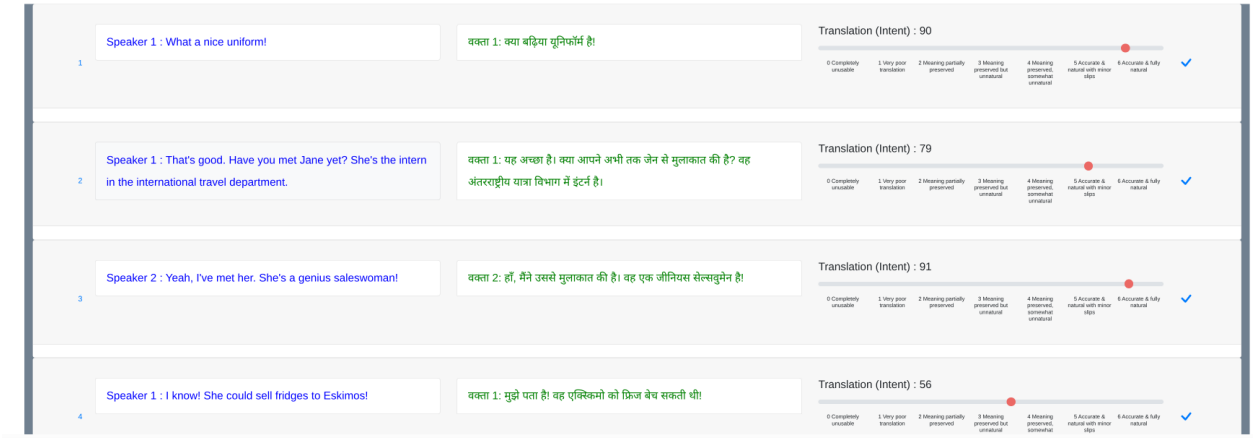

Figure 10: Utterence-Level Annotation Platform

| Sample Dialogue from SARVAM_Human_Train Configuration | | | Utterence_Level_Scores | | | |
|---|---|---|---|---|---|---|
| SOURCE | REFERENCE | SARVAM_Human_Train | Human | GPT | Gemini | Averages |
| Speaker 1: Hey Lindaï¼ did you get that letter about the new options for food service next year? | Speaker 1: अरे लिंडा, तुम्हें वो लेटर मिला क्या , जो अगले साल के फूड सर्विस ऑप्शन के बारे में आया था? | स्पीकर 1: हे लिंडा, क्या आपको अगले साल फ़ूड सर्विस के नए ऑप्शन्स वाला लेटर मिला? | 97 | 80 | 85 | 87.33 |
| Speaker 2: Not yet, are there a lot of changes? | Speaker 2: नहीं अभी तक तो नहीं मिला, क्या बहुत सारे बदलाव हैं? | स्पीकर 2: अभी नहीं, बहुत सारे बदलाव आ रहे हैं क्या? | 95 | 83 | 82 | 86.67 |
| Speaker 1: There sure are, instead of paying one feet to cover all meals for the whole school year. We are now able to choose how many meals a week we want, and can contract just for that amount. We still have to pay the whole year at the beginning, but we can choose to buy 7, 10, 14 or 21 meals per week. They give you a card with a number of meals you get each week marked on it. | Speaker 1: हाँ, काफी हैं। पहले तो पूरे साल के मील्स का एक ही बार में पूरा पेमेंट देना पड़ता था, अब ऐसा नहीं है। अब हम खुद चुन सकते हैं कि हफ्ते में कितने मील चाहिए, और उसी हिसाब से कॉन्ट्रैक्ट कर सकते हैं। हाँ, साल की शुरुआत में पूरा पेमेंट फिर भी देना होगा, लेकिन अब हम 7, 10, 14 या 21 मील हर हफ्ते खरीद सकते हैं। एक कार्ड मिलेगा, जिसमें लिखा रहेगा कि हर हफ्ते तुम्हें कितने मील मिलेंगे। | स्पीकर 1: हाँ, आ रहे हैं। पूरे स्कूल वर्ष के लिए एक ही फीट पे पूरा खाना पेवाना पड़ता था। अब हम हफ़्ते में कितने चाहें उतने वारेन मिल सके, और सिर्फ उतने के लिए कॉन्ट्रैक्ट कर सकते हैं। पूरे साल के लिए शुरुआत में ही पे करना होगा, लेकिन हम हफ़्ते में 7, 10, 14 या 21 वारेन मिल सकते हैं। आपको एक नंबर कार्ड मिलेगा, जिस पर लिखा होगा कि आपको हर हफ़्ते कितने वारेन मिल सकते हैं। | 35 | 48 | 35 | 39.33 |
| Speaker 2: That's a big change Tom, and a complicated system. | Speaker 2: ओहो, यह तो काफी बड़ा बदलाव है टॉम, और थोड़ा झंझट वाला भी लग रहा है। | स्पीकर 2: यह तो बड़ा चेंज है, टॉम, और सिस्टम भी थोड़ा जटिल है। | 82 | 80 | 78 | 80 |
| Speaker 1: Yeah, but it will be much better for people who don't eat 3 meals a day 7 days a week in the cafeteria, because they don't have to pay for meals they don't eat. | Speaker 1: हाँ, लेकिन उन लोगों के लिए अच्छा है जो कैफेटेरिया में रोज़ दिन में 3 मील्स नहीं खाते। अब उन्हें उन मील्स के पैसे नहीं देने पड़ेंगे, जो वे खाते ही नहीं। | स्पीकर 1: हाँ, लेकिन जो लोग कैफ़ेटेरिया में दिन में 3 बार खाना नहीं खाते उनके लिए यह बहुत अच्छा रहेगा, क्योंकि उन्हें उन वारेन जो खाते हैं, उनके लिए पे नहीं करना पड़ेगा। | 52 | 35 | 48 | 45 |
| Speaker 2: So, what's the deal for those who do eat at school all the time? | Speaker 2: अच्छा, तो जो लोग हर रोज़ स्कूल में खाना खाते हैं, उनके लिए क्या डील है? | स्पीकर 2: तो, जो लोग स्कूल में ही खाना खाते हैं उनका क्या? | 67 | 82 | 80 | 76.33 |
| Speaker 1: It better for them, too, because the more meals you contract for, the cheaper each one is. | Speaker 1: उनके लिए भी ठीक ही है, जितने ज़्यादा मील्स का कॉन्ट्रैक्ट करोगे, हर मील उतना ही सस्ता पड़ेगा। | स्पीकर 1: यह उनके लिए भी बेहतर होगा, क्योंकि जितने ज़्यादा वारेन आप कॉन्ट्रैक्ट करेंगे उतना ही सस्ता पड़ेगा। | 66 | 62 | 52 | 60 |
| Speaker 2: I see, it still sounds rather complicated. | Speaker 2: समझ गई, पर फिर भी थोड़ा कॉम्प्लिकेटेड सा लग रहा है। | स्पीकर 2: मैं समझ गया, यह अभी भी काफी जटिल लग रहा है। | 98 | 76 | 84 | 86 |
| Speaker 1: True, it took me several hours to figure it out. I decided to go with the 10 meal plan. | Speaker 1: सही कह रही हो, मुझे भी समझने में कई घंटे लग गए। मैंने तो 10 मील वाला प्लान ले लिया। | स्पीकर 1: यह सच है, इसे समझने में मुझे कई घंटे लग गए। मैंने 10 वारेन वाला प्लान सोचा। | 51 | 60 | 55 | 55.33 |
| Speaker 2: Why is that? | Speaker 2: वो क्यों? | स्पीकर 2: ऐसा क्यों? | 97 | 88 | 88 | 91 |
| Speaker 1: Well, I never eat breakfast and I often go away on weekends, so the 10 meal plan gives me lunch and dinner every weekday at a fairly low price, and I won't be paying for meals I don't usually eat. | Speaker 1: देखो, मैं तो ब्रेकफास्ट कभी खाता ही नहीं, और वीकेंड्स पर अकसर बाहर चला जाता हूँ। तो 10 मील प्लान से मुझे हर वीक डे पर लंच और डिनर मिल जाता है, वो भी ठीक-ठाक रेट पर। और मैं उन मील्स के लिए पेमेंट नहीं कर रहा, जो मैं खाता ही नहीं। | स्पीकर 1: दरअसल, मैं नाश्ता नहीं करता और अक्सर वीकेंड पर बाहर चला जाता हूँ, इसलिए 10 वारेन वाला प्लान मुझे हर वीकडे में लंच और डिनर काफी कम कीमत पे करा देगा, और मुझे उन वारेन के लिए भी पे नहीं करना पड़ेगा, जो मैं आमतौर पर नहीं खाता हूँ। | 49 | 62 | 58 | 56.33 |

**A sample from the best performing model: Sarvam Fine-Tuned on BaatCheet_Human_Train. Figure shows translation from English-->Hindi with MT and reference. Also presents the utterence level and dialogue level DA.**

| Dialogue_Level_Scores | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Human | | | GPT | | | GEMINI | | | AVERAGES | | |
| *Nat* | *Inf* | *Coh* | *Nat* | *Inf* | *Coh* | *Nat* | *Inf* | *Coh* | *Nat* | *Inf* | *Coh* |
| 38 | 66 | 49 | 30 | 52 | 59 | 48 | 68 | 52 | 38.67 | 62 | 53.33 |

Figure 11: A sample dialogue in our error analysis suggests that there are still formal-style dialogues. While the baseline semantics are preserved, the translations are only somewhat natural. This finding supports our conclusion that synthetic data alone is insufficient for capturing deep conversational nuances, reinforcing the necessity for larger-scale, human-curated informal dialogue datasets.

## Abstract

Machine translation systems are periodically upgraded to stronger models, but the available preference signal is human post-edits of an older system's outputs, which the newer model may already surpass. Moreover, collecting fresh post-edits for every new model is prohibitively expensive. We call this the **Stale Preference** problem. Standard DPO can fail in this setting: it may increase the likelihood of inferior post-edits, erode the model's existing quality, and fail to provide the per-token control needed to correct localized errors. We introduce **StalePO**, an objective derived from three requirements this regime imposes. Likelihood movement must be downward on both responses, the policy must be anchored to its own base response, and the KL constraint must apply at the token level. These requirements are jointly necessary. In ablations, each mechanism in isolation leaves the model's performance indistinguishable from the base model, and only their combination converts stale feedback into gains. On English-to-Hindi and English-to-Turkish localization data, StalePO improves the fraction of segments passing all LLM-as-judge MQM quality checks by 14.9 and 4.6 percentage points, respectively, with gains concentrated on style and fluency. A human evaluation under the same framework confirms these gains on English-to-Hindi, raising the fraction of segments passing all seven human checks by 13.8 percentage points.

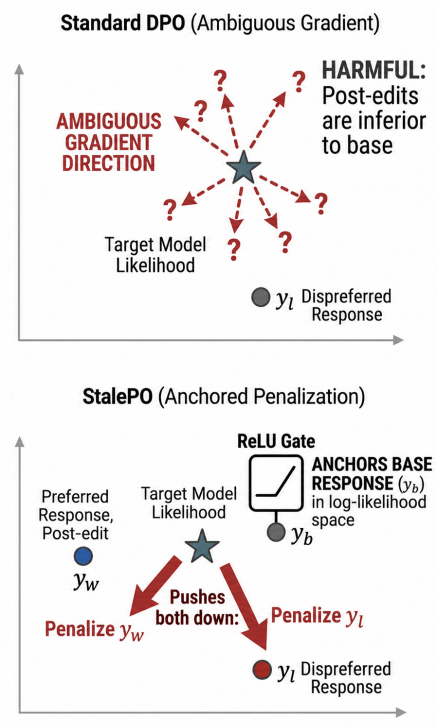

Figure 1: (Top) **DPO** increases the margin between the policy's log-likelihood of the preference pair $(y_w, y_l)$ but does not constrain the direction of either change. (Bottom) **StalePO** is designed to encourage lower log-likelihoods for both $y_w$ and $y_l$ while anchoring the policy to its own base response $y_b$. The arrows illustrate this tendency rather than a guaranteed update direction.

## 1 Introduction

Machine translation systems are periodically upgraded as stronger models become available. Further improving such a model requires human feedback on its own outputs, yet the available feedback consists of human post-edits (MTPE) collected on the outputs of the weaker systems it replaced (Berger et al., 2024). Post-editors correct existing output rather than retranslate from scratch, and collecting fresh post-edits for every model version is prohibitively expensive in pipelines that serve millions of segments each month. The preference data available for training is therefore biased toward earlier systems. Its preferred responses are typically inferior overall to what the current model already produces, yet they remain informative, because they correct genuine errors along dimensions on which the current model still underperforms, such as adherence to a target style guide. We refer to this as the *stale preference* problem.

Aligning large language models with human

*Proceedings of the Eleventh Conference on Machine Translation*, pages 146–156
October 28-29, 2026 ©2026 Association for Computational Linguistics

preferences is now a standard stage in model development (Christiano et al., 2017; Ouyang et al., 2022; Bai et al., 2022). Reinforcement Learning from Human Feedback (RLHF) introduced the core pipeline: train a reward model on pairwise human preferences, then optimize the policy with Proximal Policy Optimization (Schulman et al., 2017). Direct Preference Optimization (DPO; Rafailov et al., 2023) reparameterized this objective as a contrastive loss over preference pairs, eliminating both explicit reward modeling and online sampling, and its simplicity has made it the dominant approach for offline alignment. However, like most offline preference methods, DPO assumes that the preferred output represents a quality target the model should approach.

Stale preferences violate this assumption, and we formalize the setting in Section 2. Applying DPO in this regime exposes three structural limitations. It constrains only the *relative* likelihood change between the two responses in a preference pair, not the absolute direction of either (D'Oosterlinck et al., 2025; Pal et al., 2024; Razin et al., 2024), so it may increase the likelihood of an inferior post-edit. Its KL penalty operates only over tokens present in the preference pair, providing no mechanism to preserve the model's behavior on its own superior generations (Lee et al., 2024). Its implicit reward aggregates all token positions into a single divergence term, sacrificing the per-position control needed to target localized style errors without disturbing the rest of the sequence (Zeng et al., 2024). Section 3 examines these limitations in detail. Prior work addresses each in isolation, but no single method resolves all three, and none was designed for the stale preference regime, where all three arise together.

When these three limitations arise concurrently, DPO is unable to extract a meaningful preference signal from the preference pairs. As a result, despite deliberately curating the training data to target dimensions on which the base model underperforms, standard DPO produces negligible improvement over the base model. Avoiding this outcome requires a single objective that addresses all three limitations at once, which we introduce as StalePO (Stale Preference Optimization). Our contributions are as follows:

1. We formalize the *stale preference* problem in Section 2, in which the preferred outputs are inferior overall to the model's own generations while still carrying useful signal on the dimensions where the model underperforms.

2. We propose Stale Preference Optimization (StalePO), which incorporates three mechanisms: a tendency toward downward likelihood movement on both responses, base-response anchoring via a one-sided penalty, and per-token KL decomposition.

3. We evaluate on English→Hindi and English→Turkish localization data, improving the all-pass rate by 14.9 pp and 4.6 pp respectively, with an evaluation by professional translators confirming a 13.8 pp gain.

4. We show that preference optimization on stale data is ineffective unless directional control, anchoring, and token-level constraints are combined. Each mechanism, considered in isolation, leaves the model's performance indistinguishable from the base model.

## 2 The Stale Preference Data Problem

Staleness in preference data largely stems from the economics of post-editing. A localization pipeline serving millions of segments per month cannot afford a fresh round of human post-editing each time the underlying model is replaced, so the preference data available for fine-tuning was almost always produced against an earlier system. Because post-editors edit rather than fully retranslate, their edits stay tied to the lexical and syntactic patterns of that earlier model. As a result, these post-edits are typically inferior to the current model's outputs on most quality dimensions, while retaining an advantage on the few dimensions on which the current model remains deficient. We formalize this as follows. Let $\mathcal{K}$ be a set of translation quality dimensions and $Q_k(x, y)$ the quality of translation $y$ on dimension $k$. A preference dataset $\mathcal{D} = \{(x, y_w, y_l)\}$ is *stale* with respect to policy $\pi_\theta$ if, for a non-negligible fraction of examples, there exists a small subset $\mathcal{S} \subset \mathcal{K}$ with $|\mathcal{S}| \ll |\mathcal{K}|$ such that $Q_k(x, y_w) > Q_k(x, y_b)$ for all $k \in \mathcal{S}$ and $Q_k(x, y_w) < Q_k(x, y_b)$ for all $k \in \mathcal{K} \setminus \mathcal{S}$, where $y_b \sim \pi_\theta(\cdot|x)$. Exploiting this dual signal requires an objective that learns from the preference ordering without imitating either response, a requirement that existing methods do not address.

## 3 Background and Related Work

**Direct Preference Optimization (DPO)** (Rafailov et al., 2023) optimizes the log-ratio between preferred and dispreferred outputs via the objective

$$\mathcal{L}_{\text{DPO}}(x, y_w, y_l; \theta) = -\log \sigma(r_\theta(x, y_w) - r_\theta(x, y_l)) \tag{1}$$

where $\sigma$ denotes the logistic function and $r_\theta(x, y) = \beta \log \frac{\pi_\theta(y|x)}{\pi_{\text{ref}}(y|x)}$ is the implicit reward defined relative to a frozen reference policy $\pi_{\text{ref}}$. While DPO ensures the preferred output receives higher relative likelihood, it does not control the absolute direction of either update, so both likelihoods may rise, both may fall, or they may move in opposite directions. When the *preferred* output is in fact worse than the base model's output, this lack of directional control admits updates that raise the likelihood of an inferior post-edit, so respecting the preference ordering does not imply that the resulting policy improves.

**Anchored Preference Optimization (APO-Down)** (D'Oosterlinck et al., 2025) directly addresses this issue by biasing optimization toward lower likelihoods for both the preferred and dispreferred outputs while preserving preference separation:

$$\begin{aligned}\mathcal{L}^{\text{APO}}_{\text{down}}(x, y_w, y_l; \theta) = \sigma(r_\theta(x, y_w)) \\ - \sigma(r_\theta(x, y_w) - r_\theta(x, y_l))\end{aligned} \tag{2}$$

This reduces the directional ambiguity present in DPO by discouraging increases in absolute likelihood for both elements of the pair, without guaranteeing the sign of every update. APO-Down has two limitations, however. First, without an explicit anchor to the model's own behavior, repeated application erodes baseline generation quality, since the model receives no signal to preserve its prior competence. Second, the objective operates at the sequence level. In machine translation, many violations are localized to a small number of tokens while the majority of the sequence stays the same. Sequence-level objectives provide no mechanism to target such positions selectively.

**Other Related Work** No prior objective is designed for preference data whose preferred response is inferior to the policy's own output. Loss-function variants such as IPO (Gheshlaghi Azar et al., 2024), SLiC-HF (Zhao et al., 2023), KTO (Ethayarajh et al., 2024), NCA (Chen et al., 2024a), ORPO (Hong et al., 2024), and SimPO (Meng et al., 2024) modify the training objective or remove the reference model entirely, but all continue to treat $y_w$ as a target to approach, which is precisely what fails when $y_w$ is worse than the policy on most dimensions. Online and iterative methods (Guo et al., 2024; Wu et al., 2025; Chen et al., 2024b; Calandriello et al., 2024; Liu et al., 2024) address a different form of staleness, namely drift between the training distribution and the current policy, by refreshing the data during training. This leaves the present problem untouched, since regenerating candidates does not improve post-edits that are inferior by construction, and it additionally requires online generation or multi-stage pipelines that are impractical in a high-volume setting. Token-level credit assignment methods (Yang et al., 2025; Christopoulou et al., 2025; Zhou et al., 2025; Yin et al., 2025) show that uniform token weighting is suboptimal, but they govern where updates are applied rather than whether the target should be imitated. Finally, within machine translation, CPO (Xu et al., 2024) maximizes likelihood on winning outputs, an effective strategy when chosen translations are high-quality but directly harmful in our setting, while distributionally robust (Xu et al., 2026) and length-disentangling (Park et al., 2024) formulations address failure modes unrelated to stale preferences.

## 4 Stale Preference Optimization

Stale Preference Optimization (StalePO) addresses all three limitations within a single objective, through a directional bias, base-response anchoring, and token-level regularization.

$$\mathcal{L}_{\text{StalePO}} = \mathcal{L}_{\text{pref}} + \lambda \cdot \mathcal{L}_{\text{Anchor}} \tag{3}$$

where:

$$\begin{aligned}\mathcal{L}_{\text{pref}} = \sigma\big(\tilde{r}_\theta(x, y_w)\big) \\ - \sigma\big(\tilde{r}_\theta(x, y_w) - \tilde{r}_\theta(x, y_l)\big)\end{aligned} \tag{4}$$

$$\begin{aligned}\tilde{r}_\theta(x, y) = \beta \cdot \Bigg( \log \frac{\pi_\theta(y|x)}{\pi_{\text{ref}}(y|x)} \\ + \alpha \cdot D_{\text{SeqKL}}(x, y; \pi_{\text{ref}} \| \pi_\theta) \Bigg)\end{aligned} \tag{5}$$

$$\mathcal{L}_{\text{Anchor}} = \max\left(0, \log \frac{\pi_{\text{ref}}(y_b|x)}{\pi_\theta(y_b|x)}\right) \tag{6}$$

Here $y_b$ denotes the model's own base response to source $x$ (sampled from the policy before train-

ing, see Section 5), and $D_{\text{SeqKL}}$ is the sequential forward KL divergence defined in Equation 7, applied symmetrically to $y_w$ and $y_l$ with no stop-gradient on either side (at $\alpha$=1 this recovers TDPO1).

**Directional Control** The preference term is designed to bias optimization toward lower likelihoods for both responses. Specifically, $\sigma(\tilde{r}_\theta(x, y_w))$ discourages the probability of the preferred response, while the difference term $-\sigma(\tilde{r}_\theta(x, y_w) - \tilde{r}_\theta(x, y_l))$ favors a larger penalty on the dispreferred one. This preserves their relative ordering without requiring an explicit increase in the preferred likelihood, thereby avoiding the directional ambiguity present in DPO.

**Base-Response Preservation** The anchor term $\mathcal{L}_{\text{Anchor}}$ imposes a one-sided constraint on $y_b$. It activates only when the policy assigns lower likelihood to $y_b$ than the reference model, producing a gradient that pushes the likelihood back toward the reference, and contributes nothing otherwise. This ReLU-gated structure acts as a selective safeguard, preventing degradation of baseline behavior without interfering with preference optimization (Lee et al., 2024).

**Token-Level Regularization** When the preference term lowers the likelihood of either response, neither component above controls where the displaced probability mass goes. Both are computed from sequence-level log-ratios, which track only the total log-probability of a complete response. The policy can therefore satisfy them while concentrating each next-token distribution on a few dominant tokens. Repeated over training, such updates induce token-level mode collapse, eroding the generation diversity of the base model. To counter this, we introduce a sequential forward KL divergence:

$$D_{\text{SeqKL}}(x, y; \pi_{\text{ref}} \| \pi_\theta) = \sum_{t=1}^{T} D_{\text{KL}}\left(\pi_{\text{ref}}(\cdot|[x, y^{<t}]) \| \pi_\theta(\cdot|[x, y^{<t}])\right) \tag{7}$$

Following the TDPO1 formulation of Zeng et al. (2024), this shifts standard DPO from aggregated token log-ratios to per-token constraints, ensuring that local deviations do not cancel out across positions. By applying the forward KL at every step, the objective also exhibits a mass-covering effect, discouraging mode collapse of the reference distribution while preserving diversity, in conjunction with the preference term $\mathcal{L}_{\text{pref}}$, which drives overall preference alignment.

## 5 Experiments

### 5.1 Evaluation

Our primary evaluation uses a seven-category automated Multidimensional Quality Metrics (MQM) framework (Lommel et al., 2014; Freitag et al., 2021) with LLM-as-Judge (LAJ-MQM)-based scorers optimized for each dimension: Verity (legality), Design (markup integrity), Terminology (termbase compliance), Locale Convention (formatting and units), Style (company style adherence), Accuracy (additions, omissions, mistranslations), and Fluency (punctuation, grammar). Each scorer produces a binary pass/fail judgment per segment. All scorers are implemented with Claude Sonnet 4.5, a model whose family differs from that of the GPT-OSS policy under evaluation. This cross-family setup mitigates the self-preference bias that can arise when a model judges outputs sampled from its own family. We define the **all-pass** rate as the fraction of segments passing all seven scorers simultaneously and adopt it as our primary aggregate metric.

Reference-based metrics are unsuitable in this regime. A correct conversational transliteration that diverges from the post-edit improves translation quality while lowering BLEU and raising TER, whereas LAJ-MQM scores translations independently of the post-edits. To validate the LAJ-MQM judgments, professional translators annotate a 2,000-segment English→Hindi subset under the same seven-category taxonomy. The resulting pass-rate changes (Table 1) agree with LAJ-MQM in both direction and concentration, with the largest gains in Style and Fluency and a small Accuracy regression.

### 5.2 Setup

**Data** We begin with a large corpus of post-edits on English→Hindi and English→Turkish machine translations produced by previous generations of NMT systems. For English→Hindi data, we apply a Kimi K2.5-based classifier to retain post-edits exhibiting stylistic modernization (formal→conversational lexical shifts, passive→active simplification) and punctuation

Table 1: Performance changes relative to the Base model in percentage points (pp, higher is better). Evaluated using LLM-as-Judge (LAJ-MQM) pass rates on 5,000-segment test sets for En→Hi and En→Tr, and human MQM pass rates on a 2,000-segment En→Hi subset (24,446 words). LAJ-MQM values are mean ± standard deviation over five independent inference runs of a single training run.

normalization. This yields 24k train / 633 validation segments, concentrating supervision on style and fluency. In the notation of Section 2, this filtering retains examples whose advantage subset $\mathcal{S}$ is concentrated on style and fluency, whereas the unfiltered English→Turkish setting below leaves $\mathcal{S}$ unconstrained. In the absence of ground-truth style labels, we omit precision/recall and evaluate filtering via downstream gains (Section 6).

For English→Turkish, we retain all post-edits without filtering, yielding an unfiltered dataset of 10k train / 598 validation segments, serving as a complementary setting.

Each training example consists of a source prompt $x$ (English text augmented with a target-language style guide and termbase entries), a preferred response $y_w$ (human post-edit of the NMT output), a dispreferred response $y_l$ (raw NMT output), and a base response $y_b$ (sampled from GPT-OSS 120B at temperature 1.0, top-$p$ 1.0). We evaluate on stratified, temporally disjoint test sets of 5,000 segments per language pair. All results are reported across the seven MQM categories to capture cross-dimensional trade-offs.

**Model and Training.** We fine-tune a 120B-parameter GPT-OSS model using QLoRA (Dettmers et al., 2023) adapters on all linear projection layers. All methods are trained for 4 epochs with early stopping on a single node of 8 NVIDIA A100 GPUs using AdamW, with an effective batch size of 64, learning rate $3 \times 10^{-6}$, cosine decay, and LoRA rank $r = 8$. Hyperparameter configurations and early-stopping checkpoints for every method are selected exclusively on the corresponding validation set. The test sets are used only for final reporting. Every baseline is tuned independently over its own sweep of $\beta$ and any coefficients specific to that method. At inference, we decode with temperature 1.0 and top-$p$ 1.0.

Table 2: Component composition of each method. Down: downward directional control; Anchor: base-response anchor; TokenKL: token-level sequential KL; SFT($y_w$): supervised fine-tuning on post-edits.

| Method | SFT($y_w$) | Down | Anchor | TokenKL |
|---|---|---|---|---|
| SFT | ✓ | - | - | - |
| DPO | - | - | - | - |
| TDPO | - | - | - | ✓ |
| BAPO | - | - | ✓ | - |
| APO-Down | - | ✓ | - | - |
| BAPO-Down | - | ✓ | ✓ | - |
| **StalePO** | - | ✓ | ✓ | ✓ |

**Baselines and Ablations.** Each baseline removes one or more of StalePO's three components. **SFT** fine-tunes the base model on the post-edits $y_w$ alone, representing the "imitate-the-winner" strategy and the degenerate case of likelihood-maximizing MT objectives such as CPO (Xu et al., 2024). **DPO** (Rafailov et al., 2023) applies the standard sigmoid objective. **APO-Down** (D'Oosterlinck et al., 2025) adds the downward term only. **TDPO** (Zeng et al., 2024) adds the token-level sequential KL. **BAPO** (Lee et al., 2024) adds the base anchor. **BAPO-Down** uses the downward term with the base anchor, that is,

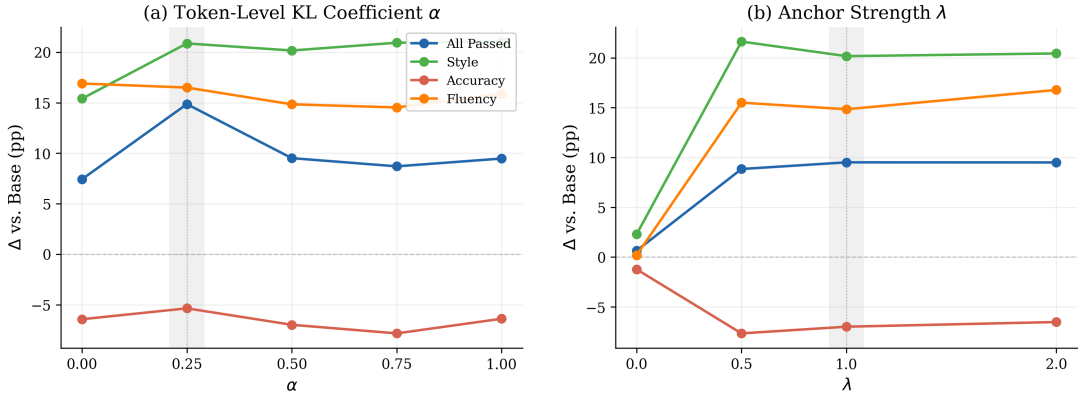

Figure 2: StalePO hyperparameter sensitivity: pass-rate change vs. base. (a) Token-level KL coefficient $\alpha$ ($\lambda$=1.0, $r$=8). (b) Anchor strength $\lambda$ ($\alpha$=0.5, $r$=8).

StalePO without the token-level KL. Table 2 summarizes the composition of each method.

## 6 Results

On English→Hindi (Table 1), StalePO achieves an improvement on all-pass rate of **14.9 pp** over the base model under LAJ-MQM. Human MQM shows a **13.8 pp** increase in all-pass rate, confirming consistent quality gains. These improvements are mainly driven by Style and Fluency, which increase by 20.9 pp and 16.5 pp, with corresponding human MQM pass-rate gains of 15.9 pp and 37.3 pp. Other dimensions remain largely stable (within ±1–2 pp). Qualitatively, the shift is a consistent move from formal Sanskrit-derived vocabulary toward the conversational transliterations mandated by the style guide. The only notable exception is Accuracy under LAJ-MQM, which decreases by 5.4 pp. This is consistent with the stale preference formulation. Gains concentrate on the small subset $\mathcal{S}$ of dimensions where the post-edits genuinely improve on the current model, here style and fluency. Concretely, the model oversimplifies translations where simplification is unwarranted, leading to degradation in the Accuracy dimension. A human MQM subcategory breakdown localizes most of this regression to minor-severity untranslated spans, while mistranslation and omission counts remain nearly unchanged.

On English→Turkish, the base model starts from a substantially stronger baseline, reflecting fewer style inconsistencies. Despite this stronger starting point, StalePO further improves performance by **4.6 pp**. Similar to English→Hindi, gains are concentrated in Style (+2.3 pp) and Fluency (+1.3 pp), while other dimensions remain stable or improve marginally. The gains are smaller and more diffuse than in the filtered English→Hindi setting, as expected when $\mathcal{S}$ is not concentrated on a single dimension by construction. This consistency across language pairs suggests that StalePO generalizes across typologically distinct settings and varying baseline quality regimes, while naive DPO fails in both.

### 6.1 Baseline Ablation

Neither imitating the post-edits nor any single component of StalePO improves on the base model. Supervised fine-tuning on the post-edits alone (SFT) is a particularly informative baseline: despite the En→Hi training data being explicitly filtered to concentrate on stylistic modernization, SFT improves Style by only +2.0 pp and the all-pass rate by only +1.8 pp, even as it raises Fluency (+12.1 pp). In other words, directly imitating the post-edits fails to internalize the very style signal the data was curated to emphasize, confirming that the stale post-edits are not a target the model should imitate.

Methods carrying a single component perform comparably to the base model. Tuned DPO shifts the all-pass rate by only −0.4 pp, TDPO by 0.5 pp, and BAPO by −0.2 pp, indicating that anchoring or an alternative optimization objective alone does not convert a stale preference signal into improved translation quality. Directional control in isolation is similarly insufficient. APO-Down improves by only 0.6 pp, and its run diverges further from the base response distribution than any anchored variant, consistent with unconstrained downward updates eroding the model's original response distribution. A plausible explanation is that, without ex-

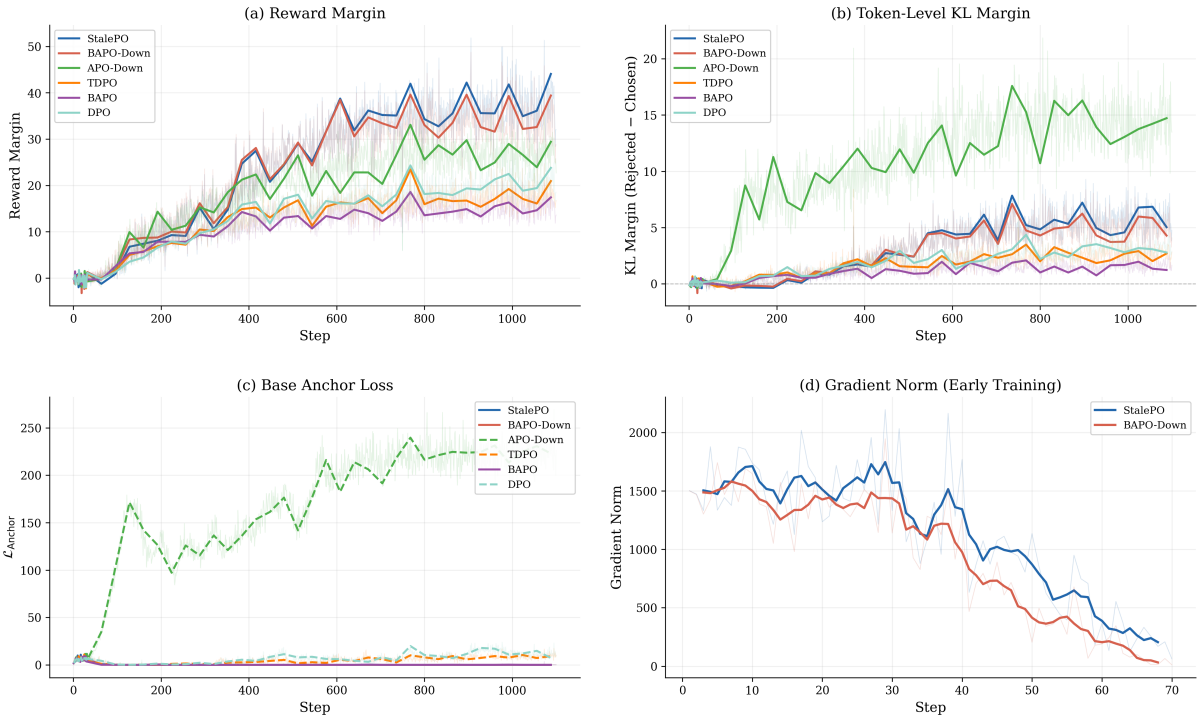

Figure 3: Training dynamics across ablation methods. (a) Reward margin. (b) Token-level KL margin (rejected minus chosen). (c) Base anchor loss $\mathcal{L}_{\text{Anchor}}$. (d) Gradient norm during early training (first 70 steps).

plicit anchoring, optimization amplifies biases in sampled outputs and drifts away from the distribution the model started from.

Introducing a base-response anchor leads to substantial improvements, with BAPO-Down improving all-pass by 7.4 pp, alongside gains in Style (15.4 pp) and Fluency (16.9 pp), though at the cost of reduced Accuracy (−6.4 pp). Building on this, StalePO attains the best overall performance of +14.9 pp, further improving Style (20.9 pp) while partially recovering Accuracy (−5.4 pp). These gains stem from the per-position divergence constraint, which limits updates on already-diverged tokens and encourages more localized, stable adaptations. Overall, the results show that anchoring, directional guidance, and token-level constraints are jointly necessary to incorporate preference signals while maintaining response fidelity.

### 6.2 Hyperparameter Ablation

We perform an ablation study on two hyperparameters: the anchor strength $\lambda \in \{0.5, 1.0, 2.0\}$, which balances preservation of the model's base behavior against learning from the preference signal, and the token-level KL coefficient $\alpha \in \{0.25, 0.5, 0.75, 1.0\}$, which modulates per-position divergence attenuation in the sigmoid saturation regime. We vary each parameter independently while holding the other fixed: the $\alpha$ sweep uses $\lambda = 1.0$, and the $\lambda$ sweep uses $\alpha = 0.5$. Our main configuration (Table 1) uses $\lambda = 1.0$, $\alpha = 0.25$, which corresponds to the peak of the $\alpha$ sweep. Figure 2 reports the resulting change in pass rate relative to the base model.

**Effect of $\alpha$.** As shown in Figure 2(a), the all-pass rate peaks at $\alpha = 0.25$ and decreases for higher values, though all configurations remain substantially above the base model.

**Effect of $\lambda$.** The anchor's effect is pronounced (Figure 2(b)): without it, all metrics remain near the base model despite the intended directional bias. Introducing even a modest anchor ($\lambda = 0.5$) produces a substantial improvement across all dimensions, although the effect plateaus at higher strengths. This behavior is consistent with the observation of Lee et al. (2024) that anchoring effectiveness saturates beyond a threshold.

### 6.3 Training Dynamics

The optimization behavior underlying these outcomes is visible in the training dynamics. Figure 3 tracks reward margins, token-level divergences, the base anchor loss, and gradient norms across methods.

**Directional Signal and Anchor Stability** APO-Down produces larger reward margins than the DPO variants under stale preferences (Figure 3(a)), indicating a stronger directional signal, but at the cost of stability. Without an anchor it diverges progressively from the base response distribution throughout training (Figure 3(c)), degrading generation quality. The anchor resolves this: StalePO and BAPO-Down both satisfy the constraint within the first seventy steps and train stably thereafter, ending two orders of magnitude below the unanchored runs on $\mathcal{L}_{\text{Anchor}}$. Sigmoid DPO methods drift moderately without the anchor but do not collapse, consistent with their inherently more conservative gradient dynamics.

**Asymmetric Divergence** Among the anchored directional variants, StalePO maintains a slightly larger late-training KL margin than BAPO-Down (Figure 3(b)), indicating stronger relative divergence along rejected trajectories. Their gradient norms begin at a comparable scale, but BAPO-Down's declines faster while StalePO retains a learning signal through early training (Figure 3(d)). Together, these patterns are consistent with the token-level KL sustaining asymmetric adaptation after the anchor has stabilized.

## 7 Conclusion

This work formalizes the stale preference problem in machine translation and proposes StalePO, an objective derived from the constraints of this setting. StalePO improves the proportion of error-free segments by 14.9 pp on English→Hindi and 4.6 pp on English→Turkish, with the largest gains in style adherence and fluency, and a human MQM evaluation corroborates the English→Hindi result at 13.8 pp.

Moreover, the stale preference problem is not specific to machine translation. It arises whenever model updates outpace the collection of fresh preference data. StalePO mitigates this issue by learning to avoid failure modes in stale preferences rather than imitating them. Extending this approach to other domains and to richer, multi-error preference data is a promising direction for future work.

## Limitations

Our work has a few limitations. First, due to budget constraints, professional human MQM annotation is not feasible at the scale of our test sets, so our primary evaluation relies on an LLM-as-Judge MQM framework. We validate it against human annotators on an English→Hindi subset and use a cross-family judge to limit self-preference bias, but our English→Turkish results are not backed by human evaluation. Relatedly, company policy prevents us from disclosing absolute MQM pass rates, so all pass-rate results are reported as changes relative to the base model. Second, StalePO offers no benefit when the updated model's outputs are already better than the post-edits on every dimension. In this case the advantage subset $\mathcal{S}$ is empty and the preference pair carries no signal to learn from, so the objective can only preserve existing behavior rather than improve it. Third, and conversely, StalePO is not designed for the standard setting where the post-edits are uniformly better than the model, because it biases both responses' likelihoods downward rather than imitating the preferred output. When the preferred output is a genuine quality target to approach, methods that imitate the winner are more appropriate.

## Acknowledgments

We sincerely thank our teammate Aiden Watson for his valuable support in facilitating access to the GPUs and other computational resources. His assistance was instrumental in enabling the experiments presented in this paper.

## A Lexical Bias of Post-Edits Toward the Legacy NMT System

We quantify the structural bias across the full English→Hindi training set (24,220 segments) using Translation Edit Rate (TER). For each segment, we compute $\mathrm{TER}(\mathrm{NMT}, \mathrm{PE})$ between the legacy NMT output and the human post-edit, and $\mathrm{TER}(\mathrm{Base}, \mathrm{PE})$ between the GPT-OSS 120B output and the same post-edit. If post-editors produced translations independent of the NMT output, both scores should be comparable.

| | **NMT ↔ Post-Edit** | **Base ↔ Post-Edit** |
|---|---|---|
| Mean TER | 0.426 | 0.517 |
| Median TER | 0.379 | 0.500 |
| Segment-level proximity | 55.3% | 23.7% |

Table 3: TER between post-edits and each system on the En→Hi training set. The remaining 21.0% of segments are equidistant.

As shown in Table 3, post-edits are substantially closer to the NMT outputs (mean TER 0.426) than to the base model outputs (0.517), a difference of 0.091 (paired $t = 46.9$, $p \ll 0.001$). Segment-level proximity reports the fraction of segments for which $\mathrm{TER}(\mathrm{NMT}, \mathrm{PE}) < \mathrm{TER}(\mathrm{Base}, \mathrm{PE})$ and vice versa. Post-edits are 2.3× more likely to be closer to the NMT output than to the base model (55.3% vs. 23.7%). This confirms that post-editors correct rather than retranslate: their edits preserve the lexical scaffolding of the original NMT output.

**Reference-based metrics invert quality rankings.** This bias propagates to evaluation when post-edits serve as references. Table 4 reports TER, COMET, chrF, and BLEU on the 5,000-segment test set, averaged over 5 runs.

SFT dominates the reference-based metrics, attaining the lowest TER and the highest chrF and BLEU, with BLEU rising 8.4 points above the base model. This is expected, since SFT is trained to reproduce the post-edits that serve as

references here, which makes it close to an upper bound on agreement with them. Its all-pass rate nonetheless improves by only 1.8 pp. DPO and TDPO also improve on all four metrics, with TDPO attaining the highest COMET, while leaving the all-pass rate essentially unchanged from the base model under LAJ-MQM. StalePO and BAPO-Down, the two methods with the largest all-pass gains (+14.9 pp and +7.4 pp), are the two worst on TER, and StalePO is worst of all on COMET, chrF, and BLEU. This inversion is expected: methods that produce higher-quality translations diverge from the NMT-anchored post-edits, incurring higher edit distances precisely because they generate superior translations. StalePO's conversational transliterations (e.g., एंटर for "enter") are penalized relative to the formal post-edit vocabulary (दर्ज), even though the transliterated forms are mandated by the style guide.

Table 4: Reference-based metrics on the En→Hi test set (5,000 segments), computed against post-edit references. Values are mean ± standard deviation over 5 runs.

| **Method** | **TER** ↓ | **COMET** ↑ | **chrF** ↑ | **BLEU** ↑ |
|---|---|---|---|---|
| Base | 51.57 ±0.48 | 83.59 ±0.16 | 55.60 ±0.31 | 37.41 ±0.47 |
| SFT | **50.18** ±0.13 | 83.65 ±0.08 | **59.66** ±0.32 | **45.82** ±0.37 |
| DPO | 50.35 ±0.17 | 83.83 ±0.23 | 56.35 ±0.16 | 39.07 ±0.37 |
| TDPO | 50.51 ±0.27 | 83.90 ±0.19 | 56.15 ±0.39 | 38.59 ±0.33 |
| APO-Down | 50.51 ±0.51 | 83.70 ±0.17 | 56.01 ±0.52 | 38.94 ±0.65 |
| BAPO | 50.41 ±0.25 | 83.84 ±0.15 | 56.08 ±0.23 | 39.05 ±0.34 |
| BAPO-Down | 56.79 ±0.11 | 83.10 ±0.14 | 52.34 ±0.26 | 41.04 ±0.21 |
| StalePO | 53.52 ±0.29 | 82.86 ±0.11 | 52.19 ±0.32 | 36.37 ±0.43 |

# Balancing Global Quality and Pronoun-Specific Feedback for Context-Aware Machine Translation

**Harshit Dhankhar[1]*, Baban Gain[2], Asif Ekbal[2], Yogesh Mani Tripathi[3]**
[1]Department of Computer Science & Engineering, University of California San Diego, USA
[2]Department of Computer Science & Engineering, Indian Institute of Technology Patna, India
[3]Department of Mathematics, Indian Institute of Technology Patna, India

## Abstract

Context-aware machine translation can expose the evidence needed for pronoun choice, but standard fine-tuning does not explicitly prioritize these sparse discourse-sensitive decisions. We study PRONMT, a reward-guided iterative self-training method that combines sentence-level quality estimation with a signed confidence signal at generated pronoun positions. For each current sentence and its preceding source context, PRONMT samples candidate translations, scores them using reference-free quality estimation together with a reference-derived pronoun label, and fine-tunes on the highest-scoring candidate. On filtered English–German Europarl and English–French News Commentary data, PRONMT improves over context-aware supervised fine-tuning on BLEU and COMET. Ablations show that pronoun-only feedback can severely degrade sentence-level translation quality on these pronoun-focused data, while hard binary feedback underperforms confidence-weighted feedback. These results indicate that targeted linguistic feedback is most useful when combined with both a global quality signal and the context relevant to the targeted decision. We make the code publicly available at https://github.com/Harshit2807161/ProNMT.

## 1 Introduction

Pronoun translation is a compact but difficult test of context-aware machine translation. A pronoun in the current sentence may be ambiguous without an antecedent or discourse cue from a preceding sentence, and a system that accepts additional context does not necessarily use that context for the relevant decision (Li et al., 2020; Appicharla et al., 2023). Figure 1 illustrates an English–German example in which the translation of *it* depends on the antecedent *advertising* in the preceding sentence.

**EN** This advertising cheapens all women.
*It* cheapens every one of us and our daughters.

**DE** Eine solche Art von Werbung erniedrigt alle Frauen.
*Sie* erniedrigt uns alle und unsere Töchter.

Figure 1: A preceding source sentence provides evidence for pronoun choice in the current sentence. Pronouns are italicized and antecedents are underlined. Data: Europarl English–German.

Context-aware architectures and training objectives improve access to information beyond the sentence boundary (Tiedemann and Scherrer, 2017; Junczys-Dowmunt, 2019; Voita et al., 2018). However, broad sentence-level objectives do not explicitly prioritize sparse linguistic decisions such as pronoun choice. Quality estimation (QE) offers a practical global signal for feedback-guided MT training because it can score candidate translations without human judgments or a reference at scoring time (Rei et al., 2021; He et al., 2024). Yet a global QE score may overlook a locally important pronoun error.

A natural response is to add a pronoun-specific signal. Such a signal introduces a second problem: optimizing a narrow local objective may reward candidates that satisfy the pronoun criterion while damaging the rest of the translation. The interaction among context, global quality, and targeted feedback is therefore central. We study this interaction through PRONMT, a reward-guided iterative self-training framework. The translation model samples candidates, a combined reward ranks them, and the highest-scoring candidate becomes the target for a supervised update. The reward contains two components: reference-free QE for global translation quality and a reference-conditioned signed confidence signal at a generated pronoun position.

Our experiments attempt to answer the following four questions:

*Work done while at Indian Institute of Technology Patna.

*Proceedings of the Eleventh Conference on Machine Translation*, pages 157–167
October 28-29, 2026 ©2026 Association for Computational Linguistics

1. Does pronoun-specific feedback add value beyond context-aware supervised fine-tuning?
2. Are global QE and local pronoun feedback complementary?
3. Is the local feedback more useful when preceding-sentence context is available?
4. Does confidence weighting rank candidates more effectively than a hard binary pronoun reward?

Our contributions are threefold. First, we formulate pronoun-aware QE-guided self-training that combines a global reference-free quality signal with reference-derived pronoun supervision. Second, we provide a controlled comparison of context-aware and context-agnostic conditions together with QE-only, pronoun-only, combined, and binary-reward variants. Third, experiments on English–German and English–French show that local pronoun feedback is harmful in isolation but complementary to global QE when the model can access potentially relevant preceding context.

## 2 Related Work

### 2.1 Context-Aware and Pronoun-Focused MT

Context-aware MT commonly incorporates preceding sentences through concatenation (Tiedemann and Scherrer, 2017; Junczys-Dowmunt, 2019), multiple encoders (Li et al., 2020), or auxiliary objectives (Appicharla et al., 2024). Prior work shows that context can improve anaphora-sensitive translation (Voita et al., 2018), but also that models may remain insensitive to whether the supplied context is relevant (Li et al., 2020; Appicharla et al., 2023). Preceding-sentence information has also been used in multilingual and document-aware MT systems (Wang et al., 2020; Sun et al., 2022; Wang et al., 2023).

ContraPro provides a large contrastive test suite for English–German pronoun translation (Müller et al., 2018). It is designed primarily for controlled evaluation rather than as a natural parallel corpus for iterative candidate-selection training. We therefore train on filtered parallel corpora and analyze the preliminary ContraPro training attempt in Section 4.2.

### 2.2 Feedback-Guided Training for MT

MT systems have been improved using human bandit feedback and other limited-feedback settings (Kreutzer et al., 2018a,b). Reinforcement learning from human feedback can optimize learned preferences, but commonly requires human annotations and additional optimization components (Ouyang et al., 2022; Santacroce et al., 2023; Ramamurthy et al., 2023). In contrast, our procedure does not optimize a policy with PPO. It uses reward-based candidate selection followed by iterative supervised updates.

### 2.3 Quality Estimation as a Training Signal

QE estimates translation quality without a reference at inference time (Rei et al., 2020b, 2021). Recent work has used QE as a reward model for MT improvement (He et al., 2024). Our focus is complementary: we test whether a global QE signal benefits from an additional linguistically targeted signal for a sparse contextual decision, and whether that local signal remains safe when optimized jointly with sentence-level quality.

## 3 Pronoun-Aware QE-Guided Self-Training

### 3.1 Task and Context Representation

Let $x_i$ be the current source sentence and $x_{i-1}$ its preceding source sentence. In the context-aware condition, the translation model receives

$$\tilde{x}_i = \langle \text{context} \rangle \, x_{i-1} \, \langle /\text{context} \rangle \, x_i, \qquad (1)$$

while the desired output is the translation of $x_i$ only. In the context-agnostic condition, the model receives $x_i$. The target reference $y_i^{\text{ref}}$ supplies the pronoun label used by the local reward. Thus, only the QE component is reference-free; the complete training objective combines reference-free QE with reference-derived pronoun supervision.

### 3.2 Candidate Selection and Iterative Updates

Let $M_i = P(y \mid x; \theta_i)$ denote the translation model at iteration $i$. For every input in a mini-batch, we sample up to $k$ distinct candidate translations using multinomial sampling. Each candidate is scored by the reward in Equation 4. The highest-scoring candidate is then used as the target for an iterative supervised fine-tuning update. Algorithm 1 summarizes the procedure.

This is reward-guided self-training rather than reinforcement learning: the reward ranks sampled candidates, but the model update is a supervised update on the selected candidate.

**Algorithm 1** PRONMT iterative self-training

**Require:** Training inputs $\mathcal{X}$, references $\mathcal{Y}$, initial model $M_0$, reward $r$, batch size $B$, temperature $T$, candidate limit $k$

**for** $i = 0, 1, \ldots, N-1$ **do**
  $D_i \leftarrow \text{SampleBatch}(\mathcal{X}, \mathcal{Y}, B)$
  $\mathcal{B} \leftarrow \emptyset$
  **for** each $(x, y^{\text{ref}}) \in D_i$ **do**
    $y_1, \ldots, y_k \sim P_T(y \mid x; \theta_i)$
    $y^* \leftarrow \arg\max_{y_j} r(x, y_j, y^{\text{ref}})$
    $\mathcal{B} \leftarrow \mathcal{B} \cup \{(x, y^*)\}$
  **end for**
  Update $\theta_i$ on $\mathcal{B}$ to obtain $M_{i+1}$
**end for**

### 3.3 Global Translation-Quality Signal

For a candidate $y$, $R_{\text{QE}}(x_i, y)$ is produced by a reference-free COMET-QE model. In the context-aware condition, the translation model receives $\tilde{x}_i$, but QE scores the candidate against the current source sentence $x_i$. This prevents the context prefix from being treated as content that should appear in the translation.

### 3.4 Signed Pronoun-Position Confidence

For a generated candidate $y = (y_1, \ldots, y_m)$, let $j$ be a position at which the decoded candidate contains a recognized target-language pronoun. We define pronoun-position confidence as

$$C_{\text{pro}}(y, j) = \max_{v \in \mathcal{V}} P(v \mid x, y_{<j}; \theta), \qquad (2)$$

where $\mathcal{V}$ is the target vocabulary. This quantity measures model confidence at the position where a pronoun is generated; it is not an independent pronoun-accuracy metric.

Let $p(y)$ be the generated pronoun and $p^{\text{ref}}$ the aligned reference pronoun. If such a pronoun is not generated we reward that case 0. The signed local reward is then:

$$R_{\text{pro}}(y) = \begin{cases} +C_{\text{pro}}(y, j), & p(y) = p^{\text{ref}}, \\ -C_{\text{pro}}(y, j), & p(y) \neq p^{\text{ref}}, \\ 0, & \text{otherwise} \end{cases} \qquad (3)$$

The combined candidate-selection reward is

$$r(x_i, y, y_i^{\text{ref}}) = \alpha R_{\text{QE}}(x_i, y) + \beta R_{\text{pro}}(y). \qquad (4)$$

QE provides a global constraint on sentence-level translation quality, while $R_{\text{pro}}$, also referred to as ProConf when averaged across multiple sentences, prioritizes the targeted pronoun decision.

Table 1: Source-sentence length statistics for ContraPro and filtered Europarl.

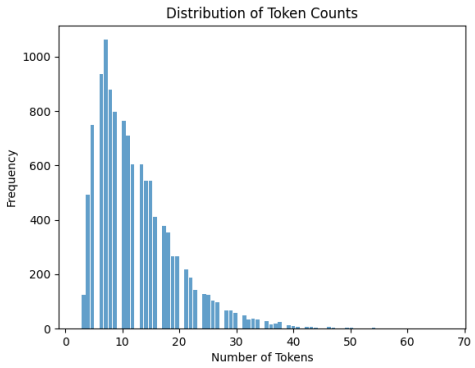
| Dataset | Mean | Median | Var. | Std. | Max | Min |
|---|---|---|---|---|---|---|
| ContraPro | 12.533 | 11.0 | 53.031 | 7.282 | 67 | 2 |
| Europarl | 33.378 | 29.0 | 404.219 | 20.105 | 212 | 1 |

### 3.5 Binary Pronoun Reward

To test whether confidence weighting is useful, we replace Equation 3 with

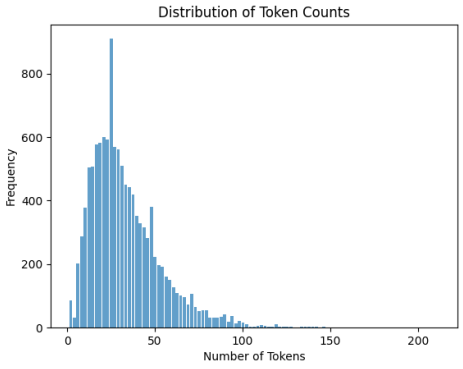
$$R_{\text{bin}}(y) = \begin{cases} +1, & p(y) = p^{\text{ref}}, \\ -1, & p(y) \neq p^{\text{ref}}, \\ 0, & \text{otherwise.} \end{cases} \qquad (5)$$

The binary variant assigns the same magnitude to every matching or non-matching candidate. The confidence-weighted variant therefore provides a finer ranking among candidate translations.



## 4 Experimental Setup

### 4.1 Pronoun-Focused Parallel Corpora



For English–German, we start from 1,920,209 Europarl sentence pairs. We retain a pair when the English sentence contains *it* exactly once, the German sentence contains exactly one singular third-person pronoun from *er*, *sie*, and *es*, and the two pronouns are aligned by `fast_align` (Dyer et al., 2013). Alignment filtering reduces noise from alternatives such as *das* and *dies* (Müller et al., 2018). The filtered data contains 117,834 *es*, 17,447 *er*, and 39,439 *sie* instances. We sample 15,000 instances per class and construct 42,750 training, 750 validation, and 1,500 test examples.

For English–French, we apply the same procedure to News Commentary v16 from OPUS (Tiedemann, 2009), retaining English *they* and its French counterparts *ils* and *elles*. The English–German setting therefore targets grammatical-gender alternatives for *it*, while English–French targets the masculine and feminine alternatives of *they*. The English–German reward weights are transferred to English–French without retuning.

For each corpus, the context-aware input prefixes the current source sentence with the preceding source sentence. The same data split and random seed are used for corresponding context-aware and context-agnostic conditions.

(b) Filtered Europarl

Figure 2: Source token-count distributions.

(a) QE reward

(b) Pronoun reward

Figure 3: Preliminary ContraPro training curves over the first 700 updates.

### 4.2 Choice of Training Data and ContraPro Analysis

ContraPro is a controlled contrastive evaluation suite rather than a natural parallel corpus designed for iterative self-training. We nevertheless conducted a preliminary training attempt. The source sentences are shorter on average than those in our filtered Europarl corpus, as summarized in Table 1 and Figure 2. Before training, the average validation COMET-QE score was 0.7636 on ContraPro and 0.6323 on filtered Europarl. This left less QE headroom in the ContraPro training attempt (see Figure 3). Sentence length may contribute to this difference, but the current experiments do not establish a causal explanation.

### 4.3 Model and Training

All experiments use the distilled 600M-parameter NLLB-200 model. Before reward-guided training, the context-aware model is adapted through supervised fine-tuning so that it learns to consume the context prefix while translating only the current sentence. This context-aware SFT model is the principal baseline for evaluating the subsequent reward-guided training stage after adaptation to the context-prefixed input format. We do not include a separately continued SFT control for the context-agnostic setting. Consequently, comparisons between context-aware and context-agnostic PRONMT should be interpreted as comparisons between the two training conditions rather than as a controlled estimate of the effect of preceding context alone.

For PRONMT, the mini-batch size is $B = 4$, and up to $k = 10$ distinct candidates are generated for each input by multinomial sampling. Iterative supervised training runs for at most 700 updates with learning rate $6 \times 10^{-5}$ and gradient accumulation of 16. The binary-reward comparison uses the same setup and is trained for 750 updates. The supervised adaptation and reward-guided stages use the settings summarized below.

### 4.4 Compared Systems

We compare the following configurations:

- **Baseline**: the NLLB-200 model before task-specific reward-guided training;

Table 2: Hyperparameters for initial context-aware supervised fine-tuning.

| Hyperparameter | Value |
|---|---|
| Learning rate | $8 \times 10^{-3}$ |
| Per-device train batch size | 8 |
| Gradient accumulation steps | 16 |
| Evaluation accumulation steps | 16 |
| Per-device evaluation batch size | 8 |
| Weight decay | 0.01 |
| Number of epochs | 10 |

- **Context-aware SFT**: supervised adaptation to the context-prefixed input format;
- **QE only**: candidate selection using $R_{\mathrm{QE}}$;
- **Pronoun only**: candidate selection using $R_{\mathrm{pro}}$;
- **PRONMT**: joint QE and confidence-weighted pronoun feedback;
- **Binary**: joint QE and binary pronoun feedback.

### 4.5 Validation and Evaluation

For each reward-weight configuration, checkpoints are evaluated every 100 updates, and the checkpoint with the highest combined validation reward is retained. The reward weights $\alpha$ and $\beta$ are then selected using COMET and BLEU on the validation set. Table 3 reports the corresponding English–German validation results. The held-out test set is used only for the final evaluations reported in Tables 4 and 5.

We report BLEU (Papineni et al., 2002) and reference-based COMET using *wmt22-comet-da* (Rei et al., 2020a). COMET is presented on a 0–100 scale. We also report the mean QE reward and mean signed pronoun-position confidence used for candidate selection. These internal reward values are diagnostic quantities, not independent measures of pronoun accuracy. English–German and English–French QE values are not directly comparable because the two experiments use different QE models.

## 5 Results and Analysis

### 5.1 Does Reward-Guided Training Improve over Context-Aware SFT?

Table 4 reports English–German test results. Context-aware SFT reaches 81.19 COMET and 25.57 BLEU. Joint QE and pronoun feedback improves these scores to 81.92 COMET and 26.96 BLEU, gains of 0.73 COMET and 1.39 BLEU. Although the COMET difference is modest, the improvement is consistent across both a learned reference-based metric and an overlap-based metric. The combined system also raises the internal pronoun-position confidence from 0.1406 to 0.4183. We do not treat this internal increase as an independent accuracy result, but it confirms that the selected candidates are more strongly aligned with the targeted reward while external translation quality is preserved.

The comparison with context-aware SFT distinguishes the initial adaptation to the context-prefixed input format from the subsequent reward-guided refinement stage. However, because PRONMT receives additional parameter updates after SFT, this comparison does not by itself isolate the effect of reward-guided candidate selection from that of additional training. We therefore interpret the gain over SFT as evidence that the complete PRONMT training procedure further improves the adapted model, rather than as a controlled estimate of the contribution of candidate selection alone.

The English–German improvement should nevertheless be interpreted as a refinement of an already strong system rather than a replacement for supervised context adaptation. Context-aware SFT accounts for most of the improvement over the raw context baseline, while the subsequent PRONMT stage is associated with a further improvement. This layered interpretation is more faithful to the training pipeline: SFT first establishes the ability to consume the extended input, and reward-guided self-training then encourages the model to prefer candidates that jointly satisfy sentence-level quality and the targeted pronoun criterion.

### 5.2 Why Are Both Reward Components Necessary?

The clearest result is the failure of pronoun-only optimization. In the context-aware English–German condition, pronoun-only training reaches a high internal ProConf value of 0.9675 but collapses to 16.79 COMET and 0.07 BLEU. The same conflict appears without context: pronoun-only training raises ProConf to 0.8998, yet COMET and BLEU fall below even the unadapted baseline. The local objective can therefore be satisfied while the rest of the translation deteriorates. ProConf should not be interpreted as pronoun accuracy, especially when

Table 3: English–German validation performance under different reward weights. $\#\text{tokens}$ is the sentence-specific token count and $\#\text{avg-len} \approx 30$ is the average source length. QE and ProConf are validation-set internal rewards.

| **Reward weights** $(\alpha, \beta)$ | **COMET** | **BLEU** | **QE** | **ProConf** |

considered without global translation metrics.

This failure is a candidate-selection analogue of reward over-optimization. The local term examines a single targeted position, so a candidate can receive a favorable local score even when its lexical choice, word order, coverage, or fluency elsewhere is poor. Repeatedly training on such candidates can amplify the mismatch between the optimized signal and the broader translation task. The near-zero BLEU score in the context-aware pronoun-only condition shows that this is not a minor trade-off. It is a qualitative collapse of the sentence-level objective. The result motivates using the pronoun signal as a preference among otherwise plausible translations, rather than as a standalone definition of quality.

QE-only selection avoids this collapse and reaches 80.06 COMET and 21.56 BLEU, but it remains below the combined system at 81.92 COMET and 26.96 BLEU. The gap is particularly visible in BLEU, where the combined objective improves by 5.40 points over QE only. A global score can distinguish broadly adequate candidates, but a sparse pronoun error may have limited influence on the sentence-level score, especially when the remaining content is translated well. The local term changes the ordering among such candidates by assigning explicit importance to the pronoun position.

The two components therefore constrain different failure modes. QE discourages candidates that satisfy the local criterion by damaging the rest of the sentence, while pronoun feedback prevents a high global score from making the targeted deci-

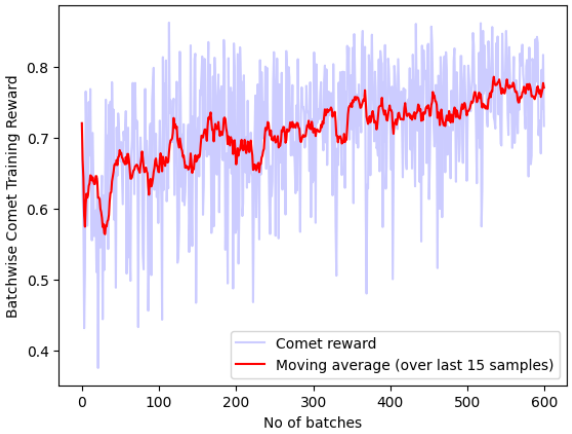
sion effectively invisible. Their combination gives the best overall balance in the context-aware setting. Importantly, the combined reward does not require both component values to rise monotonically or to have directly comparable scales. Its role is to produce a useful ordering of sampled candidates, and the held-out COMET and BLEU results indicate that this ordering is more effective than either component alone.

### 5.3 How Does Preceding Context Affect Targeted Feedback?

The combined method also improves the context-agnostic model, from 56.68 to 73.95 COMET and from 7.89 to 15.26 BLEU. This result shows that the improvement is not dependent on access to a preceding-sentence cue. The complete PRONMT training procedure also improves the model when only the current sentence is available. At the same time, the highest overall performance is obtained when reward-guided training starts from a model adapted to the context-prefixed input. Relative to no-context PRONMT, the context-aware system is higher by 7.97 COMET and 11.69 BLEU.

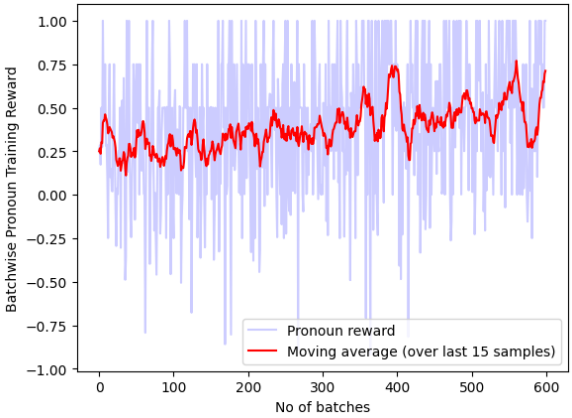
This pattern is consistent with targeted feedback becoming more informative when the model can access evidence relevant to the targeted decision. Without preceding context, some pronoun choices remain underdetermined, and the reward can only favor agreement with the reference rather than teach a reproducible contextual mapping. With context, the sampled candidates can differ in whether they exploit the available antecedent information, giving the local reward a more meaningful basis for ranking them. The result does not establish that every filtered example requires cross-sentence resolution, nor does it directly measure context usage. It instead shows that the strongest trade-off between global quality and the targeted reward occurs in the condition where potentially relevant context is available.

The raw context baseline is not the main comparison because the base model has not yet learned the artificial context format. This issue is especially visible in English–French, where simply adding the prefix lowers COMET from 74.29 to 60.58 and BLEU from 26.23 to 16.42. After context-aware SFT, performance recovers to 76.84 COMET and 28.92 BLEU. These numbers show that access to additional text is not automatically beneficial: the model first needs to learn the structural distinction between contextual evidence and content to translate. Context-aware SFT is therefore the fair baseline for assessing the contribution of PRONMT, while the raw context baseline mainly quantifies the cost of introducing an unfamiliar input format.



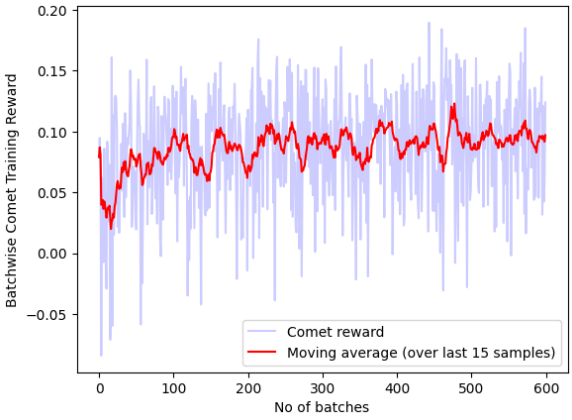
The different baseline behavior across English–German and English–French also cautions against treating context concatenation as a universally positive architectural intervention. Its value depends on adaptation, data characteristics, and how the prefix interacts with the pretrained model. The empirical pattern is narrower and clearer: once the model can process the context-prefixed format, the subsequent PRONMT stage is associated with further improvements in the produced outputs.

### 5.4 Confidence Weighting versus Binary Feedback



The binary variant obtains a larger raw pronoun reward but lower external translation scores. In context-aware English–German, binary feedback reaches 78.58 COMET and 21.58 BLEU, compared with 81.92 and 26.96 for confidence-weighted feedback. The same ordering holds without context, where the confidence-weighted system exceeds the binary variant by 10.93 COMET and 3.01 BLEU. Thus, the apparent advantage of the binary system on its own local reward does not transfer to the external metrics.

A hard $+1/-1$ signal gives every matching or non-matching candidate the same magnitude. Consequently, candidates with very different model support can become indistinguishable under the local component, and a single pronoun match can dominate small differences in QE depending on the reward scale. Pronoun-position confidence provides a finer candidate ranking because the magnitude reflects the model's confidence at the generated pronoun position. In this selection-based setting, the benefit should not be described as reducing gradient variance, since gradients are taken through the supervised update rather than through the reward. The empirical advantage is instead that confidence weighting offers more resolution when candidates are ordered before the update.



The comparison also illustrates why raw values from differently defined rewards should not be compared as though they were the same metric. A binary score is structurally encouraged to approach its extreme values, whereas confidence-weighted scores depend on the model distribution. The relevant evidence is not that one internal number is numerically larger, but that the candidate ranking

Figure 4: Batchwise reward trajectories for combined-reward training. Curves show raw values and moving averages.

induced by confidence weighting leads to better held-out translations.

### 5.5 Transfer to English–French

Table 5 reports English–French results using the English–German reward weights without retuning. In the context-aware condition, PRONMT improves over SFT from 76.84 to 79.37 COMET and from 28.92 to 30.54 BLEU. The corresponding gains are 2.53 COMET and 1.62 BLEU. The no-context condition also improves over its baseline, from 74.29 to 76.16 COMET and from 26.23 to 28.03 BLEU.

This transfer is informative because the French setting is not a direct replication of the German pronoun inventory. English–German focuses on *it* and the alternatives *er*, *sie*, and *es*, whereas English–French focuses on *they* and the gendered alternatives *ils* and *elles*. Reusing the same reward weights therefore tests whether the balance between global and local feedback remains useful when both the language pair and the targeted mapping change. The positive result suggests that the central design choice is not tied only to the numerical optimum of the English–German validation set and can transfer to a second language pair and target mapping without retuning.

The evidence is still limited to two related target languages and a single translation model, so it does not establish broad multilingual generality. It does, however, strengthen the interpretation of the English–German result. The improvement is unlikely to be solely an idiosyncrasy of one filtered corpus or one particular set of German pronouns, because the same combined objective also improves a separately constructed French setting without additional tuning. The larger COMET gain over SFT in English–French further suggests that the value of reward-guided refinement can depend on how much room remains after supervised con-

Table 5: English–French test performance. English–German reward weights are reused without retuning. QE and ProConf are internal rewards and use a different QE model from Table 4.

| Method | COMET | BLEU | QE | ProConf |
|---|---|---|---|---|
| *Without context* | | | | |
| Baseline | 74.29 | 26.2314 | 0.7610 | 0.3197 |
| PRONMT | **76.16** | **28.0341** | **0.7914** | **0.3846** |
| *With context* | | | | |
| Baseline | 60.58 | 16.4238 | 0.7571 | 0.2806 |
| Context-aware SFT | 76.84 | 28.9204 | 0.7638 | 0.1678 |
| PRONMT | **79.37** | **30.5399** | **0.8007** | **0.4908** |

text adaptation.

### 5.6 What Does Reward-Weight Selection Reveal?

Table 3 provides an additional view of the trade-off between the two reward components. In the context-aware condition, the configuration with the highest internal ProConf is $(1, 1/\#\text{avg-len})$, which reaches 0.8543, but its COMET and BLEU scores are 78.98 and 21.95. The selected configuration, $(1.2, 1/\#\text{tokens})$, has a substantially lower ProConf of 0.4213 but the best external scores of 80.72 COMET and 26.43 BLEU. This mirrors the component ablation: maximizing the local diagnostic is not equivalent to producing the best translation system.

Sentence-specific normalization of the pronoun term is the better choice at the selected QE weight, exceeding average-length normalization by 0.51 COMET and 1.19 BLEU at $\alpha = 1.2$, though the two are within 0.32 COMET at $\alpha = 1$. The comparison suggests that the balance is affected not only by the nominal values of $\alpha$ and $\beta$, but also by whether the local contribution is normalized according to each sentence. Since a pronoun-level term is combined with a sentence-level QE score, sentence-specific scaling can prevent the relative influence of the local term from changing simply because inputs differ in length.

The no-context validation results show a different optimum: $(1, 1/\#\text{avg-len})$ gives the highest COMET and BLEU, while increasing $\alpha$ to 1.2 hurts both metrics. This difference supports selecting reward weights on the validation set separately for the two input conditions rather than assuming that a single balance must be optimal everywhere. More broadly, the sensitivity table reinforces the main narrative that global and local signals are complementary but not interchangeable. Their usefulness depends on maintaining a scale at which the local term can influence candidate choice without overwhelming sentence-level quality.

### 5.7 Relationship between Internal Rewards and External Metrics

Across the ablations, internal rewards and external metrics are related but clearly not interchangeable. Pronoun-only and binary training can obtain large local values while producing lower COMET and BLEU, so the validation configuration with the highest ProConf is not the selected system. Conversely, context-aware SFT has a relatively low ProConf of 0.1406 but strong external performance. These cases show that ProConf is best understood as a description of the candidate-selection objective rather than a standalone evaluation measure.

QE is also an internal training signal, even though it is derived from a learned MT evaluation model. Optimizing the same QE model used for candidate selection may improve its score without guaranteeing equivalent gains under a separate evaluator. For that reason, the main results include reference-based COMET and BLEU, and the paper bases its conclusions on agreement between these held-out metrics rather than on the training rewards alone. The combined system's advantage is strongest when it improves both external metrics while avoiding the local-reward collapse observed in the ablations.

### 5.8 Training Dynamics

Figure 4 shows the batchwise QE and pronoun rewards for the English–German combined-reward runs. Both raw trajectories fluctuate substantially because each update is based on sampled candidates and a small mini-batch. The moving averages are therefore more informative than individual batch values. In the no-context run, the QE moving average generally rises over training, while the pronoun trajectory improves more gradually and remains highly variable. In the context-aware run, the pronoun moving average increases markedly during the early updates and then fluctuates around a higher range, while the QE trajectory improves early and later remains comparatively stable.

The trajectories are compatible with the two reward components learning at different rates. The targeted signal can change quickly when candidate pronouns are re-ranked, whereas sentence-level quality aggregates many decisions and may move more conservatively. At the same time, the occa-

sional negative or low batch rewards show that sampling continues to expose difficult cases throughout training. A smooth monotonic curve is not expected because the procedure repeatedly changes the model that generates the candidate pool.

These plots are diagnostic rather than the basis for model selection. Checkpoints are selected using the combined validation reward, and final claims are drawn from held-out COMET and BLEU. This separation is important because an apparently improving training component can still correspond to poorer external quality, as demonstrated directly by the pronoun-only and binary ablations. The curves are therefore most useful for showing that optimization is active and noisy, while the tables determine whether the resulting model is actually better.

## 6 Conclusion

We presented PRONMT, a reward-guided iterative self-training method for balancing global translation quality with pronoun-specific feedback. The experiments support three conclusions. First, context-aware supervised fine-tuning is a strong starting point, but combined reward-guided training improves further in both English–German and English–French. Second, pronoun-only feedback is unsafe as an isolated objective because a high local reward can coincide with severe deterioration in COMET and BLEU. Third, confidence-weighted feedback provides a more useful candidate ranking than a hard binary signal. More broadly, targeted linguistic feedback is most effective when it is constrained by a global quality objective and paired with access to the information relevant to the targeted decision.

## Limitations

The study covers one model and two pronoun-focused language-pair settings. The filtered corpora identify aligned pronoun alternatives, but they do not establish that every example requires preceding context. Because the evaluation sets are constructed around the targeted pronoun phenomena, improvements in BLEU and COMET on these sets do not establish improvements on naturally distributed MT data or on sentences that do not contain the targeted phenomenon. We also do not compare against contemporary LLM-based contextual MT systems; accordingly, our experiments characterize the behavior of the proposed training objective rather than establish state-of-the-art contextual MT performance. The method also depends on the reliability of the QE model, accurate pronoun identification, word alignment during data construction, and validation-based selection of the reward weights. Because English–German and English–French use different QE models, their raw QE values are not directly comparable. Finally, the method targets phenomena that can be represented through explicit token-position signals; it may not transfer directly to discourse properties that lack such localized supervision.

## Abstract

Bioinformatics is almost invisible in Machine Translation (MT) research, despite being a hard case: dense specialised terminology, a high density of Multiword Expressions (MWEs), and an acute scarcity of parallel data. We address this gap for English–French. We compile a bioinformatics parallel corpus (14,467 sentence pairs) and expand it to 236k pairs through four augmentation strategies, each profiled for lexical diversity before use, then fine-tune five compact models (223M–8B parameters) under an incremental data ablation. We evaluate with automatic metrics and with a three-rater MQM evaluation involving professional life-sciences translators and using an error typology extended with a dedicated MWE category. Domain adaptation improves every system on every metric, with fine-tuned models surpassing much larger state-of-the-art commercial models on our domain test set. Expert judgements reveal a more structured picture with Accuracy errors falling by up to 68.8% and MWE errors by up to 51.1%, while also highlighting an accuracy–fluency trade-off that the automatic metrics conceal. Notably, the least lexically diverse augmentation sources contribute gains comparable to the most diverse ones, which we advance as one candidate account of the trade-off. We release all corpora, synthetic data, and adapted models.

## 1 Introduction

Machine Translation (MT) has become a routine part of how scientific knowledge circulates, but its coverage of specialised domains is uneven. Biomedical translation has been the subject of a sustained shared-task effort (Neves et al., 2018, 2024), while the neighbouring field of bioinformatics, now central to genomics, proteomics, and translational medicine, has received essentially no attention. At the outset of this work we could identify no bioinformatics parallel corpus, no domain-adapted MT system, and no evaluation protocol designed for the domain's characteristic linguistic profile.

This absence matters for three reasons. First, bioinformatics is where much of the life sciences' methodological literature now lives, and its training and documentation materials are overwhelmingly English-first, a barrier for learners and practitioners working in other languages. Second, the domain is linguistically distinctive rather than simply "biomedical text with more code": it combines dense specialised terminology with a high density of nominal MWEs (Giraud and Gargett, 2026), so that the units a translator must get right are frequently multi-token rather than single-token. Third, and most practically, parallel data in the domain is scarce enough that the standard recipe of "fine-tune on in-domain bitext" cannot be applied directly.

We also take a position on system scale. The prevailing assumption that translation quality tracks parameter count is a poor fit for institutional deployment in the life sciences, where compute budgets are modest, data governance may preclude commercial APIs, and MT is increasingly one component in a larger pipeline rather than an end-user product. Compact, specialised translators are attractive precisely because they can be fine-tuned cheaply, deployed locally, and orchestrated as tools inside agentic workflows, where the translation task is decomposed into drafting, checking, and editing stages handled by separate components (Briakou et al., 2024; Wu et al., 2024). Establishing whether a sub-4B domain-adapted model can match a frontier general-purpose system on a specialised domain is therefore a question about system design, not only about benchmark scores.

This paper reports a full pipeline for English–French bioinformatics MT and asks:

- **RQ1**: What impact do the selected domain-adaptation strategies, in particular synthetic data augmentation, have on the effectiveness

*Proceedings of the Eleventh Conference on Machine Translation*, pages 168–182
October 28-29, 2026 ©2026 Association for Computational Linguistics

and efficiency of MT for bioinformatics?

- **RQ2**: To what extent does domain adaptation improve translation quality according to automatic metrics *and* to professional human judgement, with specific attention to terminology and MWEs?

Our contributions[1] are: (i) the first English–French bioinformatics parallel corpus and two comparable monolingual corpora, together with 174k synthetic pairs produced by four distinct strategies and profiled for lexical diversity before use; (ii) five domain-adapted systems spanning 223M–8B parameters, released openly, with a data ablation isolating the contribution of each augmentation source; (iii) an MQM-based human evaluation with three professional life-sciences translators, using an error typology extended with a dedicated MWE category and reporting high inter-rater reliability; and (iv) evidence that domain adaptation buys accuracy and terminological precision at a measurable cost in idiomaticity, a trade-off that the automatic metrics used here do not surface.

## 2 Background and Related Work

**MT for specialised and life-science domains.** Domain-specific MT has concentrated on "flagship" domains where large parallel corpora and institutional demand coincide: EU law (Koehn, 2005), patents, and broad scientific platforms such as SciELO (Soares et al., 2018). In the life sciences, the WMT biomedical task has driven most progress, working from Medline abstracts and clinical text (Neves et al., 2018; Bawden et al., 2019; Neves et al., 2023, 2024). Its recurring recipe is out-of-domain pre-training plus in-domain fine-tuning and data selection, and dedicated biomedical systems consistently beat generic ones on terminology and adequacy (Bérard et al., 2020; Liu and Huang, 2021). Two findings carry over to our setting: biomedical text has a long-tail terminological distribution that makes generic models suboptimal (Liu and Huang, 2021), and adapted systems are repeatedly observed to track source structure and lack the fluency of human translation (Neves et al., 2024), an observation our human evaluation quantifies. Bioinformatics shares the biomedical register but draws on computational, statistical, and software vocabulary alongside biological entities, limiting how far biomedical resources transfer.

[1]An earlier version of this work appeared in the author's doctoral thesis (Giraud, 2026).

**Domain adaptation.** General-purpose MT performs poorly on specialised text, with errors concentrated on exactly the lexical and phraseological phenomena specialists care about (Chu and Wang, 2018; Saunders, 2022). Fine-tuning on in-domain bitext is the dominant remedy (Sennrich et al., 2016), with evidence from legal MT (Bago et al., 2022), in-house translation-memory adaptation (Vieira et al., 2024), and scholarly communication, where Macken et al. (2024) found in a fine-grained human evaluation of English–French scientific translation that adapted systems made fewer terminology errors than a generic commercial baseline. Most relevant to our argument, Han et al. (2024) report that a small specialised clinical model outperformed a much larger general one *in expert judgement*. This is the pattern we reproduce for bioinformatics, and the reason we make expert evaluation rather than metrics the arbiter of the base-versus-adapted comparison. Fine-tuning nonetheless presupposes sufficient in-domain bitext and well-defined domain boundaries (Chu and Wang, 2018), neither of which holds here.

**Data scarcity and augmentation.** Low-resource conditions arise from under-resourced domains as well as language pairs (Haddow et al., 2022), and sparse in-domain data impedes the learning of domain terminology and MWEs (Haque et al., 2019). Back-translation of in-domain target text is a common response (Sennrich et al., 2016), effective across medical, legal, and IT domains (Kumari et al., 2021) and in biomedical shared-task submissions (Wu et al., 2022; Castaldo et al., 2024). LLMs now generate in-domain bitext directly under three broad strategies: paraphrasing, which rivals zero-shot generation (Radliński et al., 2025) but shows diminishing and eventually negative returns at volume (Sobrevilla Cabezudo et al., 2024); terminology-constrained generation, which nearly doubled correct term usage in Moslem et al. (2023); and free generation from scratch (Oh et al., 2023; Yang and Nicolai, 2023), scaled to build large synthetic corpora (de Gibert et al., 2025). Gains from added data saturate early, around 50k pairs in low-resource settings (Lee et al., 2022). Synthetic data also carries hallucinations and stylistic quirks that diverge from human translation norms (Nadăş et al., 2025). Lexical Diversity (LD) is one measurable proxy for this, and correlates with downstream quality in both LLM training (Chen et al., 2024) and back-translation for MT (Burchell et al., 2022);

we profile each of our synthetic sources on it in Section 3.4. What remains unestablished is how these strategies contribute *differentially*, since most studies test one against a natural-only baseline; our ablation separates them, and our human evaluation probes the stylistic cost they may carry.

**Compact models and efficiency.** Scaling laws favour larger models in general, but the heuristic that capability follows from scale is weakening (Hooker, 2025), and for task-constrained applications the evidence runs the other way. Wassie et al. (2024) show a domain-adapted 3.3B NLLB-200 beating fine-tuned 7–8B LLMs on biomedical translation, and Keles et al. (2024) report sub-100M biomedical models outperforming GPT-4-TURBO and Google Translate. Belcak et al. (2025) generalise this beyond MT, arguing that small models are the appropriate default for agentic workloads that repeat a narrow task under latency and cost constraints, a description that fits domain-specific MT, and that makes compact adapted translators natural tool-level components in orchestrated pipelines. Quantisation (Dettmers et al., 2022) and parameter-efficient fine-tuning (Bapna and Firat, 2019; Hu et al., 2022) make this practical; QLoRA combines both, enabling single-GPU fine-tuning without degradation relative to 16-bit training (Dettmers et al., 2023). In MT, Zhang et al. (2023) and Koneru et al. (2024) report consistent gains from PEFT, and, closest to our setup, Rios (2025) adapts FLAN-T5, LLAMA-3-8B, and TOWER-7B to the medical domain with 4-bit QLoRA. These choices are not only computational. Training a single large Transformer can emit hundreds of thousands of pounds of $CO_2$ (Strubell et al., 2019), and carbon accounting is now reportable (Lannelongue et al., 2021). Hence our restriction to sub-10B systems.

**Terminology and MWEs.** Specialised terminology is a documented MT failure point (Haque et al., 2020), and neural models are sensitive to domain shift partly because they lack parallel supervision for domain terms (Hu et al., 2019); evaluation of this is typically coarse, via term-list accuracy, and rarely covers multiword variants. Yet specialised concepts are frequently lexicalised as multiword units: multiword noun sequences are the predominant vehicle for technical term formation in English (Justeson and Katz, 1995), and scientific prose packs knowledge into dense nominal groups (Alves et al., 2024a). MWEs are the proverbial "pain in the neck" for NLP (Sag et al., 2002) because they violate compositionality (Constant et al., 2017); in MT this surfaces as literal renderings and terminological inconsistency when systems fail to treat them as single units (Monti et al., 2018; Inurrieta et al., 2020), and linguistically motivated evaluations still report weaknesses on phraseology for systems competitive on aggregate scores (Manakhimova et al., 2023). For bioinformatics specifically, Giraud and Gargett (2026) show that nominal MWEs dominate the bioinformatics inventory, with distributions varying across IMRaD sections. Since English nominal compounds must generally be unpacked into prepositional or relative constructions in French, MWEs are a natural pressure point for EN–FR MT here, and one automatic metrics are poorly placed to detect, motivating our dedicated MQM category.

**Evaluating domain-specific MT.** Reference-based metrics remain standard (Papineni et al., 2002; Snover et al., 2006; Popović, 2015; Post, 2018), supplemented by neural metrics (Rei et al., 2020). Both have limits: reference dependence penalises valid alternatives, including renderings that follow domain convention more closely than the reference (Mathur et al., 2020), and neural metrics degrade under domain shift (Zouhar et al., 2024). More pointedly, general-purpose metrics give no fine-grained signal on specific phenomena, so terminological consistency and MWE rendering can improve substantially without this being visible in BLEU or COMET (Agrawal et al., 2024). Human evaluation therefore remains the reference point (Freitag et al., 2021), and error-typology annotation such as MQM (Lommel et al., 2013; Lommel, 2018; Freitag et al., 2021) yields a structured error profile supporting diagnosis rather than ranking alone, extensible to new domains through custom categories. Three recurring methodological concerns shaped our design: crowdsourced raters are contested for domain-specific assessment (Läubli et al., 2020; Krüger, 2022); reporting of rater profiles, instructions, and agreement is frequently incomplete (Marie et al., 2021); and sentence-level evaluation sits uneasily with the view that the unit of translation is the text in context (Krüger, 2022). We follow the first two (professional domain-specialist raters, transparent protocol, reliability statistics) and return to the third in Section 6.

## 3 Experimental Setup

### 3.1 Natural parallel data

No bioinformatics parallel corpus could be identified, so one was compiled. English–French abstract pairs were sourced from (i) research articles retrieved via the PubMed and Scopus APIs and scraped from publisher sites (EDP Sciences, ScienceDirect, John Libbey Eurotext), and (ii) francophone doctoral and master's theses from HAL Thèses and `theses.fr`, which conventionally publish abstracts in both languages. This yielded 1,563 parallel abstracts (158 from articles, 1,405 from theses).

Abstracts were segmented with pySBD (Sadvilkar and Neumann, 2020), aligned with Bertalign (Liu and Zhu, 2023), and filtered with Bicleaner AI (Zaragoza-Bernabeu et al., 2022) at a stringent threshold of 0.85 (against the 0.5 used by the tool's authors) in order to retain high-quality pairs. The resulting corpus, BIOPAR, contains 14,467 sentence pairs, split 80/10/10 into train (11,567), development (1,450), and test (1,450).

### 3.2 Monolingual data

Two comparable monolingual corpora support augmentation and domain profiling. We utilised BIOMONO_EN[2] (Giraud and Gargett, 2026), a corpus comprising 4,707 bioinformatics articles from the `allofplos` collection (24.2M words), and BIOMONO_FR, comprising 212 French bioinformatics articles from ScienceDirect, *M/S*, and *Interstices* (343,834 words; 14,005 sentences).

### 3.3 Synthetic data generation

Four generation strategies were applied, chosen to target different weaknesses of the natural corpus, alongside a small quantity of mined bitext (Table 1).

**Wikipedia bitext mining.** EN/FR Wikipedia articles from six bioinformatics-adjacent categories were mined with LaBSE (Feng et al., 2022) sentence embeddings via the Sentence-Transformers mining framework (Reimers and Gurevych, 2020), retaining pairs above a similarity threshold of 1.65 (against the 1.2–1.3 usually recommended). 715 sentence pairs were retained. Unlike the four strategies below, this data is mined rather than generated, and is reported separately throughout.

**Terminology-constrained generation.** A bilingual terminology database was extracted with `tm2tb`, a KeyBERT-based (Grootendorst, 2020) bilingual extractor, and used to constrain synthetic generation. Following Moslem et al. (2022, 2023), the top-1k single-, two-, and three-word terms from the bilingual terminology database were used to constrain generation: GPT-3.5-TURBO was prompted to produce 20 in-domain English sentences containing each source term, then to translate them under the constraint that the term be rendered by its approved French equivalent. 60,039 pairs.

| Source | Pairs |
|---|---|
| BIOPAR (train split), natural | 11,567 |
| Wikipedia bitext mining | 715 |
| Terminology-constrained generation | 60,039 |
| Paraphrasing (GPT-4O) | 34,704 |
| BIOMISTRAL over-generation | 64,972 |
| BIOMONO_FR back-translation | 14,005 |
| ELRC-EMEA (biomedical) | 50,000 |
| **Total** | **236,002** |

Table 1: Composition of the training data.

**Paraphrasing.** GPT-4O generated three domain-constrained paraphrases per training-split English sentence, which were then translated. 34,704 pairs.

**Open-model over-generation.** To reduce reliance on commercial APIs, BIOMISTRAL-7B (Labrak et al., 2024) was used in an over-generation setup (Moslem et al., 2022): 15,000 randomly sampled French in-domain sentences from BIOMONO_FR were used as seeds (top-$k$ = 10, top-$p$ = 0.95, 2 returned sequences), producing roughly four synthetic sentences per seed. 64,972 pairs after back-translation.

**Back-translation.** BIOMONO_FR was back-translated with GPT-4O under a format-preserving prompt. 14,005 pairs were generated.

A further 50,000 pairs of neighbouring-domain biomedical data were drawn at random from ELRC-EMEA (Bicleaner-filtered at 0.85) to test whether adjacent-domain data still helps once in-domain synthetic data is abundant.

### 3.4 Lexical profiling of the synthetic data

Synthetic data can degrade a corpus while enlarging it: LLM outputs carry hallucinations, terminological slips, and stylistic quirks that diverge from human translation norms (Nadăş et al., 2025), and decoding strategies bias generation toward high-frequency phrasing (Holtzman et al., 2020). Lexical Diversity (LD) is one measurable dimension of this. Chen et al. (2024) report a positive correlation

[2] https://github.com/jurgigi/BioMONO

| Source | MTLD | HD-D |
|---|---|---|
| *Natural reference* | | |
| BIOPAR_EN | 89.81 | 0.8678 |
| BIOMONO_EN | 80.60 | 0.8898 |
| *Synthetic* | | |
| Back-translation | 85.50 | 0.8537 |
| Paraphrasing | 65.24 | 0.8737 |
| BIOMISTRAL over-generation | 56.45 | 0.8371 |
| Terminology-constrained | 47.20 | 0.8490 |

Table 2: Lexical Diversity of each synthetic source against natural in-domain reference corpora.

between synthetic data diversity and downstream LLM performance, and in MT specifically Burchell et al. (2022) find that LD correlates more strongly with final model quality than syntactic diversity does. Work on recursive training shows the failure mode at the limit, with output diversity collapsing over successive generations (Guo et al., 2024; Shumailov et al., 2024; Zhang and Pavlick, 2025); our setting mixes synthetic with natural data and so is not that scenario, but the direction of risk is the same.

We therefore profiled each source before use with MTLD and HD-D, two measures designed to mitigate the length sensitivity of naïve type–token ratios (Malvern et al., 2004; McCarthy and Jarvis, 2010), computed with `lexicalrichness`. All scores in Table 2 are computed on the English side, so that synthetic sources and natural reference corpora are directly comparable; BIOPAR_EN denotes the English side of the natural parallel corpus. Wikipedia mining is excluded, as 715 pairs is too small for stable MTLD estimation.

Generation method drives LD far more than volume does (Table 2). Back-translation is the only source approaching natural text, exceeding the BIOMONO_EN reference on MTLD. Since these scores are computed on the generated English side, this cannot be attributed to natural prose: it reflects the seeding, as each sentence derives from a distinct naturally occurring French sentence and generation is constrained neither by a term list nor by a paraphrase target (Fadaee et al., 2017).

It is important to note that LD captures repetition, not adequacy; a highly diverse corpus can still be terminologically wrong. LD in generated text is also sensitive to prompt and decoding configuration (Martínez et al., 2024), so these figures characterise our generation setups rather than the strategies in the abstract. Section 5 returns to these figures once the ablation results are in view.

### 3.5 Ablation scenarios

Four incremental scenarios isolate the contribution of each data type[3]: **11k** (natural only); **107k** (+ Wikipedia, terminology-constrained, paraphrased); **186k** (+ BIOMISTRAL, back-translation); **236k** (+ ELRC-EMEA biomedical).

### 3.6 Models and fine-tuning

Three architectures were fine-tuned[4] across all four scenarios: T5-BASE (223M) (Raffel et al., 2020), NLLB-200-DISTILLED-600M (NLLB Team et al., 2022), and LLAMA-3.1-8B-INSTRUCT (Touvron et al., 2023). Two further systems were fine-tuned on the 236k scenario only: MADLAD400-3B-MT (Kudugunta et al., 2023) and TOWERINSTRUCT-7B-v0.2 (Alves et al., 2024b). Encoder–decoder models were trained with `Seq2SeqTrainer`; decoder-only models with `SFTTrainer` and QLoRA (Dettmers et al., 2023). Full hyperparameters are in Appendix A.

### 3.7 Automatic evaluation

BLEU, chrF2, and TER are computed with SacreBLEU (Post, 2018), and COMET with WMT22-COMET-DA (Rei et al., 2020), on the held-out 1,450-pair in-domain test set. Comparison systems include non-adapted baselines, larger models in the same families, AYA-EXPANSE-8B, as well as commercial state-of-the-art and frontier models.[5]

### 3.8 Human evaluation

Thirty sentences (≈1,000 words) were sampled at random from BIOMONO_EN, within the 500–5,000-word range recommended for MQM linear scoring (Lommel et al., 2024). MWEs were identified by dependency parsing and list matching following Giraud and Gargett (2026), and marked inline with `<mwe>` tags so that raters could locate them; unsegmented raw source was also supplied for context.

The analysis reported here is restricted to base and domain-adapted pairs, so that the comparison isolates the effect of adaptation under matched architectures: T5-BASE vs. T5_236k, and LLAMA-3.1-8B-INSTRUCT vs. LLAMA-3.1-8B-INSTRUCT_236k. A fifth system, a commercial

[3]All training sets as well as development and test sets are available at https://huggingface.co/jurgiraud/datasets

[4]All fine-tuned models are available at https://huggingface.co/jurgiraud/models

[5]Commercial systems were accessed via their respective APIs.

baseline, was annotated in the same sessions but is excluded from this analysis, since it shares neither training data nor architecture with the adapted systems and would confound the base-versus-adapted contrast. Each rater therefore annotated 5,000 words in total. Three professional EN→FR translators specialising in the life sciences were recruited through the Société Française des Traducteurs, from a pool of 36 eligible translators identified across four professional bodies, and compensated at £0.05/word[6] (£250 each), above prevailing post-editing and proofreading rates.

The MQM typology followed Freitag et al. (2021), with two severity levels (Minor, Major; multipliers 1 and 5) and main categories Terminology, Accuracy, Linguistic conventions, Style, Locale conventions, Source error, and Other. A dedicated **Multiword Expressions** category was added to capture errors on tagged MWEs. Annotation was carried out in a purpose-built Label Studio interface with a free-text comment field per error; comments were subsequently coded thematically (Braun and Clarke, 2022) in NVivo. Raw Quality Scores (RQS) were computed per system per rater, and inter-rater reliability assessed with two-way mixed-effects ICC.

## 4 Results

### 4.1 Data ablation

Table 3 shows a consistent picture across architectures. Every scenario improves on its baseline on every metric, and the largest single step is always the first: moving from no adaptation to 11k natural pairs gains T5-BASE 4.96 BLEU, NLLB 3.11, and LLAMA-3.1 1.88. For T5-BASE, this first step alone accounts for 79% of the total adaptation gain. Subsequent increments are far smaller and no longer follow a single pattern: for T5-BASE, 11k→107k adds 0.61 BLEU, 107k→186k adds 0.65, and 186k→236k adds 0.08; for NLLB the corresponding figures are 0.57, 0.04, and 0.05.

LLAMA-3.1 is the exception to the plateau: its largest post-baseline gain (+1.41 BLEU, −2.33 TER) comes at the final 186k→236k step, where the ELRC-EMEA biomedical data is added. This is consistent with a decoder-only instruction-tuned model benefiting from additional register-consistent data even after in-domain saturation, whereas the encoder–decoder systems have already converged.

| System | BLEU↑ | chrF2↑ | TER↓ | COMET↑ |
|---|---|---|---|---|
| T5-BASE | 39.23 | 67.31 | 51.27 | 84.50 |
| + 11k | 44.19 | 71.15 | 45.98 | 85.43 |
| + 107k | 44.80 | 71.57 | 46.24 | 85.60 |
| + 186k | 45.45 | **71.99** | **45.62** | 85.61 |
| + 236k | **45.53** | 71.92 | **45.62** | **85.64** |
| NLLB-600M | 41.00 | 68.48 | 49.26 | 84.54 |
| + 11k | 44.11 | 70.90 | 46.72 | 85.41 |
| + 107k | 44.68 | 71.33 | 46.42 | 85.74 |
| + 186k | 44.72 | 71.53 | 46.38 | 85.75 |
| + 236k | **44.77** | **71.64** | **46.24** | **85.84** |
| LLAMA-3.1 | 40.39 | 69.41 | 50.36 | 85.01 |
| + 11k | 42.27 | 69.68 | 48.83 | 85.30 |
| + 107k | 42.69 | 69.83 | 48.71 | 85.30 |
| + 186k | 43.16 | 70.46 | 48.01 | 85.27 |
| + 236k | **44.57** | **71.44** | **45.68** | **85.55** |

Table 3: Data ablation across three architectures on the in-domain test set. Best per block in bold.

Total adaptation gains are largest for the smallest model: T5-BASE gains 6.30 BLEU and 1.14 COMET, against 3.77/1.30 for NLLB and 4.18/0.54 for LLAMA-3.1. Baseline quality and headroom are inversely related, and architectural differences that are visible before adaptation largely disappear after it, with all three systems converging into a 44.5–45.5 BLEU band.

### 4.2 Cross-system comparison

Table 4 places the adapted systems against non-adapted open models and commercial baselines. The best system overall is MADLAD400-3B-MT_236k, a 3B model that outperforms every commercial system tested on all four metrics, including the frontier models GPT-5.5, Claude-SONNET-5, and Claude-OPUS-5. TOWER-7B_236k is close behind and posts the highest chrF2 of any system. Four of the five adapted systems, including the 223M T5-BASE, sit within 1.3 BLEU of GPT-4O, and all five outperform Google Translate by a wide margin.

Adaptation is also more effective than scale within families: T5_236k (223M) exceeds T5-LARGE (738M) by 5.08 BLEU, and NLLB-600M_236k exceeds NLLB-200-1.3B by 1.69. Notably, BIOMISTRAL-7B, pre-trained on biomedical text, is the weakest system tested (34.31 BLEU), a reminder that adjacent-domain pre-training is not a

[6]The amount provided to participants was based on a survey conducted by the Institute of Translation and Interpreting (ITI) Medical and Pharmaceutical Network (2022) which reports the various rates used by professional translators across translation-related tasks. Available at: https://itimedical.co.uk/wp-content/uploads/2023/01/Translator_and_Interpreter_Survey_Results.pdf

Table 5: MQM error counts aggregated over three raters and 30 segments per system. Italics give the change from base to adapted.

substitute for task-specific adaptation, even though the same model proved useful as a synthetic data *generator*.

### 4.3 MQM evaluation

Table 5 aggregates error counts across the three raters. The pattern is sharply structured. Errors in the categories that matter most for technical adequacy fall steeply: Accuracy by 68.8% for T5 and 62.5% for LLAMA-3.1, Terminology by 32.3% and 48.1%, and MWEs by 51.1% and 23.5%. Segments annotated error-free rise from 12 to 30 (T5) and from 10 to 26 (LLAMA-3.1).

Style behaves differently. It is the only category that does not improve for T5, rising by 18.2%, and it improves only marginally for LLAMA-3.1 (−6.5%). After adaptation, Style becomes the single largest error category for T5_236k (65 of the

| | T5 | | | LLAMA-3.1 | | |
|---|---|---|---|---|---|---|
| | base | 236k | Δ | base | 236k | Δ |
| Rater 1 | 64.46 | 78.62 | *+21.97%* | 67.52 | 84.52 | *+25.18%* |
| Rater 2 | 87.37 | 94.91 | *+8.63%* | 84.22 | 95.72 | *+13.65%* |
| Rater 3 | 74.64 | 87.78 | *+17.60%* | 66.19 | 86.56 | *+30.78%* |
| **Mean** | 75.49 | **87.10** | *+16.07%* | 72.64 | **88.93** | *+23.20%* |
| ≥1 Major | 74.44 | 38.89 | *−47.8%* | 68.89 | 35.56 | *−48.4%* |

Table 6: MQM Raw Quality Scores per rater, and percentage of segments containing at least one Major error (mean over raters). For the RQS rows, Δ in the **Mean** row is the mean of the three per-rater percentage changes; for the Major-error row, Δ is computed on the rater means.

152 errors distributed across the five main categories), having been roughly comparable to Accuracy before. Linguistic conventions diverge between architectures: LLAMA-3.1 improves dramatically (−70.4%, from a very high base of 54), while T5 worsens slightly.

Table 6 reports quality scores. Domain adaptation raises RQS by 16.07% for T5 and 23.20% for LLAMA-3.1 on average, with every rater showing the effect in the same direction. The proportion of segments containing at least one Major error roughly halves for both architectures: 74.44% → 38.89% for T5 and 68.89% → 35.56% for LLAMA-3.1. The two adapted systems converge on a similar quality level (87.10 and 88.93) despite a 36-fold difference in parameter count, mirroring the convergence already visible in the automatic ablation.

Inter-rater reliability is high: ICC(3,1) = 0.85 (95% CI 0.47–0.98, $p < 0.01$) and ICC(3,$k$) = 0.95 (95% CI 0.72–0.99, $p < 0.01$), in the excellent range on standard interpretations (Koo and Li, 2016). Absolute severity differs between raters, with Rater 1 consistently the strictest, but relative system rankings are stable across all three.

### 4.4 Thematic analysis of translator comments

Coding of the free-text comments produced six top-level themes: Lexical Accuracy and Appropriateness; Syntactic and Grammatical Errors; Omission and Addition; Stylistic and Idiomatic Quality; Morphological and Orthographic Issues; and Multiword Expressions.

The lexical theme is the densest, with mistranslated adjectives, adverbs, and verbs alone accounting for 81 references across all four systems. Comments on base-system output typically concern out-

right failures of meaning; comments on adapted output concern finer distinctions of register and precision, for example flagging *grande* where *très grande* or *immense* would render *huge*. The distinction is diagnostic: adaptation moves the failure mode from misunderstanding to imprecision.

The MWE theme confirms the quantitative pattern while adding nuance. Base systems omit or mistranslate MWEs in ways that distort meaning, as when *in competition with each other* is rendered *en compétition* with the reciprocal element dropped. Adapted systems generally preserve MWE boundaries and components but sometimes select French realisations that raters mark as non-idiomatic rather than incorrect.

The stylistic theme is dominated by the code "grammatically correct but overliteral or unnatural," together with specific recurring complaints, notably the overuse of the preposition *pour* in constructions where French would prefer a different linker. Raters also flagged inconsistent terminology within a single system's output, a document-level failure that segment-level training does not address.

## 5 Discussion

**Bigger doesn't necessarily mean better.** On automatic metrics, compact models below 4B parameters match and at times outperform much larger open and commercial models, including frontier models such as GPT-5.5 and Claude-OPUS-5. This carries practical implications for life-sciences institutions, as compact domain-adapted models can be served locally on a single consumer GPU while keeping potentially sensitive data inside the institution, and at a fraction of the training footprint of the largest system we fine-tuned (Table 7). Compact models are also more tractable components for agentic and multi-agent pipelines, where translation is one call among several and per-call latency and cost compound, thus directly contributing to current conversations regarding compact models and their practical advantages as agents (Belcak et al., 2025). The corollary is that the relevant investment is data, not parameters. Our results suggest that the first 10k in-domain pairs deliver most of the achievable gain, that roughly 100k pairs bring systems close to their ceiling, and that further scaling of either data or model size returns little.

**Different synthetic sources do different work.** The ablation lets us attribute effects, though the pattern differs by architecture. For NLLB, the 11k→107k step, driven by terminology-constrained generation and paraphrasing, is the largest post-baseline gain; for T5-BASE it is essentially tied with the following step; and for LLAMA-3.1 the largest gain comes last. Where the 11k→107k step does help, it improves chrF2 and TER alongside BLEU, which suggests genuine structural learning rather than n-gram inflation. The 107k→186k step adds back-translated in-domain French and yields smaller but consistent gains, most plausibly on target-side fluency. The final 236k step adds neighbouring-domain biomedical data and helps least for the encoder–decoder systems, consistent with the core bioinformatics phenomena already being covered, while helping LLAMA-3.1 most. Terminology-constrained generation and back-translation are thus complementary rather than interchangeable: the former densifies coverage of the terms the domain actually uses, the latter supplies naturally occurring target-side phrasing.

The lexical profile in Section 3.4 complicates this picture. The two sources dominating the 107k scenario are by some margin the least lexically diverse of the four (MTLD 47.20 and 65.24, against 80.60–89.81 for natural in-domain text), yet they deliver gains comparable to the far more diverse back-translated data added at 186k. This sits awkwardly with the positive diversity–performance association reported by Chen et al. (2024) and Burchell et al. (2022). The likely reconciliation is that terminology-constrained data trades diversity for term coverage, which is what a terminology-dense domain most needs. Whether that trade is worthwhile depends on which errors one is willing to tolerate, a question the automatic metrics cannot answer and the human evaluation can.

**Terminology and MWEs are where domain adaptation pays off.** The dedicated MWE category earns its place in the typology. MWE errors fall by half for T5 and by a quarter for LLAMA-3.1, and the qualitative data shows the mechanism: adapted systems learn to keep multi-token units intact and to select their conventional French equivalents, where base systems decompose or drop them. Given that nominal compounds dominate the domain's MWE inventory and generally require restructuring in French, this is precisely the phenomenon a bioinformatics-specific system needs to handle, and precisely the one that a BLEU difference of a few points fails to make visible.

**An accuracy–fluency trade-off that metrics conceal.** The most consequential finding is the divergence between what the metrics and the raters see. On automatic metrics, T5_236k improves monotonically. On human judgement, its accuracy improvements are accompanied by an 18.2% *increase* in Style errors, so that stylistic quality becomes its dominant residual weakness. Adaptation appears to pull the output toward the literal, term-faithful end of the spectrum, and in doing so toward *translationese*. This matches the accuracy–fluency trade-off formalised by Lim et al. (2024) and the information-theoretic account of Flamich et al. (2025), and aligns with the biomedical MQM profile reported by Zouhar et al. (2024), where fluency errors substantially outweigh accuracy errors, in contrast to news-domain benchmarks.

Our synthetic data is a plausible contributor, and Section 3.4 gives the suspicion some empirical footing. Back-translated source text carries the artefacts of the back-translating system, and the two sources dominating the 107k scenario score well below natural in-domain text on LD, indicating training material that is more repetitive and formulaic than the prose the systems are ultimately asked to produce. Fine-tuning on such pairs may teach terminology and structure while simultaneously teaching a slightly off register. We stress that this is an association rather than a demonstrated cause: our four sources differ on many dimensions besides diversity, and LD in generated text is itself sensitive to prompt and decoding configuration (Martínez et al., 2024). If the account holds, the trade-off is not intrinsic to adaptation but a property of how the adaptation data was built, and could be attacked by filtering synthetic data on stylistic as well as semantic criteria, or by a dedicated fluency-oriented editing stage downstream of translation.

**Implications for evaluation.** On automatic metrics, adaptation looks uniformly positive: every scenario improves every score for every architecture. The raters see something more differentiated, and locate a regression in a category that the metrics do not isolate. Any evaluation of domain-specific MT that reports only sentence-level metrics will therefore overstate how close adapted systems are to being deployment-ready. The practical recommendation that follows from the human study is that domain adaptation raises the floor of quality substantially, but does not remove the need for stylistic post-editing where publication-quality French is required.

## 6 Limitations

**Single language pair.** All experiments are EN→FR. French is a well-resourced target with an established scientific register and existing terminological infrastructure; the same pipeline applied to a lower-resourced or morphologically richer target would face different constraints, particularly in terminology-constrained generation, where the assumption of a single approved target form is weaker. Extension to additional targets is the most direct next step.

**Synthetic data quality is only partially assessed.** We profile each synthetic source for Lexical Diversity (Section 3.4) and measure the downstream effect of each on translation quality, but we do not assess the intrinsic adequacy, terminological correctness, or register fidelity of the synthetic pairs themselves. LD captures repetition, not whether a generated sentence is well-formed, accurate, or stylistically typical of the domain. Given our evidence that the least diverse sources deliver gains comparable to the most diverse, a fuller pre-use audit, combining LD with adequacy checks, register comparison against natural in-domain text, and hallucination detection, would allow the trade-off to be attributed with confidence rather than inferred.

**Human evaluation scale.** Three raters, 30 segments, and four systems is at the lower bound of the range recommended by Freitag et al. (2021), chosen under budget constraints. ICC values are high but their confidence intervals are wide (ICC(3,1): 0.47–0.98), and absolute severity varies noticeably between raters. Additionally, the two best systems on automated metrics, MADLAD400-3B_236k and TOWER-7B_236k, were not included in the human study. A larger study with more raters, more segments (and therefore longer context), and full system coverage would allow significance testing rather than descriptive comparison.

## 7 Conclusion

We have presented the first end-to-end study of machine translation for bioinformatics, covering corpus construction, four synthetic augmentation strategies profiled for lexical diversity, adaptation of five compact and mid-sized systems, and expert evaluation under an MWE-extended MQM protocol. Domain adaptation works, and works

best where it matters: a 3B adapted model outperforms every commercial system we tested, including current frontier models, on the domain test set, and adapted systems reduce Accuracy errors by roughly two-thirds and MWE errors by a quarter to a half in professional judgement. It also has a cost that automatic metrics do not report: stylistic quality does not improve alongside accuracy and can degrade. For a domain where terminological precision is non-negotiable but the output will often be read by specialists rather than published, this is a favourable trade, but it is one that should be made knowingly, and it points toward adaptation pipelines that treat fluency as a separately optimised objective rather than a by-product. All corpora, synthetic datasets, and adapted models are released openly.

## Ethics Statement

The human evaluation received institutional ethics approval (reference number 2024-0259-2). Participants gave informed consent, were free to withdraw, and were compensated for their time. Annotations are reported in aggregate and by anonymised rater ID.

## Sustainability Statement

The carbon footprint of the fine-tuning runs was estimated using the *Green Algorithms* framework proposed by Lannelongue et al. (2021). Across all runs, fine-tuning consumed 137.5 kWh for an estimated 31.8 $kgCO_2e$; the per-model breakdown is given in Table 7. LLAMA-3.1-8B-INSTRUCT alone accounts for 56% of the total, while MADLAD400-3B, the best-performing system, accounts for 6.5%. These figures exclude synthetic data generation, which was performed on external API infrastructure and could not be measured.

| Model | kWh | $kgCO_2e$ |
|---|---|---|
| T5-BASE | 19.72 | 4.56 |
| NLLB-200-DISTILLED-600M | 17.21 | 3.98 |
| LLAMA-3.1-8B-INSTRUCT | 76.57 | 17.70 |
| TOWERINSTRUCT-7B-V0.2 | 15.00 | 3.47 |
| MADLAD400-3B | 8.97 | 2.07 |
| **Total** | **137.47** | **31.78** |

Table 7: Estimated energy use and carbon footprint of all fine-tuning runs.

# A Fine-tuning parameters

## A.1 Training setups

### A.1.1 T5-BASE and NLLB-200-DISTILLED-600M (`Seq2SeqTrainer`)

Both T5-BASE and NLLB-200-DISTILLED-600M were fine-tuned with the `transformers` `Seq2SeqTrainer` using the same training configuration:

- **Epochs:** 8
- **Learning rate:** $2 \times 10^{-5}$
- **Batch size:** 16 (per device)
- **Precision:** `bfloat16` (`bf16`)

### A.1.2 LLAMA-3.1-8B-INSTRUCT (`SFTTrainer` + QLoRA)

LLAMA-3.1-8B-INSTRUCT was fine-tuned using `transformers` `SFTTrainer` with QLoRA (4-bit quantization + LoRA adapters):

**LoRA configuration**

- **Rank ($r$):** 8
- **$\alpha$:** 16
- **Dropout:** 0.05
- **Target modules:** `["q_proj", "v_proj", "o_proj"]`

**Training configuration**

- **Epochs:** 4
- **Learning rate:** $1 \times 10^{-4}$
- **Batch size:** 16 (per device)
- **Gradient accumulation:** 2
- **Optimizer:** `paged_adamw_8bit`

**Chat template**

```
<|im_start|>user
{USER_PROMPT}<|im_end|>
<|im_start|>assistant
{MODEL_RESPONSE}<|im_end|>
```

## A.2 Total runtime across all runs

| Model | Total runtime (hh:mm:ss) |
|---|---|
| T5-BASE | 33:31:12 |
| NLLB-200-DISTILLED-600M | 29:03:18 |
| LLAMA-3.1-8B-INSTRUCT | 307:44:12 |

Table 8: Total fine-tuning runtime aggregated across all runs for each model.

## A.3 Compute environment

### A.3.1 T5-BASE and NLLB-200-DISTILLED-600M

- **Platform:** Google Colab[7]
- **CPU:** Intel(R) Xeon(R)
- **GPU:** NVIDIA A100-SXM4-40GB
- **RAM:** 83.5 GB

### A.3.2 LLAMA-3.1-8B-INSTRUCT

- **Operating system:** Windows 11 (Desktop)
- **CPU:** Intel Core i7-14700F
- **GPU:** NVIDIA GeForce RTX 4060 Ti
- **RAM:** 64 GB (DDR4)

cgramazi@amazon.com

## Abstract

Cross-lingual sentence alignment establishes correspondence between a document and its translation, where correspondence is not always complete, one-to-one, or monotonic. Current embedding-based aligners score sentence pairs with a multilingual encoder, then trace a single monotonic path across the full alignment grid. This forced path cascades errors through non-parallel or reordered content. We present ChainAlign, which instead adapts *seed-chain-extend* from computational genomics: it seeds multi-resolution candidate anchors from multilingual embeddings, selects the maximum-weight non-crossing subset by co-linear chaining in $O(N \log N)$ via a Fenwick tree, and fills the residual gaps with local dynamic time warping. Because the chain imposes no coverage requirement, non-parallel content becomes unaligned gaps rather than cascading errors, and multi-chain extraction handles reordering that a monotonic path cannot represent. On three benchmarks across four language pairs, ChainAlign achieves the highest strict and lax F1, ahead of Bertalign, SentAlign, and Vecalign. Evaluation shows the sparse formulation outperforms exhaustive dynamic programming using the same edge weight function.

## 1 Introduction

We present ChainAlign, a cross-lingual sentence alignment system that adapts the seed-chain-extend paradigm from computational genomics to establish sentence-level correspondences between a document and its translation. Translation is not always one-to-one. Most sentences correspond one-to-one between source and target, but translators also split and merge them, and occasionally insert, delete, or reorder content (for example, adding cultural context absent from the source). A sentence aligner is therefore only as accurate as its ability to model correspondences that are not guaranteed to be complete, one-to-one, or monotonic. These departures, not the one-to-one majority, are where current aligners still struggle, and they grow more common as training data shifts from purpose-collected parliamentary transcripts toward diffuse, web-mined, and literary sources; alignment quality increasingly bounds the machine translation and multilingual models built on top of it.

Many sentence aligners used in machine translation share a two-stage design: a multilingual encoder scores candidate pairs, and a search routine selects a globally coherent set of correspondences. The encoders have largely converged on LaBSE-style embeddings (Feng et al., 2022), and modern methods differ mainly in the search step. Every current search routine, whether the dynamic time warping of Vecalign (Thompson and Koehn, 2019), the two-pass dynamic program of Bertalign (Liu and Zhu, 2023), or the shortest-path search of SentAlign (Steingrimsson et al., 2023), traces one monotonic path across the *entire* alignment grid at a cost quadratic in the sentence counts. This forced path is precisely what fails on non-parallel or reordered content, where a poor local choice in an ambiguous region propagates forward and displaces otherwise-confident matches. Computational genomics has long solved a structurally identical problem: establishing partial, rearranged correspondences between sequences at chromosome scale. Its answer, *seed-chain-extend* (Myers and Miller, 1995; Li, 2018), finds confident local matches, chains a co-linear subset of them, and aligns densely only within the residual gaps.

ChainAlign brings this paradigm to cross-lingual sentence alignment: multilingual embeddings supply seeds, an $O(N \log N)$ Fenwick-tree chain (Fenwick, 1994) selects the optimal non-crossing anchor set, and local dynamic time warping fills residual gaps. Unlike heuristic anchoring (Kraif, 2024), anchor selection here is an optimization problem with an exact solution: co-linear chaining reduces to a weighted longest-increasing-subsequence prob-

*Proceedings of the Eleventh Conference on Machine Translation*, pages 183–198
October 28-29, 2026 ©2026 Association for Computational Linguistics

lem solvable in $O(N \log N)$, so the chain is a global optimum rather than the output of a filter.

Across three benchmarks and four language pairs, ChainAlign outperforms Bertalign, SentAlign, and Vecalign on strict and lax F1. Its advantage is sharpest off the clean case: as non-parallel content is injected into a document it stays accurate (losing under 2% strict F1 at 40% injection) because unmatched spans become gaps rather than forced errors, and its multi-chain variant recovers reordering that a single monotonic path cannot represent.

Our contributions are threefold:

1. Seed-chain-extend, the standard genome-alignment paradigm, transfers to cross-lingual sentence alignment as an $O(N \log N)$ Fenwick-tree chaining algorithm.

2. Sparse co-linear chaining outperforms exhaustive dynamic programming on sentence alignment: against a DTW baseline using the same edge weight function, it gains 1.9, 0.6, and 0.5 strict F1 points on Text+Berg, MAC, and OPUS.

3. Non-parallel spans become unaligned gaps, not cascading errors, and multiple chains capture reordering that a single monotonic path cannot.

The same sparsity enables $k > 2$ language multiple alignment (e.g., Fazili and Goswami (2026)) via $k$-dimensional chaining. We provide a sketch of the approach, leaving full-exploration to future work.

## 2 Related Work

**Cross-lingual sentence alignment.** Sentence alignment predates neural embeddings: early aligners such as Hunalign (Varga et al., 2005) relied on sentence-length statistics and bilingual lexicons. Embedding-based aligners, which now substantially outperform them, share a LaBSE-style encoder (Feng et al., 2022) and differ mainly in the search over its similarities. Vecalign (Thompson and Koehn, 2019) uses an approximate dynamic time warping (DTW) borrowed from time series (Salvador and Chan, 2007); Bertalign (Liu and Zhu, 2023) runs a two-pass dynamic program over LaBSE similarities; and SentAlign (Steingrimsson et al., 2023) casts alignment as Dijkstra shortest-path search. Closest to our approach, Kraif (2024) independently arrives at an anchor-plus-local-DP structure, but selects its anchors by heuristic filtering with no optimality guarantee. Token-level aligners such as SimAlign (Jalili Sabet et al., 2020) and fast_align (Dyer et al., 2013) address the related but distinct problem of word rather than sentence correspondence. Vecalign, Bertalign, and SentAlign each recover a single monotonic path that covers both documents in full, whether by exact search (SentAlign) or by a windowed or downsampled approximation of it (Vecalign, Bertalign). Full coverage presupposes a near-monotonic correspondence. This holds for genres typically translated literally (e.g., news) but weakens for genres translated interpretively (e.g., novels), where sentences are more likely to be reordered, split, or merged – a regime that monotonic-leaning benchmarks (Volk et al., 2010) have masked.

**Cross-domain transfer of alignment techniques.** Sequence alignment is a shared primitive across biology, natural language processing (NLP), speech, and time series (Wang and Jiang, 1994; Gale and Church, 1993; Sakoe and Chiba, 1978; Cuturi and Blondel, 2017), and importing a mature technique from one domain into another has repeatedly proven productive. Vecalign's use of DTW is itself such a transfer, from time series into sentence alignment (Thompson and Koehn, 2019). In embedding space, optimal transport has crossed into NLP for bilingual lexicon induction (Zhang et al., 2017) and cross-lingual alignment via Gromov–Wasserstein distance (Alvarez-Melis and Jaakkola, 2018; Peyré and Cuturi, 2019), while profile-HMM ideas from biology have informed speech forced alignment (McAuliffe et al., 2026). These transfers import not just an algorithm but the accumulated understanding of when it works. Our work continues this tradition, importing co-linear chaining from genomics (Myers and Miller, 1995).

**Co-linear chaining.** Co-linear chaining originates in computational genomics (Myers and Miller, 1995). An anchor is a local match with a position in each of the two sequences. Chaining selects the maximum-weight set of anchors whose positions strictly increase in both sequences. Such a set is co-linear and non-crossing: drawn as edges between the two documents, no two cross, so the selected anchors preserve order. Non-crossing is the chaining term for this order constraint; the DTW and DP literature calls the same property monotonicity, the difference being that chaining imposes it on a selected subset of anchors rather than on a complete path. Myers and Miller (1995) solve the $k$-sequence problem in subquadratic $O(N \log^k N)$

time by line sweep with orthogonal range search. For two sequences under a zero gap cost (no penalty on the distance between consecutive anchors) and strict non-overlap precedence—our setting—the optimal chain is computable exactly in $O(N \log N)$ time, dominated by sorting (Abouelhoda and Ohlebusch, 2005); we implement the anchored prefix-maximum query with a Fenwick tree (Fenwick, 1994). Abouelhoda and Ohlebusch (2005) give the best known bounds for $k > 2$ and treat the zero-gap-cost case as the base of their construction, while Mäkinen and Sahlin (2020) admit overlapping anchors. Practical genome aligners often trade this exactness for speed: minimap2 (Li, 2018), for instance, chains heuristically, bounding the predecessor search per anchor. At the sentence scale, however, the anchor set is small enough that ChainAlign retains the exact $O(N \log N)$ chain. Jain et al. (2022) further show that under a specific gap-and-overlap cost the optimal chaining cost equals an anchored edit distance (their Theorem 2), which places the chaining objective on a formal footing. Their formulation minimizes gap and overlap penalties with no per-anchor reward, so it is a different objective from ChainAlign's per-anchor weight maximization; we claim no edit-distance guarantee for our chain. Chaining alone leaves inter-anchor gaps unaligned; in genomics these are closed by local base-level DP, and the natural NLP analogue is a dense routine such as multi-resolution DTW (Salvador and Chan, 2007) applied only to the short residual spans.

**Filling the gap with ChainAlign** No prior sentence aligner uses exact co-linear chaining: Vecalign and Bertalign approximate the alignment with windowed or downsampled search, and SentAlign optimizes a full monotonic path rather than an anchor subset. Both ingredients already exist – multilingual embeddings supply high-quality anchors, and genomics supplies an exact, theoretically grounded chaining routine – yet no prior work has combined them. ChainAlign does: a sparse-then-dense structure that, because the chain imposes no coverage requirement, admits partial and non-monotonic correspondences that a single forced path cannot represent.

## 3 Method

ChainAlign's seed-chain-extend alignment spans three steps: (1) seeding forms candidates between similar sentence spans; (2) co-linear chaining selects the optimal non-crossing set of anchors; and (3) multi-resolution dynamic time warping extends the gaps between those anchors. We illustrate how ChainAlign differs from three other embedding-based aligners (Vecalign, Bertalign, and SentAlign) in Figure 1.

### 3.1 Seed: Alignment Anchor Candidates

Let $N$ and $M$ denote the number of source and target sentences respectively, assuming $N \geq M$ without loss of generality. A multilingual embedding model transforms sentences to the same vector space (see Figure 2a); we use LaBSE[1] (Feng et al., 2022); in principle, any contrastively-trained multilingual encoder can be substituted, though alignment quality may vary with the encoder's cross-lingual discriminability. Following Thompson and Koehn (2019), who embed concatenated sentence blocks for scoring $k$:$l$ alignments, we precompute embeddings at multiple resolutions (single, pairs, triples, and quadruples of adjacent sentences). For a span of $k$ consecutive sentences starting at position $i$, the multi-resolution embedding $s_i^{(k)}$ is obtained by concatenating the text of $s_i$ through $s_{i+k-1}$ (space-separated) and encoding the result as a single input to the encoder; we do not average individual sentence embeddings, as concatenation preserves inter-sentence coherence and produces more discriminative representations for merged spans. We use cosine similarity to score candidate alignments between sentence spans, creating a bipartite graph between source and target sentences where candidate edges are weighted by cosine similarity; multi-resolution edges may span multiple consecutive sentences on either side. We generate edges at resolutions (1,1), (2,1), (1,2), (3,1), (1,3), (2,2), (3,2), (2,3), (4,1), and (1,4), covering all $(k, l)$ combinations where $k + l \leq 5$.

These edges create a dense graph with up to $10NM$ edges, but we employ three techniques to reduce edge count and create a sparse search space for chaining. First, for parallel corpora where we expect near-complete correspondence, we limit candidate edges to those satisfying $|i/N - j/M| < 0.15$, i.e., source and target positions must be within 15% of each other in fractional document coordinates (Sakoe and Chiba, 1978), preventing spurious matches between similar sentences repeated throughout the text. We chose to operationalize

[1] https://huggingface.co/sentence-transformers/LaBSE

Search strategies over the alignment grid: (a)-(c) search a restricted or chunked grid and resolve m:n in stages; (d) selects a maximal-weight chain over sparse multi-resolution candidates in one step

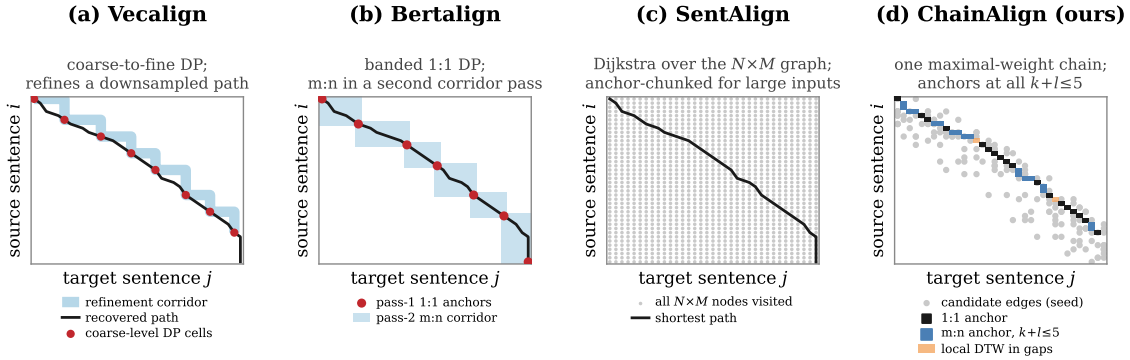

Figure 1: Search strategies over the alignment grid. All four recover a monotonic alignment but differ in what restricts the search and when m:n resolution is decided. Vecalign (a) approximates the path on a downsampled grid, then refines it in a corridor; Bertalign (b) runs a banded 1:1 DP and defers m:n to a second corridor pass; SentAlign (c) finds the optimal path over the $N \times M$ graph, chunked by 1:1 hard-delimiter anchors for large inputs. Each stages resolution and searches a dense, banded, or chunked grid. ChainAlign (d) instead seeds sparse candidates at all resolutions $k{+}l \leq 5$ at once and selects a single maximum-weight non-crossing chain, running dense DTW only in the residual gaps.

thresholds at 15% through trial and error, and implementations may elect to treat the threshold as an additional alignment hyperparameter.

Second, we filter all edges below a similarity threshold of $\tau = 0.3$. Lastly, we apply top-$K$ pruning ($K = 10$) per source row for each multi-resolution edge set. For symmetry, one may additionally retain only edges that are top-$K$ from both source and target perspectives (mutual top-$K$); in our experiments this produced identical results to unidirectional pruning. This leaves us with a sparse graph with at most $10KN = 100N$ edges, i.e., candidate anchors. The resulting sparse graph is illustrated in Figure 2b.

### 3.2 Chain: Select Alignment Anchors

The seed phase produces far more candidate edges than are mutually compatible, with many overlapping or crossing each other. The chain phase selects the maximum-weight non-crossing subset: no two selected edges may overlap in source or target position, and their relative order must be preserved in both sequences, visualized in Figure 3. This problem is known in bioinformatics as co-linear chaining (Myers and Miller, 1995), and reduces to a weighted variant of Longest Increasing Subsequence on the target dimension after sorting edges by source position.

The naive solution to weighted LIS is an $O(E^2)$ dynamic programming solution:

```
for each edge e = (s_i^(k), t_j^(l), w)
  in source order:
for each preceding edge e' = (s_i'^(k'),
      t_j'^(l'), w'):
  if i'+k' <= i and j'+l' <= j:
    dp[e] = max(dp[e], dp[e'] + w)
```

Sorting edges by source position ensures each edge is processed after all edges beginning earlier. The inner loop then reduces to a prefix maximum query on target position: among all valid predecessors, find the one with highest chain score whose target span ends before the current edge's target span begins. A Fenwick tree (Fenwick, 1994) answers prefix maximum queries in $O(\log M)$, replacing the $O(E)$ scan.

Sorting alone does not fully enforce the source non-overlap constraint: an edge is a valid predecessor only if it *ends* before the current edge begins, not merely starts before. We enforce this via deferred commitment: each edge is inserted into the Fenwick tree only after the sweep passes its source endpoint, implemented as a priority queue keyed by source end position (see Algorithm 1).

**Edge weight function.** Each candidate edge $e = (s_i^{(k)}, t_j^{(l)})$ receives a weight combining semantic similarity with a length-ratio prior:

$$w(e) = \cos^2(e) \cdot \left[\log_2\!\left(1 + \frac{\min(c_s,\, c_t \cdot r)}{\max(c_s,\, c_t \cdot r)}\right)\right]^{\frac{1}{2}} \quad (1)$$

where $\cos(e) = \cos(s_i^{(k)}, t_j^{(l)})$ denotes the multi-resolution embedding pair's cosine similarity, $c_s =$

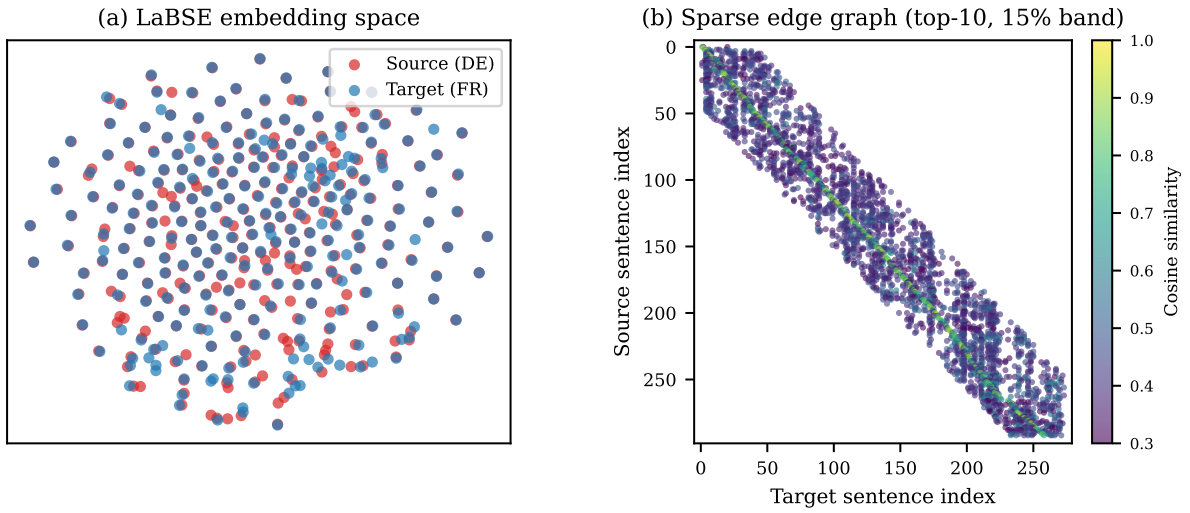

Figure 2: (a) LaBSE embeds source (DE) and target (FR) sentences into a shared space where translations cluster (shown: t-SNE). (b) The sparse 1:1 edge graph with threshold filters and top-$K$ pruning. Edges cluster on the diagonal with $\sim$5% density. Multi-res. edges (not shown) augment the graph with merged-sentence candidates.

$\sum_{m=i}^{i+k-1} |s_m|$ and $c_t = \sum_{n=j}^{j+l-1} |t_n|$ are the character lengths of source and target spans, and $r = \sum |s| / \sum |t|$ is the corpus-level character ratio.

Squaring the cosine prevents chains of many weak edges from outscoring fewer strong ones: two edges at $\cos = 0.5$ outscore one at $\cos = 0.8$ under linear weighting ($0.5 + 0.5 > 0.8$), but squaring reverses this ($0.25 + 0.25 < 0.64$). The length-ratio term follows the principle that parallel segments have proportional character lengths (Gale and Church, 1993), adapted from Bertalign (Liu and Zhu, 2023). Without this term, the chain preferentially selects narrow spans on split translations. As additional target sentences are concatenated, embedding similarity decreases, biasing the chain toward 1:2 alignments where the gold is 1:3. The length term peaks when combined target character length matches the source, counteracting this dilution (see ablation in Section 4.4).

Because the chain maximizes total edge weight rather than enforcing a path from position 0 to $N$, the backtracked chain spans only positions where high-confidence edges exist; all other positions become gaps for the extend phase. On mostly-aligned parallel corpora, this achieves high coverage, leaving small local gaps for DTW so that errors in DTW cannot propagate beyond a single gap. Nonetheless, co-linear chaining naturally handles noisy input. Unlike DTW-based aligners that force a path from $(0, 0)$ to $(N, M)$, the chain imposes no coverage requirement. Regions without high-similarity anchors are delegated to the extend phase, which aligns them if local evidence supports it or leaves them unpaired via skip transitions. This naturally handles one-sided insertions and deletions: inserted content creates gaps with no viable anchors, and the extend phase's skip cost allows those positions to go unmatched without cascading errors. Non-monotonic input can also be aligned by extracting multiple chains from the same edge set (Section 4.6).

**Algorithm 1** Co-linear Chaining

**Require:** Edges $\mathcal{E} = \{e = (s_i^{(k)}, t_j^{(l)}, w_e)\}$
**Ensure:** Maximum-weight non-crossing chain $\mathcal{C}$

```
Sort E by i

### 3.3 Extend: Fill Gaps Between Anchors

Between consecutive anchors, a gap of $g$ source and $h$ target sentences remains unaligned. We resolve

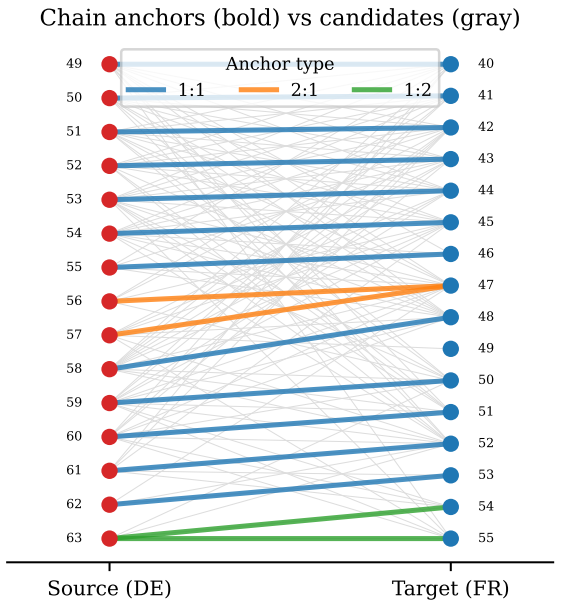

Figure 3: Chain anchors (bold, colored by resolution type) selected from candidate edges (gray). The chain selects the maximum-weight non-crossing subset, including multi-resolution anchors (2:1, 1:2) where merging is supported by embedding similarity.

these locally using multi-resolution DTW.

For each resolution $(k, l)$ with $k, l \geq 1$ and $k + l \leq 5$ – the same set used in the seed phase – we define the match score:

$$d^{(k,l)}(i,j) = \cos(s_i^{(k)}, t_j^{(l)}) - \frac{1}{2}\left(\bar{C}_{i\cdot}^{(k,l)} + \bar{C}_{\cdot j}^{(k,l)}\right) \quad (2)$$

where $\bar{C}_{i\cdot}^{(k,l)}$ and $\bar{C}_{\cdot j}^{(k,l)}$ are the row and column means of the cosine similarity matrix $C^{(k,l)}$ for resolution $(k, l)$. As opposed to using squared similarity, subtracting these means controls for sentences that are generically similar to many candidates, isolating pair-specific signal and mitigating the hubness effect, in which certain points in high-dimensional spaces appear disproportionately often as nearest neighbors (Radovanović et al., 2010; Artetxe and Schwenk, 2019).

The optimal alignment path through the gap is found via the recurrence:

$$F(i,j) = \max \begin{cases} \max\limits_{\substack{k,l\geq 1 \\ k+l\leq 5}} \left\{ F(i-k, j-l) + d^{(k,l)}(i-k, j-l) \right\} \\ F(i-1, j) + \delta \\ F(i, j-1) + \delta \end{cases} \quad (3)$$

with base case $F(0, 0) = 0$, and $\delta < 0$ a skip penalty allowing sentences to remain unaligned. We use $\delta = -0.5$ throughout; this value assumes the input is predominantly parallel, penalizing skips heavily enough that the aligner prefers low-confidence matches over gaps. When the input is known to contain substantial non-parallel content, $\delta = -0.1$ permits more gaps, which is used only in the insertion robustness experiment (Section 4.5), where non-parallel material is injected by design.

The alignment is recovered by backtracking from $F(g, h)$. Gaps between anchors are small; at this scale, unbanded DTW is both exact and negligible in runtime. Together with chain anchors, filled gaps complete the alignment.

Full pseudocode for all three phases and a complete hyperparameter listing appear in Appendix A.

### 3.4 Algorithmic Complexity

Recall that $N$ is the source sentence count, $M$ is the target sentence count, $K$ is the top-K pruning constant, and $E$ is the candidate edges post-pruning. We now introduce a new variable $L$ to refer to $\max(N, M)$ to aid complexity definition.

With top-$K$ pruning across 10 resolutions, $E \leq 10KL = O(L)$. The seed phase computes 10 cosine similarity matrices via BLAS-optimized matrix multiplication in $O(NM)$. The chain phase is $O(L \log L)$ total. It: 1) sorts $E$ edges in $O(E \log E)$; 2) performs $E$ Fenwick prefix-max queries in $O(\log M)$ each; and 3) executes $E$ heap operations in $O(\log E)$. The extend phase runs a DTW within each inter-anchor gap, at a cost equal to the gap's area – the product of its source and target spans. Because residual gaps are short each DTW is negligible[2], and the $O(L)$ gaps contribute $O(L)$ in total. Overall runtime is $O(NM + L \log L)$, dominated by the matrix multiplications in the seed phase. In practice, embedding inference is the bottleneck, and is shared across all embedding-based aligners.

Top-$K$ pruning is what bounds the candidate set at $E \leq 10KL$; the threshold $\tau$ and the diagonal band prune it further without changing this asymptotic size. The pruning is lossless: disabling all three leaves strict F1 within 0.004 on our benchmarks, so it removes redundant candidates rather than correct anchors. Sparsity is thus a tractability device, not an accuracy trade-off. Without it the seed phase retains the full $O(NM)$ graph, which does not fit in memory at book length.

[2]Our evaluations (Sec. 4) typically produced 95% anchor coverage and 1-2 sentence gaps.

## 4 Evaluations

We evaluate ChainAlign against three embedding-based sentence aligners: Bertalign, SentAlign, and Vecalign, using three benchmark corpora. Bertalign and SentAlign represent the current state of the art for embedding-based alignment. We include Vecalign under both LaBSE and the LASER embeddings it was published with, as it is the only baseline whose published configuration uses a different encoder. We do not re-evaluate earlier length- and lexicon-based aligners such as Hunalign (Varga et al., 2005), which prior work reports as substantially weaker on these benchmarks.

### 4.1 Datasets

We compare ChainAlign against Bertalign, SentAlign, and Vecalign on the following datasets:

1. Text+Berg[3] (Volk et al., 2010): Seven articles from the Swiss Alpine Club, manually aligned between French and German.

2. MAC[4]: 24 chapters sampled from six Chinese literary novels, manually aligned to their English translations.

3. OPUS Books[5]: Copyright-free books aligned at paragraph-level by András Farkas, then automatically aligned at sentence level. Sentence-level mappings are manually reviewed for a portion of books; we evaluate on seven of these (EN-DE and EN-ES). As these gold alignments originate from an automatic aligner, they exhibit a bias toward 1:1 mappings and occasional boundary errors; we use them for system comparison (where all systems face the same gold) but exclude them from our ablation study.

Sentence and token counts, gold pair counts, and the distribution of alignment types for each corpus appear in Appendix B.

### 4.2 Evaluation Scoring

We report precision, recall, and F1 under two matching criteria. Under **strict** matching a predicted pair is correct only if it exactly matches a gold pair; under **lax** matching it is correct if it overlaps a gold pair on both sides. For example, two 1:1 pairs where the gold has one 2:2 count as two false positives under strict F1 but two true positives under lax F1.

We run Bertalign[6], SentAlign[7], Vecalign[8], and ChainAlign with the same scoring script to ensure fair comparison. We exclude null alignments (1:0, 0:1) from the recall computation, consistent with Bertalign's evaluation.

We set $\tau = 0.3$ (seed similarity threshold) to maximize aggregate strict F1 across Text+Berg and MAC. Re-selecting it under two protocols that do not see the evaluation data – on a disjoint half of each corpus's documents, and on OPUS alone – recovers the reported figures to within 0.002 strict F1, and performance is flat across $\tau \in [0.20, 0.30]$. Pruning parameters ($K = 10$, band $= 15\%$) were selected for computational efficiency. No per-dataset tuning is applied.

### 4.3 Main Results

Table 1 shows the strict and lax F1 scores of ChainAlign, Bertalign, SentAlign, and Vecalign (under both LASER and LaBSE) on all three datasets, averaging the seven OPUS books (full OPUS results in Table 7).

ChainAlign achieves the highest strict and lax F1 on all three benchmarks. We outperform Bertalign by 0.5 points on Text+Berg, 0.4 on MAC, and 1.0 point on OPUS (significance in Table 1). The gap to SentAlign is larger: 0.9 points on Text+Berg, 5.7 on MAC, and 1.4 on OPUS, and larger still to Vecalign under either encoder. Lax F1 is near-perfect across all systems ($\geq$0.96), indicating that errors are predominantly boundary disagreements rather than wrong-content matches.

### 4.4 Ablation Study

Each component of our algorithm contributes positively to both Text+Berg and MAC (Table 2). The base configuration uses $(1,1)$, $(2,1)$, and $(1,2)$ edges in the seed phase with raw cosine similarity as the weight; DTW in gaps uses the full $k + l \leq 5$ set throughout. Extending the seed to all $k + l \leq 5$ resolutions provides the largest single gain on both corpora: since the chain achieves high anchor coverage and the extend phase cannot modify anchor boundaries, alignment quality depends on the chain having access to correct-width edges. The final two rows show how square cosine weighting and

Table 3: Strict F1 on Text+Berg with unrelated source content inserted at the midpoint. Vec is Vecalign (LaBSE); −LP disables the length-ratio prior. Degradation is the change from 0% to 60%. First-quartile results: Table 8.

the length-ratio prior further improve boundary selection by rewarding high-confidence, length-consistent matches.

### 4.5 Insertion Robustness

To evaluate robustness to non-parallel content, we inserted sentences from the seventh Text+Berg document (excluded from evaluation) into each remaining source document, at rates up to 60% and at two positions: the midpoint and the first quartile. Throughout we set $\delta = -0.1$ and disable the diagonal band, since one-sided insertion breaks the near-diagonal correspondence the band assumes; in our implementation the two are controlled together. The baselines are run at their default skip and null-alignment settings, which already permit unmatched content.

ChainAlign and SentAlign lose under 3 points at 60% insertion while Bertalign loses 24, roughly 4 points per 10% inserted (Table 3). Forced coverage alone does not explain this: Vecalign also aligns the full grid, yet degrades 6.2 points. The difference is plausibly how the skip cost is set, since Vecalign calibrates it from the observed cost distribution at alignment time whereas Bertalign's is fixed. This yields three tiers rather than a binary: full coverage with a fixed skip cost collapses, full coverage with a calibrated one degrades moderately, and no coverage requirement degrades least. Disabling the length-ratio prior reduces ChainAlign's degradation to 0.8 points, comparable to SentAlign's 0.7, because the prior assumes a corpus-level character ratio that one-sided insertion shifts, penalizing otherwise-valid alignments in the uncontaminated regions.

### 4.6 Non-Monotonic Alignment

While our benchmark datasets are monotonic (except for a handful of mappings in Text+Berg), real-world, noisier data has cases where mappings can cross: source sentence 1 maps to target sentence 2, while source sentence 2 maps to target sentence 1. ChainAlign can be extended to extract multiple non-overlapping chains during the chain phase.

We replace the Fenwick LIS with a gap-bounded dynamic programming algorithm following minimap2 (Li, 2018): for each edge processed in source order, we search backwards through at most $h$ predecessors, linking it to the highest-scoring predecessor whose source and target gaps are both within a threshold $G$. Edges separated by gaps exceeding $G$ cannot belong to the same chain, causing the DP to naturally segment the input into monotonic blocks. After the forward pass, we extract chains via multi-backtrack: starting from the highest-scoring unused edge, we trace parent pointers to recover a complete chain, mark its positions as used, and repeat until no edges remain. Each chain is internally monotonic; chains may cross each other globally. Extend runs independently within each chain, filling gaps between consecutive anchors with local DTW. Pairs produced by extend that conflict with positions claimed by other chains are discarded.

On the Text+Berg documents concatenated with shuffled target ordering[9] (991×1011 sentences), single-chain alignment achieves 0.721 strict F1 while multi-chain extraction ($G$=3, $h$=200, minimum chain length 1, no banding) recovers 0.927, within 1.4 points of aligning each document independently (0.941).

### 4.7 Runtime

Figure 4 shows algorithm-only wall-clock time (excluding embedding inference, which is shared across all systems) on an AMD EPYC 7R13 (8 vCPU, 16 GB RAM). All timings are the median of five runs after four warmup iterations. SentAlign uses its default subdivision threshold; it is infeasible beyond 5K sentences due to memory requirements.

ChainAlign and Bertalign exhibit similar scaling, both dominated by embedding similarity computation. ChainAlign is approximately 1.4× slower due to pre-computing 10 full similarity matrices (one per $(k, l)$ combination) for sparse edge extraction, whereas Bertalign computes multi-resolution similarities lazily within a narrow corridor defined by its first-pass anchors. Vecalign scales more gently than either, since its coarse-to-fine DP never forms the full $O(NM)$ similarity matrix, but its larger constant factors leave it slower than both at every size we test: 0.23 s against 0.04 s at 200 sentences, narrowing to 14.7 s against 14.1 s at 14K.

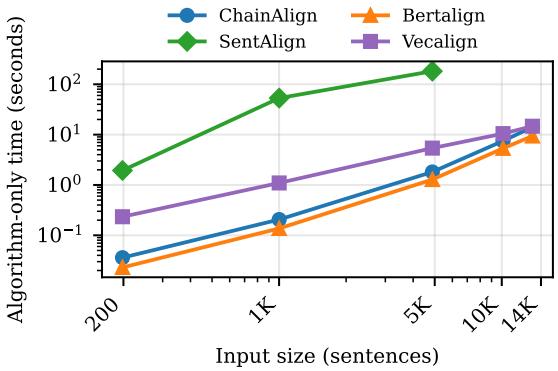

Figure 4: Algorithm-only runtime (log scale) versus input size, the geometric mean of source and target sentence counts. ChainAlign and Bertalign scale comparably, both dominated by $O(NM)$ similarity computation. Vecalign scales near-linearly but with higher constant factors, remaining slower than both across the tested range. SentAlign is 100–250× slower and infeasible beyond 5K sentences.

## 5 Discussion

ChainAlign achieves the highest strict and lax F1 on all three benchmarks; the improvement over Bertalign is significant on OPUS Books and within sampling noise on Text+Berg and MAC, while the improvements over SentAlign and Vecalign are significant on all three. Our central contribution is the application of co-linear chaining to sentence alignment: both problems seek a maximum-weight non-crossing subset of candidate matches between two sequences, and the genomics literature offers efficient and exact algorithms that cross-lingual sentence aligners have not previously exploited.

In computational biology, seed-chain-extend typically serves as a heuristic approximation to exhaustive dynamic programming over the full alignment space. Our results show that for sentence alignment, the sparse formulation outperforms exhaustive DP. To control for the scoring function, we evaluated a DTW baseline using the same $\cos^2$ weighting and length-ratio penalty as our edge weight function; it remains 1.9, 0.6, and 0.5 points behind on Text+Berg, MAC, and OPUS, respectively (Table 2). We hypothesize that the advantage lies in DTW's forced-path property: to produce a complete alignment from $(0, 0)$ to $(N, M)$, DTW must commit to transitions in regions of ambiguous similarity, and poor local choices propagate forward, displacing subsequent high-confidence matches.

[9] Source: documents 001–007 in their natural order; target: the same documents concatenated in the order 003, 001, 005, 002, 007, 004, 006.

The chain phase selects the globally optimal anchor set; DTW then operates in small, isolated gaps where errors cannot propagate.

Beyond aggregate F1, error profiling on Text+Berg and MAC reveals that ChainAlign predominantly over-splits, whereas Bertalign over-merges. The over-splitting reflects a structural property of the chain phase: we maximize the sum of edge weights, so two moderate-confidence 1:1 edges can collectively outscore a single higher-confidence 2:1 edge. The $\cos^2$ weighting and length-ratio prior both reduce this bias but do not eliminate it entirely. Bertalign's forced-path DP exhibits the opposite tendency: when boundary evidence between adjacent sentence pairs is weak, the merged $n{:}m$ embedding scores higher than the individual 1:1 embeddings, and the DP selects the merge. These complementary error profiles suggest that a hybrid approach could reduce both failure modes simultaneously.

A natural remedy for the over-splitting is a gap cost on the chain, penalizing uneven advancement between successive anchors as in genomic chaining (Li, 2018). We tested the separable cost $\lambda\,(g_s + g_t)$, where $g_s$ and $g_t$ are the source and target sentences left unaligned between an anchor and its predecessor; it folds into the Fenwick prefix-max and reduces to our objective at $\lambda = 0$. Split false positives fall monotonically as $\lambda$ increases, from 36 to 18 (4.19% to 2.10% of predicted pairs), but strict F1 moves by at most 0.004, and the best $\lambda$ is inconsistent across benchmarks: Text+Berg peaks near 0.005 and MAC near 0.05, and each corpus's optimum degrades the other. The chain trades split errors for merge errors rather than eliminating them. We suspect the limited benefit is intrinsic: minimap2's anchors are near-uniform-weight $k$-mer matches, so its gap cost supplies the signal that separates true chains from spurious ones, whereas here the squared cosine already carries it; and its penalty approximates a stationary indel prior in which uneven advancement is error, whereas between sentences it reflects translation style. The coupling that expresses that penalty, $|g_s - \rho\, g_t|$, also cannot be answered by a prefix-max query, and would forfeit the $O(E \log E)$ chain and its generalization to $k > 2$ languages.

The insertion robustness and non-monotonic results both reflect the same underlying property: sparse anchor-based alignment makes no coverage guarantee, so non-parallel content creates gaps rather than cascading errors. SentAlign shares this property and similarly handles insertion well, but cannot recover non-monotonic structure. Bertalign's forced path degrades under both conditions. Multi-chain extraction extends this robustness to reordered documents, recovering 0.927 strict F1 on shuffled input versus 0.721 for single-chain alignment, within 1.4 points of aligning each document independently.

Runtime scaling confirms that the sparse formulation incurs no practical overhead: ChainAlign and Bertalign are both dominated by embedding similarity computation and scale comparably, and Vecalign, despite its near-linear coarse-to-fine search, is slower than both across the tested range; SentAlign's Dijkstra-based search is two orders of magnitude slower still.

## 6 Open Research Areas

Co-linear chaining's sparsity also makes simultaneous alignment of $k > 2$ languages tractable: intersection pruning across all pairwise language combinations keeps the edge count $O(L)$, and co-linear chaining generalizes to $k$ dimensions via nested Fenwick trees with chain step $O(L \log^{k-1} L)$. In preliminary experiments on 3- and 4-way alignment, this single-pass, pivot-free approach matches or outperforms pivot-based methods, with no pivot-induced inconsistencies. Given that multiway parallel corpora yield substantially stronger cross-lingual representations than bilingual data (Fazili and Goswami, 2026), high-quality multiway alignment is increasingly important. We leave a full investigation to future work.

## 7 Conclusion

We presented ChainAlign, which applies co-linear chaining from computational genomics to cross-lingual sentence alignment. The chain selects a maximum-weight non-crossing anchor set, and multi-resolution DTW fills the residual gaps. On three benchmarks across four language pairs, ChainAlign outperforms Bertalign, SentAlign, and Vecalign on both strict and lax F1. Because the chain imposes no coverage requirement, non-parallel content creates gaps rather than cascading errors, and multi-chain extraction recovers reordering that a single monotonic path cannot represent.

## 8 Limitations

We evaluate with a single embedding model (LaBSE). While the algorithm is model-agnostic,

alignment quality depends on the encoder's cross-lingual discriminability, and we do not empirically verify performance with alternative encoders. Our threshold $\tau = 0.3$ is robust across all benchmarks tested but may require adjustment for encoders with different similarity distributions. Finally, our evaluation focuses on European and Chinese language pairs; performance on low-resource or typologically distant pairs (e.g., agglutinative languages) remains untested.

## A Full Algorithm and Hyperparameters

Algorithms 2–4 provide complete pseudocode for all three phases of ChainAlign. Table 4 lists all hyperparameters, which are fixed across all experiments with no per-dataset tuning. Given precomputed multi-resolution embeddings, the algorithms fully specify the alignment procedure.

| Parameter | Value |
|---|---|
| Similarity threshold $\tau$ | 0.3 |
| Band fraction $b$ (parallel text only) | 0.15 |
| Top-$K$ per row per resolution | 10 |
| Cosine exponent | 2 |
| Length-ratio prior exponent | 0.5 |
| Skip cost $\delta$ (parallel text) | $-0.5$ |
| Skip cost $\delta$ (non-parallel) | $-0.1$ |
| Max resolution $k + l$ | 5 |
| Embedding model | LaBSE |

Table 4: Hyperparameters (fixed across all experiments). The band and the skip cost are controlled together: the $\delta = -0.1$ configuration, used where input is not assumed parallel, also disables banding, since displaced correspondences would otherwise fall outside the window.

## B Corpus Statistics

Table 5 reports the size and alignment-type composition of each benchmark.

Gold alignment types are distributed as shown in Table 6. This is consistent with the extended resolutions and the length-ratio prior producing their largest gains on MAC (Table 2), since both target precisely the split-boundary decision. Per-document sentence counts range from 36 to 293 for Text+Berg (mean 142), 100 to 335 for MAC (mean 200), and 686 to 4,668 for OPUS (mean 2,067).

## C OPUS Per-Book Results

Table 7 shows the strict and lax F1 scores for all five systems on each OPUS book individually.

## D Insertion Robustness at Both Positions

Table 8 reports the insertion experiment of Section 4.5 at both insertion positions.

**Algorithm 2** ChainAlign: Seed Phase

**Require:** Source embeddings $\mathcal{S}^{(k)}$, target embeddings $\mathcal{T}^{(l)}$, source segments $s_{1..N}$, target segments $t_{1..M}$, threshold $\tau$, band fraction $b$, top-$K$
**Ensure:** Candidate edge set $\mathcal{E}$

Compute corpus-level character ratio $r \leftarrow \sum |s_i| / \sum |t_j|$
$\mathcal{E} \leftarrow \emptyset$
**for** each resolution $(k, l)$ with $k \geq 1,\ l \geq 1,\ k + l \leq 5$ **do**

## Abstract

Learned quality estimation (QE) models such as COMETKiwi are widespread and work well for general machine translation evaluation. However, they are known to struggle on unseen domains, limiting their performance in a real-world localisation context. We show that they are insensitive to some important factors in localisation, such as whether numbers are translated accurately, or even whether the correct number of spaces and punctuation are preserved in a translation. Further, a key capability for optimisation of machine translation is the ability of QE models to accurately rank different translations of a single segment, which suffers significantly from the domain transfer. In the absence of large-scale direct assessment data, we propose principled fine-tuning approaches to reduce the domain gap with even small amounts of post-editing data. Using a multi-task fine-tuning approach and a simple tokeniser intervention, we create a QE model which proves markedly better at distinguishing preferred post-edits from rejected initial translations in a localisation context. We show that preferences and artificial continuous scores stabilise each other, and argue that to calibrate metrics both in terms of their absolute scores and comparisons between translation of the same source, both types of signal are needed.

## 1 Introduction

Learned neural machine translation metrics are known to struggle in unseen domains (Zouhar et al., 2024). Both reference-based metrics and quality estimation models such as COMETKiwi (Rei et al., 2022), have been trained primarily on news and wiki text. In real-life commercial localisation workflows, the domains vary from spec sheets to user interface labels to legal text (e.g., Buschbeck and Exel, 2020; Lin et al., 2022). Additionally, localisation workflows require the consistent use of dedicated terminology, and following specific style guidelines. As illustrated in Figure 1, quality estimation (QE) is highly vulnerable to this domain shift, with $\text{GEMBA}_{\text{ESA}}$-QE and $\text{COMETKiwi}^{22}_{\text{DA}}$ both unable to consistently identify the preferred translation on localisation data, while performing well on WMT data.

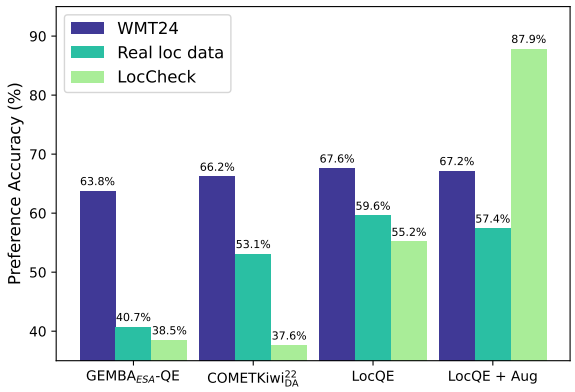

Figure 1: Comparison of $\text{GEMBA}_{\text{ESA}}$-QE, $\text{COMETKiwi}^{22}_{\text{DA}}$, and our LocQE models: Preference accuracy on public data (WMT24) is much higher than on real localisation data (here: internal post-edit data), or on long-tail issues important to localisation (LocCheck). Domain adaptation reduces the gap significantly, but to solve for long-tail issues, data augmentation is needed.

At the same time, QE is highly relevant for localisation workflows. Firstly, due to the nature of post-editing, any available references are frequently similar to the hypotheses, biasing reference-based metrics towards the originally used machine translation model. Secondly, effective QE is needed for finetuning workflows such as direct quality optimisation (DQO; Uhlig et al., 2025). In this context, an especially important capability is *segment-level ranking* of different translations of the same source, so that QE can reliably pick preferred translations.

| − Können Sie bestätigen, dass die Eingabe 777777 eine Zahl mit sieben Ziffern hat? | 85.57 |

Table 1: Exemplars of localisation-specific issues that COMETKiwi misses. The model cannot see non-breaking spaces ("[NBSP]"), may prefer a grammatical sentence with a hallucination over the correct translation of a cloze ("_____"), and is not sensitive enough to errors in long numbers.

Not only is there a marked drop in performance compared to WMT data (Figure 1), but we also empirically observe that 1) Translators and reviewers react strongly to specific issues that the models either cannot see at all—such as the incorrect use of non-breaking spaces—, or even reward, such as hallucinating a word to fill a cloze; and 2) For long numbers, incorrect translations are not consistently distinguished and caught. Examples are shown in Table 1. These are mostly long-tail issues, meaning they occur rarely in training or test data, but since human translators often consider them trivially wrong, they may erode trust if not caught.

To address the domain shift, we aim to adapt a QE model in the absence of large-scale human score data by leveraging post-edits. In addition to this adaptation training, we analyse QE model performance on the aforementioned long-tail issues, and propose adapting the input tokeniser so that models can actually "see" some of these issues.

Although other high-quality QE models have been proposed since its release, COMETKiwi$^{22}_{DA}$ [1] represents a very good tradeoff between strong performance and a lightweight model. It is both cheap to run and efficient to fine-tune for quick iteration. It has also been found to outperform LLM-based metrics at segment-level ranking (Moghe et al., 2025). Therefore, we use COMETKiwi$^{22}_{DA}$ as the base model for experimentation in this work.

Our key contributions are:

1. We formulate a lightweight, data-efficient approach to domain adaptation for QE models without human direct assessments, using post-edits and simple heuristics as our training signal. Tokeniser adaptation allows the model to learn specific relevant patterns.

2. We describe a new challenge set for localisation-specific issues (LocCheck), and a new human-annotated localisation dataset (LocHD).

3. We demonstrate improvements on the two newly-proposed datasets, as well as for preference accuracy on natural target-domain data.

Our code for regenerating LocCheck, and the LocHD data, are released on GitHub.[2]

## 2 Related Work

### 2.1 COMETKiwi models

The COMET framework was initially proposed in Rei et al. (2020). In it, multilingual encoders are fine-tuned to predict normalised human direct assessments of machine translations. The first COMET models required a reference, but later iterations expanded to QE with COMET-QE (Rei et al., 2021) and COMETKiwi (Rei et al., 2022), as well as error span prediction with xCOMET models (Guerreiro et al., 2024).

### 2.2 Domain Adaptation for Metrics

Similarly to any fine-tuned language model, the COMET models can struggle when applied to unseen domains, as Zouhar et al. (2024) show for reference-based neural models. Sharami et al. (2023) also discuss this phenomenon for quality estimation, and fine-tune a model pre-trained on out-of-domain data with progressively more specific target-domain data. They produce target-domain augmented data by inferencing an MT model and scoring its hypothesis against the existing reference

[1] We use this notation to disambiguate model versions, referring specifically to `wmt22-cometkiwi-da`.

[2] https://github.com/lilt/loc-qe

translation via TER (Snover et al., 2006), and evaluate their QE model on correlation with HTER ("Human-targeted Translation Edit Rate", referring to the edit rate between a hypothesis and a human post-edit given that hypothesis). The present work instead evaluates both against preferences derived from post-edits and ESA scores (Error Span Annotation, Kocmi et al., 2024b) from professional annotators. We use two types of training signal derived from these post-edits: continuous scores and preference pairs.

Another related approach is "poor man's quality estimation" (Zouhar et al., 2023). They suggest pre-training quality estimation with large-scale *metric estimation* (i.e., predicting the scores of a reference-based metric) before fine-tuning with small amounts of human labels. In the present work, we instead use metric estimation as a continuous training signal for domain adaptation.

MS-COMET (Kocmi et al., 2022) is a complete re-training of COMET and COMET-QE with much larger training corpora of 2 M and 3.5 M human-annotated segments, respectively. They cover over 110 languages and 15 domains, using only annotations from professional translators. In contrast to the original COMET models, they use raw direct assessment scores, despite the risk of scores becoming incomparable across languages. Our approach requires much less data, and we keep z-score normalisation intact.

Schmidt et al. (2026) analyse system-level and segment-level accuracy of metrics across domains, showing that while human annotators exhibit independent noise around a "true" rating, metrics tend to exhibit correlated errors. They aim to disentangle domain shift from noise in human labels, and demonstrate metric biases on out-of-domain data.

### 2.3 Contrastive Training

Contrastive training has been proven effective for representation learning in the past, such as in InfoXLM (Chi et al., 2021) or mSimCSE (Wang et al., 2022). Preference tuning of LLMs has enjoyed great popularity in recent years, from RLHF (Christiano et al., 2017; Ouyang et al., 2022) and direct preference optimisation (DPO; Rafailov et al., 2023), to specialised workflows such as DQO (Uhlig et al., 2025). Like the present work, Berger et al. (2024) discuss using machine translated segments and their corresponding post-edits as preference pairs, though they apply them to DPO on LLMs for machine translation.

The original COMET paper includes a ranking-based metric version, which creates a score from the Euclidean distance of the hypothesis to both the source and reference, learned via Triplet Margin Loss (Rei et al., 2020). However, this method relies on a reference, unlike our approach, and it produces scores directly from model representations rather than using a regression head. It is also not regularised, meaning that the model tends to distribute scores unevenly. The COMET-Rank model was dropped in later iterations of COMET.

Recently, Proietti et al. (2026) proposed a relative quality estimation framework that takes in a source segment and two candidate translations, thus focusing on segment-level ranking accuracy. However, their system cannot return absolute scores, making the ratings more difficult to interpret.

The most conceptually similar work to ours is Tan and Monz (2025), who use raw human scores as inputs to induce preference pairs with a variable margin, then train using a Bradley-Terry objective. Similarly to us, they are motivated by relatively poor metric performance at a segment level. Compared to our work, they train larger models using a reference and WMT-domain data, whereas we focus on domain adaptation and do not have access to an independent reference or continuous human ratings. By leveraging post-edits into both preferences and continuous scores, using a multi-task training setup, we avoid the need for post-hoc calibration of output scores.

### 2.4 Metric Challenge Sets

ACES and SPAN-ACES (Amrhein et al., 2023; Moghe et al., 2025) are metric challenge sets intended to profile strengths and weaknesses of machine translation metrics on different subcategories of translation accuracy issues. They do not cover surface issues other than some relatively easy punctuation errors. ACES covers many language pairs, though with a very small number of examples for some. Metrics are scored on whether a "good" translation is ranked higher than a translation with the error under examination. We use a similar design for our LocCheck dataset, but focus on localisation-specific issues such as those discussed in the introduction.

## 3 Datasets

In this section, we summarise the datasets used in this study. Table 2 lists the dataset sizes.

| Corpus | train | dev | test |
|---|---|---|---|
| ACED corpus | 17,455 | 7,884 | 9,922 |
| ACED (prefs) | 2,179 | 1,056 | 959 |
| Internal | 10,000 | 1,000 | Table 11 |
| LocHD | – | – | 3,000 |
| WMT24 (prefs) | – | – | 5,718 |
| ACES | – | – | 36,476 |

Table 2: Dataset sizes, in number of rows, used in our experiments. For details on the per-language distribution and number of test segments we create from internal data, see Appendix Table 11.

**Internal Localisation Data.** Internally, we have access to a large collection of localisation-specific data across various client domains and language pairs, of which a large percentage has been post-edited by humans. The data includes, for example, technical documentation, user interface text, lists of features, and other specialised content. There is a history of edits for each segment, but there are no at-scale direct assessments.

In order to adapt QE models to the localisation domain, we process the post-edits in two different ways, producing both artificial continuous scores and preference pairs. To obtain preference pairs, we take machine translated segments as the negative sample, and the post-edited version provided by a human reviewer as the positive sample, provided an edit was made. We have no independent reference in this setting. To create artificial scores, we treat the human-edited segment as a reference and use a surface metric (chrF++) to provide a score for the machine-translated segment. Additionally, we use heuristics to identify major errors that resulted in small chrF changes, and reduce the score in such cases. We then apply z-score normalisation, treating each client project as one annotator, and rescale the scores to the range [0,1]. Further data processing details can be found in Appendix A. Additionally, in Appendix A.4, we describe a small validation study for both types of internal data.

Despite the potential subjectivity of post-edits (cf. Popović, 2021), they are the best human-created quality signal we have. Therefore, we use preference accuracy as the main evaluation metric on this data.

**ACED Localisation Data.** The ACED corpus is a public collection of English-to-German localisation data, initially for Translation Error Correction (Lin et al., 2022). For each segment, it includes a source, target, and perturbed target, where the perturbed target represents the initial hypothesis and the target is the post-edited segment. The data is spread across three sub-datasets with different domains: ASICS (marketing copy for an activewear company), EMERSON (industrial product listings for a manufacturer), and DIGITALOCEAN (software engineering tutorials).

We use the predefined train, dev, and test splits, but merge them across sub-datasets for a larger data size. We apply the same transformations as for our internal data to obtain preference pairs and continuous scores. Note that the number of preference pairs is especially limited, since not all segments in ACED received a post-edit. Table 2 lists the merged data sizes for ACED.

**Localisation Data with Human Scores (LocHD).** For evaluation purposes, we construct a **Loc**alisation **H**uman **D**ata corpus. We translate 300 segments from English into ten target languages[3] using a selection of different commercial models, then collect Error Span Annotations (Kocmi et al., 2024b) from professional translators, who were paid standard rates. We refer to this corpus as LocHD from here on.

The source data originates from a real client project, and includes primarily user interface text and help documentation. Since this data does not contain personally identifiable information in the translation segments, we only pseudonymise the annotators involved before release. There were between three and five annotators involved in the project per target language. Annotations were reviewed on a spot-checking basis, but independent overlapping annotations were not collected. LocHD contains hypotheses but no references.

We compute z-scores per annotator and evaluate QE models on a global correlation (Kendall's $\tau$) with the z-scores. This data is not suitable to transform into preference pairs because we only have one scored translation per segment, so we only use it to compute correlations.

**LocCheck.** Motivated by the observations stated in the introduction and exemplified in Table 1, we create a localisation-specific challenge set addressing a specific set of potential issues. We think of this dataset as a kind of CheckList (Ribeiro et al.,

[3] Arabic, German, Spanish, Finnish, French, Japanese, Polish, Portuguese, Swedish, and Turkish.

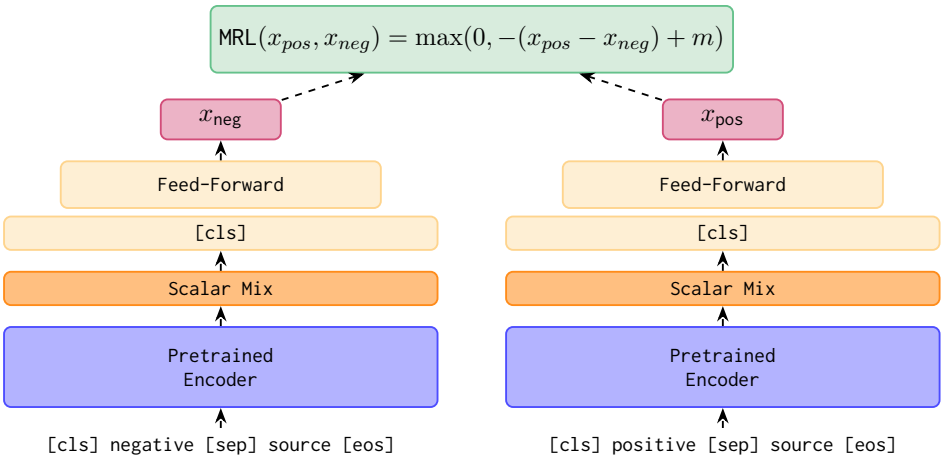

Figure 2: Margin Ranking Loss applied to a COMETKiwi model. Figure adapted from Rei et al. (2020, 2022).

2020), covering behaviours that may appear simple on the surface but could get lost while optimising for other skills. Specific points we address here include the translation of long number sequences, the preservation of leading or trailing whitespaces, the correct use of non-breaking spaces in French, the translation of all-caps sentences, and more.

We create both an internal and a public data split: For the public split, we augment data from WMT25 and BOUQuET (Omnilingual MT Team et al., 2025), whereas the internal split is sourced from real samples in our internal data. We create an internal split because these specific issues are rarer in public MT datasets. We include eleven target languages in LocCheck, all translating from English: Arabic, German, Spanish, Finnish, French, Hindi, Japanese, Polish, Russian, Thai, and Chinese. Our public split is missing Finnish, Polish and Thai as target languages because they were not present in WMT25 or BOUQuET.

Each row consists of a source, a reference, a positive sample, and a negative sample which is identical to the positive sample except for the variable under study. We ensure that the reference differs from the positive and negative samples. Appendix E.1 gives a detailed description of each heuristic, and shows the distribution of samples in both splits. The code for the public test set is released for reproducibility.

**Training data augmentation.** By definition, many phenomena in LocCheck are long-tail issues: Although they are rated as important by translators, they occur rarely in real-world data. Therefore, we create augmented training data to ensure the model sees these patterns. We apply the same transformations that were used to create LocCheck to a portion of our internal data, yielding 5k pairs.

**WMT Data.** COMETKiwi (Rei et al., 2022) was originally trained with normalised direct assessments from the WMT years 2017-20 (Bojar et al., 2017, 2018; Barrault et al., 2019, 2020). We experimented with mixing in data from those years during training to mitigate forgetting, and test on preference pairs derived from WMT24 (Kocmi et al., 2024a) to validate the general performance of our finetuned metrics. See Appendix A.3 for how we process this data.

## 4 Metric Adaptation

### 4.1 Multi-Task Training

Rather than fine-tuning solely on preference pairs or continuous scores, we implement a multi-task training regime. We randomly mix samples from both datasets—continuous or contrastive—in every single batch. The respective losses for each type of data are described in this section. We compute the appropriate loss only for the corresponding samples, making the final batch loss a mixture of both losses. We balance the influence of each loss by varying the data distribution, empirically selecting a ratio of 2:1 in favour of continuous scores (cf. ablation in Appendix D).

**Contrastive training with preference pairs.** For training with preference pairs, we use the Margin Ranking Loss (MRL; Herbrich et al., 2000) to encourage the model to score the preferred hypothesis above the rejected one:

$$\text{MRL}(x_{pos}, x_{neg}) = \max(0, -(x_{pos} - x_{neg}) + m) \quad (1)$$

where $x_{pos}, x_{neg}$ are the scores of the preferred and rejected inputs, respectively, and the margin $m$ is a hyperparameter. Figure 2 shows the loss schematic for MRL applied to COMETKiwi.

**Regression on continuous scores.** With the artificial continuous scores, we use the standard mean-squared error (MSE) loss. A single score is computed for the hypothesis and compared against the target score described in § 3.

### 4.2 Tokeniser Adjustments

Some of the LocCheck rules involve special characters such as non-breaking spaces, which COMETKiwi$^{22}_{\text{DA}}$ ignores due to its tokeniser. The process of tokenisation involves multiple steps, all of which influence the outcome (cf. Schmidt et al., 2024): Normalisation, pretokenisation, tokeniser inference, and post-processing. We propose adjusting the pretokenisation step of the encoder model's tokeniser, adding new tokens for special whitespace and other control characters. These are targeted interventions which somewhat change the distribution of tokenised texts seen by the model, but leave the majority of segments unchanged. Specifically, we keep trailing and multiple spaces, and add missing tokens which enable the model to "see" the most relevant special characters. Details of the tokeniser modifications are in Appendix B.

### 4.3 Models

**Main system.** We finetune COMETKiwi$^{22}_{\text{DA}}$ with the updated tokeniser using the multi-task loss on internal data. We use 10k samples of MSE data and 5k preference pairs for MRL. For comparison, we show runs with each loss individually, using a total of 15k samples respectively. Finally, we add the 5k samples of augmented preference pairs for a LocQE version with data augmentation. Since these augmented data are minimal pairs exemplifying the rules in LocCheck, they only provide an explicit signal to the model in cases where the baseline ranking is wrong, and none otherwise.

**Public data analog.** Similarly, we finetune models on the ACED data, using all available preference pairs and inferred continuous scores for the respective losses. Due to the limited training set size in ACED, we also added 5.7k WMT data samples to both of these training sets, keeping all data for the multi-task training here.

**Hyperparameters.** The margin $m$ for the MRL loss is set to 0.02 (cf. ablation in Appendix C). We unfreeze the entire encoder, including the embedding layer, from the beginning of finetuning, in order to train the added token embeddings. Instead of freezing the encoder, we add learning rate warmup to stabilise training, and increase both the effective batch size and the learning rates. We use 50 warmup steps, an encoder learning rate of 1e-5, and a feedforward layer learning rate of 1e-4. The effective batch size is 512. We apply early stopping with a checkpoint every epoch, training for up to five epochs. The results show individual runs with a fixed random seed.

**GEMBA Baseline.** We additionally compute reference-free GEMBA$_{\text{ESA}}$-QE (Kocmi and Federmann, 2023; Kocmi et al., 2024b) with GPT-4.1 as the backbone. GEMBA has been shown to yield good system-level pairwise accuracy but perform relatively poorly at the segment level.

## 5 Domain Adaptation Results

### 5.1 Effective domain adaptation leveraging a small number of post-edits

Figure 3 shows the accuracy of the QE models at selecting the preferred translation over the rejected on the respective target test set. The baseline COMETKiwi$^{22}_{\text{DA}}$ struggles to identify preferred segments in our internal data, while it performs better initially on the ACED corpus. GEMBA$_{\text{ESA}}$-QE performs even worse at this task. Both the contrastive and the multi-task training consistently improve preference accuracy on the target corpus, adding between 6.1 and 13.8 percentage points. MSE fine-tuning worsens preference accuracy on internal data, while for ACED, the addition of original training data seems to reduce forgetting and improve overall performance.

In Appendix Table 10, we show performance of the fine-tuned models on WMT24 preference accuracy and ACES score as a proxy of general capability. We find that WMT24 preference accuracy stays within a relatively small range regardless of fine-tuning objective, though MRL-only with internal data degrades it slightly and multi-task training improves it somewhat. ACES score collapses with MRL-only training on internal data, and suffers al-

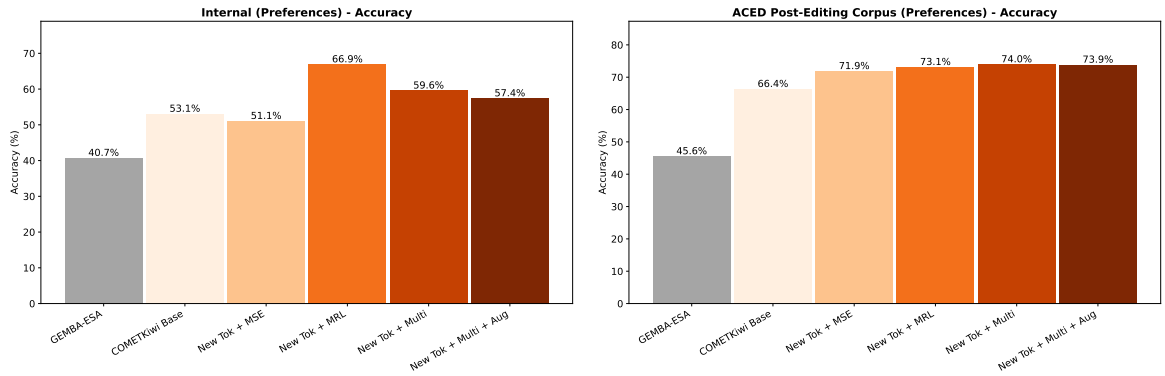

Figure 3: Performance on the respective target test set, in terms of preference accuracy. Left: Internal data. Right: ACED corpus. Per-language-pair performance for the internal data is listed in Appendix Table 12.

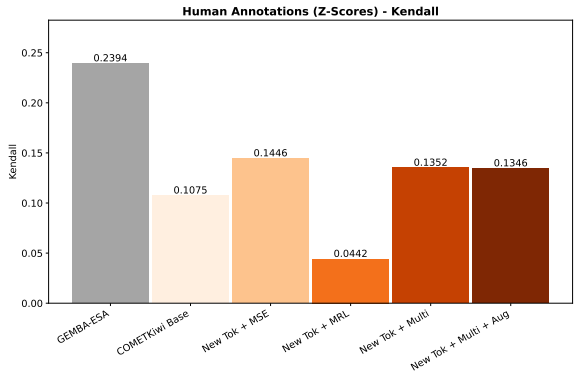

Figure 4: Overall performance on LocHD, in terms of global Kendall's $\tau$. Fine-tuning was done on internal data. Per-language-pair performance is listed in Appendix Table 14.

most regardless of the setting. When training with MRL on ACED plus original training data, ACES score is relatively unaffected. With the exception of MRL-only on internal data, the fine-tuned models also still outperform $\text{GEMBA}_{\text{ESA}}$-QE on ACES. We surmise that including original training data helps to stabilise general model capabilities, but so does the multi-task training setup. Our analysis in § 5.2 sheds further light on this observation.

Meanwhile, Figure 4 shows global Kendall's $\tau$ on the LocHD corpus. $\text{COMETKiwi}^{22}_{\text{DA}}$ initially performs much worse at this than $\text{GEMBA}_{\text{ESA}}$-QE, improving somewhat with our internal data training. Notably, MSE training improves global Kendall the most, while MRL-only training further worsens performance on global Kendall despite the matching domain. Multitask training strikes a balance between the two, yielding an overall improvement on both preference accuracy and global Kendall. Next, we analyse why this is the case.

## 5.2 Score distribution analysis

We observe that global correlation and segment-level accuracy conflict, with models that perform well by one of these measures tending to do worse on the other. This is in keeping with analysis by DiIanni and Deutsch (2025), who emphasise the difference between Global and Segment-Wise correlations: Global correlations try to place translations on an overall distribution of human scores, while segment-wise correlations or accuracy compare translations given the same source. Importantly, performance on one of these aspects does not translate directly to the other—for instance, human score noise in a regression setting (cf. Schmidt et al., 2026) might obscure direct comparisons. We argue that both are relevant in a localisation context, but segment-wise performance is more well-defined in our setting.

The two losses, MSE and MRL, intuitively represent a *global* and a *segment-wise* objective. When training purely on continuous scores, the model learns from isolated scores given to translations of many different sources, and can merely approximate comparisons between different translations of the same source. By contrast, when training purely on preference pairs, the model learns to compare translation quality given the same source, but has no anchor for the absolute score value.

To visualise the issue, we plot scores on the internal LocCheck split before and after fine-tuning. Figure 5 (left) shows MRL by itself: Since many preference pairs need to be reversed compared to the base model's judgements—remember that baseline performance on internal preference data was just above guessing level—, the model learns to fulfill the loss by compressing the output scores to a band roughly twice the size of the margin.

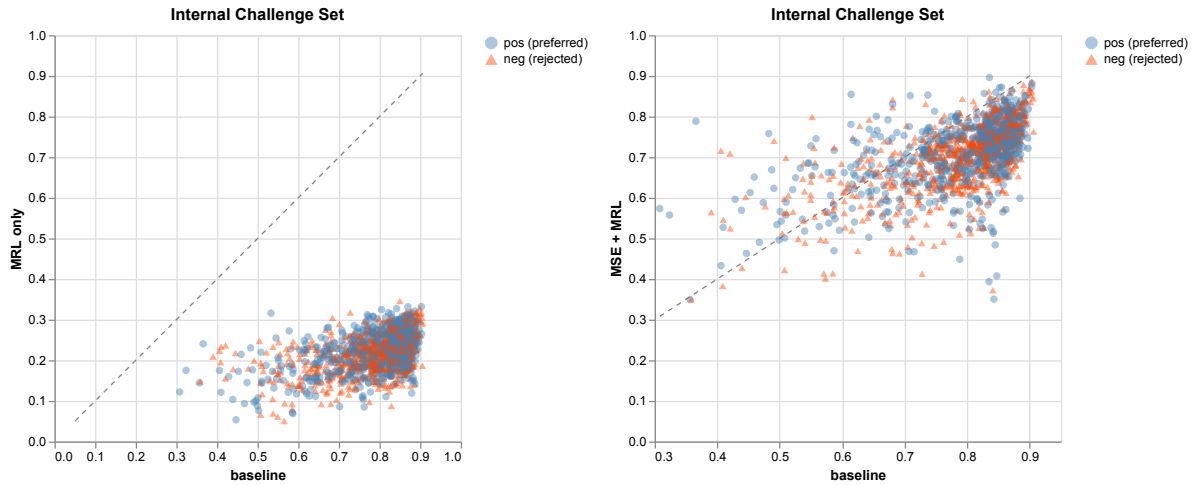

Figure 5: Scatter plots contrasting fine-tuned vs. baseline COMETKiwi scores on internal LocCheck split. Left: Model fine-tuned only with MRL; Right: Multi-task training.

This collapsed score distribution then makes it very difficult for the model to preserve ranking across different sources, affecting global Kendall.

**Regularising MRL.** Since our preference-pair data does not contain human scores, or held-out references with which to compute artificial scores, we initially attempt to regularise MRL against COMETKiwi$^{22}_{\text{DA}}$'s original score. The equation and ablation study are described in Appendix C. This regulariser partially mitigated score collapse. However, due to the large number of samples where the baseline is wrong, MRL and the regulariser frequently conflict, producing worse overall outcomes with a stronger regularisation weight.

In our main multi-task training setup, we instead process the data in two separate ways, inducing a chrF++-based score to regress towards for MSE, and creating preference pairs for MRL. Figure 5 (right) shows the resulting score distribution on LocCheck: Scores remain much more spread out across the range, while still producing better separation between the positive and negative samples.

## 6 LocCheck Results

Table 3 shows results on LocCheck, both the public and the internal split. The baseline COMETKiwi$^{22}_{\text{DA}}$ performs poorly on both splits, well below guessing on the public split. We performed additional checks to rule out corrupt data, then tested our fine-tuned models on both splits. We ablate our tokeniser adjustments and fine-tuning approaches separately from each other. In Figure 1 we show the macro average over both splits.

| Model | Internal | Public |
|---|---|---|
| baseline | 45.1 | 30.1 |
| + new tokeniser | 49.5 | 35.8 |
| **+ MSE** | | |
| base tokeniser | 56.3 | 40.5 |
| new tokeniser | 61.6 | 41.4 |
| **+ MRL** | | |
| base tokeniser | 41.9 | 50.3 |
| new tokeniser | 54.0 | 54.2 |
| **+ MSE + MRL** | | |
| new tokeniser | 64.1 | 46.3 |
| + data augmentation | **89.6** | **86.1** |

Table 3: Effect of the tokeniser and data augmentations on preference accuracy (%) over LocCheck. **Internal** is our in-house challenge set; **Public** is the same set of heuristics applied to WMT25 system outputs and the BOUQuET test split. Best result per column in **bold**.

**Tokeniser adaptation helps with learning specific patterns.** Results on LocCheck demonstrate a large improvement (4-10 percentage points in most cases) simply due to the tokenizer adjustments: Replacing the tokeniser allows the model to 'see' leading and trailing spaces for the first time, for instance. The All Caps rule is learned better with the new tokeniser, while the NBSP rule can only be learned correctly with the new tokeniser. Appendix E.2 offers more detail on how the individual categories respond to the new tokeniser, as well as to the different fine-tuning approaches. However, the overall results are not satisfactory,

even with multi-task fine-tuning: While accuracy on the internal split has reached 64%, accuracy on the public split is still below guessing level.

**LocCheck needs data augmentation.** As expected, adding this augmented data allows the fine-tuned model to rank the majority of samples correctly, now approaching 90% on both data splits. However, preference accuracy on the main test set drops somewhat across language pairs, compared to the regular multi-task training (see Appendix Table 12). This reflects the shift in the training distribution, and indicates that the mentioned "rules" may in fact not be consistently applied by the post-editors. This result suggests that although QE models can be efficiently taught to respect explicit editing rules, heuristics may equally remain a useful tool in the localisation pipeline.

## 7 Conclusions

Real-life localisation data is significantly different from public machine translation and metric benchmarks, introducing a domain shift that affects QE models strongly. To help with the evaluation of QE models for a localisation context, we have proposed two new datasets: LocCheck, focused on localisation-specific long-tail issues, and LocHD, a dataset of realistic translations annotated with ESA scores from professional translators.

To bridge the domain gap in the absence of traditional metric training data, we have demonstrated a data processing approach to leverage in-domain post-edits into two types of signal: Between-source regression of continuous scores and within-source ordering of preference pairs. Both approaches individually have their limitations, and indeed, initial results illustrate the trade-off between global between-source correlation and within-source preference accuracy. To address this trade-off, we combine both losses in a multi-task training approach, where they stabilise each other and yield better overall results. Our recommendation for future adaptation and/or training of metrics, therefore, is to consistently incorporate training signals at both the global and the segment level.

Using these two signals enables us to perform data-efficient domain adaptation without requiring human scores. Specifically, we adapted COMETKiwi$^{22}_{\text{DA}}$ to localisation data with training sets of only 10k-20k samples, less than 1% of its original training data. Along with targeted tokeniser interventions, our fine-tuning approaches yield LocQE models more suited to localisation data. To contend with long-tail issues described by translators, we find that targeted data augmentation is required.

**Future Work.** The application of modified QE models to MT preference optimisation training, such as DQO, could yield deeper insights into their behaviour. We leave this exploration to future work.

## Limitations

We acknowledge several limitations of this work. Primarily, some of the data for our main experiments is internal and cannot be published. However, we have made an effort to provide comparable experiments on similar, previously published data, showing qualitatively similar results, to share code for reproducibility, and to describe the internal data in detail.

The post-edits used are potentially noisy, particularly in the sense that different stylistic preferences may apply for different client projects. Our analysis in Appendix A.4 gives a further sense of the subjectivity of edits, indicating that not every preference pair is likely to yield a helpful signal. Nevertheless, our results show promising results for domain adaptation even with this limitation.

Additionally, we have demonstrated our approach on only one type of quality estimation model. This was done for efficiency and cost reasons, as COMETKiwi is a lightweight model that makes it easier to inference and fine-tune. Tuning a significantly larger model such as MetricX-24 would have been out of scope for this project.

## AI Assistant Information

Coding assistants were used in implementing the data processing, fine-tuning approaches, and creating the plots. The outputs were thoroughly checked and tested for purpose. No LLMs were used in the writing of this article.

## Acknowledgments

The data processing, tokeniser adaptation, and fine-tuning setups were implemented by KH during an internship at LILT, advised by JW. GB provided significant help in running further ablations and combining the two losses into the multi-task fine-tuning. KH wrote the paper draft with input from both co-authors.

Thank you to Kaden Uhlig for helpful discussions during the development of this project. We also thank the anonymous reviewers for their insights and feedback.

## A Data Processing Details

We filter our internal data substantially before processing it. For the initial filtering, we use these heuristics:

- Only use documents with any human reviews
- Only use language pairs with $> 5,000$ segments available after document filtering
- Only using segments with $> 5$ but $< 425$ characters (around the $99^{th}$ percentile in length)

We then process data into preference pairs on one hand and continuous scores on the other hand, as described below. After applying both transformations separately, we sample train, dev, and test splits from both types of data, ensuring that each individual client project is assigned to only one split across both datasets to prevent overlap.

### A.1 Preference Pairs from Post-Edits

To create the preference pairs from our post-edit data, we filter for segments where the final translation was provided or approved by a human reviewer, treating this as the preferred translation. As negative samples, we use previous machine-translated versions of the segment, where they differ from the final version. Table 11 lists absolute test set sizes, and relative train and development set sizes across all language pairs used. For the ACED corpus, we always use the post-edited segment as the preferred, provided it is different from the machine translated segment. Because significant portions of the ACED data were not edited, this unfortunately limits the number of available preference pairs from this corpus (cf. Table 2).

### A.2 Continuous Scores from Post-Edits

Using HTER (human-targeted translation edit rate), as part of the training signal for metrics is an established practice (e.g., Sharami et al., 2023). That said, TER is somewhat unstable on a segment level, especially when segments are short—a common occurrence in our data. Thus, we select chrF++ as our surface metric for measuring post-edit distance. Additionally, we use heuristics to identify numbers, URLs, and "DNTs" (**D**o **N**ot **T**ranslate) which the reviewer had to edit. Since these are semantically major errors which may result only in a small edit distance, we subtract an additional 20 chrF points for these cases (equivalent to 5 out of a maximum score of 25 in MQM; see Freitag et al., 2021). Finally, we calculate z-scores from these artificial scores, and rescale them to between [0,1].

| System | MT | AI-PE | Human |
|---|---|---|---|
| MT | - | 0.26 | 0.14 |
| AI-PE | 0.43 | - | 0.23 |
| Human | 0.61 | 0.52 | - |

Table 4: Pairwise system comparison results from an internal study, where each cell indicates the win rate of the system listed in the row when compared against the system listed in the corresponding column. MT refers to machine translation, AI-PE to automatic post-editing of MT output, and Human to final human translation.

| Metric | $\rho$ | $\tau$ |
|---|---|---|
| $\text{COMET}^{22}_{\text{DA}}$ | 0.404 | 0.282 |
| $\text{COMETKiwi}^{22}_{\text{DA}}$ | 0.371 | 0.253 |
| BLEU | 0.166 | 0.115 |
| chrF++ | 0.227 | 0.158 |
| TER | -0.195 | -0.137 |

Table 5: Segment-level Spearman R ($\rho$) and Kendall's Tau ($\tau$) correlations between ESA scores and automatic evaluation metrics in the internal study. BLEU, chrF++, and TER are computed using their segment-level variants. Only MT and AI-PE annotations are included, with the final human translation serving as the reference for reference-based metrics.

### A.3 WMT Data Processing

To use the WMT data in both our training losses, we need both continuous scores and preference pairs. As continuous scores, we use z-scores derived from the DA or ESA annotations, rescaled to between [0,1]. To transform the data into preference pairs, we compare the scores of all submissions for a given segment. If the z-scores of two candidates are more than one standard deviation apart, we use them as a preference pair. The raw scores act as a sanity check: We never use a submission as the rejected translation if its raw score is 98 or higher. We subsample the WMT24 preference accuracy test set to one preference pair per source, in order to keep the test set size manageable.

### A.4 Quality Validation of Internal Data

To provide a clearer sense of our internal data, we annotate a sample ($n = 984$ annotations across 317 source segments in 53 documents) of English-German hypotheses in an ESA setting (Kocmi et al.,

2024b). The annotators in this small validation study are German-speaking NLP practitioners, and the data is sampled independently from LocHD. The data sample is drawn randomly from our internal data, but with the criterion that there are three hypotheses present: A machine translation, an AI post-edit, and a final human post-edit. Wherever possible, we show document context.

Table 4 shows how often each type of hypothesis wins against the other hypotheses. That is, the human translation won over the MT system 61% of the time while the MT system was rated preferable over the human translation 14% of the time. The rest are ties. These win rates show how often our annotators agreed with the the edits made by the AI-PE or the human post-edit, effectively giving us a sense of how often edits are subjective.

Table 5 reports segment-level Spearman's rank correlation ($\rho$) and Kendall's Tau ($\tau$) between human judgements and automatic evaluation metrics. Annotations corresponding to the final human post-edit are excluded and instead used as a reference, resulting in a total of 644 annotations. Overall, we observe slightly stronger correlations than those reported by (Rei et al., 2022). While neural metrics show very similar correlation values, surface-level metrics show substantially higher correlations compared to prior work. This can be attributed to the bias introduced by the post-editing setting in which the data was generated. Later edits tend to be close to the original version, which is measured by BLEU, TER and chrF++.

## B Details of Tokeniser Modifications

The pretrained encoder used by COMETKiwi$^{22}_{\text{DA}}$ is based on XLM-R (Conneau et al., 2020), specifically, InfoXLM (Chi et al., 2021). Thus, it uses the XLM-R tokeniser, with a vocabulary of ca. 250k subword tokens, trained with SentencePiece (Kudo and Richardson, 2018) and implemented for inference in the Huggingface `tokenizers` library.

By default, the XLM-R tokeniser splits on any whitespace, stripping away trailing and multiple spaces. It also replaces spaces with the "metaspace" character. Since we are only inferencing the tokeniser, it has already learned exclusively tokens that do not cross whitespace boundaries. Rather than implement a new whitespace pretokeniser, we can simply remove this processing step to preserve trailing and multiple spaces without significantly changing the subword token sequence, as long as we keep the metaspace replacement.

Regarding the special space and control characters, the `tokenizers` library allows us to add tokens which bypass the Unicode normalisation step. We add the non-breaking space (NBSP) in the narrow and regular form, the zero-width non-joiner (ZWNJ), the zero-width space (ZWSP) and control characters such as the left-to-right (LTR) and right-to-left (RTL) marker as additional tokens. In the model's embedding layer, the new tokens are initialised according to the AvgEmb procedure shown by Hewitt (2021).

## C MRL Regulariser and Margin Ablation

Margin Ranking Loss comes with the *margin* hyperparameter $m$. Rather than set it only empirically, we test a range of margins in this section.

Additionally, we test a simple regularisation technique: MRL on its own cannot provide a signal about appropriate absolute values. However, computing a continuous score for both the positive and negative sample would require a held-out reference, which we do not have access to for our internal data. Therefore, we compute the original model's score on both the positive and negative sample, and use these scores as a regularisation target.

Using mean-squared error (MSE) between the predicted score $x_i$ and the original score $y_i$, as a regulariser, the full loss equation becomes:

$$\begin{aligned}\mathcal{L} &= \text{MRL}(x_{pos}, x_{neg}) \\ &\quad + \lambda_r(\text{MSE}(x_{pos}, y_{pos}) + \text{MSE}(x_{neg}, y_{neg}))\end{aligned} \tag{2}$$

We ablate the hyperparameters $m$ and $\lambda$, testing margins $m \in \{0.0, 0.01, 0.02, 0.05, 0.1\}$, and regulariser weights $\lambda \in \{0.0, 0.01, 0.05, 0.1, 0.5, 1\}$. Figure 6 shows the resulting pareto curve over two metrics: Segment-wise preference accuracy and global Kendall's $\tau$, both measured on our internal test set.

Since COMETKiwi$^{22}_{\text{DA}}$ starts out with poor preference accuracy on our internal data, this regulariser frequently conflicts with MRL. Tuning the strength of the regularisation loss via $\lambda$ proves insufficient for balancing the two: The majority of points on the pareto curve has a $\lambda = 0.0$. Therefore, we discard regularisation to the original scores, and instead focus on multi-task training.

We select a margin of 0.02, which sits on the pareto curve, and corresponds to the common semantics of COMET-type metrics, where a differ-

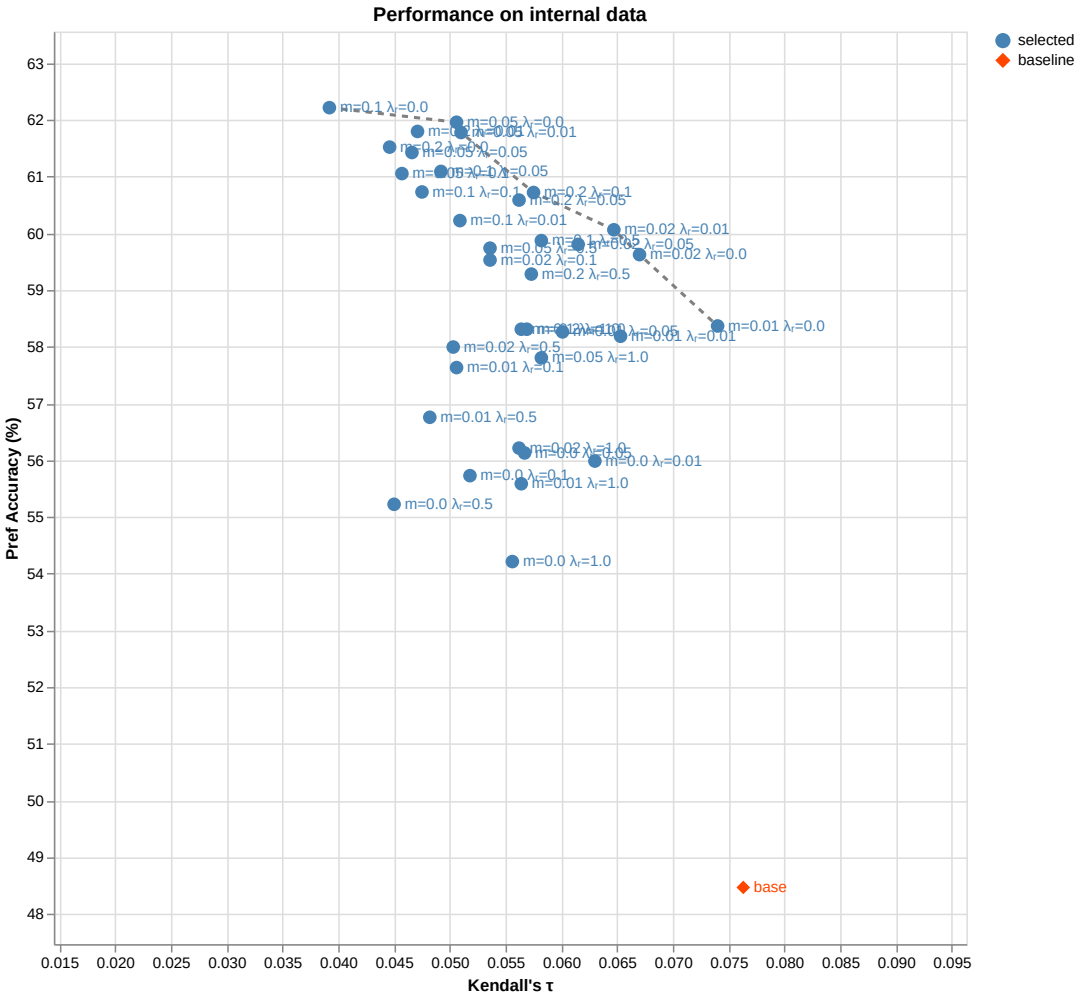

Figure 6: Pareto curve of Kendall's $\tau$ vs. preference accuracy achieved by contrastive training with different settings for $m$ and $\lambda$.

ence of 0.02 already corresponds to a meaningful difference in quality (cf. Kocmi et al., 2024c).

## D Data Mix Ablation

In the multi-task setup, we balance the influence of the two losses by varying the composition of the training data. This leaves open two choices: the share of original training data (WMT2017-20) mixed into the training data, and the ratio between continuous scores (MSE) and preference pairs (MRL). Table 6 shows our ablation experiment for both choices.

First, we vary the share of internal data from 0% to 100%, applying the same mix to the MSE and the MRL side (10k samples each). We originally mixed in WMT data to mitigate forgetting (cf. § 3). In the multi-task setting, however, preference accuracy improves with a growing share of internal data across all preference-based test sets, including WMT24 itself. Only ACES and the global correlations benefit from added WMT data, mirroring the trade-off between segment-wise and global performance discussed in the main text. We decide to train our final models on internal data only.

Then, we vary the ratio of MSE to MRL samples on this internal-only mix, from pure MRL to pure MSE at a matched total budget of 15k samples. The two extremes recover the single-loss failure modes: Pure MRL yields the highest preference accuracy on the internal test set, but collapses the global correlations and ACES performance, while pure MSE shows the opposite behaviour. Between the extremes, the measures trade off smoothly. We select the 2:1 ratio, which achieves the best WMT24 accuracy and strong LocCheck performance, and retains most of the global-correlation gains of MSE-only training, at a small cost in preference accuracy on the internal test set.

## E LocCheck Details

### E.1 Composition

We include eleven language pairs in LocCheck, translating from English into the following target languages: Arabic, German, Spanish, Finnish, French, Hindi, Japanese, Polish, Russian, Thai, and Chinese. These target languages cover both very high-resource and more mid-resource language pairs, seven different scripts, and as many language families. We apply the following heuristics to find and create positive and negative samples:

- **Copy URLs.** Although URLs may be localised, an MT model cannot know the localised URL and so should be expected to copy the source URL if no other instruction is given. We sample translations where a URL was changed during the post-editing process. We ensure that the reference and positive sample contain the source URL, then place the changed URL in the negative sample.
- **Copy DNTs. D**o **N**ot **T**ranslate items are elements within the segment, usually marked by a specific syntax, that should be copied to the correct place in the target segment, and must not be translated. We sample segments where a DNT item was changed during the post-editing process, analogously to URLs.
- **Long Numbers.** If a number is mistranslated, the metric should catch this and consider it a major error, even if the number is long. We sample translations organically containing long digit sequences, and check that the intermediate translation matches the reference. Then, we randomly remove, add, or swap one or more digits, and place the resulting digit sequence within the negative sample.
- **Leading/Trailing Spaces.** Translators are careful to leave leading and trailing spaces in a segment unchanged, but the default tokenisation of COMETKiwi models drops these entirely. We sample translations with leading or trailing spaces, then randomly add, remove, or replace whitespace characters from these leading or trailing space sequences. The whitespace characters we sample from for addition or replacement are the regular space, tab, NBSP, ZWSP, and ZWNJ.
- **Extra Period.** If a longer segment does not end in a period, language models still sometimes prefer a translation ending in a period, but translators do not. We sample segments with a minimum of ten source words that do not end in a period, then add the appropriate sentence-ending symbol for each script to the negative sample.
- **All Caps.** If the source segment is written in all-caps, a translation in all-caps should be preferred to a translation in sentence case. We sample segments in sentence case and use the initial translation as the negative sample, then

upper-case the source, positive sample, and reference. This criterion is only applicable in Latin and Cyrillic script.

- **Spanish ¿ and ¡.** We want to verify that the sentence-initial exclamation mark and question mark in Spanish are treated correctly by the metrics. We sample Spanish sentences containing these characters and remove them to create the negative sample.

- **French NBSPs.** French has specific rules about where non-breaking spaces should be used, but COMETKiwi models cannot differentiate special space characters. We sample French segments where a NBSP occurs with punctuation, and randomly either remove the NBSP or replace it with a regular whitespace character.

- **Unicode Spaces.** Some segments contain special Unicode whitespace and control characters such as NBSP, narrow NBSP, zero-width space, zero-width non-joiner (ZWNJ), zero-width joiner (ZWJ), ideographic space, and the LTR/RTL marks. These are stripped by the original tokenizer but often need to be kept in the translation. We find segments where the reference contains any of these characters. We use the initial translation as a positive example if it contains the characters as well; otherwise, we use the reference. We produce the negative example by either dropping the special character or replacing it with a regular space.

Table 7 shows the composition of the Localisation CheckList by language pair and error category.

Table 9: Performance of COMETKiwi models on the Localisation CheckList set by error category. Fine-tuning was done with the internal dataset throughout.

### E.2 Analysis of Results

Table 9 breaks down the performance of COMETKiwi variants, fine-tuned on internal data, by category. Long numbers show a strong improvement under MSE fine-tuning. Recall that we explicitly subtracted from the chrF scores assigned to segments failing this criterion, so the QE model has clearly learned to attend to this pattern due to this data augmentation.

As expected, the category of leading and trailing spaces is strongly helped by allowing the model's tokeniser to see the whitespace in question. Fine-tuning harms performance here, likely not providing a useful signal for this category. After adding augmented examples to the training data the model learns to recognize the leading and trailing spaces difference with 78.2% accuracy.

Regarding the NBSP, merely adding it to the tokeniser harms performance because there is now a new, untrained token in many of the segments. Fine-tuning with MSE helps but does not restore performance to baseline—chrF++ does not distinguish the NBSP either. Here, however, contrastive and multi-task fine-tuning proves effective: Our localisation data clearly contains a number of segments where this type of edit was made, and consistently so. Adding augmented training data further raises performance to 88%. A similar picture emerges for the broader Unicode Spaces rule.

Accuracy on the 'Extra Period' category stays in a similar range across training approaches, again suggesting a scarcity of useful signal. This is supported by the result after adding augmentation, which helps the model to perfectly distinguish this phenomenon very well. Additionally, fine-tuning is relatively effective at making the model rate an all-caps translation of an all-caps source above the sentence-case version, but data augmentation is once again necessary to consistently demonstrate the rule.

The Spanish punctuation marks stand out somewhat: The base QE model already shows very high performance on this category. Fine-tuning with MSE hurts compared to the baseline, and even the multi-task training with data augmentation stays slightly behind the baseline, but this is likely noise due to a small sample size.

## F Additional Results

We check the general capabilities of our fine-tuned models on the ACES challenge set (Amrhein et al., 2023), primarily tracking the aggregated ACES-Score. Table 10 shows the ACES-Score (Amrhein

et al., 2023) achieved by fine-tuned metrics, a proxy for their general capabilities. It also lists their preference accuracy on the WMT24 test set. Table 11 lists the dataset sizes of our internal data per language pair, while Table 12 shows per-language-pair performance of fine-tuned metric and QE models on that same data. Tables 14 and 15 break down the per-language-pair performance of our QE models on LocHD.

[2]Kitami Institute of Technology, Japan

## Abstract

Previous methods for post-editing the output of a dedicated Neural Machine Translation (NMT) system using a general-purpose Large Language Model (LLM) rely on correcting a single hypothesis generated by the NMT model's decoder. However, in low-resource scenarios – such as Ainu-to-Japanese translation – the low accuracy of initial NMT outputs often leads to error propagation, where LLMs fail to override systemic NMT hallucinations or syntactic errors.

In this paper, we propose a novel machine translation framework that incorporates information from an NMT model into an LLM, while bypassing the limitations of single-sentence correction. Instead of using raw NMT text, our method extracts token-level probability distributions from the NMT decoder and combines them with entries obtained by looking up a bilingual dictionary, having the LLM construct the final translation from these two sources of information. By grounding the LLM in both the NMT's internal confidence signals and external linguistic knowledge, our approach effectively mitigates the bias toward poor-quality NMT outputs.

Empirical evaluations on Ainu-Japanese parallel data using chrF, semantic similarity, and perplexity demonstrate that our method outperforms six baseline approaches in specific domains in the Ainu-to-Japanese direction, that is, when translating *into* the high-resource language. In the opposite direction, the method yields no improvement, as its effectiveness is bounded by the LLM's ability to generate the target language. Furthermore, perplexity analysis confirms that LLM-driven translation substantially enhances linguistic fluency compared to traditional NMT outputs.

## 1 Introduction

The Ainu language has been classified by UNESCO (Moseley, 2010) as a critically endangered language, making its preservation and transmission a matter of urgent priority. In recent years, machine translation has been actively researched as part of efforts to revitalize such endangered languages. Machine translation can serve as a valuable tool for language learning and revitalization. For example, Coleman et al. (2024) have proposed a tool for language learners that utilizes machine translation for a no-resource language.

Neural Machine Translation (NMT), the current mainstream approach, requires vast amounts of training data. However, many endangered languages, including Ainu, are low-resource languages with limited data available for training, which prevents sufficient model training. Consequently, NMT performance for such languages remains low and is not yet at a practical stage.

In recent years, the massive knowledge base and natural text generation capabilities of general-purpose Large Language Models (LLMs) have garnered attention, leading to their application in machine translation. Research by Gain et al. (2025) reports that while LLMs outperform dedicated NMT systems in translations between high-resource languages, their performance remains inferior to NMT in translations involving low-resource languages.

Furthermore, methods that combine NMT and LLMs have been proposed. One such approach is post-editing. For instance, Nielsen et al. (2025) proposed a method in which an LLM corrects incorrect words in NMT output by referring to entries looked up in an external bilingual dictionary. However, in this method the LLM only references the single best sentence output by the NMT model, meaning that if the NMT output quality is low, the LLM is heavily influenced by those errors and cannot fully correct them. Moreover, because only the

*Proceedings of the Eleventh Conference on Machine Translation*, pages 220–238
October 28-29, 2026 ©2026 Association for Computational Linguistics

final decoded sentence is passed to the LLM, the confidence information held internally by the NMT model – which embodies the statistical knowledge specialized for the translation task – is discarded. Additionally, since the task is framed as fixing a small number of incorrect words in an otherwise adequate translation, the natural language generation capability of the LLM is not fully exploited.

In this study, we propose a method called Distribution-based Generation (Dist-Gen), in which an LLM is prompted to construct sentences by referencing three pieces of information: the input text, the per-token probability distribution obtained during NMT inference, and additional lexical information. In this process, we strictly prioritize the following criteria in this order: (1) naturalness of the sentence, (2) consistency with the provided lexicon, and (3) adherence to the probability distribution. By doing so, we aim to surpass the translation accuracy of conventional methods by maximizing the use of both the NMT's specialized statistical knowledge and the text generation capabilities of the LLM, while suppressing the negative impact of errors in NMT outputs. While the use of lexical information follows an established line of research on dictionary-based prompting of LLMs (Ghazvininejad et al., 2023; Lu et al., 2024; Zheng and Yu, 2025), the novel element of Dist-Gen is the injection of the NMT decoder's token-level probability distributions into the prompt.

We perform evaluation experiments comparing the proposed approach with NMT-only and LLM-only baselines, as well as a previous LLM-as-post-editor method, using a small-scale Ainu-Japanese parallel corpus. As a result, we find that while Dist-Gen works effectively in translating from Ainu to Japanese when using a well-trained NMT model and an appropriate domain lexicon, its effectiveness is limited in other contexts. Furthermore, through comparisons using perplexity, we demonstrate that in most cases, LLMs improve the fluency of the text.

## 2 Related Work

### 2.1 Application of LLMs to machine translation

In recent years, the large-scale knowledge and natural text generation capabilities of general-purpose LLMs have gained attention, leading to their increasing application in machine translation. In particular, for translation tasks between high-resource languages, performance exceeding that of conventional, dedicated NMT has been confirmed (Zhu et al., 2024). However, because LLMs are insufficiently trained on low-resource languages, it has been reported that their performance in translation tasks involving low-resource languages remains low and inferior to that of traditional NMT systems. Furthermore, trends in translation accuracy vary depending on the translation direction; it has been shown that while relatively high scores are obtained in translations from low-resource languages to high-resource languages, scores tend to be lower in translations from high-resource to low-resource languages (Gain et al., 2025).

### 2.2 Dictionary-based prompting of LLMs

Supplying bilingual dictionary entries in the prompt is an established technique for improving LLM-based translation involving low-resource languages. Ghazvininejad et al. (2023) propose DiPMT, a method in which the dictionary translations of selected source words are appended to the translation prompt, and report gains in both low-resource and out-of-domain translation. Lu et al. (2024) extend this idea with Chain-of-Dictionary prompting, in which each source word is accompanied by a chain of its translations into several auxiliary high-resource languages, substantially improving the translation of low-resource languages by ChatGPT. Zheng and Yu (2025) incorporate per-character dictionary definitions into the prompts of an LLM fine-tuned for translating Tangut – an extinct language with scarce parallel data – into Chinese.

The lexicon component of Dist-Gen instantiates this line of work: dictionary entries obtained through exact-match lookup are embedded in the prompt (see Section 3.2). What distinguishes our method from these approaches is the injection of the token-level probability distributions produced by the NMT decoder, which none of the above methods exploits.

### 2.3 Combining NMT systems and LLMs

Methods that combine NMT and LLMs are also being actively researched. One such approach is the "post-editing method", in which an LLM corrects the translations produced by an NMT system. As one example of a post-editing method, Nielsen et al. (2025) proposed an approach as shown in Figure 1. In this method, the LLM corrects incorrect

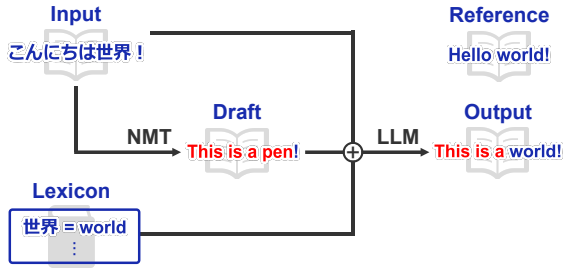

Figure 1: Overview of a simple LLM-as-post-editor method for word correction (Nielsen et al., 2025), applied to Japanese-English machine translation

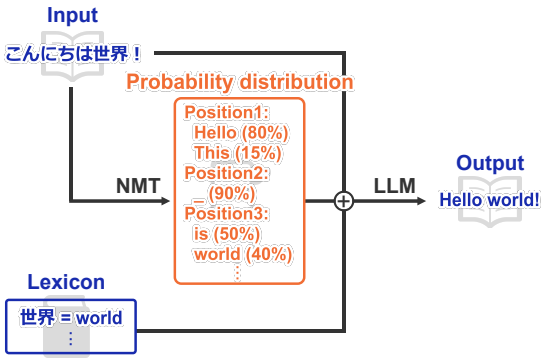

Figure 2: Overview of the proposed method

words in the NMT-generated translation by referencing external lexical information.

In this approach, the LLM only targets the single final sentence produced by the NMT system. However, as shown in Figure 1, there are many cases, especially in low-resource languages, where the entire sentence is significantly incorrect or contains grammatical errors. In such cases, there is a concern that the LLM may be heavily influenced by the errors in the NMT output, resulting in no improvement in overall quality. Additionally, when the LLM performs corrections, it treats tokens with high and low logits (token confidence) from the NMT internal state equally. This means that the statistical information specialized for translation task possessed by the NMT model is not being fully utilized. Furthermore, the task formulation used in this method frames the problem as fixing a small number of incorrect words in an otherwise high-quality translation. Although the LLM outputs a complete sentence, this framing discourages it from restructuring the translation or repairing the context surrounding the substituted words, so its inherent natural text generation capability is not fully leveraged.

In this study we address these challenges, aiming to suppress the negative influence of NMT output on LLMs, maximizing the use of NMT-specific statistical information along with LLMs' extensive knowledge and natural text generation capabilities, and ultimately achieving translation accuracy that surpasses conventional methods.

## 3 Methods

In this paper, we propose a method called Distribution-based Generation (Dist-Gen). As shown in Figure 2, Dist-Gen simultaneously provides an LLM with three pieces of information: the source sentence, the probability distributions at each token position output by the NMT model, and an external lexicon, and has the LLM construct the final translation. By inputting the probability distributions obtained during the generation process rather than a single translation determined by the NMT model, it becomes possible to leverage diverse information about tokens that were not selected but were strong candidates according to the NMT model. This allows for greater utilization of the translation-task-specific statistical information that the NMT model possesses. Furthermore, rather than having the LLM merely *correct* the final output of the NMT model, by having it proactively *construct* sentences based on the provided information, we also expect the LLM to demonstrate its inherent natural language generation capability.

Dist-Gen consists mainly of the following three processing steps:

1. Collecting probability distributions from NMT model
2. Preparing lexical information
3. Text generation with LLM

In the remainder of this section, we describe the details of the processing at each step.

### 3.1 Collecting probability distributions from NMT model

In Dist-Gen, rather than using the single final token sequence (translation) constructed by the decoder, we extract and utilize the probability distributions obtained by applying the softmax function to the logits at each step. Specifically, the NMT model is run with standard greedy decoding, and at each decoding step along the resulting decoding path, the probability distribution over the vocabulary computed at that step is recorded. To reduce

the number of input tokens to the LLM and to mitigate noise, we do not retain the full distributions, but apply a candidate-filtering step defined as follows: at each decoding position, a token is retained as a candidate if it satisfies at least one of two conditions: (i) its probability is at least an absolute inclusion threshold (0.1 in this paper), or (ii) it is selected jointly by *top-p* (Holtzman et al., 2019) and *top-k* (Fan et al., 2018) filtering, i.e., it belongs to the smallest set of most probable tokens whose cumulative probability reaches $p$ (0.9 in this paper), truncated to the $k$ most probable tokens ($k = 5$ in this paper). The absolute threshold thus acts as an unconditional inclusion criterion, ensuring that candidates with moderately high probability are not omitted by the other two criteria. The filtering is applied independently at each decoding position, so the number of retained candidates may vary across positions. All three filtering parameters (the threshold, $p$, and $k$) were selected heuristically, without a systematic parameter search or tuning on a development set, and we did not conduct an ablation or sensitivity analysis of these values; their systematic evaluation is left for future work. The candidates retained at each position are represented as a flat list of token–probability pairs, sorted in descending order of probability. These lists are serialized position by position and embedded in the LLM prompt in the format shown in Prompt 2 (Section 3.3). This allows the LLM to refer to multiple token candidates that the NMT model retained as top candidates, thereby preserving the statistical information about the translation task acquired through NMT training while minimizing the risk of errors caused by inappropriate token selection.

### 3.2 Preparing lexical information

To supplement the LLM's knowledge, external lexical information is embedded in the prompt: each word of the source sentence is looked up in a bilingual word list, and the entries retrieved in this way are included in the prompt. The lookup is performed by surface matching against the word list. The language-specific matching procedures used for the two languages studied in this paper are described in Section 4.3. Each entry in the lexicon includes a source-language word, its translation, part of speech, and optional grammatical attributes. For the format of the lexical information, a Markdown table (as shown in Prompt 1) is adopted. This tabular format is intended to help the LLM accurately grasp the correspondence between each source word and its gloss as structured data.

Note that no word-sense disambiguation is performed when lexicon entries are selected for inclusion in the prompt. Homographs are registered in the word list as separate entries — for example, the Ainu word *an* has one entry with the gloss いる and another with ある (both meaning *to exist*, used for animate and inanimate referents, respectively) — and dictionary lookup (Section 4.3) embeds all entries matching a source word into the prompt simultaneously, as reflected in Prompt 1, where both glosses of *an* appear. Which of the presented glosses to adopt, if any, is thus left to the LLM, which can draw on the part of speech and grammatical attributes accompanying each gloss, the sentence context, and the probability distributions supplied by the NMT model. Under the priority hierarchy described in Section 3.3, this choice is governed first and foremost by the naturalness of the resulting sentence (priority 1).

```
| Source | Gloss | POS | Attr |
| :--- | :--- | :--- | :--- |
| un | ～へ | 格助詞 | - |
| cise | 家 | 名詞 | - |
| an | いる、ある | 自動詞 | 単数形 |
```

Prompt 1: Example of lexical information embedded in the LLM prompt (in the case of Ainu → Japanese translation)

### 3.3 Text generation with LLM

The original source sentence, the per-token probability distributions generated by the NMT model, and the lexical information defined in Section 3.2 are combined to form a user prompt and sent to the LLM along with a system prompt (shown in Appendix B). Inspired by the findings of Braun et al. (2025), who have demonstrated that structured descriptions improve the reasoning performance of LLMs, we adopt Markdown format as the overall prompt format. Furthermore, we choose English as the language of the prompt[1].

The format for describing the per-token probability distributions collected from the NMT model

[1] In preliminary experiments, we also tested prompts written in Japanese, but found them to perform slightly worse than their English counterparts (see Appendix C).

is as shown in Prompt 2, where each token position explicitly lists the candidate tokens retained by the filtering procedure of Section 3.1, together with their probabilities. This allows the LLM to quantitatively refer to how confidently the NMT model was inclined to select each token (the contribution of these numerical values is examined in the ablation of Appendix F). Given these position-wise candidate lists, the LLM generates a single output sentence. Note that it is not asked to explicitly search over combinations of the listed candidates, so no combinatorial expansion of the candidate space takes place. Furthermore, as described below, it may also produce tokens outside the retained candidate lists when necessary for a natural translation.

Prompt 2: Example of token candidate information in Dist-Gen (Ainu to Japanese)

The system prompt is designed to strictly enforce the following priorities in the specified order, with the instruction that higher-priority requirements must be satisfied even at the expense of lower-priority ones.

1. Naturalness of the generated text
2. Consistency with the provided lexicon
3. Consistency with the probability distributions supplied by the NMT model

By establishing this priority order, even if a token has been assigned a low probability by the NMT model, the LLM is able to re-evaluate its appropriateness in the given context and adopt it. Furthermore, by prioritizing naturalness of the text over consistency with lexical information, the LLM's generative capabilities can be fully exercised, leading to improved fluency in the output. In addition, rather than framing the task as a post-editing correction task, the LLM is instructed to construct the final translation itself. This further enables the LLM to exercise its inherent generative capabilities to a greater degree.

## 4 Experiments

### 4.1 Datasets

We use two Ainu-Japanese parallel datasets: one consisting primarily of sentences from the Saru dialect of Ainu and the traditional oral literature domain (Nowakowski et al., 2018) (90,780 entries), and another derived from a modern-day textbook for Ainu language learning (Nakagawa, 2021), also based on the Saru dialect, but centered on the everyday conversation domain (485 entries). The oral literature domain corpus is characterized by expressions reminiscent of classical literary language found in folktales, while the everyday conversation domain corpus is characterized by expressions resembling modern colloquial speech.

For external lexical information, we use 976 entries from the Saru dialect Ainu word list provided by the Foundation for Ainu Culture (Foundation for Research and Promotion of Ainu Culture) as a supplementary material to their learning materials for the same dialect, focusing on conversational contexts. The lexicon is manually preprocessed and converted into JSONL format, with each entry containing an Ainu word, its Japanese equivalent, part of speech, and optional grammatical attributes.

### 4.2 Experimental setup

To evaluate the effectiveness of Dist-Gen, we conduct comparisons using the following seven methods.

- Fine-tuned NMT (mBART)
- LLM-only (GPT-5.2)
- LLM-only with lexicon
- Post-editing
- Post-editing with lexicon
- Dist-Gen
- Dist-Gen with lexicon

The suffix "with lexicon" indicates that lexical information as described in Section 3.2 is provided. Dist-Gen with lexicon is the proposed method, while the remaining six serve as baselines.

All methods with an NMT component share the same model, namely mBART50[2] (Tang et al., 2020) with 0.6B parameters, fine-tuned on the training corpus described in Section 4.1 (detailed training configurations and hyperparameters are provided in Appendix D). For the methods utilizing an LLM, we use GPT-5.2 (detailed configurations regarding the computing infrastructure, training times, and token usage statistics are provided in Appendix E). To ensure fairness across methods, the prompts provided to the model in the LLM-only experiment and the baseline post-editing methods were designed to contain a comparable amount of descriptive content to that of the proposed method. Specifically, the post-editing instructions were designed to go beyond simple vocabulary substitution by also instructing context-sensitive grammatical corrections, thereby aligning the conditions with the reasoning task performed by Dist-Gen.

Regarding lexicon presentation, Nielsen et al. (2025) argue that all entries in the dictionary should be included in the prompt rather than limiting it to only the relevant entries, and that selective presentation can in fact lower scores. However, in our experiments, we adopted a design in which the dictionary lookup selects only the entries found in the source sentence, from a practical standpoint, taking into account LLM context size limitations, API token consumption, and inference speed (please refer to Section 4.3 for details). As a result of these design choices, the only remaining difference from Dist-Gen is that the baseline post-editing method performs corrections based on a translation already finalized by the NMT model. This allows us to evaluate the impact of the changes we have introduced regarding how the LLM interacts with the NMT model's output.

### 4.3 Dictionary lookup

For Ainu-side dictionary lookup, we apply whitespace-based tokenization combined with an exact-match filter on tokens. It is assumed that the positions at which whitespace is inserted for tokenization are consistent between the Ainu word list and the search query.

[2] https://huggingface.co/facebook/mbart-large-50-many-to-many-mmt

| Direction | Test domain | Token | Type |
|---|---|---|---|
| Ain → Jpn | conversation | 81.5% | 57.6% |
| Ain → Jpn | oral literature | 73.9% | 39.9% |
| Jpn → Ain | conversation | 44.2% | 38.1% |
| Jpn → Ain | oral literature | 41.9% | 33.8% |

Table 1: Coverage of the test sets by the 976-entry lexicon: the percentage of source token occurrences (Token) and of distinct source token types (Type) for which dictionary lookup retrieved at least one lexicon entry. Punctuation-only units are excluded.

For Japanese-side dictionary lookup, we combine the Aho-Corasick algorithm (Aho and Corasick, 1975) with longest-match filtering in order to efficiently perform dictionary lookup in an agglutinative language with ambiguous word boundaries. The Aho-Corasick algorithm constructs all vocabulary entries in the dictionary as a finite automaton, enabling pattern matching across all entries in $O(n)$ time complexity, where $n$ is the length of the input sentence. The Aho-Corasick algorithm was implemented using the pyahocorasick library (version 2.3.0).

To quantify how often the lexicon can actually participate in translation, Table 1 reports its coverage of the two 485-sentence test sets used in our experiments (see Section 4.1), defined operationally as the fraction of source tokens (and of distinct source token types) for which the lookup procedure described above retrieved at least one of the 976 lexicon entries. Because the lookup rules differ between the two directions (exact token match on the Ainu side, longest substring match on the Japanese side), the absolute values should not be compared across directions. In both directions, coverage is higher on the daily conversation test set than on the oral literature test set, as expected given that the word list focuses on conversational contexts. The gap is most pronounced for Ainu word types (57.6% vs. 39.9%). Note, however, that even on the oral literature test set the lexicon still matches 73.9% of Ainu source token occurrences, a point we return to in Section 5.3.

### 4.4 Evaluation metrics

#### 4.4.1 String similarity

We use chrF (Popović, 2015), which is based on character $n$-gram precision, and is known for high reliability in morphologically rich, agglutinative languages such as Ainu and Japanese (Popović, 2016; Bapna et al., 2022). Measurements are conducted using sacreBLEU (Post, 2018) (version

2.6.0). For statistical significance testing, we apply the Bootstrap method (Koehn, 2004) built into sacreBLEU, performing 5,000 resampling iterations at a significance level of 0.05.

#### 4.4.2 Semantic similarity

To capture semantic similarity that surface-level matching metrics such as chrF cannot fully measure, we adopt a metric based on SentenceBERT (Reimers and Gurevych, 2019) and cosine similarity that has previously been used to evaluate Japanese machine translation output by Usui and Komiya (2023)[3]. This metric is computed by encoding both the hypothesis and the reference sentence using a SentenceBERT model and comparing the resulting vector representations via cosine similarity (using scikit-learn 1.7.0 (Pedregosa et al., 2011)). In this study, we use `sonoisa/sentence-bert-base-ja-mean-tokens-v2`[4] as the Japanese sentence encoder[5]. For brevity, we refer to this metric as SBERT-cos in the remainder of the paper. Since there exists no SentenceBERT model (or any other reliable text embedding model) for Ainu, evaluation using this metric is restricted to the Ainu → Japanese translation task. For statistical significance testing, we apply a Bootstrap method (using SciPy 1.15.3 (Virtanen et al., 2020)) with 5,000 resampling iterations at a significance level of 0.05.

#### 4.4.3 Perplexity

To evaluate the fluency of generated translations, we employ perplexity as an additional metric. Following previous work on machine translation evaluation, we interpret lower target-language language model perplexity as an indicator of higher fluency (Edunov et al., 2020). In this study, we use `rinna/japanese-gpt2-medium`[6] as the language model for computing perplexity of Japanese sentences, following prior Japanese NLP work that used this model for perplexity-based fluency estimation (Hatagaki et al., 2022). For the same reason as with SBERT-cos described above, we only apply this metric in the Ainu-to-Japanese translation direction.

[3]The reason for not using standard metrics such as COMET is that they do not support the Ainu-Japanese language pair.

[4]https://huggingface.co/sonoisa/sentence-bert-base-ja-mean-tokens-v2

[5]To verify that it is adequate for our purpose, we evaluated it on the two standard Japanese semantic textual similarity benchmarks by correlating the cosine similarity of the two sentence embeddings with the human similarity rating of each pair. The Spearman rank correlation is 0.806 on the JSTS validation set (1,457 pairs; JGLUE v1.3, Kurihara et al., 2022) and 0.772 on the JSICK test set (4,927 pairs; Yanaka and Mineshima, 2022), indicating that the cosine similarity of this encoder tracks human judgments of sentence similarity closely.

## 5 Results and discussion

### 5.1 Main experiment results

In this experiment, we use 80,829 samples from the oral literature corpus to train the NMT model, 8,981 samples from the same corpus are used as the development set, and all systems are evaluated using 485 samples from the daily conversation corpus. The results are presented in Table 2, with the highest score for each metric shown in bold, and scores that show a statistically significant improvement over mBART indicated with an underline.

For the Ainu-to-Japanese translation direction, Dist-Gen with lexical information achieves substantially higher chrF and SBERT-cos scores compared to both mBART and GPT-5.2, while also slightly outperforming the baseline post-editing method. Notably, it is the only method for which statistically significant improvements over mBART are observed in both string- and semantic similarity scores. Appendix H complements these aggregate scores with a qualitative analysis of representative success and failure cases.

Dist-Gen with the lexicon consistently outperforms the variant without it, confirming the utility of this additional information. This is consistent with the high coverage of the daily conversation test set by the lexicon (81.5% of Ainu source tokens – see Table 1), which lets the lexical hints reach most of the source vocabulary. The relatively low difference in performance between Dist-Gen without lexical information and mBART can be attributed to the tendency of the LLM to prioritize the tokens with the highest probabilities in the distributions provided by the NMT model, effectively rendering the generated translations equivalent to mBART's greedy decoding outputs. In contrast, when lexical information is provided, it guides token selection, enabling the model to select tokens that are contextually or lexically appropriate even if they are not the top candidates from the NMT model. This finding is supported by the results in Table 3, which shows that the edit distance between mBART's predictions and the translations generated by our method is larger when lexical information is provided.

| Direction | Metric | mBART | GPT-5.2 | GPT-5.2 w/ lexicon | Post-editing | Post-editing w/ lexicon | Dist-Gen | Dist-Gen w/ lexicon |
|---|---|---|---|---|---|---|---|---|
| Ain → Jpn | chrF ↑ | 28.295 | 19.078 | 26.676 | 31.805 | 31.569 | 29.832 | **32.238** |
| | SBERT-cos ↑ | 0.741 | 0.563 | 0.686 | 0.747 | 0.746 | 0.739 | **0.760** |
| | Perplexity ↓ | 2779.653 | **1184.260** | 1564.530 | 2577.165 | 2233.552 | 2352.701 | 1930.589 |
| Jpn → Ain | chrF ↑ | **50.180** | 24.575 | 27.959 | 45.551 | 46.627 | 45.591 | 40.757 |

| Direction | Post-editing | Post-editing w/ lexicon | Dist-Gen | Dist-Gen w/ lexicon |
|---|---|---|---|---|
| Ain → Jpn | 0.272 | 0.341 | 0.247 | 0.342 |
| Jpn → Ain | 0.269 | 0.253 | 0.195 | 0.367 |

Table 3: Levenshtein distances between mBART's translations and the outputs produced by methods informed by it.

Another important finding is that, when equipped with lexical information, Dist-Gen outperforms the baseline post-editing method. We explain this by the fact that when correcting vocabulary based on the external lexicon, the surrounding context and phrasing must also be revised simultaneously. In post-editing, GPT-5.2 has to resolve this solely based on its own internal knowledge, whereas in Dist-Gen, the model can extensively reference the statistical information provided by the NMT model, allowing it to either select from those candidates or use them as a guide during revision.

Regarding the higher scores yielded by the post-editing method without lexical information compared to the variant using that information, a possible explanation is that without lexical constraints the model can focus exclusively on grammatical correction, whereas providing lexical information introduces multiple simultaneous subtasks, potentially degrading performance. Furthermore, Nielsen et al. (2025) argue that all available lexical items, rather than their subset, should be included in the prompt, and that providing a limited selection can in fact lead to lower scores. A similar tendency may be responsible for the results observed in our experiment. On the other hand, the positive results achieved by our proposed method demonstrate that even a limited amount of lexical information can be effectively utilized.

Moreover, Dist-Gen with lexical information achieves the lowest perplexity score among all methods except GPT-5.2 alone, quantitatively confirming that the proposed method produces the most fluent Japanese output compared to the other methods. In particular, the lower score compared to post-editing suggests that instructing the model to construct rather than correct a translation allows the LLM to fully leverage its natural language generation capabilities. Furthermore, the improvement in perplexity when lexical information is provided indicates that accurate lexical hints enable the LLM to further improve the quality of the generated sentences in terms of linguistic fluency.

For the Japanese-to-Ainu translation direction, GPT-5.2 alone achieves markedly lower scores compared to all other methods. This is consistent with the findings of Gain et al. (2025), who report that LLMs exhibit lower accuracy when translating from a high-resource language to a low-resource language. All methods incorporating GPT-5.2 exhibit substantial score degradation, which can be attributed to the fact that GPT-5.2 had at most marginal exposure to Ainu in pre-training, making appropriate generation difficult and causing frequent hallucinations. Example (d) in Appendix H illustrates this generation-side failure: a correct content word present in both the NMT output and its probability distributions is preserved by none of the LLM-based methods.

Notably, in this direction Dist-Gen with lexical information scores *lower* than Dist-Gen without it (40.757 vs. 45.591 chrF), reversing the pattern observed for Ainu-to-Japanese translation. This contrast is consistent with the Levenshtein distances in Table 3: lexical information encourages the LLM to depart further from the NMT model's top candidates (edit distance of 0.367 vs. 0.195). Such departures are beneficial when the LLM can competently generate the target language, as in the Ainu-to-Japanese direction, but harmful when it cannot – in Japanese-to-Ainu translation, each departure from the NMT distribution becomes an opportunity for hallucination.

### 5.2 Performance in ultra-low resource setting

In many underresourced languages, the available data is even scarcer than in the case of the Ainu-

| Direction | Metric | mBART | GPT-5.2 | GPT-5.2 w/ lexicon | Post-editing | Post-editing w/ lexicon | Dist-Gen | Dist-Gen w/ lexicon |
|---|---|---|---|---|---|---|---|---|
| Ain → Jpn | chrF ↑ | 5.284 | 19.078 | **26.676** | 11.453 | 23.612 | 8.903 | 24.428 |
| | SBERT-cos ↑ | 0.262 | 0.563 | **0.686** | 0.391 | 0.652 | 0.315 | 0.649 |
| | Perplexity ↓ | 2220.596 | **1184.260** | 1564.530 | 1934.950 | 1850.031 | 2324.198 | 1561.723 |
| Jpn → Ain | chrF ↑ | 11.914 | 24.575 | 27.959 | 24.834 | **29.556** | 21.364 | 27.938 |

Table 4: Scores for each method by translation direction in extremely low-resource setting. Bold indicates the best value for each metric; underline indicates a statistically significant improvement over mBART.

Japanese pair. Table 4 presents the scores obtained when the data used to fine-tune the NMT model is artificially reduced to 1,000 samples (train: 900, dev: 100) from the oral literature corpus, with 485 samples from the daily conversation corpus used for evaluation.

When mBART fine-tuned in an extremely low-resource setting is used, GPT-5.2 achieves the highest scores across all evaluation metrics for the Ainu-to-Japanese translation direction. In contrast, mBART's scores are extremely low, rendering it barely functional as a translation system. All hybrid methods utilizing mBART are heavily influenced by the very low-quality information generated by the NMT model and fail to surpass the performance of GPT-5.2 alone. Nevertheless, focusing on post-editing and Dist-Gen with lexical information, while their scores remain below those of GPT-5.2, they achieve a certain degree of improvement over mBART across all evaluation metrics, suggesting that LLMs can compensate to some extent through using lexical information and contextual understanding.

A similar trend is observed for the Japanese-to-Ainu direction, where post-editing with lexical information slightly surpasses GPT-5.2. This indicates that correcting an NMT-generated sequence, even of low quality, may be more effective than having the LLM generate an entirely unknown language from scratch. Dist-Gen, on the other hand, does not show performance gains. This is presumably because the probability distributions at each NMT decoding step are extremely flat[7], causing the token candidates presented to the LLM to act as noise, which in turn prevents the model from selecting appropriate tokens and induces hallucinations. Example (c) in Appendix H illustrates this failure mode on an individual test sentence.

Regarding perplexity, the results follow nearly the same trend as those reported in Section 5.1, quantitatively demonstrating that Dist-Gen with lexical information is capable of producing fluent output even in an extremely low-resource setting. In contrast, Dist-Gen without lexical information yields a higher perplexity than mBART. Given the low chrF and SBERT-cos scores, this suggests that low-quality probability information acts as noise, leading the model to generate inappropriate and unnatural translations.

### 5.3 Performance on in-domain data

Table 5 presents the scores obtained when a hold-out set of 485 samples from the oral literature corpus, that is, belonging to the same domain as the NMT model's training data, are used as test data. The fine-tuned NMT model used here is the same as in the main experiment (see Section 5.1).

For both Ainu-to-Japanese and Japanese-to-Ainu translation directions, mBART achieves the highest chrF and SBERT-cos scores. Furthermore, mBART's scores are higher than those reported in Section 5.1, confirming that fine-tuning successfully adapted the model to the in-domain data. In contrast, GPT-5.2 scores lower than in the cross-domain experiment, suggesting that the oral literature domain may be more challenging for GPT-5.2 than the daily conversation domain. Regarding post-editing and Dist-Gen, the variants without lexical information generally outperform those with lexical information. A possible explanation is that the lexical information, being closer to the daily conversation domain, could not be effectively utilized in the oral literature domain. The coverage statistics in Table 1 support this explanation: on the oral literature test set the lexicon covers markedly fewer Ainu word types than on the daily conversation test set (39.9% vs. 57.6%), leaving much of the domain-specific vocabulary without lexical support. At the same time, its token coverage remains high (73.9% of Ainu source token occurrences), so conversational-domain glosses are still frequently injected into the prompt – rather than remaining inert, the lexicon thus actively sup-

[7] Average entropy measured on the evaluation data is 0.77 bits, compared to 0.33 bits for the model used in the main experiment.

| Direction | Metric | mBART | GPT-5.2 | GPT-5.2 w/ lexicon | Post-editing | Post-editing w/ lexicon | Dist-Gen | Dist-Gen w/ lexicon |
|---|---|---|---|---|---|---|---|---|
| Ain → Jpn | chrF ↑ | **32.357** | 10.892 | 12.888 | 27.965 | 23.886 | 30.604 | 25.764 |
| | SBERT-cos ↑ | **0.750** | 0.436 | 0.485 | 0.711 | 0.670 | 0.738 | 0.690 |
| | Perplexity ↓ | 4886.807 | 1682.437 | **908.624** | 3185.450 | 3196.457 | 2404.371 | 2776.565 |
| Jpn → Ain | chrF ↑ | **52.346** | 19.083 | 20.105 | 40.831 | 40.836 | 47.352 | 38.701 |

Table 5: Scores for each method by translation direction on data matching the NMT fine-tuning domain. Bold indicates the best value for each metric; underline indicates a statistically significant improvement over mBART.

plies domain-mismatched hints, which is consistent with the observed degradation. The clearest instance involves the person-marking clitics *a=*, *=an*, and *i=*. The lexicon glosses them with their first-person plural readings typical of daily conversation (私たち, 'we'), whereas in Ainu oral literature the same clitics conventionally mark the protagonist-narrator's first person singular, which the reference translations render as 私 ('I') or leave implicit. These glosses were injected into 187 of the 485 Ainu-to-Japanese prompts, and Dist-Gen with lexical information demonstrably followed them: 150 of its outputs contain the plural pronoun 私たち, while only 2 of the 485 reference translations do. For example, for the source *i= hawekoyki* (reference 母に叱られました, 'I was scolded by my mother'), the gloss *i=* → 私たちを ('us') yields the output 私たちを叱りつけました ('[someone] scolded us'). These findings indicate that lexical information must be drawn from the same domain as the evaluation data and must be accurate.

Comparing perplexity scores, the overall fluency is lower than that observed with the daily conversation corpus (Table 2). This is likely because `rinna/japanese-gpt2-medium`, trained on modern text, struggles to predict oral literature domain data.

## 6 Conclusions and future work

In this paper, we proposed Distribution-based Generation (Dist-Gen), a framework in which an LLM constructs translations by referencing per-token NMT probability distributions and external lexical information, rather than correcting a single NMT hypothesis as in conventional post-editing.

Experiments using an Ainu-Japanese parallel corpus demonstrate that Dist-Gen with lexical information achieves statistically significant improvements over mBART in chrF and SBERT-cos for cross-domain Ainu-to-Japanese translation, and consistently generates more fluent output as measured by perplexity. These results confirm that exposing the LLM to the NMT model's token-level distributions reduces the impact of individual decoding errors while enabling fuller use of the LLM's generative capabilities.

Our analyses also reveal clear boundary conditions. When the NMT model is undertrained due to severe data scarcity, its flat probability distributions act as noise rather than useful signal, causing Dist-Gen to underperform GPT-5.2 alone. Furthermore, lexical resources must be domain-matched to be beneficial – a mismatch between the lexicon and the evaluation domain consistently degrades performance. For the Japanese-to-Ainu direction, all LLM-augmented methods struggle due to GPT-5.2's insufficient exposure to Ainu in pre-training, highlighting a fundamental limitation of applying LLMs to translation into critically low-resource languages.

Although Dist-Gen is designed to reduce the error propagation inherent in post-editing a single NMT hypothesis, some risk of error propagation still remains, due to the fact that the token-level probability distributions are collected in a single NMT inference pass, without any involvement of the LLM, and are fixed thereafter. Any deficiency in these distributions is thus carried over into the candidate pool from which the LLM constructs the translation. A natural way to relax this constraint – and to make fuller use of the LLM's generative capabilities and lexical information – would be to involve the LLM in the NMT decoding process itself, letting it guide token selection at each step. We regard this as a promising direction for future research. Other directions for future work include evaluation on additional language pairs and other LLMs (including open-weight models, which can also be fine-tuned for the translation task), a systematic evaluation of the candidate-filtering parameters introduced in Section 3.1, as well as combining Dist-Gen with more advanced lexicon-enhanced prompting protocols such as DiPMT (Ghazvininejad et al., 2023).

## Limitations

In this paper, we proposed a framework in which an LLM constructs translations by referring to token-level NMT probability distributions and external vocabulary information. However, experiments were conducted only for a single language pair, Ainu-Japanese, and we did not perform experiments applying it to other language pairs. Furthermore, we have not verified whether the proposed method remains effective when the NMT model and LLM are replaced with other models. In addition, the effectiveness of the proposed method is confined to specific conditions: it requires a well-trained NMT model and a domain-matched lexicon, and it improves translation only *into* the high-resource language (Ainu-to-Japanese). In the Japanese-to-Ainu direction, where the LLM must generate a language to which it has had at most marginal exposure in pre-training, the proposed method does not outperform the fine-tuned NMT model, and neither probability-distribution nor lexical information can compensate for this generation-side limitation. Moreover, the experiments do not fully isolate the contribution of the probability values themselves. An ablation that removes the numerical probability values from the prompt while keeping the candidate lists and their order (Appendix F) shows no detectable loss in the Ainu-to-Japanese direction, the only direction in which the proposed method improves over mBART, whereas it significantly lowers chrF in the Japanese-to-Ainu direction. The gains reported in this paper should therefore be attributed to exposing the LLM to the probability-derived candidate sets as a whole, rather than to the explicit confidence values. The ablation does not separate the effects of candidate selection and ranking. Finally, our evaluation relies on automatic metrics alone. Although the sentence encoder underlying SBERT-cos correlates well with human similarity judgments on standard Japanese benchmarks (Section 4.4.2), neither SBERT-cos nor perplexity has been validated against human judgments on the translations evaluated in this paper, and we did not conduct a human evaluation. We consider these to be the main limitations of this paper and topics for future research.

## A Software and data availability

The code and prompts used in the experiments are publicly available at https://github.com/nnna1224/dist-gen.

The parallel corpora and the Ainu word list used in our experiments (Section 4.1) are copyrighted third-party resources, and therefore we are not in a position to redistribute them.

## B Prompt details

An example of the system prompt used in Dist-Gen is shown in Prompt 3.

## C Prompt language comparison

As stated in Section 3.3, English is used as the prompt language in all experiments. This choice was informed by a preliminary experiment in which Dist-Gen with lexical information was run in the main experimental setting (Section 5.1) using prompts translated into Japanese, with all other conditions unchanged. Table 6 reports these results side by side with the corresponding English-prompt scores from Table 2. The Japanese-prompt variant performed slightly but consistently worse on all metrics: by 0.598 chrF and 0.010 SBERT-cos in the Ainu-to-Japanese direction, and by 0.242 chrF in the Japanese-to-Ainu direction. We therefore adopted English prompts throughout the experiments.

| Direction | Metric | English prompt | Japanese prompt |
|---|---|---|---|
| Ain → Jpn | chrF ↑ | **32.238** | 31.640 |
| | SBERT-cos ↑ | **0.760** | 0.750 |
| Jpn → Ain | chrF ↑ | **40.757** | 40.515 |

Table 6: Preliminary comparison of English and Japanese prompts for Dist-Gen with lexical information in the main experimental setting. Bold indicates the better value for each metric.

## D Training configuration

Table 7 summarizes the hyperparameters used for NMT fine-tuning.

For tokenization, we used the pretrained mBART50 tokenizer without retraining its SentencePiece model. We added `ain_XX` as an additional language ID special token for Ainu and resized the model's token embeddings accordingly. No Ainu-specific subword units were added to the tokenizer.

```
You are an expert linguistic editor
specializing in Ainu-to-Japanese
translation refinement.
Your task is to construct the most
natural Japanese sentence based on the
provided source text, glossary hints,
and NMT token predictions.

### CRITICAL PRIORITY HIERARCHY
Follow these priorities in strict order.
A lower priority must never compromise a
higher priority.

1. Naturalness & Fluency (Top Priority)
- The output MUST be a grammatically
natural and fluent Japanese sentence.
- If a glossary term or high-probability
token makes the sentence sound awkward,
unnatural, or grammatically incorrect,
YOU MUST DISCARD OR MODIFY IT.
- Context and flow are more important
than literal word matching.

2. Glossary Consistency (Secondary)
- Attempt to use the provided dictionary
meanings.
- However, if the dictionary meaning
conflicts with Priority 1 (Naturalness),
you are authorized to ignore the
dictionary.

3. Token Alignment (Tertiary)
- Use the NMT token list as a structural
hint or draft.
- Do not blindly follow high-probability
tokens if they result in unnatural
Japanese.

### Output Constraints
- Output ONLY the final Japanese
sentence.
- Do NOT provide any preamble,
explanation, notes, or reasoning.
- Do NOT include symbols like "_" or "</
s>".
```

Prompt 3: System prompt in Dist-Gen

| Hyperparameter | Value |
|---|---|
| Optimizer | Adafactor |
| Learning rate | $2 \times 10^{-5}$ |
| Learning rate scheduler | Linear decay |

## E Computational cost and token usage

### E.1 NMT Models

All local training and NMT inference experiments were conducted on a machine equipped with a single NVIDIA GeForce RTX 3090 GPU (24GB VRAM). The total computational budget expended for training our local models was approximately 159.4 GPU hours, which consists of the following components:

- **NMT configuration for the experiments described in Sections 5.1 and 5.3:** 6.282 days (approximately 150.8 hours) spent on fine-tuning.
- **NMT configuration for the experiments described in Section 5.2:** 8.589 hours spent on fine-tuning under the specified resource constraints.

In contrast to the training phase, the computational overhead required for local NMT inference during the evaluation phase was negligible, consuming only a few minutes to process the entire test dataset.

### E.2 Large Language Model (GPT-5.2)

All LLM calls used GPT-5.2 (`gpt-5.2-2025-12-11`) via the official API. Temperature was set to 0.0 to ensure reproducibility. Max output tokens was set to 100 to suppress wasted token consumption caused by repetition loops. All other parameters were left at their defaults.

Table 8 shows the average total number of tokens per sentence and the total number of tokens for each method and translation direction across all three experiments (n = 485 sentences per experiment).

## F Ablation: removing the numerical probability values

In Dist-Gen, the candidate list at each decoding position conveys information from the NMT distribution in two ways: (i) through which tokens are retained and in which order they are listed (Section 3.1), and (ii) through the numerical probability attached to each candidate (see Prompt 2). To isolate the contribution of the latter, we conducted an ablation in the main experimental setting (Section 5.1) in which the numerical values are removed from the prompt while everything else is held fixed: each candidate is presented as `token` instead of `token(prob: 0.xxx)`, and the source sentences, the candidate sets, their order, the system prompt, and the lexicon condition are identical to those of the corresponding Dist-Gen run. Note that this ablation does not remove all information derived from the NMT distributions: the selection and the ranking of the candidates are still determined by their probabilities. What is removed is thus the explicit magnitude of the probabilities and of the differences between them.

Table 9 reports chrF for both translation directions, and Table 10 reports SBERT-cos for the Ainu-to-Japanese direction. In both tables, differences are computed from the unrounded scores as the ablated condition minus the original Dist-Gen condition. Statistical significance is assessed with the same procedures as in Section 4.4.1 and Section 4.4.2: for chrF, the paired bootstrap resampling test of sacreBLEU (with 5,000 resampling iterations), reported as $p$-values; for SBERT-cos, a paired bootstrap of the mean difference (with 5,000 resamples), reported as 95% confidence intervals.

In the Ainu-to-Japanese direction, removing the numerical values has no detectable effect: chrF changes by $-0.009$ without and by $-0.367$ with lexical information, neither of which is significant, and both SBERT-cos confidence intervals include zero. The absence of a measurable difference is not due to the LLM ignoring the change in the prompt: only 34.6% (without lexicon) and 38.1% (with lexicon) of the ablated outputs are string-identical to the corresponding Dist-Gen outputs. The outputs

| Direction | Method | Main experiment (Section 5.1) | Ultra-low resource (Section 5.2) | In-domain (Section 5.3) | Overall |
|---|---|---|---|---|---|
| Ain → Jpn | Dist-Gen w/ lexicon | 820.36 (397873) | 1058.43 (513340) | 718.04 (348247) | 865.61 (1259460) |
| | Dist-Gen | 667.04 (323513) | 905.45 (439143) | 583.68 (283085) | 718.72 (1045741) |

| Direction | Post-editing | Post-editing w/ lexicon | Dist-Gen | Dist-Gen w/ lexicon |
|---|---|---|---|---|
| Ain → Jpn | 0.473 | 0.763 | 0.675 | 0.826 |
| Jpn → Ain | 0.673 | 0.660 | 0.608 | 0.716 |

Table 11: Levenshtein distances between mBART's translations and the outputs produced by methods informed by it, in ultra-low-resource setting.

| Direction | Post-editing | Post-editing w/ lexicon | Dist-Gen | Dist-Gen w/ lexicon |
|---|---|---|---|---|
| Ain → Jpn | 0.318 | 0.433 | 0.290 | 0.418 |
| Jpn → Ain | 0.335 | 0.298 | 0.181 | 0.367 |

Table 12: Levenshtein distances between mBART's translations and the outputs produced by methods informed by it, on data matching the NMT fine-tuning domain.

do change, but to translations of statistically indistinguishable quality under both metrics.

In the Japanese-to-Ainu direction, in contrast, removing the numerical values lowers chrF by about 4.7 points in both lexicon conditions, and only 9.9% (without lexicon) and 12.2% (with lexicon) of the outputs remain identical. The numerical values thus appear to keep the LLM's output closer to the NMT model's preferred tokens, which is beneficial in this direction, where every departure of the LLM-based systems from mBART's output tends to lower chrF (Table 2) because of the LLM's limited command of Ainu. Even with the numerical values, however, Dist-Gen (45.591) remains below mBART (50.180; Table 2), so the values mitigate a degradation rather than produce an improvement.

The ablation indicates that in the direction where Dist-Gen improves over mBART, the improvement cannot be attributed to the explicit confidence values. It is consistent with being carried by the probability-derived candidate sets and their ranking, by the lexical information, and by the generation (rather than post-editing) formulation of the task – the present ablation does not separate these factors, and an ablation that additionally removes the ranking (e.g., by shuffling the candidate order) is left for future work.

## G Levenshtein distance

We report Levenshtein distances between mBART translations and the outputs of post-editing and Dist-Gen for the ultra-low resource and in-domain settings.

Table 11 shows the results for the ultra-low resource setting, and Table 12 shows the results for the in-domain setting.

## H Qualitative analysis

This appendix complements the aggregate scores with four representative examples: two success

cases and two failure cases. The examples were identified by inspecting the outputs of all compared systems in all experimental settings and both translation directions.

For each example we report the source, the reference, and the outputs of all compared systems together with sentence-level chrF (computed with sacreBLEU 2.6.0, as in Section 4.4.1), the lexicon entries retrieved for the source sentence where relevant, and the part of the NMT token-level probability distributions most relevant to the phenomenon in question (probabilities rounded to three decimal places; "_" marks the SentencePiece word-boundary marker, as in Prompt 2). Two caveats apply throughout. First, chrF is a surface string-similarity metric and does not by itself establish semantic or grammatical correctness, so we discuss the correctness of content words separately from the scores. Second, each case is a single example: we restrict ourselves to differences that are directly observable in the outputs and refrain from causal claims about how the models internally used particular signals.

### H.1 Example (a): avoiding a mistranslation fixed in the 1-best hypothesis

Table 13 shows an Ainu-to-Japanese example from the main experiment (Section 5.1). The source contains the personal name *Cikiriaskay*. mBART renders it by its literal meaning as 「足が達者だ」 (roughly "being good on one's feet"), and both post-editing variants retain this reading, which is fixed in the single NMT hypothesis they receive. Dist-Gen with lexical information instead produces the transliteration チキリアスカイ (one syllable away from the reference チキリアシカイ) and obtains the highest sentence-level chrF among all systems. The initial character of the transliteration, チ, occurs in the NMT distribution only as the third-ranked candidate at position 2 (probability 0.027), far below the literal reading 足 (0.493). The candidate that initiates the transliteration is thus visible to Dist-Gen through the retained NMT candidate list, but not to post-editing, which receives only the 1-best hypothesis.

Two observations bound what this example can show. First, both GPT-5.2 variants, which see the source (where the name appears in Latin script) but no NMT information, produce the same transliteration; the example therefore demonstrates an output-level difference between constructing a translation from the distribution and correcting the 1-best hypothesis, but cannot by itself establish that Dist-Gen causally exploited the lower-ranked candidate. Second, the retrieved lexicon entries contain no translation of the name itself, yet Dist-Gen *without* lexical information retains the literal reading; in this instance, the departure from the 1-best hypothesis thus occurred only under the lexicon-informed prompt.

### H.2 Example (b): content-word correction supported by lexical information

Table 14 shows an Ainu-to-Japanese example from the main experiment. mBART renders the bird name *eyami* (カケス, 'Eurasian jay') as 刺繍 ('embroidery'), and the NMT distribution supports this error with high confidence (刺 0.472 at position 7, 繍 0.942 at position 8), while the first character of the correct word, カ, is only the second-ranked candidate (0.181). The retrieved lexicon, however, contains the entry *eyami* → カケス. All three lexicon-informed systems produce the identical, correct output この鳥はカケスだ。, whereas none of the corresponding no-lexicon variants recovers the bird name: GPT-5.2 transliterates the source word (エヤミ), and both post-editing and Dist-Gen follow the NMT reading 刺繍.

This illustrates the value of accurate, domain-matched lexical information for content words. Note that the effect is shared by all three lexicon-informed methods, so it is not a Dist-Gen-specific advantage.

### H.3 Example (c): failure under highly uncertain NMT distributions

Table 15 shows a Japanese-to-Ainu example from the ultra-low-resource setting (Section 5.2). Here the NMT distributions are extremely flat: the top-1 probability is below 0.5 at 11 of the 15 decoding positions, with a mean of 0.384 across positions. Moreover, the reference content words *yupo* ('elder brother') and *hemanta* ('what') never appear among the retained candidates, and *kusu* surfaces only through the lower-ranked subword candidate `_kus` (positions 8, 9, and 11). Dist-Gen with lexical information assembles its output from the lexicon hints (*te*, *ari*) and from candidates recurring across positions (*a=*, *kor*, *an*, *pe*, *ne*, *na*); the reference words *yupo* and *hemanta* and the sequence *e= a wa e= an* are all absent from its output, whose sentence-level chrF (10.99) falls below both GPT-5.2 variants and both post-editing variants.

For the same source sentence in the main setting,

| | Output | chrF |
|---|---|---|
| Source | Cikiriaskay sekor ku= rehe an . | — |
| Reference | チキリアシカイ と 言い ます 。 | — |
| mBART | 足 が 達者 だ と 私 の 名前 です 。 | 5.24 |
| GPT-5.2 | 「チキリアスカイ」と私は名乗っている。 | 19.84 |
| GPT-5.2 w/ lexicon | 「チキリアスカイ」と私の名前がある。 | 18.95 |
| Post-editing | 足が達者だというのが私の名前です。 | 6.13 |
| Post-editing w/ lexicon | 「足が達者だ」と私の名前がある。 | 2.45 |
| Dist-Gen | 「足が達者だ」と私の名前です。 | 5.08 |
| Dist-Gen w/ lexicon | 「チキリアスカイ」と言うのが私の名前です。 | **22.86** |
| Lexicon | sekor → 〜と; ku= → 私; rehe → 〜の名前; an → いる、ある | — |

```
position 2: 足 0.493, 千 0.259, チ 0.027, ま 0.026, 道 0.024
position 6: 達 0.487, 利 0.050, 悪い 0.036, よ 0.036, き 0.034
```

Table 13: Example (a): a proper name in the source (main setting, Ainu-to-Japanese; abbreviations as in Table 2). chrF is sentence-level chrF against the reference. The box shows the retained NMT candidates at the two positions corresponding to the literal reading 足…達者; the transliteration-initial チ is the third-ranked candidate at position 2.

| | Output | chrF |
|---|---|---|
| Source | tan cikap eyami ne . | — |
| Reference | この 鳥 は カケス で ある 。 | — |
| mBART | この 鳥 は 刺繍 し て ある 。 | 26.58 |
| GPT-5.2 | この鳥はエヤミというものだ。 | 17.31 |
| GPT-5.2 w/ lexicon | この鳥はカケスだ。 | **55.02** |
| Post-editing | この鳥は刺繍してある。 | 26.58 |
| Post-editing w/ lexicon | この鳥はカケスだ。 | **55.02** |

| Dist-Gen w/ lexicon | この鳥はカケスだ。 | **55.02** |
| Lexicon | tan → この; cikap → 鳥; eyami → カケス; ne → 〜だ | — |

```
position 7: 刺 0.472, カ 0.181, 玉 0.043, 山 0.020, 杭 0.017
position 8: 繍 0.942
```

Table 14: Example (b): the domain content word *eyami* (main setting, Ainu-to-Japanese; abbreviations as in Table 2). chrF is sentence-level chrF against the reference. The box shows the retained NMT candidates at the positions where mBART generates 刺繍 (‘embroidery’).

where the mean top-1 probability is 0.737, Dist-Gen with lexical information produces *Ku=yupo! Makanak wa te ta arok wa an?* (chrF 28.95). This contrast is consistent with the entropy-based explanation in Section 5.2: flat, low-quality distributions act as noise rather than signal.

### H.4 Example (d): loss of a correct content word in generation into Ainu

Table 16 shows a Japanese-to-Ainu example from the main experiment. The reference contains the content word *wentarap* (‘to dream’), mBART’s output preserves it, and the NMT distributions contain the corresponding subword sequence with high confidence (`_went` ranked first at position 2 with probability 0.285, followed by the near-deterministic continuations `a` 0.973 and `rap` 1.000). The correct content word was therefore available to the LLM-based systems both in the 1-best hypothesis (for post-editing) and in the probability distributions (for Dist-Gen). Nevertheless, none of the six LLM-based outputs preserves the contiguous string *wentarap*: five render the source word 夢 as (a fragment of) the romanized Japanese *yume*, and Dist-Gen without lexical information deforms the sequence into *Wen a=rap*. Accordingly, mBART obtains the highest sentence-level chrF (62.47).

This example shows that supplying correct NMT evidence does not guarantee its preservation when the LLM must generate into the low-resource language (this generation-side limitation was also discussed in Section 5.1 and in the Limitations section).

## Abstract

Machine Translation (MT) for low-resource languages has been challenging so far, mainly due to the small size or lack of parallel sentences. Parallel sentence mining and filtering are two automatic approaches which aim to identify and curate such resources. Yet, they usually rely on multilingual representation as a backend, which is known to be of poorer quality for low-resource language pairs, leading to the introduction of noisy pairs. We devise SNAPP, a post-processing pipeline which combines a segment-level filtering technique with an unsupervised neural aligner to remove highly similar but non-parallel sentence pairs. Modular components further enable more specific adaptation to the language pair under consideration. We evaluate filtering performance on three language pairs of varying typological distance. Finally, we show improvement on the downstream MT performance with our post-processing pipeline for the two harder language pairs.

## 1 Introduction

While Neural Machine Translation (NMT) achieves impressive performance in high-resource settings (Vaswani et al., 2017), its effectiveness drops significantly when applied to languages with limited parallel data (Kvapilíková and Bojar, 2023, *inter alia*). As the main bottleneck comes from the scarcity of data for such languages, a notable approach is to build such training corpora automatically from existing data. Parallel sentence mining, hence, aims to extract pairs of translated sentences from two monolingual corpora of comparable domains but not sentence-aligned (Zweigenbaum et al., 2017). However, embedding-based extraction approaches are prone to erroneously pairing sentences that exhibit high lexical similarity but diverge in meaning (Hangya and Fraser, 2019).

In this article, we hence introduce SNAPP (Segment-level Neural Alignment Post-Processing), a post-processing pipeline designed to improve the quality of mined parallel corpora in low-resource settings. Our approach combines the segment-level filtering approach of Hangya and Fraser (2019) with the neural alignments from SimAlign (Jalili Sabet et al., 2020). We extend it with additional noise-reduction techniques, including vector space correction, stop-word filtering, and punctuation handling. We evaluate the effectiveness of our approach by applying the filtering pipeline to the BELOPSEM dataset (Okabe et al., 2025b), which features three low-resource language pairs with varying degrees of typological distance: Occitan–Spanish (OCI–ES), Chuvash–Russian (CHV–RU), and Upper Sorbian–German (HSB–DE). Our filtering pipeline yields performance improvements across all evaluated pairs, systematically increasing retrieval scores over the baseline mining pipeline.

Furthermore, we investigate the impact of the resulting corpus quality on downstream MT performance for the HSB–DE and CHV–RU language pairs. We compare the NLLB model (NLLB Team et al., 2024) across four distinct training configurations: a zero-shot baseline, alongside three fine-tuned variants based on mined and filtered translation pairs. We observe improvement thanks to our approach, as more parallel pairs are found.

Our main contributions are as follows: (1) We propose a post-processing pipeline for parallel sentence filtering that integrates an unsupervised neural aligner into a segment-level filtering approach, with modular components for language-specific adaptation. (2) We empirically demonstrate the robustness and effectiveness of our pipeline across three low-resource language pairs of varying typological distances. (3) We show that the improved parallel corpus quality directly leads to enhanced downstream NMT performance.

We publicly release the SNAPP pipeline.[1]

## 2 Related Work

### 2.1 Parallel sentence mining and filtering

**Mining** Given the scarcity of parallel training data for NMT models in low-resource scenarios, parallel sentence mining aims to identify translation pairs in comparable monolingual texts, where sentences are not aligned. The BUCC 2017 Shared Task (Zweigenbaum et al., 2017) established a benchmark and evaluation protocol for the task, focusing on four high-resource language pairs. Later approaches improved mining quality with sentence-level embeddings to identify such translation pairs (i.a., Artetxe and Schwenk, 2019).

**Filtering** Mined corpora are known to contain non-translation pairs, which affect the quality of the downstream MT performance. Parallel sentence filtering aims to remove such noise to compile a high-quality parallel training data. The WMT 2018 and 2019 Shared Tasks (Koehn et al., 2018, 2019) focused on cleaning the provided noisy parallel corpora and evaluated their success based on the performance of the trained MT systems. While Koehn et al. (2018) provided noisy data for the high-resource English–German language pair, Koehn et al. (2019) introduced a low-resource scenario to increase the task's complexity, where direct filtering via multilingual sentence embeddings proved highly effective (Chaudhary et al., 2019).

Building upon these efforts, Sloto et al. (2023) focused on the entire data curation process by providing participants with unaligned monolingual corpora before any sentence mining. In these sentence extraction pipelines, cross-lingual sentence embeddings have proven highly advantageous for initial candidate retrieval in low-resource scenarios (Chaudhary et al., 2019; Koehn et al., 2019). However, such embedding-based approaches are prone to erroneously pairing sentences that exhibit high lexical similarity but diverge in meaning (Hangya and Fraser, 2019). Therefore, recent Shared Task findings advocate for the subsequent application of robust alignment and data filtering steps (Sloto et al., 2023), for instance, through a combination of fine-grained sentence alignment and multi-stage filtering heuristics (Steingrimsson, 2023).

Another approach to remove noisy pairs from parallel corpora is to rely on classification tools, such as Bicleaner (Zaragoza-Bernabeu et al., 2022) or the approach of Jiang et al. (2026). They need, however, to be trained on parallel corpora. We do not consider classification systems, as such translation pairs are scarce.

### 2.2 Mining for low-resource languages

Multilingual embedding-based methods have also been successfully applied to mine parallel data to noticeably improve low-resource Machine Translation (Kvapilíková and Bojar, 2023). Yet, previous work mostly relied on fine-tuning or distilling existing multilingual models with parallel data (Heffernan et al., 2022; Tan et al., 2023), while such resources are limited for low-resource language pairs. The PaSeMiLL mining pipeline (Okabe and Fraser, 2025) provides a standardized setting to evaluate such embedding-based extraction methods in low-resource settings. The pipeline computes sentence embeddings by mean-pooling token embeddings extracted from a pre-trained language model. To identify semantically related sentence pairs, it evaluates candidate similarities using the Cross-Domain Similarity Local Scaling (CSLS) metric (Lample et al., 2018), which mitigates the hubness problem in vector spaces. Subsequently, candidate pairs are filtered out if their similarity score falls below a threshold computed dynamically (Okabe and Fraser, 2025). Additionally, the implementation allows for the application of Cluster-based Isotropy Enhancement (CBIE) (Rajaee and Pilehvar, 2021), which locally corrects embedding biases to improve overall vector-space isotropy before the extraction.

## 3 Background

### 3.1 UnsupPSE: Segment-level filtering

To filter out sentence pairs with high lexical overlap but diverging meaning, Hangya and Fraser (2019) propose 'UnsupPSE', an algorithmic segment-level filtering approach. Operating strictly on the word level, the method greedily aligns each source word $s_i$ to its most similar target word $t_j$ using static embeddings evaluated via the CSLS metric and orthographic similarity. Unaligned tokens receive a similarity value of zero. To accommodate a small amount of unaligned words, similarity scores are smoothed using a window-based local average. A token sequence forms a contiguous segment if all averaged scores exceed a predefined threshold. Figure 2 in Appendix A shows the window-based

[1] https://github.com/TUM-NLP/SNAPP

averaging of a HSB–DE candidate pair.

Each segment is matched at most once to the counterpart sharing the highest number of word alignments. To reduce noise, candidate segment pairs are discarded if they fail to meet constraints on minimum length or maximum length difference (default: 5 words).

Finally, the overall similarity of the candidate pair is evaluated using a combined metric that weights the sum of all alignment similarities by the length of the longest segment, normalized by the respective lengths of the source and target sentences. The candidate pair is retained if this final score exceeds a tunable threshold.

### 3.2 SimAlign: Neural word alignment

Statistical alignment methods, such as fast_align (Dyer et al., 2013), require large amounts of parallel data for reliable bilingual alignments, which makes them ill-suited to low-resource scenarios. This motivates the use of unsupervised neural aligners, which rely primarily on semantic similarity rather than co-occurrence. A state-of-the-art neural alignment tool is SimAlign (Jalili Sabet et al., 2020), which leverages pre-trained multilingual word embeddings to determine the semantic similarity between source and target tokens. This neural unsupervised approach is particularly beneficial in low-resource scenarios, as it allows for zero-shot use without requiring parallel training data. By relying on cross-lingual transfer, it can establish reliable mappings provided that the underlying multilingual language model offers meaningful semantic representations for the specific low-resource language. SimAlign provides three distinct alignment heuristics (Argmax, Itermax, and Match), which offer different trade-offs between alignment precision and recall. We detail the methods in Appendix B.

## 4 Filtering pipeline

Our SNAPP filtering pipeline essentially combines the UnsupPSE approach (Hangya and Fraser, 2019) with the neural alignment tool SimAlign (Jalili Sabet et al., 2020). Figure 1 provides a summarized overview of the pipeline.

### 4.1 Pre-processing

**Tokenization and embedding** The filtering pipeline receives a candidate sentence pair in the source and target languages. Using a multilingual pretrained language model (mPLM) and its tokenizer, the pipeline tokenizes both sentences and extracts their contextualized embeddings. Furthermore, as in the UnsupPSE approach, subword tokens are aggregated to the word level (based on whitespace and punctuation boundaries) by averaging their respective embeddings. An example of this token aggregation is provided in Appendix C.

**Mean vector subtraction** To mitigate the 'Cone Effect' (Ethayarajh, 2019), the resulting vectors are then centered by subtracting the language-specific mean vector. This mean vector is computed before the pipeline's execution by averaging the embeddings of all tokens from the initial monolingual corpus of the respective language. We consider two computation methods: either from a fixed monolingual corpus only ('static') or from the dataset to process ('dynamic') for better adaptability.

### 4.2 Word alignment and token similarity

**Word alignment** After the pre-processing step, we apply the neural alignment tool SimAlign (Jalili Sabet et al., 2020) to words. Following Jalili Sabet et al. (2020), we extract contextualized representations from the 8th layer of the language model across the entire pipeline, including for SimAlign. Among its three alignment heuristics, we mainly use the Argmax strategy due to its stricter alignment criterion (cf. Appendix B). It notably leads to high precision with minimal false positives that could negatively affect later scoring. These word alignments are later used to compute cosine similarity scores instead of CSLS. Because our pipeline processes candidate pairs sequentially, computing the neighborhood-based CSLS score for contextualized word representations across the entire vocabulary would be computationally prohibitive. Instead, pairing standard cosine similarity with mean-vector subtraction provides an efficient and effective alternative to counteract vector space anisotropy. We rely on the aggregated word-level embeddings to assess the semantic similarity of the aligned pairs.

**Stop-word filtering** To further reduce noise, the filtering pipeline can additionally ignore *unaligned* stop-words given their limited semantic value. Due to typological differences in a language pair, such words can be less frequent or absent in one of the two languages (e.g., articles in Slavic languages). Since they can break segment-level alignments on one or both sides of a pair, we allow this step to be applied independently to the source ('src') or the target ('trg'). This post-processing module relies

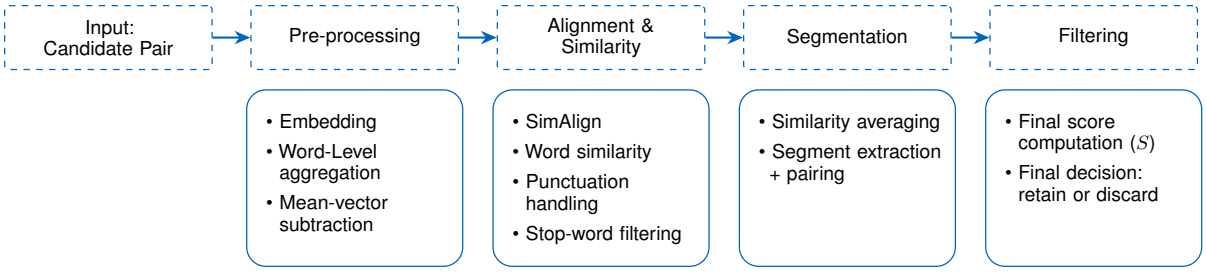

Figure 1: Simplified visualization of the proposed filtering approach: SNAPP.

on a list of stop-words. Appendix D describes how we collected the stop-words for three of the languages which did not have available lists.

### 4.3 Parallel segment extraction

Following the segment-level approach of Hangya and Fraser (2019), the cosine similarity scores are averaged using a window-based method, to bridge small semantic gaps between token alignments (cf. Figure 2). Crucially, this smoothing compensates for certain missed alignments (i.e., false negatives) from the previous step. However, it is simultaneously highly sensitive to false-positive alignments, which would artificially inflate adjacent scores during the averaging process. Thus, this windowing technique complements the conservative Argmax alignment strategy well. Tokens with an averaged similarity score exceeding a tunable threshold are aggregated into contiguous segments. The target segments are then mapped to their respective source segments via a greedy assignment strategy based on the number of shared alignments. We enforce a 0.25 upper bound on the relative length difference between paired segments. This step aims to identify truly parallel segments while simultaneously mitigating additional noise by penalizing unaligned or non-parallel text spans.

### 4.4 Filtering

Finally, we compute a filtering score $S$ according to Equation (1) to determine whether a candidate pair should be retained. This formula formalizes the segment-weighted scoring metric as implemented in Hangya and Fraser (2019):

$$S(s,t) = \frac{\sum_{(s_i,t_j)\in A} sim(s_i,t_j)}{|t|} \cdot \frac{|seg_{max}|}{|s|}, \quad (1)$$

where $A$ represents the set of all aligned word pairs $(s_i, t_j)$ obtained via SimAlign (Jalili Sabet et al., 2020), $sim(s_i, t_j)$ denotes their cosine similarity score, $seg_{max}$ corresponds to the longest extracted segment in the source sentence $s$, and $|s|$ and $|t|$ represent the respective lengths of the source and target sentences after any applied stop-word removal.

Although the formula remains identical to that of Hangya and Fraser (2019), the underlying components are derived through distinct methodologies. Specifically, we substitute the static dictionary-based word alignments with SimAlign, replace the CSLS score with the cosine similarity, and we additionally remove stop-words, notably altering the algorithm's behavior. If the score $S$ exceeds a tunable threshold $\alpha$, the candidate sentence pair is retained, otherwise it is discarded.

## 5 Sentence filtering experiments

### 5.1 Sentence mining setup

#### 5.1.1 Datasets and languages

We evaluate the efficacy of our SNAPP filtering approach and focus on the language pairs in BELOPSEM,[2] a mining benchmark for low-resource languages (Okabe et al., 2025b). It features three language pairs of varying language proximity (and hence difficulty): Occitan–Spanish, Upper Sorbian–German, and Chuvash–Russian. Here, each low-resource source language is paired with a high-resource target language.

The design of the corpus follows the established BUCC Shared Task method (Zweigenbaum et al., 2017): true translation pairs have been randomly injected in two comparable but non-parallel monolingual corpora. The aim is hence to retrieve only the parallel sentences with minimal noise.

Table 1 details the sentence counts for each dataset of a language pair in BELOPSEM. The training set is a small set to set the filtering threshold, while the test set is larger to replicate an actual mining scenario.

[2] https://github.com/shuokabe/Belopsem

| Language | Train | | | Test | | |
|---|---|---|---|---|---|---|
| pairs | source | target | parallel | source | target | parallel |
| OCI–ES | 7,899 | 7,780 | 486 | 23,675 | 23,334 | 1,457 |
| CHV–RU | 7,998 | 7,994 | 499 | 23,995 | 23,985 | 1,498 |
| HSB–DE | 15,980 | 15,999 | 1,000 | 47,847 | 47,999 | 3,000 |

Table 1: Number of sentences in the BELOPSEM dataset.

#### 5.1.2 Baseline mining systems

To establish a robust baseline for evaluating our approach, we employ the PaSeMiLL mining pipeline. We consider two settings where Glot500-m (Imani et al., 2023) serves as the model backend, following (Okabe et al., 2025b). This mPLM extends XLM-R (Conneau et al., 2020) specifically to low-resource languages. It notably covers the three low-resource languages of the mining benchmark.

First, we consider its setting with the improved cross-lingual representation (with Cluster-Based Isotropy Enhancement, or CBIE) and denote it as the 'baseline'. We also report the performance with the pipeline's native post-processing approach as 'baseline+PP', where sentences are ranked according to the ratio of aligned words in a sentence pair. This setting also uses a lower similarity threshold to start from a larger pool of sentence pairs (and thus a higher recall value).

#### 5.1.3 Mining evaluation

We assess the quality of the final mined and filtered corpora using the standard precision ('P'), recall ('R'), and F1-score ('F') metrics with the provided gold sentence pairs. We also report the number of sentence pairs ('#Pairs') after mining or filtering.

### 5.2 Post-processing: Main results

**Overall performance** Table 2 illustrates the performance gains achieved by our post-processing approach in its optimal configuration for each language pair. Compared to both the standard baseline and its native post-processing setting, our filtering pipeline consistently increases the F1-score across all three language pairs. Applying this post-processing step allows the PaSeMiLL mining pipeline to operate with a low filtering threshold (here: $-1.0$) in order to maximize initial recall. Although this approach successfully increases recall, it inherently leads to a substantial rise in false positives. While our filtering pipeline yields precision for OCI–ES that is comparable to the base PaSeMiLL mining pipeline, it demonstrates a notable improvement in precision for CHV–RU and HSB–DE. Consequently, the combination of higher recall and a comparable or improved precision yields more accurate overall results than the baseline PaSeMiLL mining pipeline. The hyperparameters used to obtain the results are presented in Appendix E.

| Method | P | R | F | Δ F | #Pairs |
|---|---|---|---|---|---|
| **Occitan–Spanish (OCI–ES)** | | | | | |
| baseline | 90.50 | 77.14 | 83.29 | Ref. | - |
| baseline+PP | 90.38 | 79.27 | 84.46 | +1.17 | - |

| **SNAPP (best)** | 55.83 | **44.73** | **49.67** | **+8.16** | **1,200** |
| **Upper Sorbian–German (HSB–DE)** | | | | | |
| baseline | 60.74 | 33.47 | 43.15 | Ref. | - |
| baseline+PP | 61.03 | 43.53 | 50.82 | +7.67 | - |
| PaSeMiLL (thr. = -1.0) | 3.48 | 55.50 | 6.55 | - | 47,847 |
| SNAPP (fast_align) | **89.73** | 30.00 | 44.97 | +1.82 | 1,003 |
| **SNAPP (best)** | 80.26 | **49.73** | **61.41** | **+18.26** | **1,859** |

Table 2: Post-processing performance with Precision (P), Recall (R), and F1-score (F) across the three language pairs. 'Δ F' presents the F1-score gain against the baseline. Baseline results are referenced from Okabe et al. (2025b) with the CBIE configuration.

Regarding computational cost, our pipeline processes approximately 5,000 candidate pairs per hour on a single NVIDIA A100 GPU (80GB VRAM).

**Neural vs. statistical alignment** Furthermore, Table 2 compares the performance of our filtering approach when using neural versus statistical alignments. Specifically, we evaluate the neural aligner SimAlign (Jalili Sabet et al., 2020) against a baseline employing the fast_align statistical tool (Dyer et al., 2013). Both pipeline variants were executed using identical hyperparameter configurations. Fast_align requires the entire corpus to generate alignments, whereas our pipeline processes candidate pairs sequentially. To accommodate this, we pre-computed and filtered the statistical alignments for the PaSeMiLL candidate pairs and accessed them dynamically during our post-processing phase. While statistical tools rely on large parallel corpora and often struggle under low-resource or noisy conditions, neural aligners leverage pre-trained language models to operate effec-

tively in zero-shot scenarios. Consequently, SimAlign yields a substantial performance improvement over fast_align as shown in Table 2. Appendix F further details the underlying causes of imprecise alignments produced by fast_align in our scenario and discusses various settings for filtering noise before running the pipeline.

### 5.3 Ablation studies

Our pipeline allows for the activation and configuration of various components to adapt filtering to the characteristics of the language pair. This section evaluates the impact of these diverse configurations on the overall filtering performance across the BELOPSEM language pairs. As the punctuation handling configuration did not yield notable performance improvements, a detailed analysis of this component is deferred to Appendix G.

We evaluate three components of our pipeline: (1) The mean-vector subtraction component ('mean vect.') applied to embeddings in three configurations: no subtraction ('w/o'), static mean vector ('s'; using the training set), or dynamic mean vector ('d'; using the training or test set). (2) The stop-word filtering component ('SW'), which can be applied to the source ('src') or target ('trg') languages. (3) The SimAlign alignment method, where words can be aligned according to the three heuristics: Argmax ('A'), Itermax ('I'), or Match ('M'). Tables 3, 4, 5, and 10 evaluate the impact of individual components by varying one factor at a time while keeping all other parameters fixed at the optimal configuration for the respective language pair.

We stress here that the optimal configurations were strictly selected based on their performance on their respective *training* sets. The tables report the results of these selected configurations evaluated on the unseen test sets, with the chosen optimal configuration for each language pair highlighted in gray. Notably, punctuation handling was enabled exclusively for OCI–ES and remained disabled for both CHV–RU and HSB–DE. We perform our ablation study starting from the optimal setting (which depends on the language pair), varying one factor at a time.

#### 5.3.1 Mean vector subtraction

Table 3 displays the effect of mean vector subtraction on the word embeddings during the word-level aggregation stage, as described in Section 4.1. We observe that applying this module significantly improves performance by helping cross-lingual alignment. Without mean vector subtraction, the post-processing stage retains most of the false positives extracted by the initial PaSeMiLL mining pipeline. The severe drop in precision (compared to the best-performing configuration) and the high recall indicate the negative effect of anisotropy in the raw vectors provided by Glot500-m. Without centering the vector space, the embeddings tend to point in a similar direction, leading to high cosine similarity scores even for wrongly aligned tokens (Ethayarajh, 2019). Thus, the subsequent window-based averaging yields inflated final filtering scores and allows numerous false positives to remain after the final filtering step. By subtracting the mean vector for each language, the respective embedding spaces are shifted towards the origin, effectively mitigating this directional imbalance.

| Lang Pair | mean vect. | SW src | SW trg | Sim-Align | P | R | F | # Pairs |
|---|---|---|---|---|---|---|---|---|
| OCI–ES | w/o | No | No | A | 34.53 | **84.56** | 49.03 | 3,568 |
| | s | No | No | A | 89.55 | 81.74 | 85.47 | 1,330 |
| | d | No | No | A | **89.62** | 81.74 | **85.50** | 1,329 |
| CHV–RU | w/o | Yes | Yes | I | 8.15 | **51.74** | 14.07 | 9,515 |
| | s | Yes | Yes | I | 54.65 | 44.73 | 49.19 | 1,226 |
| | d | Yes | Yes | I | **55.83** | 44.73 | **49.67** | 1,200 |
| HSB–DE | w/o | No | Yes | A | 10.10 | **54.40** | 17.03 | 16,162 |
| | s | No | Yes | A | **80.26** | 49.73 | **61.41** | 1,859 |
| | d | No | Yes | A | 80.25 | 49.70 | 61.38 | 1,858 |

Table 3: Ablation study: Mean vector configuration. We keep the other settings fixed compared to the best setting (notably Itermax for CHV–RU).

Regarding the computation method, we observed little difference between both static and dynamic mean vectors; hence, applying this step is crucial, regardless of the method. Ultimately, this subtraction enables a more robust distinction between true translations and noise, thereby yielding higher-quality filtering during post-processing.

#### 5.3.2 Alignment methods

Table 4 displays the effect of the three alignment methods in SimAlign. We observe that Argmax yields the best overall performance for the OCI–ES and HSB–DE datasets. This method benefits from a conservative selection strategy that retains only mutually maximal alignments, thereby increasing the probability of correctness. The subsequent window-based averaging effectively compensates for the omitted alignments, resulting in high precision while maintaining a high recall.

| Lang Pair | mean vect. | SW src | SW trg | Sim-Align | P | R | F | # Pairs |
|---|---|---|---|---|---|---|---|---|
| | d | No | No | A | **89.62** | 81.74 | **85.50** | 1,329 |
| OCI–ES | d | No | No | I | 85.57 | 83.05 | 84.29 | 1,414 |
| | d | No | No | M | 83.92 | **83.12** | 83.52 | 1,443 |
| | d | Yes | Yes | A | **60.26** | 39.79 | 47.93 | 989 |

Table 4: Ablation study: SimAlign alignment method.

In contrast, we note a performance drop for Argmax on the CHV–RU dataset compared to Itermax and Match. Belonging to distinct language families (Turkic and Slavic, respectively), the CHV–RU pair exhibits the largest typological distance among the evaluated datasets, with fewer direct one-to-one word correspondences. Consequently, the strict alignment criteria of Argmax produce too few alignments compared to Itermax and Match. This severe sparsity cannot be fully mitigated by the window-based averaging, causing true positives to fall below the filtering threshold.

Since Itermax and Match inherently lead to a greater number of alignment links, they prove advantageous for this language pair with a more substantial typological distance. While both algorithms inevitably introduce more false alignments (lowering precision), the substantial gain in recovered true positives (higher recall) effectively offsets this drawback, yielding a higher overall F1-score.

#### 5.3.3 Stop-word filtering

We investigate the impact of filtering unaligned stop-words in Table 5. In general, stop-word filtering bridges minor semantic gaps, yielding larger contiguous segments and a subsequent increase in overall recall (e.g., by up to 12.90 percentage points for HSB–DE). Simultaneously, however, the volume of noise within the remaining pairs increases, which leads to a decline in precision (dropping by 12.87 percentage points for HSB–DE). It emerges that the impact of stop-word filtering depends on the linguistic distance between the source and target languages. While the pipeline does not benefit from this filtering for OCI–ES, it contributes to the performance for CHV–RU and substantially for HSB–DE. The latter two language pairs exhibit a larger linguistic distance compared to the closely related OCI–ES.

## 6 Downstream evaluation: MT

### 6.1 Methodology

To evaluate the impact of the proposed filtering on the quality of the training corpus for MT systems, we compare the performance of NLLB (facebook/nllb-200-distilled-600M) (NLLB Team et al., 2024) in different settings for the two harder language pairs: HSB–DE and CHV–RU.

#### 6.1.1 Datasets

**Training** To replicate an actual parallel data curation scenario, we rely on the correspondence between Wikipedia articles, in which some sentences are naturally parallel. We use the Wikipedia dataset provided by Wikimedia[3] as our initial set of 'comparable' monolingual corpora. We only consider articles whose titles match; the resulting datasets mainly contain named entities (mostly place and person names). Moreover, since articles are usually longer on the (target) high-resource side than the (source) low-resource language, we cap their length to 1.5 times the number of sentences of the low-resource source side.

**Evaluation** We evaluated the performance of the NLLB model for HSB–DE on the development set of the WMT 2025 Shared Task on LLMs with Limited Resources for Slavic Languages (Okabe et al., 2025a).[4] For CHV–RU, we use the established FLORES+ MT benchmark (NLLB Team et al., 2024) which extends the previous version from Guzmán et al. (2019) and Goyal et al. (2022).

| | HSB–DE | | | CHV–RU | | |
|---|---|---|---|---|---|---|
| | HSB | DE | source | CHV | RU | source |
| train | 34,445 | 42,668 | Wikipedia | 111,156 | 139,327 | Wikipedia |
| test | 4,000 | | WMT | 1,012 | | FLORES+ |

Table 6: Number of sentences in the monolingual training set before mining and in the MT test set.

Table 6 summarizes the dataset sizes before the mining step (i.e., after the title matching and truncation of the target side) and the evaluation set.

#### 6.1.2 MT methodology

We mine and filter the datasets from Section 6.1.1 and then fine-tune the NLLB model (NLLB Team et al., 2024) under four configurations.

**Baseline** We consider NLLB in a zero-shot setting as a baseline. While German and Russian were included in the pre-training corpus of the model, Upper Sorbian and Chuvash were not (NLLB Team et al., 2024). Consequently, zero-shot evaluation is only applicable in the low-resource to high-resource translation direction. For this setting, we feed the input text into NLLB using its closest supported language proxy as the source language code: Czech (`ces_Latn`) for Upper Sorbian and Kazakh (`kaz_Cyrl`) for Chuvash.

**Fine-tuning configurations** Beyond the zero-shot setting, we consider three fine-tuning configurations. First, we use the corpus mined with the base PaSeMiLL pipeline ('baseline' in Table 2) configured with the optimal dynamic filtering threshold for each language pair ($\lambda = 1.5$ for HSB–DE and $\lambda = 1.8$ for CHV–RU). We denote this setting 'FT-mined'. Both subsequent configurations are based on the candidate pairs, retrieved by the PaSeMiLL mining pipeline with a static filtering threshold of $\lambda = -1.0$ to maximize initial recall. We then apply our post-processing pipeline configured with the best-performing hyperparameters (Table 8). In the third configuration, we assess our best post-processing pipeline to curate sentence pairs ('FT-sentences'). Finally, we also extract the longest contiguous segment pairs ('FT-segments') for each candidate pair. This setting aims to keep parallel *segments* from non-parallel (but similar) sentence pairs, including those below the final filtering threshold.

**MT training** Following the established paradigm of rapid adaptation for low-resource languages (Neubig and Hu, 2018), we fine-tune the `facebook/nllb-200-distilled-600M` architecture across the three evaluated settings. For this, we follow Ahmadi et al. (2025) and expanded the tokenizer by introducing '`hsb_Latn`' and '`chv_Cyrl`' as new language tokens. We initialized their embeddings with the pre-trained weights from closely related, better-resourced anchor languages. Specifically, we use Czech ('`ces_Latn`') for Upper Sorbian, and Kazakh ('`kaz_Cyrl`') for Chuvash, as both belong to the same language family and share the same script.

All configurations were fine-tuned for 3 epochs using the AdamW optimizer with an initial learning rate of $2 \times 10^{-5}$, a weight decay of 0.01, a per-device batch size of 8, and a maximum sequence length of 128 tokens.

#### 6.1.3 Evaluation

For each language pair, we translate sentences in both directions. We evaluate the quality of the translation using the standard BLEU (Papineni et al., 2002) and chrF2 scores (Popović, 2015), computed with the sacreBLEU toolkit (Post, 2018).[5] We do not consider neural metrics to keep a consistent evaluation setting across all directions; Upper Sorbian and Chuvash are currently not supported by such systems.

### 6.2 MT results

Table 7 displays the MT performance with NLLB for both directions of the two language pairs. We observe that in all four translation directions, our filtering pipeline leads to improved MT scores compared to the zero-shot setting, when applicable, and the standard mining system (FT-mined), based on the chrF2 score. Between the sentence and segment extraction, we do not see a clear trend. Since the larger size of the training corpus does not imply a performance increase, the extracted segments appear to contain more samples but more noise. To verify translation performance gains, we conducted paired bootstrap resampling (1,000 resamples) using sacreBLEU (Post, 2018). Improvements over the baseline are statistically significant ($p$-value $< 0.01$), with full $p$-values reported in Appendix H.

To ensure that our performance gains are driven by data quality rather than simply increased data

[5] sacreBLEU signatures: BLEU: `nrefs:1|case:mixed|eff:no|tok:13a|smooth:exp|version:2.5.1`; chrF2: `nrefs:1|case:mixed|eff:yes|nc:6|nw:0|space:no|version:2.5.1`.

| Direction | Setting | # Pairs | # Words | chrF2 | BLEU |
|---|---|---|---|---|---|
| HSB → DE | zero-shot | - | - | 35.60 | 9.20 |

| | FT-segments | 11,622 | 113,272 | 43.20$^{*\dagger}$ | 14.40$^{*\dagger}$ |
| DE → HSB | FT-mined | 2,169 | 32,647 | 27.20 | 4.20 |
| | FT-sentences | 3,919 | 50,972 | 28.90$^{*\dagger}$ | 5.00$^{*\dagger}$ |
| | FT-segments | 11,622 | 113,272 | **29.60**$^{*\dagger}$ | **5.60**$^{*\dagger}$ |
| CHV → RU | zero-shot | - | - | 21.00 | 1.60 |
| | FT-mined | 7,789 | 55,866 | 21.00 | 2.50 |
| | FT-sentences | 26,877 | 249,881 | 31.60$^{*\dagger}$ | 7.10$^{*}$ |
| | FT-segments | 69,568 | 735,944 | **33.10**$^{*\dagger}$ | **7.40**$^{*}$ |
| RU → CHV | FT-mined | 7,789 | 55,866 | 20.00 | 1.40 |
| | FT-sentences | 26,877 | 249,881 | **23.70**$^{*\dagger}$ | **2.50**$^{*}$ |
| | FT-segments | 69,568 | 735,944 | 22.80$^{*\dagger}$ | 2.30$^{*}$ |

Table 7: Downstream machine translation performance of the NLLB model for HSB–DE and CHV–RU. '# Pairs' indicates the number of sentence or segment pairs used for fine-tuning. '# Words' represents the number of words in the high-resource language. Superscript $*$ denotes statistically significant improvement (or difference) over 'FT-mined', while † indicates a significant difference between 'FT-sentences' and 'FT-segments' ($p$-value $< 0.01$).

volume, we additionally evaluated the models using fine-tuning corpora with a matching number of words on the high-resource language side. Results and analysis for this experiment are detailed in Appendix I. Under this matched setting, the FT-sentences configuration still leads to better translation quality than FT-mined, whereas FT-segments can fall below it.

## 7 Conclusion

We present SNAPP, a parallel sentence filtering system, which post-processes sentence pairs based on unsupervised neural alignments to identify their matching *segments*. SNAPP aims to address one weakness of mean-pooled embedding approaches in mining, where sentence pairs with high lexical overlap but different meanings could not be discarded. Our system was mainly applied to low-resource pairs, which suffer more from the issue due to poorer multilingual representation. Our pipeline yields improved mining quality for three low-resource language pairs compared to the existing baseline, PaSeMiLL. We further included components for language-specific adjustments; word-level mean vector subtraction led to notably better filtering performance thanks to fewer false positives. Further improvements were also observed from stop-word filtering and the alignment strategy in SimAlign, depending on the language distance between the source and target languages. Finally, we examined the impact of this improved corpus quality on the downstream performance of machine translation systems. By evaluating the NLLB model (NLLB Team et al., 2024) across four distinct configurations (a zero-shot baseline, alongside fine-tuning on mined PaSeMiLL sentences, post-filtered sentences, and post-filtered segments), we observed improved translation performance thanks to our proposed filtering system compared to the base mining pipeline.

Future work will extend the approach to other low-resource language pairs, specifically with larger typological differences (as in CHV–RU). We will further investigate the conditions in which extracted *segments* can consistently improve MT performance and outperform mined sentence pairs.

## Limitations

First, the performance of our proposed filtering approach is inherently bounded by the recall achieved during the initial sentence-mining phase (in our case, the PaSeMiLL mining pipeline; Okabe and Fraser, 2025). All sentence pairs missed at this step will be irrecoverable by our system.

A major factor influencing performance for both mining and filtering in our experiments is the embedding quality produced by the underlying language model. Glot500-m was pre-trained on monolingual sentences for all three low-resource languages. Our approach may, hence, yield different results for other languages and models, depending on their pre-training data.

We mainly focus on Glot500-m and do not consider more advanced sentence embedding approaches, such as LaBSE (Feng et al., 2022) or SONAR (Duquenne et al., 2023). As our goal is to mine and filter parallel sentences for low-resource languages, we posit that such resources are not available to fine-tune (Kvapilíková and Bojar, 2023) or distill (Heffernan et al., 2022; Tan et al., 2023) the sentence embedding models. The mining and filtering approach in our work only relies on monolingual pre-training (Glot500-m), which is more accessible to low-resource languages.

Moreover, the compiled stop-word lists can be considered another limiting factor due to their heuristic construction. While our pipeline operates unsupervised, relying only on monolingual pre-training, using stop-word filtering introduces a reliance on human effort and external resources.

Specifically, manually verifying the 300 most frequent candidate words required approximately two hours per language and depended on the availability of pre-annotated corpora (e.g., UD treebanks) or existing translation tools. For extremely low-resource languages, such datasets and systems are often not available, thereby restricting the portability of this specific component. Solely relying on function words for the creation of the stop-word list does not cover all language-specific stop-words.

## A Illustration of the UnsupPSE approach

Figure 2 displays an adapted version of the segment-level processing of Hangya and Fraser (2019).

## B SimAlign: Alignment strategy comparison

SimAlign provides three alignment strategies: Argmax, Itermax, and Match. While the Argmax strategy aligns tokens that are mutually most similar, Itermax applies this approach iteratively to increase the total number of alignments. Match, in contrast, considers the alignment task as a graph theory problem and computes a maximum-weight maximal matching. Hence, Argmax favors alignment precision, whereas Itermax and Match lead to higher recall.

## C Example of token aggregation

Figure 3 shows an example of the subword aggregation to move from the subword to the word tokenization level. In this specific example, we use the SentencePiece tokenizer from Glot500-m (Imani et al., 2023) to tokenize the sentence.

## D Stop-word list compilation

Obtaining predefined stop-word lists for low-resource languages is often challenging. A common approach to generate such lists involves processing a corpus of arbitrary sentences and calculating the term frequency of each word (Manning et al., 2008). Based on the premise that stop-words exhibit high frequency, the heuristic applied here considers the 300 most frequent words as stop-words. To further minimize the risk of including non-stop-words, each candidate word was manually verified against the annotated corpus provided by Universal Dependencies (Nivre et al., 2020).[6] Words absent from the corpus were verified by translating them into a high-resource language using respective translation tools.[7] For Chuvash, no annotated corpus was available. Therefore, we used a Russian stop-word list provided by NLTK (Bird et al., 2009) and translated the stop-words based on a Chuvash–Russian dictionary. The pre-compiled stop-word lists for Chuvash, Upper Sorbian, and Occitan are made publicly available in the accompanying code repository (linked in Section 1).

Table 8: Best-performing hyperparameters of the post-processing pipeline for each language pair. *Static filtering threshold for the PaSeMiLL mining pipeline.

Table 8 summarizes the hyperparameters used in the filtering pipeline to obtain the results reported in Tables 2, 3, 4, and 5.

## F fast_align: Performance comparison

| Method / Configuration | Metrics | | |
|---|---|---|---|
| **Alignment** | **P** | **R** | **F** |
| **Occitan–Spanish (OCI–ES)** | | | |
| Dice Threshold = 0.1 | **96.44** | 48.39 | 64.44 |
| **Dice Threshold = 0.01** | 94.06 | **70.69** | **80.72** |
| Dice Threshold = 0.001 | 93.75 | 70.01 | 80.16 |
| **Chuvash–Russian (CHV–RU)** | | | |
| Dice Threshold = 0.1 | **80.32** | 13.35 | 22.90 |
| **Dice Threshold = 0.01** | 67.85 | 20.43 | 31.40 |
| Dice Threshold = 0.001 | 65.24 | **21.43** | **32.26** |
| **Upper Sorbian–German (HSB–DE)** | | | |
| Dice Threshold = 0.1 | **92.86** | 04.33 | 8.28 |
| **Dice Threshold = 0.01** | 89.73 | 30.00 | **44.97** |
| Dice Threshold = 0.001 | 85.54 | **30.37** | 44.82 |

Table 9: Comparison of fast_align results for BELOPSEM language pairs.

As previously noted, the alignments produced by fast_align (Dyer et al., 2013) tend to contain significant noise when applied to non- and partially parallel corpora. This noise primarily stems from the log-linear reparameterization underlying the fast_align model. Consequently, fast_align inherently prioritizes alignments that lie close to the diagonal between the source and target sentences (Dyer et al., 2013). In the context of non-parallel or partially parallel candidate pairs, this geometric

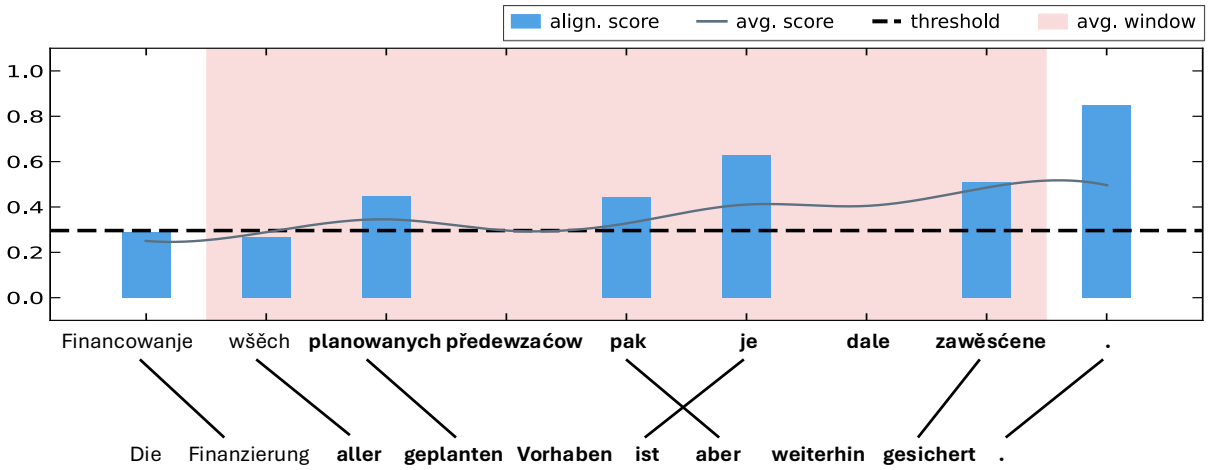

Figure 2: Visualization of the token alignment, averaging, and the subsequent building of contiguous segments for the HSB–DE language pair (adapted from Hangya and Fraser, 2019). The blue bars represent the cosine similarity values of aligned words. Contiguous segments are marked in **bold**. We use a window size of 7 for the averaging and a threshold of 0.3 for the contiguous segments. We present an actual translation pair for HSB–DE from BELOPSEM ('However, the funding for all planned projects remains secure.' in English).

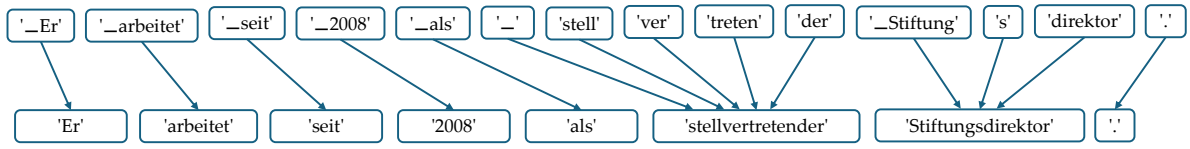

Figure 3: Example token aggregation according to the algorithm of the post-processing script.

bias leads to many erroneously aligned words. To mitigate this issue, a pre-filtering step is applied to the fast_align output before it is accessed by the post-processing pipeline. We apply the Dice Coefficient (Dice, 1945) to the obtained alignments to evaluate association strength solely based on alignment frequencies. Alignment pairs whose Dice Coefficient falls below a predefined threshold are classified as noise and subsequently discarded. The Dice Coefficient is defined as follows:

$$\text{Dice Coefficient} = \frac{2 \cdot h}{a + b} \qquad (2)$$

In this context, $h$ denotes the frequency with which the words $w_1$ and $w_2$ are aligned with each other across the entire fast_align output. Furthermore, $a$ and $b$ represent the total number of times $w_1$ and $w_2$ appear within the initial fast_align alignments, respectively.

Table 9 compares the final post-processing performance when the initial fast_align output is pre-filtered using different Dice Coefficient thresholds. The results demonstrate that a threshold of 0.1 is too strict, incorrectly filtering out a large portion of valid word alignments. During the subsequent post-processing phase, this severe alignment reduction drastically shortens the detected parallel segments, ultimately resulting in a high number of false negatives.

## G Ablation study: Punctuation handling

Punctuation handling entails the removal of the final token if it consists solely of punctuation marks. This approach is designed to mitigate the noise introduced by the terminal punctuation mark, which is frequently aligned with its corresponding counterpart. Through subsequent window-based averaging, this terminal mark can artificially inflate the overall similarity, particularly for short sentences. Although this configuration does not contribute to the overall performance of the post-processing pipeline, it nevertheless provides insights into the false positives present within the remaining candidate pairs. By comparing the results in Table 10, we can confirm that a significant amount of noise is introduced by the artifactual inflation of similarity scores caused by final punctuation tokens. While this approach filters a substantial amount of noise, it simultaneously results in a decline in recall.

| Lang Pair | mean vect. | SW src | SW trg | Sim-Align | Punct. Handl. | P | R | F | Pair Num. |
|---|---|---|---|---|---|---|---|---|---|
| OCI–ES | d | No | No | A | No | 84.97 | **83.05** | 84.00 | 1,424 |
| | d | No | No | A | Yes | **89.62** | 81.74 | **85.50** | 1,329 |

| | d | No | Yes | A | Yes | **91.71** | 43.90 | 59.38 | 1,436 |

Table 10: Ablation study results of the punctuation handling configuration.

## H Statistical significance of the MT results

Table 11 reports the empirical $p$-values obtained from statistical significance testing on the machine translation results presented in Table 7. We conducted paired bootstrap resampling with 1,000 resamples using the `sacreBLEU` toolkit (Post, 2018). Across all four translation directions, both `FT-sentences` and `FT-segments` achieve statistically significant gains over the baseline (`FT-mined`) for both chrF2 and BLEU ($p < 0.001$). Furthermore, the direct comparison between `FT-sentences` and `FT-segments` indicates statistically significant differences ($p < 0.001$) in all settings, with the sole exception of the BLEU scores for both translation directions between Chuvash and Russian (CHV–RU).

| Direction | Comparison | chrF2 | BLEU |
|---|---|---|---|
| HSB → DE | FT-mined vs. FT-senten. | $< 0.001$ | $< 0.001$ |
| | FT-mined vs. FT-segm. | $< 0.001$ | $< 0.001$ |
| | FT-senten. vs. FT-segm. | $< 0.001$ | $< 0.001$ |
| DE → HSB | FT-mined vs. FT-senten. | $< 0.001$ | $< 0.001$ |
| | FT-mined vs. FT-segm. | $< 0.001$ | $< 0.001$ |
| | FT-senten. vs. FT-segm. | $< 0.001$ | $< 0.001$ |
| CHV → RU | FT-mined vs. FT-senten. | $< 0.001$ | $< 0.001$ |
| | FT-mined vs. FT-segm. | $< 0.001$ | $< 0.001$ |
| | FT-senten. vs. FT-segm. | $< 0.001$ | 0.0689 |
| RU → CHV | FT-mined vs. FT-senten. | $< 0.001$ | $< 0.001$ |
| | FT-mined vs. FT-segm. | $< 0.001$ | $< 0.001$ |
| | FT-senten. vs. FT-segm. | $< 0.001$ | 0.0709 |

Table 11: Empirical $p$-values computed via paired bootstrap resampling (1,000 resamples) across all evaluated model pairs.

## I Size-matched MT results

A potential confounding factor in the downstream MT results (Section 6.2) is the varying size of the corpora used to fine-tune the NLLB model (NLLB Team et al., 2024). To isolate the impact of data quality from data quantity, we conducted an additional evaluation using size-matched corpora. We sub-sampled the `FT-sentences` and `FT-segments` corpora to match the target-side word count for `FT-mined`. For `FT-sentences`, we retained the top-$k$ candidate pairs with the highest alignment similarity scores, whereas for `FT-segments`, we prioritized the longest available segment pairs.

Table 12 presents the downstream MT performance using these size-matched corpora. With the exception of the BLEU score difference between `FT-segments` with `FT-sentences` and `FT-mined` for RU→CHV, all observed differences between systems are statistically significant ($p < 0.01$). Crucially, the `FT-sentences` configuration continues to significantly outperform the `FT-mined` baseline. This confirms that our filtering pipeline yields intrinsically higher-quality parallel data, demonstrating that the improvements in Section 6.2 are not merely an artifact of larger data volume.

Conversely, the size-matched `FT-segments` configuration exhibits significant performance degradation compared to the baseline in several directions. This contrasts with our original unconstrained findings and suggests that while segment-level extraction is highly effective at scale, it potentially introduces context fragmentation when the overall training volume is severely restricted.

| Direction | Setting | # Pairs | # Words | chrF2 | BLEU |
|---|---|---|---|---|---|
| HSB → DE | zero-shot | - | - | 35.60 | 9.20 |
| | FT-mined | 2,169 | 32,647 | 42.60 | 15.30 |
| | FT-sentences | 2,556 | 32,653 | **43.90**$^{*\dagger}$ | **16.40**$^{*\dagger}$ |
| | FT-segments | 1,353 | 32,659 | 41.20$^{*\dagger}$ | 12.90$^{*\dagger}$ |
| DE → HSB | FT-mined | 2,169 | 32,647 | 27.20 | 4.20 |
| | FT-sentences | 2,556 | 32,653 | **28.80**$^{*\dagger}$ | **5.10**$^{*\dagger}$ |
| | FT-segments | 1,353 | 32,659 | 25.80$^{*\dagger}$ | 3.50$^{*\dagger}$ |
| CHV → RU | zero-shot | - | - | 21.00 | 1.60 |
| | FT-mined | 7,789 | 55,866 | 21.00 | 2.50 |
| | FT-sentences | 10,068 | 55,898 | **25.80**$^{*\dagger}$ | **3.70**$^{*\dagger}$ |
| | FT-segments | 958 | 55,912 | 22.50$^{*\dagger}$ | 2.00$^{*\dagger}$ |
| RU → CHV | FT-mined | 7,789 | 55,866 | 20.00 | 1.40 |
| | FT-sentences | 10,068 | 55,898 | **20.70**$^{*\dagger}$ | **1.70**$^{*}$ |
| | FT-segments | 958 | 55,912 | 18.20$^{*\dagger}$ | 1.60 |

Table 12: Downstream machine translation performance of the NLLB model for HSB–DE and CHV–RU. '# Pairs' indicates the number of sentence or segment pairs used for fine-tuning. '# Words' represents the number of words in the high-resource language. Superscript $*$ denotes statistically significant difference compared to 'FT-mined', while † indicates a significant difference between 'FT-sentences' and 'FT-segments' ($p$-value $< 0.01$).

# Dynamic Lagging using Stable-Prefix Training for Simultaneous Translation

**Hieu Hoang** Microsoft

**Amittai Axelrod**

**Matt Post** Microsoft

## Abstract

In streaming simultaneous speech translation, the speech translation system is trained to learn a read-write policy that alternates between consuming source words and generating target ones. In a cascaded setting, the output from the speech recognizer is passed to a separate machine translation component, making it more difficult to learn such a policy. Approximations such as fixed wait-$k$ strategies or target-suffix deletion can be employed, but these approaches do not provide the model with a streaming system's flexibility to make contextual read-write decisions. This paper presents a training strategy for a cascaded machine translation system that enables it to dynamically decide how much of the growing source prefix to translate. We achieve this by fine-tuning a large language model (Qwen3-8B) on *stable prefixes* of the training data, which are produced by pairing every source sentence prefix in the training data with the longest translation of that prefix that is shared with the full source sentence translation. We fine-tune variants of the model on different subsets of the prefixes and compare against wait-$k$ and target-suffix deletion. We also investigate the effect of fine-tuning the target-token generation confidence. Our experiments show that stable prefixes improve the quality-latency tradeoff when translating from English into German, Japanese, and Chinese across a range of test sets.

## 1 Introduction

Simultaneous speech translation begins translating before the complete speech input has been observed. In this setting, there is a natural tradeoff between translation quality (which is highest when the entire input is available) and latency (which is lowest when the system begins translating right away). A number of approaches have been developed to address this tradeoff, including fixed schedules such as wait-$k$ (Ma et al., 2019), adaptive policies that make the read-write decision dynamically (Gu et al., 2017; Zheng et al., 2020), re-translation (Arivazhagan et al., 2020b), or local agreement (Polák et al., 2022).

A cascaded pipeline, where the text output of an automatic speech recognition (ASR) system is passed to a machine translation (MT) system, continues to be an effective approach (Bentivogli et al., 2021). For the machine translation component, a cascade can employ a specialized streaming architecture or make use of off-the-shelf, standard translation systems or large language models, which can also be tuned or adapted in different ways. The machine translation system must determine how much of the input it will translate, but for standard architectures, the options are often limited to wait-$k$ or target-suffix deletion (masking), which are coarse policies that are not responsive to the source context.

In this paper, we train an MT system to dynamically decide how much output it is willing to commit to. We do this by introducing the idea of a *stable translation prefix*, a translation of a source prefix that has been truncated for consistency with the full-sentence translation. This is computed by first using a trained MT system to translate the source side of every sentence in the training data, as well as every prefix of those sentences, and then pairing each source prefix with the longest common prefix between its translation and the full-sentence translation. These pairs then constitute training data that can be used for fine-tuning, allowing the model to learn how much to "trust" any particular source prefix.

Our experiments demonstrate the effectiveness of this approach. In experiments fine-tuning Qwen3-8B, we observe substantial improvements in the latency-quality Pareto frontier for models trained on these prefixes and evaluated with wait-$k$, target-

*Proceedings of the Eleventh Conference on Machine Translation*, pages 254–268
October 28-29, 2026 ©2026 Association for Computational Linguistics

suffix deletion, and a tuned confidence threshold. These findings hold across three language pairs (en-de, en-ja, and en-zh) on FLEURS (Conneau et al., 2022), WMT24++ (Deutsch et al., 2025), and CoVoST 2 (Wang et al., 2020) test sets.

## 2 Background

Simultaneous machine translation begins translating before the entire input is received. In the streaming setting (Cho and Esipova, 2016), the output, once generated, cannot be revised, and the system's core task is to determine whether to read the next source token or generate a target token.[1] Early work learned this policy directly, either with reinforcement learning (Gu et al., 2017) or with supervised agents trained from oracle decisions (Zheng et al., 2020). Fixed policies offer a simpler alternative. In particular, wait-$k$ reads $k$ source tokens and then alternates between reading and writing (Ma et al., 2019), providing an explicit latency-quality control but without considering the context. These transduction approaches commit target tokens incrementally. This formulation is naturally suited to simultaneous translation but requires new training and inference paradigms.

Cascaded approaches, which feed the output of an ASR system into an MT one, remain popular (Bentivogli et al., 2021). This setting permits the use of specialized encoder-decoder models (Huang et al., 2020), but it is also possible to use standard translation models which either translate input chunks independently, or which repeatedly re-translate the source, constrained each time to the previously generated target prefix (Polák et al., 2022).

A key distinction for the MT component is whether the architecture is the "standard" model (trained to consume the entire input and produce an output) or has been adapted for streaming (and has been trained to use or dynamically decide a customized read-write policy). Standard models are limited in their ability to control the amount of output text. One approach is to impose a wait-$k$ policy on top of the model. Another is to use "target suffix deletion (mask-$k$)" (Arivazhagan et al., 2020b), which removes words from the end of the partial translation. This allows the caller to wait until the next, longer partial source without committing to the complete partial translation, at the cost of some latency, and it reflects the fact that translation uncertainty falls as more of the source is observed. However, both these approaches are coarse controls that do not take into account the actual uncertainty or stability of the translation at each point in the source. Our approach is to train the model on dynamically-determined stable prefixes and to use a tuned confidence threshold.

With the high performance of LLM-based translation systems, it is natural to incorporate them into speech translation pipelines. Yang et al. (2025b) surveys the integration of the speech modality into (largely text-based) LLMs. A number of papers construct training data that is amenable to multi-turn dialog (Ouyang et al., 2025; Wang et al., 2025). Agostinelli et al. (2024) provide a fine-tuning and evaluation framework for LLMs, and Fu et al. (2025) train on interleaved source-target pairs under latency constraints. This paper uses Qwen3-8B (Yang et al., 2025a) as a base translation model for evaluation and fine-tuning.

Prefixes have been used in various ways for training and inference. In prefix training (Niehues et al., 2016), each (source, target) training pair is randomly truncated. Sen et al. (2023) explore self-training on tagged prefix training data, demonstrating increased monotonicity and reduced flicker in a re-translation setting. At inference time, Polák et al. (2022) compared hypotheses in the beam, and found the best performance from "local agreement", which computes a target prefix from a sequence of translations of growing source prefixes. The local agreement criterion itself was introduced by Liu et al. (2020), who commit the longest prefix shared by consecutive hypotheses. The same principle of committing only the stable portion of a hypothesis underlies re-translation systems that stabilize the output prefix as more source arrives (Niehues et al., 2016, 2018; Arivazhagan et al., 2020b), and agreement between successive prefix translations was already exploited as a commit criterion by Cho and Esipova (2016). Our approach extends work in prefix training with the idea of a "stable" prefix: a distilled translation prefix anchored to the full-sentence translation.

## 3 Approach

### 3.1 Prefix Translation Synthesis

Our goal is to produce a system which, when presented with a source prefix, will only translate as

[1] We follow Arivazhagan et al. (2020a) in distinguishing streaming from re-translation approaches, in which the output can be changed.

| # | type | source prefix | translation | stable prefix |
|---|---|---|---|---|
| | final | Does he playfully tease you? | Neckt er dich spielerisch? | Neckt er dich spielerisch? |
| 1 | partial | Does | Macht | |
| 2 | partial | Does he | Tut er das | |
| 3 | partial | Does he playfully | Tut er das spielerisch | |
| 4 | partial | Does he playfully tease | Neckt er | Neckt er |

Table 1: Stable-prefix extraction for a German example. Not until step 4 is a partial translation a prefix of the full-sentence translation.

much of it as it can do so reliably. Past work in prefix training relies on randomly sampling the prefix, which does not properly account for prefix ambiguity. We address that by constructing training data based on the notion of a **stable prefix**.

Given a monolingual source sentence $s$ and a translation system $t$, we produce a translation $f = t(s)$. We also compute $p_i = t(s_{1..i})$, where each $s_{1..i}$ contains the first $i$ words of $s$.

Let $\ell_i = |\operatorname{lcp}(p_i, f)|$ be the length of their longest common word-level (EN→DE) or character-level prefix (EN→JA and EN→ZH).

For source prefix $s_{1..i}$, we define the *stable prefix* as $p'_i = f_{1..m_i}$, where $m_i = \max_{j \le i} \ell_j$.

Thus the target prefix grows monotonically: once content has agreed with the full-source translation and been committed, a noisier later partial translation cannot retract it. This increases the prefix translation length and stability of the training data. The pseudocode for this procedure can be found in Appendix A.

The stable-prefix translation corpus is merged with the full translations when finetuning the model at a fixed ratio. Table 1 contains an example. As we translate successively longer source prefixes, the translations in the "translation" column exhibit "jitter." Any suffix of the partial translation beyond the stable prefix is unstable and is removed.

### 3.2 LLM Prompting

The LLM is prompted to generate translations of a source prefix. It is told that the input is a partial source sentence; its input and output are not constrained or truncated. New source arriving incrementally is translated by appending it to the previously observed source and re-prompting the model to translate in the same manner. The previously committed target is supplied as a forced prefix. An incremental input that completes the source sentence is also force-decoded with the previously committed translation, but the model is explicitly told it is a complete sentence. The architecture is flicker-free by construction, as the model has the previous translation as context but cannot change it.

Consider the source sentence example *Scientists discovered a new species in the rainforest*, where the model assistant has already committed a translation for the prefix *Scientists discovered a new*:

| | |
|---|---|
| **User**$_1$ | *Scientists discovered a new* |
| **Asst.**$_1$ | *Wissenschaftler entdeckten eine neue* |

When the next chunk *species* arrives—the sentence is still incomplete—the model is re-prompted with the source observed so far and the committed target as a forced prefix, and emits only the new continuation:

| | |
|---|---|
| **User**$_2$ | *Scientists discovered a new species* |
| **Forced**$_2$ | *Wissenschaftler entdeckten eine neue* |
| **Asst.**$_2$ | *Art* |

Finally the chunk *in the rainforest* completes the sentence; the model is re-prompted with the full source—now flagged as complete—and the committed target as a forced prefix, and emits the remaining continuation:

| | |
|---|---|
| **User**$_3$ | *Scientists discovered a new species in the rainforest* |
| **Forced**$_3$ | *Wissenschaftler entdeckten eine neue Art* |
| **Asst.**$_3$ | *im Regenwald* |

## 4 Experimental setup

### 4.1 Models

We use Qwen3-8B (Yang et al., 2025a) throughout this paper.

### 4.2 Data

A common practice in MT and LLM training is to use a more capable model to generate distilled data for a less capable model. We take a self-distillation approach, using a single model to generate synthetic parallel data and then fine-tuning on this data to make the model prefix-aware for streaming translation.

Self-distillation also provides a soft upper bound on performance, enabling us to compare the fine-tuned model with the original model that generated the data. Distilled data is also more regular than raw parallel data, so more prefix examples can be extracted to enrich the training data for the prefix-aware model.

We experiment in three language directions: EN→DE, EN→JA, and EN→ZH. The source sentences are a randomly sampled subset of the WMT24 training data (Kocmi et al., 2024, EN→DE) and WMT25 training data (Kocmi et al., 2025, EN→JA and EN→ZH).

20 million parallel full sentences are synthesized as well as their corresponding prefix pairs for each language direction using the base LLM. The stable prefixes are then generated from this data as described in Section 3.1.

Validation is performed on held-out data (newstest2019 (Barrault et al., 2019) for EN→DE and wmttest2023 (Kocmi et al., 2023) for EN→JA and EN→ZH) for full sentence pairs. We also validate on stable prefix pairs held out from the training data along with their full sentence pairs.

The models are evaluated on WMT24++ (Deutsch et al., 2025), FLEURS (Conneau et al., 2022), and CoVoST 2 (Wang et al., 2020) using COMET-22-DA (Rei et al., 2022) and MetricX-24-Hybrid-XL (Juraska et al., 2024).

### 4.3 Training and Validation

We finetune two models, `prefix` and `continuation`, both using LoRA adapters (Hu et al., 2022) with default settings and the Adam optimizer (Kingma and Ba, 2015), with a learning rate of $5 \times 10^{-6}$ and an effective batch size of 128.

Training follows the force-decoding paradigm described in Section 3.2; non-initial prompts are given the source translation from the beginning of the sentence and force-decode with the previous target prefix. Loss is applied only to the continuation and end-of-sequence tokens.

The different training strategies for the `prefix` and `continuation` models are described in the next two sections.

#### 4.3.1 `prefix` model

**Training** draws an equal mixture of prefix and full-sentence examples and trains them as cross-entropy tasks. Samples from the prefix corpus are prompted with the initial translation prompt; full-sentence pairs use the final translation prompt. Thus the `prefix` model learns the initial-prefix and initially-complete boundary cases, but it receives no examples containing an already committed target prefix and no intermediate continuation examples.

**Validation** occurs every 500 updates and measures COMET on the full-sentence development set and on prefix pairs. Prefix COMET is first averaged within each observed-source-length bin and then equally across bins; the selection score is the equally weighted mean of this prefix score and full-sentence COMET. Training stops when the validation score does not improve for 5 consecutive epochs; the highest-selection-score checkpoint is then used for evaluation.

#### 4.3.2 `continuation` model

**Training** is initialised from the `prefix` model. Whereas `prefix` is trained only on the initial-prefix and full-sentence boundary cases, the `continuation` model adds two similar tasks; *continue* translates a chunk of words where its prefix has already been translated, and *final-continue* translates the final chunk of the sentence given an already-committed target prefix. These four tasks are sampled during training with the following probabilities:

- *initial* 60%
- *continue* 20%
- *final-continue* 10%
- *initially-complete* 10%

**Validation and checkpoint selection.** We hold out a fixed slice of 64 training sentences. On each held-out sentence we imitate inference: the source is revealed a few words at a time, and at every step

the model continues from *its own* previously committed text (using the same force-decoding prompt as training, never the gold prefix); these are then concatenated into one complete translation of the sentence. COMET is computed for this incrementally built translation, and for translating the whole sentence at once. The selection score is the equally weighted average of these two COMET scores. Training stops when the validation score does not improve for 5 consecutive epochs.

### 4.4 Evaluation

We apply two evaluation methods: binary-segmentation translation and incremental translation.

In the first case, we segment the source sentences at every word boundary into two segments and translate the prefix and the suffix. The prefix translation is used as context, via force decoding, to translate the suffix. The COMET score (Rei et al., 2022) is computed over the concatenated prefix and suffix translations. This reveals how translation quality changes depending on where the source is segmented.

The incremental evaluation is more realistic, as it simulates source text arriving incrementally in chunks of different lengths, reflecting the conditions of a live simultaneous translation scenario. At each step, the model has to decide whether—and how much—to commit to the translation output. We use Average Lagging (Ma et al., 2019) to measure how long a system waits before producing translation output: for a value $k$, the system produces the translation only up to input token $n - k$.

## 5 Results

### 5.1 Finetuning LLM

The results of the binary segmentation evaluation are summarized in Table 2 and visualized in Figure 1 for the `base` (pre-trained LLM), `prefix`, and `continuation` models. We measured average lag and the COMET score on the test set when translating full sentences.

We also calculated the COMET score at each segmentation position. If a particular sentence is shorter than the segmentation point, its score is taken as the COMET score of the full sentence. The *Worst* score in Table 2 corresponds to the lowest COMET score observed across all segmentation positions for each model.

Table 2: Average Lagging and COMET ($\times 100$) on FLEURS. *Full* is complete-sentence COMET; *Worst* is the minimum corpus-average COMET over source boundaries.

| ID | model | AL | Full | Worst |
|---|---|---|---|---|
| **EN→DE** | | | | |
| 1 | `base` | **0.82** | 85.9 | 80.9 |
| 2 | `prefix` | 2.21 | **87.1** | **85.1** |
| 3 | `continuation` | 2.21 | 86.1 | 81.2 |
| **EN→JA** | | | | |
| 4 | `base` | **0.11** | 89.2 | 81.3 |
| 5 | `prefix` | 3.06 | **90.4** | **90.0** |
| 6 | `continuation` | 1.06 | 89.2 | 75.7 |
| **EN→ZH** | | | | |
| 7 | `base` | 0.60 | 88.1 | 85.8 |
| 8 | `prefix` | 3.11 | **88.8** | **88.4** |
| 9 | `continuation` | **0.55** | 88.3 | 85.5 |

We note a few interesting observations:

- The prefix models translate full sentences better according to COMET, even better than the base model from which the distilled data came. This resembles the "born-again" phenomenon, in which a student trained on a teacher's predictions surpasses that teacher despite sharing its architecture, because self-distillation can regularize and reweight the learning signal (Furlanello et al., 2018); here, the large ratio of full-sentence examples likely strengthens that effect. Continuation matches the pre-trained model.

- The `base` model is most aggressive at committing translations. The average lag of the `prefix` model is significantly higher (worse) than the other models, for all 3 language pairs. The bottom row of Figure 1 indicates the `prefix` model sees a lot more source tokens than the other models for a given quantity of output tokens.

- Figure 1 shows that base-model translation quality dips at early word positions when source sentences are segmented, translated in two parts, and the translations recomposed. The `prefix` model is noticeably better than the `base` model in all three languages at the cost of higher latency. The `continuation` model is a little better than `base`.

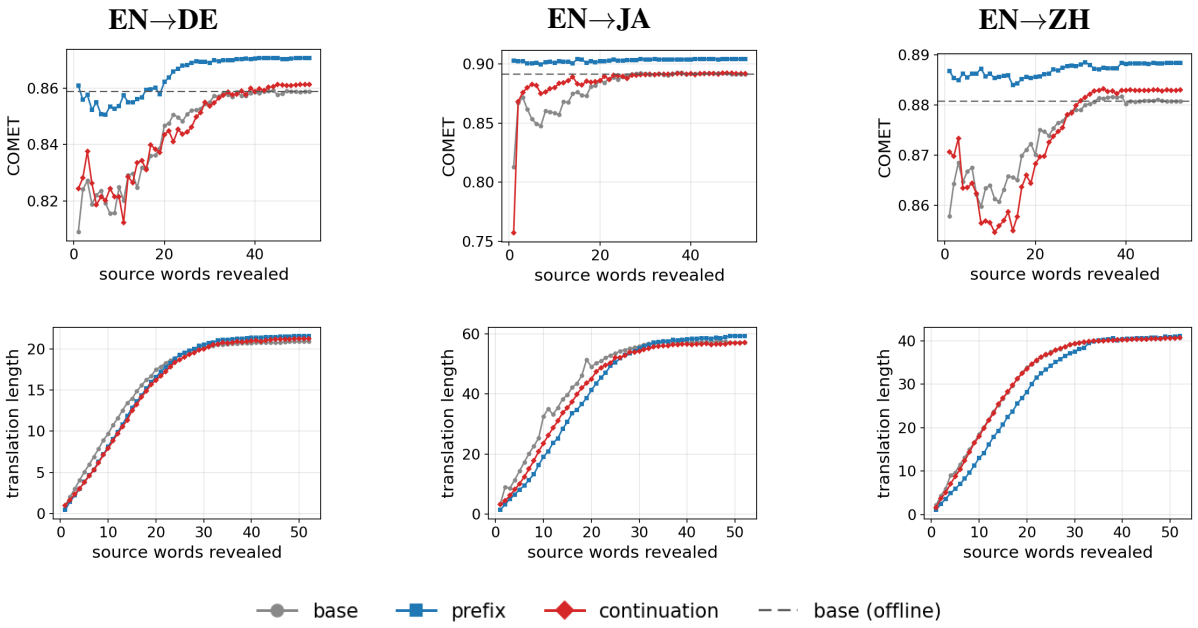

Figure 1: Binary source-completion on FLEURS: COMET of the recomposed translation (top) and prefix-translation length (bottom) versus source words revealed, for the pre-trained `base` and the prefix adapter `prefix`.

### 5.2 Pareto frontier

The binary segmentation evaluation provides insight into how the models perform when translating source prefixes of varying lengths; however, it is not a realistic simulation of real-time translation scenarios, where the source unfolds incrementally in unpredictably sized chunks.

We simulate this scenario by incrementally revealing randomly sized source chunks to the models, with the chunk sizes drawn from a uniform distribution between 1 and 5. The average quality of the full, concatenated translation is measured against latency to gauge the trade-off between the two competing priorities for each model.

On their own, each of the models occupies one point in the quality-latency space. We now introduce three inference-time mechanisms to control the trade-off between translation quality and latency for any model, which lets us trace out a continuous Pareto frontier for each model.

1. **wait-*k***: the classical wait-$k$ policy with its own canonical read schedule—read the first $k$ source words, then alternate reading one source word and committing one target unit ($g(t) = \min(k+t-1, |x|)$). A larger $k$ waits for more source tokens before committing, thus raising latency.

2. **target suffix deletion**: at each non-final step the model generates its full continuation but deletes the last $d$ target units (words, or characters for EN→JA/ZH) before committing. This holds back the least-reliable tail tokens from the output; larger $d$ is more conservative and adds latency.

3. **confidence**: a threshold $\tau$ on the stop-versus-continue margin between the probability of generating EOS (end of sentence) versus anything else. The action chosen is:

$$\Delta = P(\text{best non-EOS}) - P(\text{EOS}),$$
$$a(\Delta;\tau) = \begin{cases} \text{COMMIT}, & \Delta \geq \tau, \\ \text{STOP}, & \Delta < \tau. \end{cases} \quad (1)$$

$\tau \to -1$ commits aggressively, for low latency, while $\tau \to 1$ waits for the whole source, recovering the offline translation. Using the model's own output confidence to drive the read/write decision follows a line of adaptive simultaneous-translation policies (Cho and Esipova, 2016; Gu et al., 2017; Zheng et al., 2019, 2020; Ma et al., 2020).

Table 3 and Figure 2 compare the three mechanisms for each model.

The finetuned models achieve a much better quality–latency trade-off under any mechanism, though the confidence mechanism is clearly the best of the three in most cases.

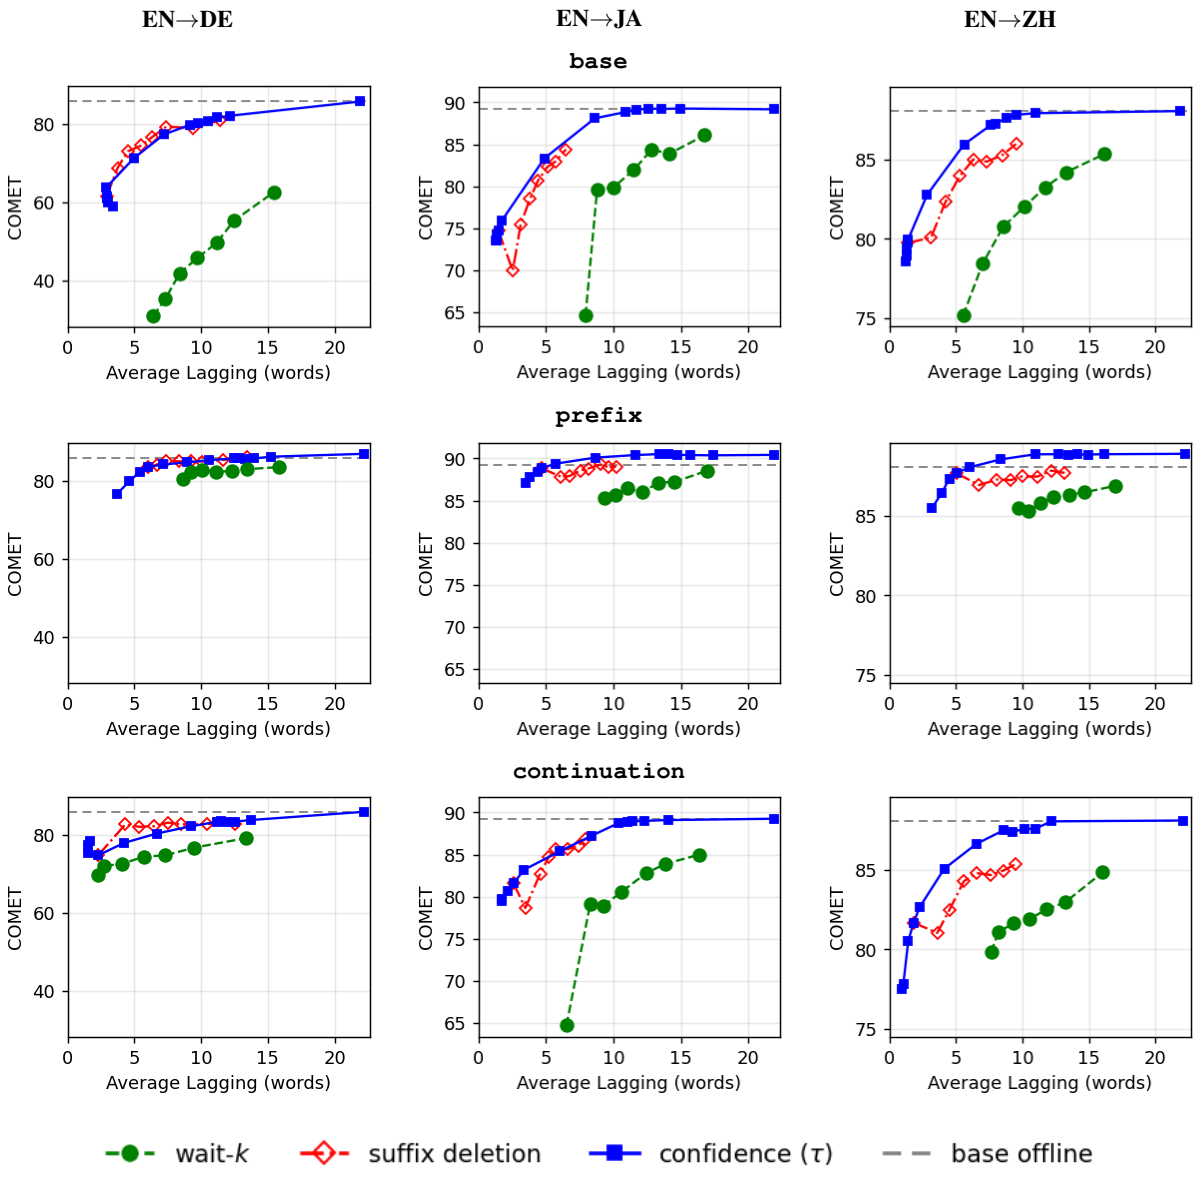

Figure 2: The three latency mechanisms per model (rows) × EN→{DE,JA,ZH} (columns) on FLEURS.

Of the two finetuned variants, the `prefix` model is better than the `continuation` model, confirming the previous subsection's results. This can be explained by the fact that continuing from a previous translation is already implicit in the `prefix` model's training: the `continuation` task of explicitly teaching the model to continue a translation dilutes the useful supervision, adding little information while complicating the prefix/full-sentence data mix.

Wait-$k$'s rigid read-write schedule constrains what the model sees and forces it to commit on a fixed cadence. On the base model, this causes hallucinations, especially at low $k$, hence the low COMET score. The prefix-aware finetuned models reduce this degeneracy, but it remains uncompetitive.

Suffix deletion is not constrained by wait-$k$'s read schedule at low $k$: it can use the whole source prefix, so it translates better than wait-$k$ and occasionally beats the confidence mechanism. However, it can also hallucinate and repeat—content the deletion then discards, wasting computation—and it can only *increase* latency by holding back the tail of the translation.

Overall, confidence is the best performing mechanism on all language pairs, models, and latency ranges (apart from `base` EN→DE) but is particularly effective with the finetuned models. The mechanism is *well-behaved at its endpoints*. At $\tau = 0$ the rule reduces exactly to greedy decod-

Table 3: Latency-mechanism AUC on FLEURS summarizing Figure 2: COMET over Average Lagging. **Bold**: best mechanism per row; ⋆: best per language.

| | wait-$k$ | suffix del. | confidence |
|---|---|---|---|
| `base` | | | |
| EN→DE | 47.9 | **75.1** | 75.0 |
| EN→JA | 76.8 | 82.7 | **85.6** |
| EN→ZH | 81.1 | 84.5 | **86.2** |
| `prefix` | | | |
| EN→DE | 65.0 | 73.7 | **78.9** |
| EN→JA | 78.6 | 85.0 | **87.2**⋆ |
| EN→ZH | 81.7 | 85.3 | **87.0**⋆ |
| `continuation` | | | |
| EN→DE | 74.8 | 80.2 | **81.9**⋆ |
| EN→JA | 76.8 | 84.5 | **86.5** |
| EN→ZH | 80.7 | 84.2 | **86.5** |
| `full-control` | | | |
| EN→DE | — | — | **76.0** |
| EN→JA | — | — | **87.1** |
| EN→ZH | — | — | **86.5** |

ing. At $\tau = 1$ it waits for essentially the whole source before committing, recovering the offline translation. In between, the commit is *confidence-adaptive* rather than positional. At negative $\tau$ it commits aggressively for lower latency, trading off translation quality.

### 5.3 Calibration of commit/wait confidence

When applied to the prefix or continuation models, which are trained to handle partial source inputs, the confidence mechanism becomes most effective. To distinguish the effect of stable-prefix supervision from generic full-sentence adaptation, this calibration analysis includes a full-sentence-only control for each language direction: a fresh adapter trained from the base model without stable-prefix examples. Its role is specifically to test whether ordinary full-sentence finetuning can account for changes in commit/wait confidence.

We test whether the continue-versus-stop signal is better calibrated using a FLEURS stable-prefix oracle (Figure 3). For each of 64 test sentences, the base model translates the complete source and every proper source prefix; the oracle at each boundary is the running-max longest common prefix with the complete-source translation. We force-

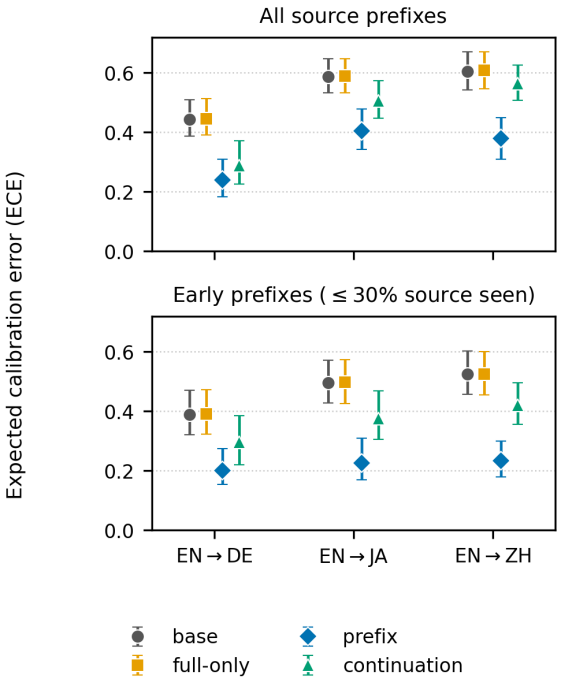

Figure 3: Expected Calibration Error (lower is better) of normalized commit confidence $q_{\text{go}}$ against the FLEURS stable-prefix oracle. Bars are 95% intervals from 1,000 sentence-level bootstrap samples. *Top:* all non-final source prefixes; *bottom:* prefixes with at most 30% of the source visible.

decode the previous oracle target, label each newly licensed target token as GO followed by one STOP, and score every model on these identical states using

$$q_{\text{go}} = \frac{P(\text{best non-EOS})}{P(\text{best non-EOS}) + P(\text{EOS})}. \quad (2)$$

The full-sentence-only controls closely match `base` in all three directions, whereas the `prefix` model is substantially better calibrated: relative to `base`, ECE is reduced by 31–46%. On early prefixes with at most 30% of the source visible, the reductions are 48–55%.

`continuation`'s ECE also improves on `base`, but less than `prefix`. The contrast with the full-sentence-only controls indicates that generic adaptation alone does not explain the calibration gain from stable-prefix training.

Training with the stable-prefix corpus thus not only produces models that are better at translating partial source inputs, but also improves commit/wait confidence calibration against the stable-prefix oracle.

Table 4: COMET quality–latency frontier AUC summarizing Figure 5 over Average Lagging, for EN→{DE,JA,ZH}. Each column scores one sweep on the shared latency interval for that dataset–language panel; best per row in **bold**.

| | base | | | ft. + conf. | |
|---|---|---|---|---|---|
| | wait-$k$ | suf. del. | conf. | prefix | cont. |
| **FLEURS** | | | | | |
| DE | 48.2 | 75.1 | 75.1 | 79.0 | **81.9** |
| JA | 77.0 | 82.7 | 85.6 | **87.3** | 86.5 |
| ZH | 81.1 | 84.5 | 86.2 | **87.0** | 86.5 |
| **WMT24++** | | | | | |
| DE | 43.7 | 63.6 | 65.1 | 69.6 | **74.6** |
| JA | 73.1 | 79.2 | 80.6 | **83.7** | 79.3 |
| ZH | 75.7 | 80.4 | 81.4 | **83.3** | 80.3 |
| **CoVoST2** | | | | | |
| DE | 68.2 | 80.5 | 78.0 | 81.3 | **83.1** |
| JA | 77.2 | 82.1 | 83.3 | 84.4 | **85.0** |
| ZH | 81.8 | 85.0 | 85.2 | **86.5** | **86.5** |

The full-sentence-only model's full sentence translations (86.8/90.5/88.8) are better than the `base` model and similar to `prefix`, confirming the "born-again" effect. Its AUC (last three rows of Table 3) likewise rises above `base` and nearly matches `prefix` because its full sentence translation pulls up the entire curve. However, as Figure 4 shows, its latency-quality tradeoff consistently drops relative to `prefix` when pushed for lower latency, reflecting its uncalibrated performance.

### 5.4 Evaluations on other test sets

The FLEURS comparison in the previous section carries over to the other test sets. Table 4 and Figure 5 repeat the evaluation on WMT24++ and CoVoST2 alongside FLEURS: the `base` model is swept with wait-$k$, suffix deletion, and confidence, while the finetuned models use the confidence mechanism.

The explicit `base` confidence sweep controls for the inference mechanism when comparing the pretrained and finetuned models. By COMET AUC, `prefix` with confidence improves over `base` with confidence in all nine dataset–language panels. `prefix` has the higher quality ceiling, while `continuation` is useful for the lowest-latency frontier.

Appendix Table 6 and Figure 6 present the corresponding MetricX results; they support the same conclusions as the COMET-based analysis.

## 6 Conclusion

We presented a method for identifying *stable training prefixes*, which are translations of source-sentence prefixes that are in common with their corresponding full-sentence translations. Rather than translating the currently available source prefix in its entirety or applying a fixed truncation rule, the model learns how much target content to commit. This provides a dynamic, context-sensitive approach to determining how much of an input prefix to translate, in the context of simultaneous translation. In our experiments, we mixed this data with normal, full-sentence training data and fine-tuned a large language model. Inference with the model focused on a prefix-decoding strategy, a streaming approach that does not modify the output, once committed, and is therefore flicker-free by design. Experiments with Qwen3-8B on EN→DE, EN→JA, and EN→ZH show improved latency-accuracy trade-offs under a number of decoding strategies.

We trained two model variants, `prefix` and `continuation`, to handle initial and ongoing translation tasks. Of these, `prefix` dominates most of the Pareto frontier in its latency range. The `continuation` model can reach slightly lower latency points, but with a trade-off in translation quality. Although the `prefix` model used only initial-prefix source segmentations, its performance generalized to random read schedules and continuations, a result that held across language pairs, datasets, and evaluation metrics.

The training also substantially improves calibration of commit/wait confidence against a FLEURS stable-prefix oracle, reducing ECE by 31–46% overall and 48–55% on early source prefixes. A single confidence threshold is the best of the three training-free latency mechanisms on the finetuned models we tested. It outperforms wait-$k$ and suffix-deletion in all language pairs as measured by AUC, and extends the reachable frontier to higher and lower latency.

## 7 Limitations

Our experiments cover only three language pairs, all originating in English, and we fine-tune under only a single translation engine; further experimentation is required to test whether the results generalize.

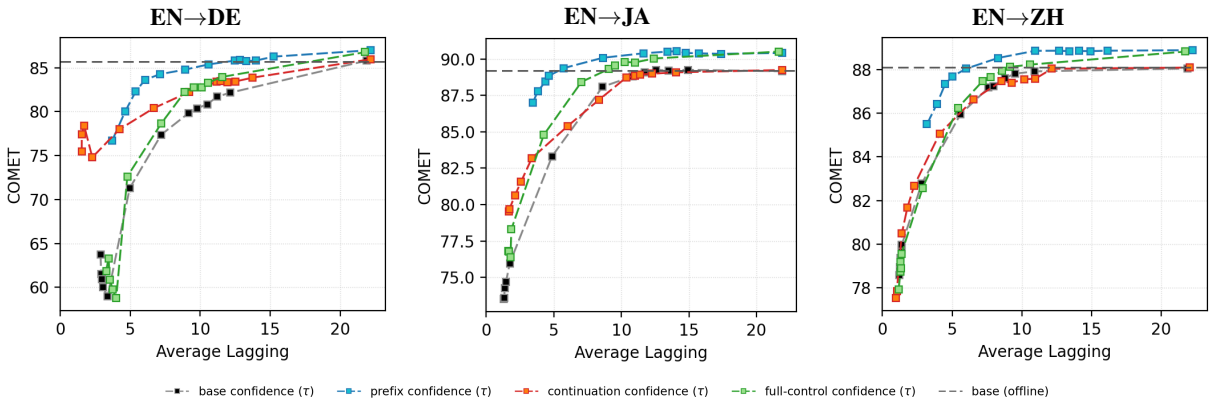

Figure 4: Confidence quality–latency frontiers on FLEURS for `base`, `prefix`, `continuation`, and the `full-control` adapter.

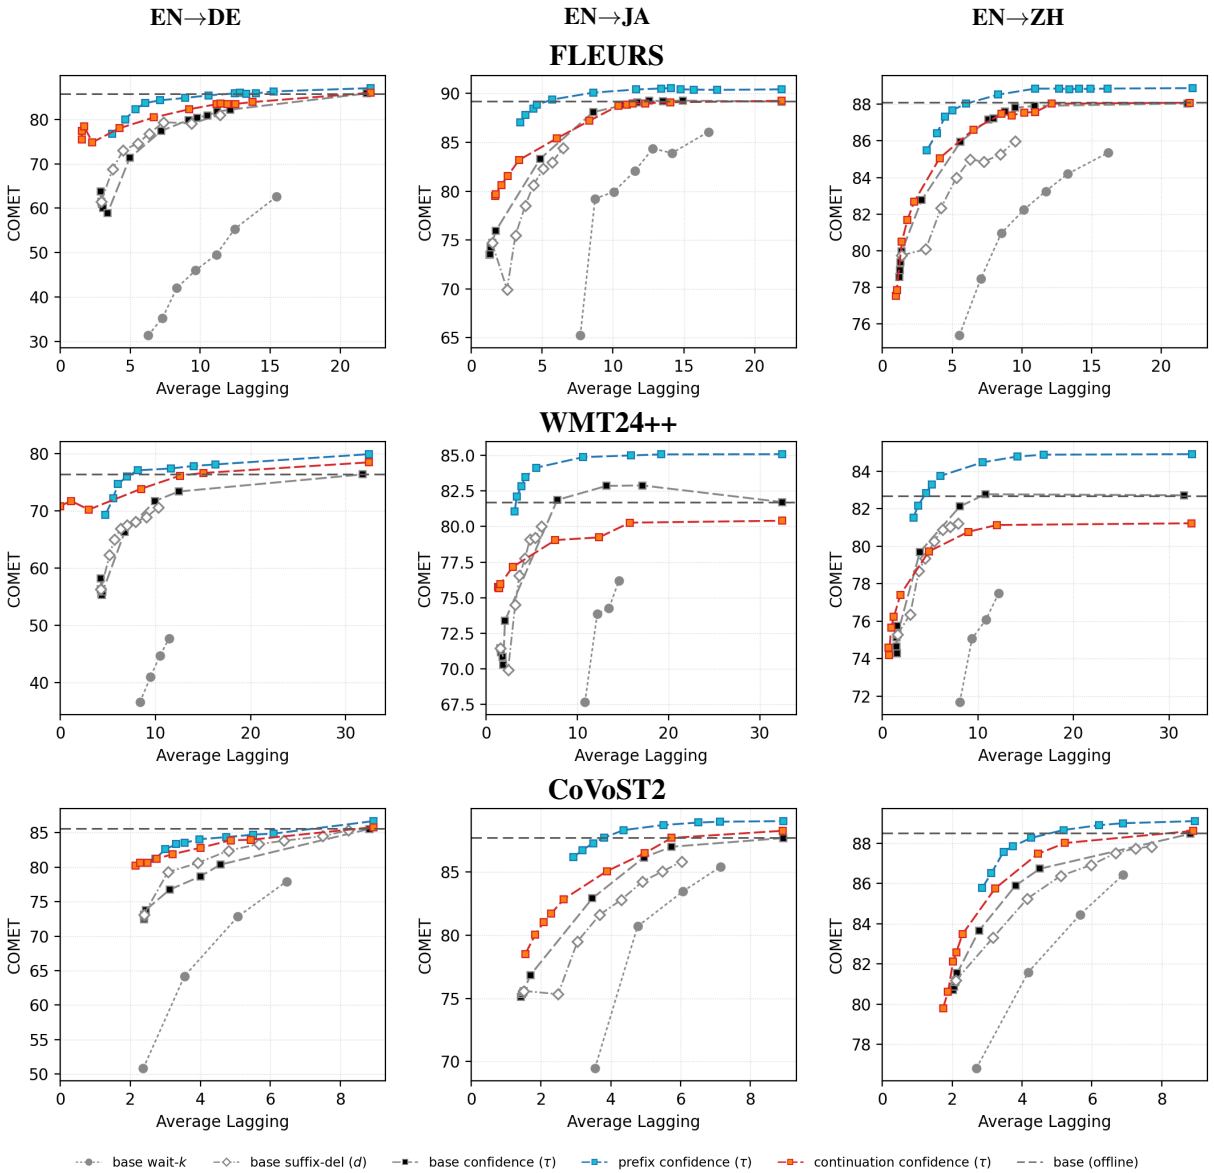

Figure 5: COMET quality–latency tradeoff on FLEURS, WMT24++, and CoVoST 2 (rows) × EN→{DE,JA,ZH} (columns). Each panel compares `base` under wait-$k$, suffix deletion, and confidence with `prefix` and `continuation` under confidence.

# Appendices

## A Stable-prefix construction

**Input:** source sentence $s = (w_1, \ldots, w_n)$; translation model $t$

**Output:** prefix training pairs $D$

1. Set $T \leftarrow t(s)$, $m \leftarrow 0$, and $D \leftarrow \varnothing$.
2. For $i = 1, \ldots, n$:
   (a) Set $s_i \leftarrow (w_1, \ldots, w_i)$ and $P_i \leftarrow t(s_i)$.
   (b) Set $\ell_i \leftarrow |\operatorname{lcp}(P_i, T)|$.
   (c) Enforce monotonicity: $m \leftarrow \max(m, \ell_i)$.
   (d) Add $(s_i, T_{1..m})$ to $D$.
3. Return $D$.

Here lcp is the longest common target prefix. The running maximum ensures that the committed target length never decreases even as more source words arrive.

## B Reproducibility details

**Average Lagging.** We use the standard Average Lagging of Ma et al. (2019). Latency is measured in source-word units. For a sentence with $n$ source words and $T$ committed target units, let $g_i$ be the number of source words read when target unit $i$ is committed, $\gamma = T/n$, and $\tau$ the first target position committed after all $n$ source words have been read (or $T$ if this never occurs). We compute

$$\mathrm{AL} = \frac{1}{\tau} \sum_{i=1}^{\tau} \left( g_i - \frac{i-1}{\gamma} \right). \tag{3}$$

The target units are whitespace-delimited words for German, and characters for Japanese and Chinese.

**Attainable-envelope AUC.** Each dataset–language panel uses one shared latency interval $[L, U]$, where $L$ and $U$ are respectively the minimum and maximum AL over the union of all operating points from all compared sweeps in that panel. We evaluate 101 equally spaced budgets $b_j = L + j(U - L)/100$. For COMET, let $S_s$ be sweep $s$'s set of (AL, quality) points, let $q_{\mathrm{worst}}$ be the lowest COMET value anywhere in the panel, and define

$$\begin{aligned} \mathcal{Q}_s(b) &= \{q : (a, q) \in S_s,\ a \le b\}, \\ F_s(b) &= \begin{cases} \max \mathcal{Q}_s(b), & \mathcal{Q}_s(b) \neq \varnothing, \\ q_{\mathrm{worst}}, & \text{otherwise}, \end{cases} \\ \mathrm{AUC}_s &= \frac{1}{101} \sum_{j=0}^{100} F_s(b_j). \end{aligned} \tag{4}$$

| Direction | `prefix` | `continuation` |
|---|---|---|
| EN→DE | 2,000 / 4,500 (576k) | 3,500 / 6,000 (768k) |
| EN→JA | 1,000 / 3,500 (448k) | 10,500 / 13,000 (1.664M) |
| EN→ZH | 2,000 / 4,500 (576k) | 8,500 / 11,000 (1.408M) |

Table 5: Selected update / final update evaluated before stopping; parentheses give the total number of optimized records through the final update (updates multiplied by effective batch size 128).

Thus every sweep has the same domain and denominator, including below its minimum attainable latency. For MetricX, where lower is better, we replace both maxima by minima and use the panel's highest error as $q_{\mathrm{worst}}$. The five sweeps are `base` with wait-$k$, suffix deletion, or confidence, and `prefix` and `continuation` with confidence.

**Optimization.** The evaluated adapters use LoRA rank 16, scaling factor 32, dropout 0.05, and no bias, applied to the attention $q$, $k$, $v$, and output projections and the MLP gate, up, and down projections. The continuation stage initializes the selected prefix adapter and keeps the same adapter trainable. Both stages use fused AdamW, a constant learning rate of $5 \times 10^{-6}$ without warmup, gradient clipping at 1.0, and an effective batch size of 128.

**Corpus parsing and sampling.** The synthetic corpus was constructed from a nominal 20 million source sentences per language direction. However, very little of the corpus is actually used in training because training stops early when the validation loss stops improving. Table 5 shows the number of updates and total records processed for each language direction.

## C LLM Prompt Templates

All prompts use a single force-decode turn rendered through the Qwen3 chat template (thinking disabled): a system message, one user message carrying the instruction and all source observed so far, and an open assistant turn seeded with the committed target (empty on the first step) that the model continues. The instruction takes one of two forms depending on whether the sentence is yet complete. The examples below use the running source and committed translation example from the LLM prompting in Section 3.2:

### C.1 Prompts

**Initial translation** With no target committed yet, the single user turn translates the source observed so far and the model writes from an empty prefix:

```
[system]    You are a professional simultaneous
            translator from English to German.
[user]      An initial English segment has
            arrived, but the sentence is not
            complete. Translate only what is
            supported so far. Output ONLY the
            German translation.
            English: Scientists discovered a new
-->         Wissenschaftler entdeckten eine neue
```

**Continuation translation** Once a target prefix has been committed, the model is restarted with all source observed so far and the committed target supplied as a forced prefix; free decoding then emits only the new continuation:

```
[system]    You are a professional simultaneous
            translator from English to German.
[user]      An initial English segment has
            arrived, but the sentence is not
            complete. Translate only what is
            supported so far. Output ONLY the
            German translation.
            English: Scientists discovered a
            new species
[forced]    Wissenschaftler entdeckten eine neue
-->         Art
```

**Final translation** When the full sentence has arrived, the instruction switches to its final form: the user turn carries the complete source and the committed target is again forced, so the model produces only the remaining continuation:

```
[system]    You are a professional simultaneous
            translator from English to German.
[user]      The final English segment has
            arrived; the sentence is now
            complete. Keep the existing German
            unchanged and output ONLY the new
            continuation needed to complete the
            translation.
            English: Scientists discovered a new
            species in the rainforest.
[forced]    Wissenschaftler entdeckten eine neue
            Art
-->         im Regenwald.
```

## D MetricX evaluation

As a metric-robustness check we re-score the FLEURS, WMT24++, and CoVoST 2 evaluations with MetricX, a reference-based error metric that uses a range of 0-25 (lower is better). Figure 6 is the MetricX copy of the quality–latency mechanism comparison in Figure 5. Table 6 reports the corresponding MetricX frontier AUC for each sweep. The qualitative ordering carries over between metrics: `prefix` is strongest at higher latency, while `continuation` reaches the lowest-latency band.

Table 6: MetricX-error quality–latency frontier AUC corresponding to Table 4 (lower is better), for EN→{DE,JA,ZH}. Each column scores one sweep on the shared latency interval for that dataset–language panel; best per row in **bold**.

| | base | | | ft. + conf. | |
|---|---|---|---|---|---|
| | wait-$k$ | suf. del. | conf. | `prefix` | `cont.` |
| **FLEURS** | | | | | |
| DE | 10.4 | 4.2 | 4.5 | 3.1 | **2.5** |
| JA | 7.7 | 6.2 | 5.1 | **4.3** | 4.6 |
| ZH | 4.0 | 3.0 | 2.6 | **2.2** | 2.3 |
| **WMT24++** | | | | | |
| DE | 9.3 | 6.7 | 6.1 | 5.0 | **4.3** |
| JA | 8.1 | 6.9 | 6.3 | **5.4** | 6.2 |
| ZH | 4.9 | 4.0 | 3.6 | **3.1** | 3.6 |
| **CoVoST2** | | | | | |
| DE | 4.5 | 2.4 | 2.9 | 2.1 | **1.9** |
| JA | 5.7 | 4.8 | 4.5 | **4.0** | **4.0** |
| ZH | 2.3 | 1.9 | 1.8 | **1.6** | **1.6** |

## Abstract

English workplace requests often omit relationship information needed for pragmatically appropriate Vietnamese person reference and politeness. We evaluate translations generated with and without explicit sender–recipient profiles for 30 requests using two large language models (LLMs), Gemini 3.5 Flash and SEA-LION, with judgments from two native speakers of Vietnamese. Two native speakers of Vietnamese judged whether translations were correct and natural and whether they suited the displayed relationship. Adding profiles produced no statistically detectable overall improvement in appropriateness; translations generated without profiles already received high ratings. In a prespecified role-reversal evaluation, the same translations were judged first under their intended hierarchical relationships and later under reversed relationships. All 20 Gemini translations generated with profiles were judged appropriate under the intended relationship, compared with four after reversal; SEA-LION's result was inconclusive. A post-hoc side-by-side comparison also favored Gemini's translations generated with profiles but found no detectable SEA-LION preference. These results suggest that when most translations receive positive yes/no ratings, role reversal and direct comparison can reveal differences those ratings alone miss. Fixed evaluation order and reuse of the annotators in the follow-up limit causal interpretation.

## 1 Introduction

When translating from English, the source utterance may underspecify attributes of the message sender and recipient or other contextual information needed to choose the socially and pragmatically appropriate forms in the target language (Vincent et al., 2022). In Vietnamese, the relationship between the interlocutors can affect how speakers refer to themselves and address others through pronouns, kin terms, names, titles, or status terms (Sidnell and Shohet, 2013). These contexts can also affect politeness and deference marking through particles such as *dạ* and *ạ* (Sidnell and Shohet, 2013; Nguyen and Ho, 2013). A machine translation (MT) output can preserve what is being requested and be grammatical, yet use unsuitable forms of address, a mismatched level of formality, or an inappropriate way of making the request for that relationship. Evaluation without relationship information cannot directly assess this fit.

Vu et al. (2024) test a translation model that also predicts which source expressions refer to the same entity. Their English-to-Vietnamese evaluation targets the distinction between inclusive *we* (*chúng ta*) and exclusive *we* (*chúng tôi*), a distinction absent in English. On 173 cases, pronoun-translation accuracy was 18.50% for their coreference-aware Trans+Coref model, versus 12.71% for Base Doc and 14.45% for G-Transformer. Base Doc is their Transformer baseline trained on multiple sentences; G-Transformer is a document-level comparison model that incorporates context in its encoder. These are systems from the cited study, not our profile-free BASE condition. Even with context, most targeted pronouns were translated incorrectly.

Workplace requests are messages asking someone to carry out a work-related action. They provide useful test data for evaluating English-to-Vietnamese pragmatic appropriateness because workplace roles allow sender–recipient relationships to be defined explicitly. A Vietnamese role-play study associated relative power with request-strategy and address-term choices (Nguyen and Ho, 2013). A dyadic profile describes the message sender, recipient, and their relationship; here, the profiles represent synthetic workplace scenarios. To our knowledge, this is the first direct test of whether English-to-Vietnamese MT outputs generated from explicit workplace sender–recipient profiles fit their

intended relationships.

We study 30 English workplace requests in three relationships: junior-to-manager (*upward*), manager-to-junior (*downward*), and equal rank (*peer*). For Gemini and SEA-LION, BASE generates a translation without sender–recipient profiles; DYAD adds the intended profiles; and SWAPPED generates a new translation after the roles are exchanged. Google Translate supplies a BASE-only conventional MT comparison.

Two native speakers of Vietnamese completed two passes. Without profiles, they judged *acceptability*: whether a translation was correct, natural, and preserved the requested meaning and action. With profiles visible, they judged *pragmatic appropriateness*: whether its wording suited the displayed relationship. Each hierarchical DYAD translation was then judged in a later task with the roles reversed, keeping the Vietnamese text unchanged. This differs from SWAPPED, which generates a new translation. In an explicitly post-hoc follow-up, the same annotators compared 58 displayed BASE–DYAD pairs side by side.

In this paper, we address the following research questions:

**RQ1.** Does providing explicit sender and recipient role information in the prompt improve pragmatic appropriateness in English-to-Vietnamese machine translation output?

**RQ2.** For hierarchical cases, how does the judged pragmatic appropriateness of a realized DYAD translation change when the same Vietnamese text is evaluated under its intended sender–recipient profiles versus the reversed profiles?

**Contribution.** We provide a two-stage human-evaluation protocol and a fixed-translation role-reversal test that distinguish translation acceptability from relationship-dependent fit.

**Main findings.** The clearest result from the pre-specified analyses was Gemini's fixed-text contrast: 20/20 appropriate under intended profiles versus 4/20 under later reversed profiles (Holm-adjusted $p = .00006104$). The text stayed unchanged, but intended profiles were always rated first. SEA-LION's contrast was inconclusive. RQ1 detected no overall improvement from adding profiles. Post-hoc, 41/44 choices between Gemini translations favored DYAD: 18/20 for one annotator and 23/24 for the other. These are individual preferences, not 44 independent source pairs. Neither SEA-LION test detected a preference.

## 2 Related Work

### 2.1 Vietnamese person reference and social relations

Vietnamese person reference forms an integrated relational system encompassing pronouns, kin and status terms, names, titles, and zero reference (Sidnell and Shohet, 2013; Ton, 2018). These choices depend on the speaker's attributes and the relationship between participants, including age, status, closeness, stance, and the activity (Sidnell and Shohet, 2013; Ton, 2018). Even in a two-person conversation, how each person refers to themselves may depend on different factors from how they address the other. Equal rank does not determine a single neutral form of address: choices can express closeness, distance, or mutual respect, or temporarily downplay hierarchy (Sidnell and Shohet, 2013).

The relationship also affects how a request is phrased. In Vietnamese role-play data, equal-power speakers used imperatives more often, while lower-to-higher requests favored *query-preparatory forms*: questions about the conditions for carrying out an action, such as ability or willingness. Address terms, honorific elements, and modal particles were also common (Nguyen and Ho, 2013). An indirect request is not automatically more appropriate than a direct one; an imperative can suit the relationship when its wording and forms of address fit the context. Speakers may omit explicit person reference when context makes clear who is meant, but omission can still create ambiguity or sound rude (Ton, 2018).

These choices pose a translation problem when English leaves participant roles unstated: the Vietnamese translation must still suit the intended interaction, whether person reference is explicit or omitted. Preserving the requested action and grammaticality alone therefore does not ensure an appropriate form of address or request. The English wording may nevertheless hint at a relationship, so missing explicit roles should not be treated as an absence of relationship cues (Vincent et al., 2022).

### 2.2 Pragmatics and context in machine translation

MT studies use different kinds of context. Document-context models use surrounding sentences or information about expressions that refer to the same entity. In English-to-Vietnamese translation, such models can improve BLEU (Bilingual Evaluation Understudy), which measures word-

sequence overlap with reference translations, while remaining weak on distinctions such as inclusive versus exclusive *we* (Vu et al., 2024). Other work supplies speaker or addressee attributes directly, including gender, number, or desired formality. These attributes can control socially or grammatically marked wording but can also introduce unwanted changes (Vincent et al., 2022). English-to-Vietnamese neural machine translation (NMT) has likewise used formal and informal labels, with contrastive data containing person-reference and deferential markers (Vakharia et al., 2023). In these settings, however, the desired attribute is specified directly rather than inferred from a workplace relationship.

Other approaches condition translation on a speaker's identity or on instructions about audience, purpose, and tone. Speaker-conditioned English-to-Japanese models improved some pronoun and sentence-final-particle choices but not honorific accuracy in a small manually evaluated subset; honorific choices depend on the speaker–hearer relationship, not just the speaker (Nagato and Matsuzaki, 2025). Translation guided by audience, purpose, tone, or setting can also receive human judgments that differ from general automatic metrics (Kayano and Sugawara, 2025). A recent preprint extends instruction-conditioned translation to broader audience and intent adaptation (Merx et al., 2026). Our DYAD condition instead supplies factual descriptions of both workplace participants. We distinguish generating a new translation after role reversal (SWAPPED) from judging the original DYAD translation under a reversed displayed relationship.

### 2.3 Human evaluation of pragmatic translation

General translation quality and fit to a specific relationship are different questions. Human document-level MT evaluation has assessed pronouns, titles, honorifics, social relationships, and style, while also finding disagreement among professional annotators (Kim, 2025). Human rankings for a specified translation purpose can differ from rankings based on a general automatic metric (Kayano and Sugawara, 2025). PhoMT is a Vietnamese–English parallel dataset and MT benchmark (Doan et al., 2021). In its human evaluation, three Vietnamese annotators compared anonymously presented, shuffled translations; the study reported agreement before discussion and then resolved disagreements. Its best-translation task did not separately assess social context. Work on formality control also supports evaluating meaning preservation, fluency, and the targeted social dimension separately rather than combining them in one score (Niu et al., 2018).

| Source-form stratum | Up | Down | Peer | Total |
|---|---|---|---|---|
| Imperative/direct | 3 | 4 | 3 | 10 |
| Modal/query-preparatory | 3 | 3 | 4 | 10 |
| Elaborated/mitigated | 4 | 3 | 3 | 10 |
| Total | 10 | 10 | 10 | 30 |

Table 1: Purposive allocation of source requests across operational source-form strata and relationship directions.

## 3 Experimental Design

### 3.1 English source requests

We selected 30 workplace requests from the Enron Email Corpus (Klimt and Yang, 2004). Candidate discovery used a pinned revision of the `corbt/enron-emails` dataset.[1] Selection was manual and purposive. Each request had to contain one reasonably clear request head act (the clause or phrase performing the request), be comprehensible without its email, omit personal information and opaque references needed for interpretation, fit the controlled workplace relationships, and fill one of three ten-item surface-form quotas. The private source inventory records the final English texts, operational strata, and assigned relationship directions, but not record keys, source spans, checksums, or the intermediate candidate pool. Candidate discovery and source-span verification cannot be replayed from it.

The requests were grouped by their surface form: ten were imperative or direct, ten used modal or query-preparatory forms, and ten were more elaborated or heavily mitigated. These groups were used to balance the dataset; they are not independently validated pragmatic-strategy labels. We assigned ten requests to each relationship direction and kept the three groups approximately balanced across directions (Table 1). These directions were created for the experiment and do not represent the relationships between the original Enron senders and recipients. Assigning synthetic relationships does not establish that the English requests lack implicit relationship cues.

[1] https://huggingface.co/datasets/corbt/enron-emails/tree/cfc06c758093d90993abce1a43668fb7357258a6

### 3.2 Social profiles and relationship directions

The participant profiles were constructed for the experiment rather than recovered from the original emails. In every scenario, both participants were described as 30-year-old Vietnamese women employed by the same company. They knew each other professionally but were not relatives or personally close, and their interactions were ordinary workplace exchanges. Holding age, gender, employer, and familiarity constant made organizational role the primary profile difference. The experiment therefore does not test the effects of age, gender, or intimacy.

The relationship scenarios were formed as follows: an upward relationship designated a junior analyst as sender and a department manager as recipient. The downward relationship reversed these roles, with a department manager sending a request to a junior analyst. The peer relationship paired an analyst in Team A with an analyst in Team B at the same organizational level. The sample comprised ten upward, ten downward, and ten peer source scenarios.

In the DYAD condition, the model received the intended sender and recipient profiles. In the SWAPPED condition, the two workplace roles were exchanged and the model generated a new translation of the same English request based on the modified profiles. For hierarchical scenarios, this reversed the relationship direction; for peer scenarios, it exchanged the team labels without changing rank. The latter served only as a stability control. All other profile fields remained unchanged.

### 3.3 Systems and prompting conditions

We evaluated two LLMs and one conventional MT baseline; all 210 selected outputs were generated on July 20, 2026 (UTC). Gemini used the `v1beta` `generateContent` API with identifier `gemini-3.5-flash`, pinned catalog version `3.5-flash-05-2026`, temperature 0, and a 1,024-token limit. SEA-LION ran locally through Ollama as `aisingapore/Qwen-SEA-LION-v4-32B-IT:latest`, with temperature 0, `num_predict=1024`, `num_ctx=4096`, seed 42, and streaming disabled. A July 29 registry lookup described the mutable tag as a Qwen3 model with 32.8 billion parameters, stored in GGUF, a model-weight file format, with the Q4_K_M quantization setting. Because the lookup occurred after generation, it does not verify the checkpoint used at execution. Google Translate used `googletrans` 4.0.2 against the recorded `translate.googleapis.com` endpoint for `en–vi` and exposed no decoding controls. Both LLMs produced BASE, DYAD, and SWAPPED outputs; Google Translate produced BASE only.

The preserved prompt templates and request records show what information was sent in the user and system messages. Gemini BASE used one translation-only user instruction plus the source; DYAD and SWAPPED added the complete speaker, addressee, and directed-relationship profiles to that message, with no system message. SEA-LION used a professional-translator system message and the source as the user message, adding the complete social context to the system message for DYAD and SWAPPED. Google Translate received the byte-identical source with `en`/`vi` language codes and no social context. Every rendered prompt is retained in the private records.

Automatic SDK/client retries were disabled. The runner selected the first fully validated output, preserved failures, and reused validated outputs on rerun; invalid generations were rejected, not repaired. The default allowed at most five attempts per run with exponential backoff, but attempts accumulated across runs. Invocation commands and attempt overrides were not recorded. Source bytes and profiles remained fixed, and selected provider text was retained verbatim without manual editing.

### 3.4 Output inventory

The inventory comprised 210 generated records: 90 per LLM (30 in each condition) and 30 Google Translate BASE records. The 60 SWAPPED records are included in this total.

Each annotator evaluated 210 outputs plus 15 hidden repeats in each of two main passes: 225 items per pass and 450 presentations, each eliciting one judgment. The 40 fixed-text counterfactual presentations brought the primary-experiment total to 490 judgments per annotator. The post-hoc preference task added 58 displayed pairs, bringing the total to 548 judgments per annotator; two additional identical pairs were structural ties and were not presented.

## 4 Human Evaluation

### 4.1 Annotators and adjudication

Two native speakers of Vietnamese, identified as A1 and A2, independently annotated every item. Both completed secondary schooling in Vietnamese,

held bachelor's degrees in computing-related fields, had Vietnamese-NLP experience through coursework, research, or development, and met at least B1 English on the Common European Framework of Reference for Languages (CEFR); neither reported formal linguistics training. Recruitment used personal and professional CS/AI/NLP networks; B1 English was required and Vietnamese-NLP experience preferred. The main-task agreement estimated approximately 5–10 hours in flexible 45–60-minute sessions. Each primary annotator received USD 110 for the main task; follow-up compensation was set at an additional USD 20 for 58 comparisons (USD 130 in total per annotator). A Vietnamese-speaking NLP researcher served as the expert adjudicator (ADJ) but did not complete the full task. ADJ reviewed all disagreements and all CANNOT ASSESS or TECHNICAL PROBLEM responses. For each reviewed judgment, ADJ saw both annotators' original responses, any reasons, the English source, the Vietnamese translation, and the displayed relationship; provider, model, and condition remained hidden. Comparable recent work used one native-speaker annotator per target language (Merx et al., 2026); here, two independent primary annotators covered every item, enabling agreement and rater-specific sensitivity analyses.

ADJ assigned a separate final outcome and rationale to each flagged acceptability or pragmatic-appropriateness judgment, retaining both annotators' original responses. Reliability used the original responses; the research-question analyses used the final outcomes.

### 4.2 Main two-stage task

The main task was divided into two complete passes over the translation set. In the first pass, annotators evaluated every English source request and Vietnamese translation without seeing the system, generation condition, or sender–recipient profiles. They judged whether the Vietnamese was a correct and natural translation that preserved the main meaning and requested action. We refer to this first-pass judgment as *acceptability*. A NO response could therefore indicate either a meaning error or unacceptable Vietnamese wording; the combined question did not distinguish between these causes. The entire first pass was submitted and locked before the second pass began.

In the second pass, the same English requests and Vietnamese translations were presented again, this time with the complete sender and recipient profiles. Annotators then judged whether each translation was socially and pragmatically appropriate for the displayed workplace relationship. For SWAPPED outputs, the displayed profiles were the exchanged profiles supplied at generation. Thus, context was absent throughout the first pass and available throughout the second; the two judgments were not elicited sequentially within a single presentation.

| Task | Substantive responses | Special responses |
|---|---|---|
| Main acceptability and pragmatic appropriateness; counterfactual appropriateness | YES; NO | CANNOT ASSESS; TECHNICAL PROBLEM |
| Post-hoc preference | A better; B better; no preference | CANNOT ASSESS; TECHNICAL PROBLEM |

Table 2: Response options as displayed to annotators. A/B are blinded translation labels, mapped to BASE/DYAD for analysis.

Table 2 lists the available responses for each task. In both main passes, CANNOT ASSESS and TECHNICAL PROBLEM required a short reason, whereas reasons for YES and NO were optional. We treated CANNOT ASSESS as missingness rather than as a midpoint or negative judgment. In our terminology, a *main-task item* is one source–translation pair scheduled in both passes, a *presentation* is one display of that item in one pass, and a *judgment* is one response to the evaluation question asked in that pass.

The deployed guides instructed annotators to use native-speaker judgment and did not impose automatic accept/reject rules for neutral wording, omitted address or person reference, ellipsis, imperatives, or overt hierarchy marking.

### 4.3 Fixed-translation counterfactual evaluation

For each of the 20 hierarchical sources, the task reused one DYAD translation from each LLM. Each annotator judged these 40 translations under reversed roles, without changing the Vietnamese text. Peer cases were excluded because exchanging equal-rank team labels does not reverse a hierarchy.

Intended-profile ratings came from the main appropriateness pass; reversed-profile ratings came from a later task. Intended ratings always came first, with at least 20 intervening presentations between

paired ratings. Because displayed profiles and evaluation timing changed together, memory, learning, fatigue, threshold drift, and demand effects remain possible. BASE outputs were not reversed.

Unlike SWAPPED, this task generated no new translations. It cannot establish the effect of profile prompting on generation or reveal the model's reasoning.

### 4.4 Randomization and quality control

The provider, model, and generation condition remained hidden throughout annotation and adjudication. A1 and A2 received independently randomized item orders; within each annotator, both main passes used the same 225-item order. The schedule also placed at least 20 intervening items between original-role and SWAPPED outputs of the same source and between an original item and its hidden repeat. Fifteen scheduled items were duplicated without identification; each appeared in both passes, producing 15 original–repeat comparisons per construct and annotator. We define within-annotator consistency as the exact-category match rate on these original–repeat pairs.

## 5 Statistical Analysis

### 5.1 Analysis scope and inferential approach

Our paired analyses concern these 30 selected requests, the generated translations, and the annotation procedure used here, not broader populations of languages, speakers, or model outputs. RQ1 and RQ2 use the prespecified exact McNemar test at $\alpha = .05$. Source-pair percentile-bootstrap intervals (Efron, 1979) describe effect magnitude; the exact tests determine statistical significance. Non-significance is not evidence of equivalence or no effect.

As prespecified, we repeated RQ1 and RQ2 separately using each annotator's original judgments, with the same exact tests and Holm families. These sensitivity checks assess dependence on adjudication without pooling the two annotators' responses.

### 5.2 Reliability

Inter-annotator reliability was calculated before adjudication and separately for acceptability, pragmatic appropriateness, and counterfactual pragmatic appropriateness; the three judgment sets were not pooled. Hidden repeats were excluded from the inter-annotator calculations. For each judgment set, we report raw agreement across all four response categories, raw agreement and Cohen's $\kappa$ (Cohen, 1960) on the YES/NO subset, and, on the same YES/NO subset, prevalence- and bias-adjusted kappa, PABAK $= 2p_o - 1$. Because $\kappa$ is sensitive to response prevalence, it is interpreted alongside raw agreement and PABAK (Byrt et al., 1993), with a prevalence warning when the pooled proportion of YES responses is at least .90.

We obtained 95% confidence intervals (CIs) for raw agreement, $\kappa$, and PABAK from 2,000 item bootstraps (seed 20260718). For each statistic, bootstrap samples in which it was undefined were excluded from its interval calculation and counted. The interval limits were the 2.5th and 97.5th percentiles of the remaining estimates. Within-annotator consistency used the 15 hidden original–repeat pairs for each main construct. The prespecified rule required PABAK $\geq .60$ and raw YES/NO agreement $\geq .80$ for both main constructs. Because PABAK $= 2p_o - 1$, these thresholds are equivalent on the same binary pairs; both are retained. No counterfactual threshold was prespecified.

### 5.3 RQ1: BASE–DYAD comparison

For each LLM separately, RQ1 compares BASE and DYAD outcomes for the same source requests, giving at most 30 paired sources per comparison. The source request is the paired unit, and the analysis uses post-adjudication outcomes. We report three outcomes: acceptability, pragmatic appropriateness, and joint success, which requires both judgments to be YES. Google Translate is reported descriptively and is not part of this contrast because it has no DYAD condition.

For each outcome, we use an exact two-sided McNemar test (McNemar, 1947) on improved and worsened discordant pairs. The implementation doubles the smaller binomial tail under $B \sim \text{Binomial}(b + c, .5)$, caps the result at one, and returns $p = 1$ when $b + c = 0$. We report the paired success-rate difference, DYAD minus BASE, with a descriptive source-pair percentile-bootstrap 95% interval. Holm's step-down procedure (Holm, 1979) corrects the two LLM comparisons within each outcome family.

### 5.4 RQ2: Fixed-text fit comparison

The primary RQ2 analysis uses 20 hierarchical sources per LLM. Each pair contains two final appropriateness judgments of the same DYAD translation: one from the earlier main pass under the

intended profile and one from the later role-reversal task under the reversed profile. The paired difference is intended minus reversed. We use the same exact McNemar implementation, descriptive percentile-bootstrap interval, and two-LLM Holm family as above.

The newly generated SWAPPED outputs provide a separate descriptive check. We report their appropriateness under the exchanged profiles and whether each DYAD–SWAPPED pair contains identical text after normalization. For this text-identity check, Unicode Normalization Form C (NFC) gives canonically equivalent character sequences the same form; we then apply case folding, collapse whitespace, and remove terminal punctuation. For each LLM, we also compare the final appropriateness outcomes of the ten peer DYAD translations with their SWAPPED counterparts. This checks stability when equal-rank team labels are exchanged. These peer pairs receive no inferential test and are not pooled with the hierarchical RQ2 comparison. Outcomes by source-form group are also descriptive because each group contains only ten sources.

### 5.5 Special responses and sensitivity analysis

CANNOT ASSESS and TECHNICAL PROBLEM remain distinct. For acceptability and pragmatic appropriateness, the primary analyses exclude any comparison pair containing either response and report the number excluded.

For joint success, we first combine the two judgments for each translation. A TECHNICAL PROBLEM response takes precedence and excludes the affected comparison pair. Otherwise, a NO on either question means joint failure, even if the other response is CANNOT ASSESS. With no NO response, any CANNOT ASSESS means a missing joint outcome; two YES responses mean joint success. A comparison pair containing a missing joint outcome is excluded.

The prespecified sensitivity analysis instead treats CANNOT ASSESS as NO; TECHNICAL PROBLEM remains excluded. Holm correction is applied separately within the primary and sensitivity-analysis families. Success-rate denominators contain only YES and NO outcomes, and special responses are reported separately by system and condition.

| System | Condition | Acceptable | Appropriate |
|---|---|---|---|
| Gemini | BASE | 30/30 | 28/30 |
| | DYAD | 30/30 | 30/30 |

## 6 Results

### 6.1 Descriptive outcomes and measurement quality

Table 3 reports the post-adjudication outcomes. All 210 generated records were evaluated. Before adjudication, neither annotator selected CANNOT ASSESS; one Google Translate BASE pragmatic-appropriateness item received a TECHNICAL PROBLEM response (see Table 2 for response options). After adjudication, two final outcomes were CANNOT ASSESS, one Google Translate BASE and one SEA-LION BASE, both for pragmatic appropriateness and each arising from a YES/NO disagreement that ADJ judged not assessable; no final outcome was TECHNICAL PROBLEM. The SEA-LION BASE–DYAD pragmatic-appropriateness and joint-success comparisons consequently contained 29 paired sources, and every other RQ1 comparison contained 30. Recoding CANNOT ASSESS as failure in the prespecified sensitivity analysis did not change any inferential conclusion.

Before adjudication, raw agreement was 91.4% for acceptability, 87.1% for pragmatic appropriateness, and 80.0% for counterfactual appropriateness (Table 4). For acceptability, 95.2% of the pooled responses were YES. With YES so common, expected agreement in the kappa calculation was already 90.7%. Observed agreement was only slightly higher, at 91.4%, yielding $\kappa = .072$ despite high raw agreement. This prevalence problem (Byrt et al., 1993) is why we report kappa alongside 91.4% raw agreement and PABAK $= .829$. Both main constructs met the prespecified reliability rule. Counterfactual PABAK was .600 [.300, .850]; its interval was wide, and no threshold was prespecified for that judgment set.

Both annotators exactly reproduced 15/15 acceptability and 14/15 pragmatic hidden-repeat judgments. The primary experiment produced 980 re-

| Construct | $n_{\text{all}}/n_{\text{YN}}$ | Raw agr. [95% CI] | $\kappa$ [95% CI] | PABAK [95% CI] |
|---|---|---|---|---|
| Accept. | 210/210 | .914 [.876,.948] | .072 [-.042,.274] | .829 [.752,.905] |
| Prag. | 210/209 | .871 [.828,.919] | .370 [.180,.550] | .751 [.656,.837] |
| Counterf. | 40/40 | .800 [.675,.925] | .578 [.293,.800] | .600 [.300,.850] |

Table 4: Pre-adjudication reliability; hidden repeats excluded. Upper row: estimate; lower row: 95% CI. Raw agreement uses four categories; $\kappa$ and PABAK use YES/NO. Acceptability $\kappa$ reflects 95.2% pooled YES prevalence.

| Judgment | A1 | A2 | Neither |
|---|---|---|---|
| Acceptability | 3 | 15 | 0 |
| Pragmatic appropriateness | 15 | 10 | 2 |
| Counterfactual appropriateness | 6 | 2 | 0 |
| All reviewed cases | 24 | 27 | 2 |

Table 5: Which annotator's response matched the final outcome in the 53 adjudicator-reviewed cases. Neither denotes a final outcome matching neither original response.

sponses, including 60 hidden-repeat responses (15 items $\times$ two constructs $\times$ two annotators). The remaining 920 responses formed 460 pairs of ratings, one rating from each annotator. The annotators agreed on 407 pairs. The other 53 required adjudication: 52 involved YES/NO disagreements and one involved a special response. Table 5 shows whose response matched the final outcome.

### 6.2 RQ1 result: No aggregate gain

Adding dyadic profiles did not yield a statistically detectable aggregate improvement for either LLM (Table 6). Gemini's pragmatic-appropriateness rate increased from 28/30 (93.3%) under BASE to 30/30 (100%), a paired difference of 6.7 percentage points (95% CI [0.0, 16.7]); the two discordant pairs improved and none worsened (exact $p = .500$, Holm-adjusted $p = 1.000$). For SEA-LION, the matched rate increased from 25/29 (86.2%) to 26/29 (89.7%), a difference of 3.4 points (95% CI [-10.3, 17.2]); three pairs improved and two worsened (exact and Holm-adjusted $p = 1.000$).

Acceptability and joint success followed the same pattern; no RQ1 outcome family produced an adjusted $p$-value below .05. The positive point estimates remain imprecise, so RQ1 supports neither an aggregate gain nor equivalence.

| Outcome | $n$ | B% | D% | $\Delta$ pp [95% CI] | $b/c$ | Raw $p$ Holm $p$ |
|---|---|---|---|---|---|---|
| *Gemini* | | | | | | |
| Accept. | 30 | 100 | 100 | 0.0 [0.0,0.0] | 0/0 | 1.000 1.000 |
| Prag. | 30 | 93.3 | 100 | 6.7 [0.0,16.7] | 2/0 | .500 1.000 |
| Joint | 30 | 93.3 | 100 | 6.7 [0.0,16.7] | 2/0 | .500 1.000 |
| *SEA-LION* | | | | | | |
| Accept. | 30 | 90.0 | 96.7 | 6.7 [0.0,16.7] | 2/0 | .500 1.000 |
| Prag. | 29 | 86.2 | 89.7 | 3.4 [-10.3,17.2] | 3/2 | 1.000 1.000 |
| Joint | 29 | 79.3 | 86.2 | 6.9 [-10.3,24.1] | 4/2 | .6875 1.000 |

Table 6: Paired RQ1 comparisons. B/D: BASE/DYAD percentages; $\Delta$ =D–B; $b/c$: improved/worsened. CIs: descriptive percentile bootstraps. Exact McNemar $p$-values: upper row, raw; lower row, Holm-adjusted within outcome.

### 6.3 RQ2: Gemini fixed-text contrast

Under the sequential fixed-text evaluation, Gemini's realized DYAD outputs showed a large intended-versus-reversed fit contrast (Table 7). All 20 were appropriate under their intended hierarchical profiles, whereas 4/20 remained appropriate when the same text was later evaluated under reversed profiles. The paired difference was 80 percentage points (descriptive 95% bootstrap interval [60, 95]); 16 pairs were intended-only and none reversed-only (exact $p = .00003052$, Holm-adjusted $p = .00006104$).

For SEA-LION, 17/20 translations were appropriate under intended profiles and 13/20 under later reversed profiles, a difference of 20 points (descriptive 95% bootstrap interval [5, 40]). Four paired differences were positive and sixteen were zero; an all-zero bootstrap resample has probability $(16/20)^{20} = .0115$, so the descriptive percentile interval begins at 5 points. The prespecified exact McNemar test was nonsignificant (raw and Holm-adjusted $p = .125$) and controls the conclusion; the SEA-LION evidence remains inconclusive.

Pre-adjudication rater-specific checks retained the conclusions: no RQ1 contrast was Holm-significant (minimum adjusted $p = .500$ for A1 and $p = .250$ for A2); RQ2 remained detectable for Gemini ($p = .00006104/.00001526$) but inconclusive for SEA-LION ($p = .375/.2266$) for A1/A2, respectively.

| Measure | Gemini | SEA-LION |
|---|---|---|
| Paired sources $n$ | 20 | 20 |
| Appropriate, intended | 20/20 | 17/20 |
| Appropriate, reversed | 4/20 | 13/20 |
| Difference (pp) | 80 | 20 |
| 95% CI (pp) | [60,95] | [5,40] |
| Intended-only | 16 | 4 |
| Reversed-only | 0 | 0 |
| Raw $p$ | .00003052 | .125 |
| Holm $p$ | .00006104 | .125 |

Table 7: Sequential fixed-text RQ2 comparison. Intended judgments preceded reversed judgments; BASE was not reversed. Differences are intended minus reversed; intended-only and reversed-only count discordant pairs. CIs are descriptive percentile bootstraps; exact McNemar tests determine inference.

### 6.4 Secondary diagnostics

Under their exchanged profiles, 20/20 hierarchical SWAPPED outputs from Gemini and 15/20 from SEA-LION were pragmatically appropriate. The two normalized texts differed in every hierarchical DYAD–SWAPPED pair for both systems. Among peer pairs, they differed in 6/10 Gemini pairs and 4/10 SEA-LION pairs; nevertheless, all ten peer pairs for each system retained the same positive pragmatic outcome across conditions. In the supplementary BASE–DYAD identity check, the normalized texts differed in all 30 Gemini pairs and 28/30 SEA-LION pairs; the two identical SEA-LION pairs were peer scenarios. These diagnostics are descriptive: textual difference is neither sufficient evidence of pragmatic adaptation nor a substitute for the fixed-text RQ2 contrast.

Outcomes by source-form stratum were also descriptive. Gemini's two BASE pragmatic failures both occurred among elaborated or heavily mitigated requests (8/10 BASE versus 10/10 DYAD); its direct and modal strata were 10/10 in both conditions. SEA-LION's BASE and DYAD counts were 8/10 versus 9/10 for direct requests, 9/10 versus 10/10 for modal requests, and 8/9 versus 8/10 for elaborated requests. These groups are too small to support inferential claims about source form.

## 7 Post-Hoc Preference Experiment

### 7.1 Design and analysis

This post-hoc exploratory follow-up was designed after the frozen binary analysis. It tested whether direct comparison could reveal relative differences not distinguished by the high binary appropriateness rates. It complements rather than replaces the main-study results.

**Materials.** The experiment reused the exact frozen BASE and DYAD outputs; no translations were regenerated. The comparison set contained $30 \times 2 = 60$ source–LLM pairs. Two SEA-LION pairs were identical after the normalization described in Section 5 and were recorded as structural ties without human presentation, leaving 58 displayed pairs per annotator. Google Translate, SWAPPED outputs, and counterfactual items were excluded.

**Participants.** The same two annotators, A1 and A2, independently completed the follow-up. Both had previously judged the outputs in the main task, creating the possibility of repeated-exposure effects. Their preference judgments were retained without adjudication.

**Procedure.** Each item presented the English source request, the intended sender–recipient profiles, and two translations labeled A and B. The mapping from A and B to BASE and DYAD was independently randomized for each annotator and remained hidden, as did the LLM identity. A/B position assignment was generated deterministically with seed 2026072901; presentation order used seed 2026072918 for A1 and 2026072927 for A2. Annotators selected one of the five preference responses in Table 2. A written reason was collected with each response but was not included in the quantitative analysis.

**Analysis.** We analyzed each annotator and LLM combination separately, giving four comparisons. For each, an exact two-sided binomial test compared the number of preferences for BASE with the number for DYAD, excluding no-preference and special responses. We report the DYAD proportion among these preferences, a 95% Clopper–Pearson confidence interval (Clopper and Pearson, 1934), and a Holm-adjusted $p$-value across the four tests. Agreement was calculated for BASE, DYAD, and no preference, excluding the displayed pair containing a special response. The two annotators' judgments were not pooled as 116 independent observations.

### 7.2 Preference results

Table 8 reports the annotator-specific comparisons. Both annotators' Gemini results favored DYAD after Holm correction; neither SEA-LION result did. For the special responses listed in Table 2, both annotators recorded CANNOT ASSESS for the same

| Stratum | D/B/NP/CA | D/dir. | 95% CI | Holm $p$ |
|---|---|---|---|---|
| Gemini A1 | 18/2/10/0 | 18/20 | [.683,.988] | .0012 |
| Gemini A2 | 23/1/6/0 | 23/24 | [.789,.999] | $< .0001$ |
| SEA-LION A1 | 8/7/12/1 | 8/15 | [.266,.787] | 1.000 |
| SEA-LION A2 | 11/3/13/1 | 11/14 | [.492,.953] | .1147 |

Table 8: Post-hoc BASE–DYAD preferences. D/B/NP/CA are counts for DYAD, BASE, no preference, and CANNOT ASSESS; D/dir. is DYAD/directional. CIs are exact Clopper–Pearson.

SEA-LION pair, and neither recorded a TECHNICAL PROBLEM.

### 7.3 Agreement and pair-level outcomes

A1 and A2 matched on 35/57 eligible pairs (61.4%) for the three substantive categories; one special-response pair was excluded. Across all five categories, they matched on 36/58 pairs (62.1%). In 19 of the 22 disagreements, one annotator chose BASE or DYAD while the other chose no preference; in the other three, one chose BASE and the other DYAD. None was adjudicated.

Across all 60 source–LLM pairs, the pair-level outcome breakdown was 21 unanimous DYAD, 3 unanimous BASE, 11 unanimous no preference, 19 mixed-with-no-preference, 3 direct splits, 1 unavailable special-response pair, and 2 structural ties. The module was explicitly post-hoc, was completed by the original annotators, and is interpreted separately from primary RQ1.

## 8 Discussion

Gemini's DYAD translations were appropriate under 20/20 intended and 4/20 later reversed profiles (Holm-adjusted $p = .00006104$); SEA-LION's 17/20 versus 13/20 contrast was inconclusive. The Vietnamese text stayed unchanged, but intended profiles were always rated first. The 80-versus-20-point drops do not rule out order effects that differ between systems, even though the same annotators saw interleaved items. Without reversed BASE judgments, RQ2 cannot determine whether supplied profiles, English source cues, or model defaults produced the relationship-specific wording.

RQ1's high BASE appropriateness rates left only two Gemini and four SEA-LION outputs that could improve. No overall gain was statistically detectable after Holm correction.

The explicitly post-hoc comparison supplied a complementary measurement finding: 41/44 directional choices across the original annotators' Gemini judgments favored DYAD (18/20 and 23/24; both Holm-significant), while neither SEA-LION test detected a preference. The task followed the primary analysis and reused its annotators, so this finding remains hypothesis-generating.

These findings support judging Vietnamese translations with the intended relationship visible: person reference and request wording depend on participant relations (Sidnell and Shohet, 2013; Nguyen and Ho, 2013). Our task supplies factual profiles rather than prescribed formality labels (Vakharia et al., 2023). Two translations can both fit the intended relationship yet differ in preference. Between-system differences remain descriptive because no interaction was tested.

Future work should preregister analyses, evaluate both BASE and DYAD outputs under the same fixed-text role-reversal protocol with counterbalanced evaluation order, use independent follow-up raters, and broaden the profile inventory. Comparing the reversal contrasts would help assess whether relationship sensitivity differs between translations generated with and without supplied profiles.

## 9 Conclusion

In this 30-request sample, Gemini's fixed-text DYAD outputs fit 20/20 intended versus 4/20 reversed profiles; SEA-LION was inconclusive. RQ1 detected no aggregate gain. Post-hoc, 41/44 Gemini choices favored DYAD; neither SEA-LION test found a preference. Near the upper bound, binary ratings can miss pragmatic differences.

## Limitations

This study uses 30 purposively selected short workplace requests in one translation direction, English to Vietnamese. The source-form strata provide descriptive balance; the sample is neither random nor representative. The controlled profiles cover only one scenario family: same-company, 30-year-old Vietnamese women who know each other professionally but are not personally close. The findings therefore do not generalize directly to other genres, age or gender combinations, degrees of familiarity, customer-facing relationships, languages, or model versions. The operational source-form strata were also not independently validated as pragmatic-strategy categories.

The experiment evaluates two LLMs and one conventional baseline; Google Translate was accessed through the unofficial `googletrans` interface rather than a frozen official API. With only two primary annotators, individual interpretations may strongly influence the aggregate results, so the findings should not be read as uniform Vietnamese norms. The combined acceptability question does not distinguish meaning errors from unnatural or grammatically unacceptable Vietnamese, and a negative pragmatic judgment does not identify which person-reference, register, or request-form feature caused it. Gemini did not expose an immutable checkpoint digest or provider-default decoding fields, and Google did not expose its backend model/version. The Ollama server build, exact invocation commands, and any attempt overrides were not recorded.

The BASE–DYAD comparison changes both relationship information and prompt length, so RQ1 does not isolate how context affects generation. The fixed-text RQ2 contrast avoids those generation differences but has a fixed-order limitation: intended judgments occurred in the main task before reversed judgments in a later module. Spacing was controlled, but reversal order was not randomized. Memory, learning, fatigue, threshold drift, demand effects, and module framing may contribute to the observed contrast. Because BASE outputs were not reversed, RQ2 does not estimate the causal effect of profile prompting. The original annotators also completed the post-hoc preference task after prior exposure to the outputs. Finally, RQ1 contains at most 30 pairs per LLM and RQ2 20; estimates are imprecise, and nonsignificance is not evidence of no effect.

## Ethical Considerations

Human evaluation involved two paid adult native speakers of Vietnamese as primary annotators, referred to pseudonymously as A1 and A2, and an expert adjudicator, ADJ, who served as a research contributor. Before manuscript submission, both primary annotators provided explicit written consent to research use of their completed contributions and to reporting them in an academic paper under the pseudonymous labels A1 and A2. Their judgments are reported only as aggregate or pseudonymous rater-specific summaries, and their qualifications only collectively. The task involved ordinary language judgments and did not solicit sensitive personal information. No names, contact information, item-level judgments, free-text reasons, adjudication rationales, case or presentation identifiers, timestamps, or private audit records are released.

OpenAI tools, including Codex, were used to assist with manuscript planning and organization, code development and debugging, formatting checks, and language revision. Anthropic Claude also assisted with the camera-ready revision. All AI-assisted output was reviewed and verified by the authors, who retain full responsibility for the analyses, citations, interpretations, and claims.

## A Data Availability

The research artifact is available at `https://github.com/CoolJosh0221/en-vi-dyadic-mt-artifact`. The package contains:

- the 30 selected English requests and their synthetic intended profiles;
- 199 distinct combinations of English source text, Vietnamese translation, and displayed context, covering the textual content of the 210 generated records;
- recorded generation parameters and the prompt/message structure;
- machine-readable aggregate and pseudonymous rater-specific summary tables, verification code, a manifest, and checksums.

Deduplication by source text, translation, and displayed context removes 11 duplicate entries from the 210 generated records. The package does not include the exact system/condition mapping needed to recover all 210 labeled records, or the verbatim prompt files retained privately. Its code checks inventory totals and exact-test calculations from the reported aggregate counts; it does not reconstruct those counts from item-level judgments or recompute all confidence intervals.

The primary annotators authorized research-publication use under the pseudonymous A1 and A2 labels, but public release of item-level judgments and free-text responses is outside the documented consent scope. Judgments, reasons, adjudication records, timestamps, schedules, and linkage identifiers therefore remain restricted at the item level. The intermediate source-candidate pool and record-level Enron keys, spans, and checksums remain unavailable, so candidate discovery and source-span verification cannot be replayed.

# Which Metric for Which Script? A Quantified Meta-Evaluation of Automatic Metrics and LLM Judges for Low-Resource Indic Machine Translation

## Abstract

Machine translation shared tasks publish several automatic metrics and rank systems on one of them, assuming the choice is inconsequential. We test this assumption on the WMT 2025 and WMT 2026 Low-Resource Indic Language Translation tasks, where pre-trained multilingual encoders are unavailable for several target scripts and languages. As no human gold standard evaluation exists at scale, we adapt the Quantified Reproducibility Assessment (QRA) framework across 20 WMT26 and 14 WMT25 directions, to measure agreement between six automatic metrics and two LLM judges as independent measuring instruments. We show that QRA's Type I measure fails under this repurposing when instruments sit on different scales, and suggest a rank-based repair. Using a script-controlled natural experiment (Manipuri evaluated in both Bengali and Meitei Mayek) and a null-output validity test, we observe that neural metrics inflate scores for text in scripts outside the encoder's coverage and compress it into a narrow discriminative band. Switching to Meitei Mayek raises BERTScore and COMET by 21.6 and 23.3 points, respectively, though language and content are unchanged, and no metric preserves system ranking; on degenerate output the two retain 0.81 and 0.61 points on English-to-Indic directions. The effect reverses in the opposite direction. Metric choice should follow script coverage, not language identity. Lacking human judgments, our claims concern instrument behaviour, not human preference. The code and resources are available on our Github.[2]

## 1 Introduction

Machine translation shared tasks have converged on a reporting convention: publish a table of automatic metrics, and rank participating systems on one of them. The Workshop on Machine Translation (WMT) 2025 Low-Resource Indic Language Translation task (Pakray et al., 2025, 2026) follows this convention. It reports BLEU, METEOR, TER, chrF++, BERTScore, ROUGE-L, chrF, Cosine-Similarity and COMET. WMT 2025 covered 7 language pairs, spanning 14 translation directions: Assamese, Manipuri, Khasi, Mizo, Nyishi, Bodo, and Kokborok, each paired with English. WMT 2026 covered 10 language pairs, spanning 20 translation directions: Assamese, Mizo, Khasi, Manipuri (in Bengali and Meitei Mayek scripts), Bodo, Kokborok, Karbi, Nagamese, and Tagin. Nyishi was withdrawn from the 2026 edition.

The convention carries an implicit assumption: that the metrics broadly agree, so that the choice of which to rank on is a matter of taste rather than of consequence. For high-resource language pairs, this assumption is defensible and has been extensively validated against human judgments (Freitag et al., 2021, 2022, 2023). For the languages in this task, it has never been tested. Several of them are written in scripts that appear in no major multilingual encoder's pretraining data; several have no meaningful presence in the corpora on which COMET and BERTScore were built. A metric whose backbone cannot represent the target language at all will still return a number, which will still be used to rank systems.

This paper asks what those numbers are worth. We take the WMT25 & WMT26 results table as our object of study and treat metric disagreement as the phenomenon to

[†] The first two authors made equal contributions to all aspects of the main paper; both are designated as first authors.

be measured rather than as noise to be averaged away. Meta-evaluation of MT metrics is conventionally framed in terms of correlation with human judgment. That framing requires a gold-standard, but for the languages under consideration, there is no gold-standard judgment at scale. We therefore adopt a different apparatus: the Quantified Reproducibility Assessment framework of Belz et al. (2026), which supplies a taxonomy of four result types and a matching set of continuous-valued measures reported at system, quality-criterion and study level. QRA is designed to quantify agreement between repeat measurements. We repurpose it to quantify agreement between instruments, which the International Vocabulary of Metrology explicitly licenses[3]: §3.2 lists different measuring systems we used: six metrics and two LLM judges become eight measuring systems applied to a common measurand. QRA's Type I measure, the bias-corrected coefficient of variation (CV*), presupposes that the values being compared share a scale. Metrics do not: on WMT26, BERTScore occupies an interquartile range of [81.9, 94.5] while BLEU occupies [7.4, 22.4]; on WMT25, the offset is starker still, with METEOR reported on a 0–1 scale (IQR [0.08, 0.45]) alongside BLEU on 0–100 (IQR [2.1, 13.7]). Applied naively, CV* reports catastrophic disagreement that is entirely an artefact of scale offset. We report this as a negative result, and propose a rank-based system-level measure that answers a related but distinct question.

The task design contains an unusually clean identification strategy. Manipuri is evaluated twice in WMT26, once in Bengali script and once in Meitei Mayek, with nine teams submitting to both English→Manipuri directions and eight to both Manipuri→English directions. Language, content, reference construction and system are held constant; only the orthography of the target varies. A metric that measures translation quality should be approximately invariant to this change. A metric that is in fact measuring the tractability of the target string to its own tokeniser should not be. The remaining languages supply the converse contrast: six WMT26 targets are written in Latin script and two in Bengali, so script is held constant while pretraining coverage varies. Manipuri isolates orthography at fixed language; these sets isolate language at fixed orthography. We formalise this as a coverage-tier analysis in §4.3.

A natural experiment can show that metrics disagree, and can show which of them behaves implausibly, but it cannot by itself say which is right when two metrics diverge on a specific segment. For that we turn to LLM-as-judge, applied not as a substitute gold standard but as an adjudication instrument on a targeted sample: the segments where COMET is high and BLEU is low. Such segments have two possible explanations. Either the translation is adequate but lexically, morphologically or syntactically distant from the reference, in which case BLEU is penalising legitimate variation and COMET is correct; or the translation is fluent but unfaithful, in which case COMET is rewarding surface plausibility and BLEU is correct. Distinguishing these is a well-posed question that a judge model can answer at the segment level, and it is the question our error taxonomy is built to separate.[4]

Our contributions are as follows:

- A script-controlled natural experiment showing that BERTScore and COMET inflate by over 20 points when the same language is written in a script outside the encoder's coverage, and that no metric preserves system ranking across that change.
- The first application of the QRA Type I, II and IV apparatus to an MT shared task, reported at all three of its levels.
- A documented failure of QRA Type I under cross-instrument comparison, together with a rank-based repair and a size-controlled variant.
- Evidence on discriminative power and floor behaviour: BERTScore compresses into a 12.6-point band in WMT26 while WMT25's embedding-based Cosine-Similarity is the most dispersed instrument of that year at 62.4% of its scale,

[3] https://www.bipm.org/documents/20126/2071204/JCGM_200_2012.pdf

[4] We selected our LLM-as-Judge models based on the translation accuracy of the low-resource language pair (Mni_Beng→Eng) (BLEU scores; *Gemini 3.1 Flash Lite*: 28.18, and *Claude Opus 4.8*: 27.17). Claude Opus 4.8 was the version available at selection time; Opus 5 was used for the judge runs reported below.

and the scores that all six metrics assign to output known a priori to be worthless.
- An LLM-judge adjudication of BLEU–COMET disagreement cases on English-Manipuri, distinguishing reference mismatch from genuine translation error.
- Tier-conditional recommendations for metric selection and shared-task reporting.

## 2 Related Work

### 2.1 Automatic metrics

MT evaluation splits into two lines. Surface metrics score $n$-gram overlap with a reference: BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and chrF/chrF++ (Popović, 2015, 2017). They need no target-language model, but correlate weakly with quality once systems are close (Mathur et al., 2020). Neural metrics instead score similarity in a pretrained encoder's embedding space: BERTScore (Zhang* et al., 2020) and COMET (Rei et al., 2022). WMT22 found these more reliable than BLEU and recommended dropping it (Freitag et al., 2022). Both rely on XLM-R-style encoders (Conneau et al., 2020), whose pretraining coverage is uneven across languages and scripts.

### 2.2 Meta-evaluation

WMT's Metrics Shared Task ranks metrics by correlation with expert human ratings (Freitag et al., 2021, 2022, 2023). This needs a large annotated pool, which does not exist for most languages studied here. Mathur et al. (2020) showed that correlations with human judgments depend strongly on the set of evaluated systems, limiting the usefulness of raw correlation scores alone. Quantified Reproducibility Assessment (QRA) offers an alternative by evaluating automatic metrics as measurement instruments rather than against a human gold standard. It quantifies reproducibility using metrology-inspired measures of agreement and variability between evaluation instruments (Belz et al., 2022; Belz, 2022). QRA++ extends this to a four-type taxonomy of NLP results (Belz, 2025). Both were built for repeated measurement by a single method, not for comparing structurally different instruments applied once each. No prior study has applied the QRA++ apparatus to the full metric and judgment suite of a shared task.

### 2.3 Coverage and script bias

Pretraining coverage is uneven: XLM-R performance generally correlates with the amount of pretraining data available for each language (Conneau et al., 2020). Tokeniser studies report a similar disparity at the subword level: under-represented languages and scripts often require substantially more tokens to encode the same content (Petrov et al., 2023), increasing inference costs for multilingual language models. This work explains why coverage should distort scores, but it does not measure that distortion for a metric under controlled conditions.

### 2.4 Low-resource Indic MT

NLLB (Team et al., 2022), IndicTrans2 (Gala et al., 2023) and Sarvam-translate (Sarvam AI, 2025) cover most Indic languages studied here, and shared-task systems fine-tune similar backbones. These papers report BLEU, chrF, and COMET-style scores as evidence of quality, without testing whether the metric itself is valid for the language-script pair being scored.

### 2.5 LLM-as-judge

A newer line of work scores translations by prompting a general-purpose language model rather than training a dedicated metric. GEMBA shows that zero-shot GPT prompting can achieve competitive, state-of-the-art system-level accuracy against human MQM judgments (Kocmi and Federmann, 2023). Zheng et al. (2023) study LLM judges more broadly and reports position bias, verbosity bias, and self-preference bias. These biases carry over to translation judging unless checked directly. The models used as judges, including GPT-4 (OpenAI, 2023), Gemini (Gemini Team, 2023), and Claude (Anthropic, 2024), are trained on the same skewed script distribution as the embedding encoders behind neural metrics. Whether this skew affects judge scores on low-coverage scripts remains untested.

## 3 Dataset and Instruments

### 3.1 Data Used

We use the official results of the WMT Low-Resource Indic Language Translation shared

task, WMT25 (Pakray et al., 2025) and WMT26 (Pakray et al., 2026). WMT25 covers 14 directions across 7 languages (Assamese, Manipuri, Khasi, Mizo, Nyishi, Bodo, Kokborok). It has 18 participating teams and up to 8 primary submissions per direction. Scores are reported on BLEU, METEOR, ROUGE-L, chrF, TER, and Cosine-Similarity, the last restricted to Indic→English directions. WMT26 extends the task to 20 directions across 10 languages. Nyishi is withdrawn; Karbi, Nagamese, and Tagin are added, and Manipuri is split into Bengali and Meitei-Mayek script variants (Huidrom et al., 2026). It has 24 participating teams and up to 15 primary submissions per direction. Its metric suite is BLEU, METEOR, TER, chrF++, BERTScore, and COMET, replacing ROUGE-L/Cosine-Similarity with two embedding-based metrics. Both editions report only system-level scores, split into primary and contrastive/constrained submissions per team. We experiment and report our results and analyses on the languages mentioned above.

As a special case, we choose a specific subset from the WMT 2025 test set (Pakray et al., 2025), specifically the directions of translation from and into Manipuri to English (mni→en and en→mni), in order to diagnose errors at the segment level as well as LLM-as-a-judge experiments. The only occurrence of the Manipuri language in the WMT 2025 benchmark is in the Bengali writing system. To study the effects of metric divergence along with subword segmentation and model architectures under this low-resource condition, we use the translation outputs of our competing submission pipeline, which follows the iterative back-translation and fine-tuning methodology (bt+ft+iter)[5] using subword regularization atop the IndicTrans2 multilingual backbone. Using this controlled dataset allows us to directly test LLM evaluators against surface and neural metric divergence on a real-world, highly agglutinative target language.

### 3.2 Instruments Used

The instruments used in our study can be classified into three categories:

- **Surface N-gram Metrics**: In WMT25, n-gram metrics include BLEU, METEOR, ROUGE-L, chrF, and TER, while WMT26 includes BLEU, METEOR, TER, and chrF++. These metrics measure lexical and character-level overlap with a reference string.
- **Neural Embedding Metrics**: These metrics calculate similarity in the embedding space of a pre-trained multilingual encoder. It includes metrics such as Cosine-Similarity (WMT25), BERTScore and COMET (WMT26).
- **LLM Judges**: For our segment-level diagnostics and error adjudication, we employ two cutting-edge large language models as evaluators: *claude-opus-5* and *gemini-3.1-flash-lite*.

## 4 Experimental Design

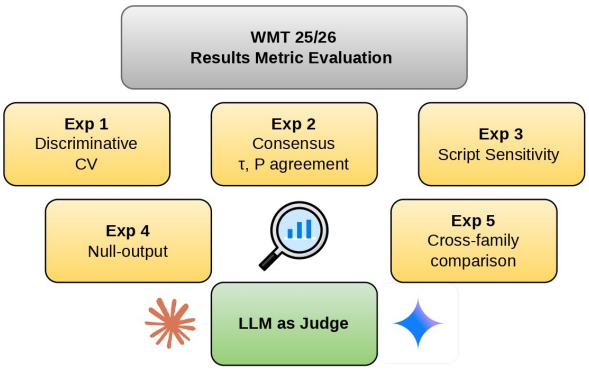

Figure 1: Overview of WMT 2025/2026 results metric evaluation experiments.

We report five experiments, ordered by the strength of the claim each can support as presented in Figure 1. Experiments 1 (§4.1) and 2 (§4.2) establish what the instruments do relative to one another: whether each can separate systems at all (Type I), and how far each agrees with the consensus of the rest (Types II and IV). Neither licenses a validity claim, since instruments may agree and be jointly wrong. Experiments 3 (§4.3) and 4 (§4.4) supply that validity anchor without human annotation, by constructing conditions in which the correct answer is known in advance, a script change that should leave scores invariant, and degenerate output that should score near zero. Experiment 5 (§4.5) then adjudicates the residual: for segments where two metrics diverge

[5]bt: back translation, ft: forward translation, iter: iterative pseudo labelling

and neither prior construction applies, we ask a second instrument family which of them is right.

### 4.1 Experiment 1: Discriminative power (Type I over systems)

An instrument with a negligible spread across systems cannot support a ranking, however well it correlates with anything else. Experiment 1 therefore precedes all correlation analysis: it asks whether each instrument separates the objects of measurement at all.

For each language pair we compute CV* of each instrument across systems, together with the observed range and the effective number of distinct values, aggregated at the quality-criterion and study levels. Alongside this we report the rank-based Type I of §A.2 in the QRA3 template at the system, quality-criterion and study level, together with its size-controlled variant, in which each pair is subsampled to a fixed $K$ systems over $B$ draws (§A.2, Size Control; §A.3) so that dispersion is comparable across pairs of unequal size. For the system-type analysis supporting Narrative (b), CV* over instruments is additionally grouped by the taxonomy, quantifying how far a system type's standing depends on which instrument is chosen.

TER is unbounded above, and its cross-system CV* is inflated accordingly; we report it with that caveat rather than reading it as discriminative strength.

### 4.2 Experiment 2: Consensus centrality (Types II and IV)

Experiment 2 asks which instruments agree with the consensus of the others, and where that agreement breaks down.

For each language pair we compute all pairwise $r$, $\rho$ and $\tau_b$ between instruments, Kendall's $W$ over the full instrument set, and $P$ over all instrument pairs (§A.1 Measures). A leave-one-out summary reports, for each instrument, its mean $\tau_b$ and mean $P$ against the remaining instruments. Results are given at the quality-criterion and study level (Table 4), and computed separately for metrics alone and for metrics together with the judge scores. We additionally test whether concordance varies with task difficulty, by regressing quality-criterion-level $W$ on mean BLEU, and with the number and diversity of entrants.

We report $r$, $\rho$ and $\tau_b$ jointly rather than selecting one, following the rationale of Belz and Thomson (2026) that the three afford different perspectives on the same set of scores. This is not a formality on these data: we observe language pairs in which a single outlier system sustains a near-perfect Pearson correlation between two instruments whose rank agreement is approximately zero from this experiment.

### 4.3 Experiment 3: Script sensitivity and coverage tiers

Experiment 3 is the paper's identification strategy. It asks whether instrument scores are driven by translation quality or by whether the target script falls within the instrument's pretraining coverage, and it does so by exploiting a natural experiment embedded in the task design.

Manipuri is evaluated in two scripts, Bengali and Meitei Mayek, with nine (En→Mni) and eight (Mni→En) systems submitted per script. Since only orthography varies across these paired subsets, a valid metric should score them equally; deviation signals an instrument artefact, not a quality difference, giving a validity test that requires no human annotation.

For each paired system we compute the per-instrument score shift, Meitei Mayek minus Bengali, with bootstrap intervals on the mean shift (Table 5), and for each instrument the Kendall $\tau_b$ between its rankings of the paired systems under the two scripts. The Manipuri-to-English direction serves as a control: the output language is English in both conditions, so shifts should be markedly smaller there than in the English-to-Manipuri direction. An instrument that fails this control is unstable for reasons beyond target-script coverage, and we report such failures separately. §4.2 and §6.1 provide insights into the data used and the impact of script coverage bias, particularly for the Manipuri language, including a discussion of any expected or significant discrepancies related to script coverage.

### 4.4 Experiment 4: Null-output validity testing

Experiment 4 supplies a second validity anchor from a second class of cases in which the cor-

rect answer is known *a priori*. Where Experiment 3 fixes quality and varies script, Experiment 4 fixes the verdict, the output is worthless, and asks what each instrument returns. More details in Appendices D and E.

We identify degenerate primary submissions, defined as those scoring BLEU $\leq 1.0$, a set that includes empty outputs, wrong-script outputs and outputs in the wrong language. For each instrument we report its floor over this set and the *floor-inflation ratio*: the instrument's score on the degenerate system divided by its score on the top-ranked system in the same language pair, with bootstrap intervals (Table 6). The analysis is framed as a one-sided test against the null that the instrument score is independent of the degenerate-competent distinction.

An instrument whose floor sits close to its ceiling cannot support absolute quality claims even where its rankings remain serviceable. We report this distinction of rank-preserving but not scale-meaningful explicitly in this paper.

### 4.5 Experiment 5: Cross-family comparison and adjudication

Experiments 3 and 4 establish that certain instruments behave implausibly under constructed conditions. They do not determine which instrument is correct on an ordinary segment where two diverge. Experiment 5 addresses that question on a targeted sample, using the judge protocol of §4.6.

We compute the Type II and Type IV apparatus across instrument families, as set out in Table 7. Between the n judges we report Kendall's $\tau_b$ and $P$ on each scalar criterion at segment level; with $k = 2$, Kendall's $W$ reduces to a function of Spearman's $\rho$, which we report in its place. Cohen's $\kappa$ between judges on the error-type label constitutes the only Type III (§A.1, Measures) result in the paper. Type I is computed as CV* between judges on each scalar criterion, per segment and aggregated to criterion and study level, reported with bootstrap intervals given the noise inherent at $n = 2$.

### 4.6 LLM-as-judge protocol

To better understand the divergence between COMET and n-gram overlap-based metrics such as BLEU, we conduct a qualitative analysis using an *LLM-as-a-Judge* framework. Specifically, we evaluate individual test examples to characterize the nature of the translations produced by our systems. The LLM is prompted to assess each translation along three dimensions: *adequacy*, *fluency*, and *semantic equivalence* with respect to the reference translation. Beyond these evaluation criteria, the judge is also instructed to identify and categorize *errors* in the system output into five predefined classes: *lexical variation*, *word-order variation*, *morphological variation*, *named-entity variation*, and *genuine meaning error*. For each identified error, the LLM additionally provides a *confidence* score and a *textual rationale* explaining the assigned error category. This analysis allows us to distinguish cases where metric discrepancies arise from linguistic variation from those that reflect genuine semantic errors.

We use *claude-opus-5* and *gemini-3.1-flash-lite* for our experiments. The prompts used for this experiments can be seen in appendix 21.

## 5 Results & Analysis

### 5.1 Experiment 1: Discriminative Power (CV*)

Table 3 shows a consistent pattern across both years: surface n-gram metrics (BLEU, ROUGE-L, METEOR) reach CV* (lower the better) of 44–74%, while embedding-based metrics compress this spread sharply. BERTScore and COMET fall to 6.5% and 17.4% in WMT2026, and Cosine-Similarity to 40.7% in WMT2025.

This gap widens further on the lowest-resource, script-uncovered pairs (e.g. English→Kokborok, BLEU CV* = 162.46%, $n$=2 systems), a pattern Experiment 3 examines directly by coverage tier. At the WMT2026 category level, Category 2 systems get a higher CV* than Category 1 for every instrument except TER, and BERTScore stays flat across categories, so its low discriminative power is not category-specific. Several WMT2025 pairs have only 2–3 systems, widening their Confidence Interval(CIs), so study-level numbers are more reliable than individual QC-level cells. Overall, BLEU-family metrics separate systems most in both years,

while BERTScore/COMET's low CV* raises the RQ1 concern that neural metrics may lack the spread needed for fine-grained ranking in this setting.

### 5.2 Experiment 2: Consensus Centrality

Table 4 shows TER as the least central instrument in both years, well behind the rest. In WMT2026, chrF++ is most central and every other instrument, including BLEU and the neural metrics, is significantly less central after Holm correction ($p_{\text{adj}} < 0.05$).

In WMT2025, Cosine-Similarity ranks highest, but with only 2–9 systems per pair (several pairs at just 2–3), none of the top four instruments differ significantly from one another.

Figure 2 confirms TER correlates weakest with every other instrument in both years ($\tau_b$ 0.59–0.65 in 2026, 0.63–0.76 in 2025), while WMT2026's chrF++/BERTScore/COMET and WMT2025's METEOR/chrF/Cosine-Similarity form tight clusters ($\tau_b \geq 0.85$). At the QC level, agreement drops on the lowest-resource pairs: WMT2026's English→Karbi ($W$=0.44) and English→Tagin ($W$=0.54) are weakest, and two WMT2025 pairs (Bodo→English, Kokborok→English) have too few systems for $W/P$ to be computed. Instrument agreement is high overall (median $\tau_b > 0.8$), with TER as the only consistent outlier across both datasets.

### 5.3 Experiment 3: Script Sensitivity and Coverage Tiers

Table 5 shows that the script effect is significant only for some instruments and flips direction between the two translation directions. In en→indic, BERTScore and COMET inflate Meitei-Mayek scores over Bengali (both CIs exclude 0); the lexical metrics show no significant shift. In indic→en, this reverses: BLEU, METEOR, chrF++ and COMET score Meitei-Mayek significantly lower, and TER significantly worse; only BERTScore is not significant. No instrument is script-biased in the same direction both ways. Figure 3 shows top-median inflation rising with coverage tier[6,7] for TER, METEOR and chrF++ in WMT2026, while BERTScore stays flat and low (0.9–4.2) at every tier; COMET is flat through tier 3 (1.5–4.8) then jumps to 11.1 at tier 4. BLEU peaks at tier 3 (13.1) and falls at tier 4 (9.3). WMT2025 shows no clean monotonic trend: BLEU, TER and chrF peak at tier 2 and fall at tier 4, likely because those tier-4 pairs have only 2–3 primary systems, capping the top-median gap; WMT2025 also has no tier-3 pairs, since its Manipuri is undifferentiated and assigned to tier 2. METEOR, ROUGE-L and Cosine-Similarity stay near zero across all WMT2025 tiers, but this reflects their 0–1 scale, not genuine flatness. Overall, script and coverage effects are evident for several instruments but depend on direction and year, rather than following one consistent pattern.

### 5.4 Experiment 4: Null-Output Validity

We flag primary submissions with BLEU $\leq$ 1.0 as degenerate and compute each instrument's *floor-inflation ratio*: score on the degenerate system over score on the pair's top primary system (inverted for TER), so 0 is ideal and 1 is worst. WMT26 has 16 degenerate systems across 11/20 pairs; WMT25 has 5 across 4/14 pairs. BLEU and METEOR stay near the floor in both years (ratios $\leq$0.11, Table 6), confirming surface-overlap metrics are validity-safe on null output. The worst offender differs by year and is not a fixed metric-family property: WMT26's embedding-based metrics fail most, with BERTScore (0.81) and COMET (0.61) unable to separate degenerate from top-system output, concentrated on Tier 3–4 pairs such as Manipuri (Meitei-Mayek) and Tagin (Figure 4, also see §4.4 for more details), a coverage-driven failure; WMT25 has no embedding metric, and instead TER fails worst (0.42), driven almost entirely by a single short-reference case, English→Kokborok (0.99). Since the two years share no common failing instrument, null-output inflation is instrument- and dataset-specific, and Narrative (a)'s tier-conditional recommendation should weight per-pair ratios over the study-level mean.

[6]Tier defines how well a language/script pair is represented in the pretraining data of the encoders behind BERTScore and COMET.

[7]Tier 1 = well-covered by the multilingual encoder's pretraining; Tier 4 = essentially absent from it, with Tiers 2–3 as intermediate degrees of underrepresentation.

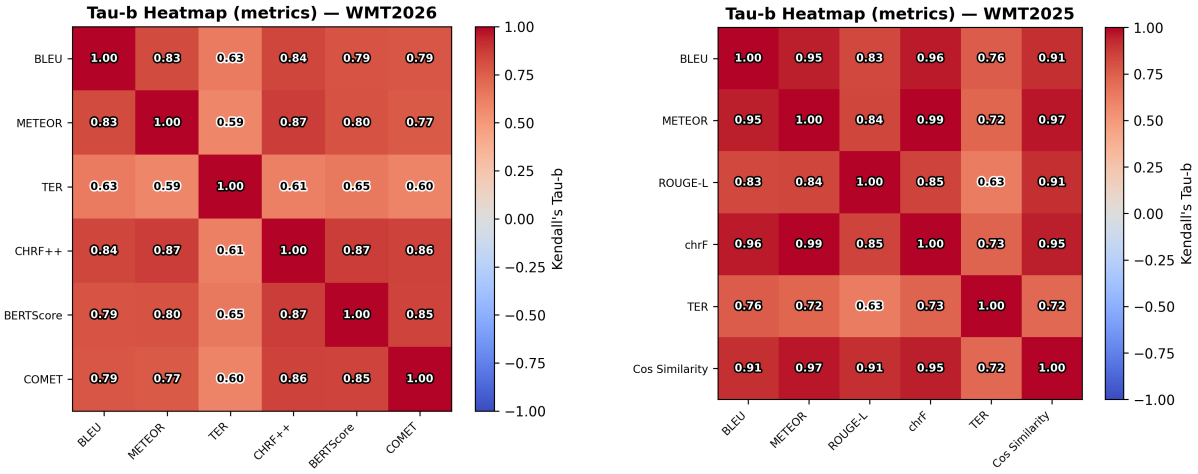

Figure 2: Instrument–instrument $\tau_b$ heatmap, metrics scope. Left: WMT2026. Right: WMT2025.

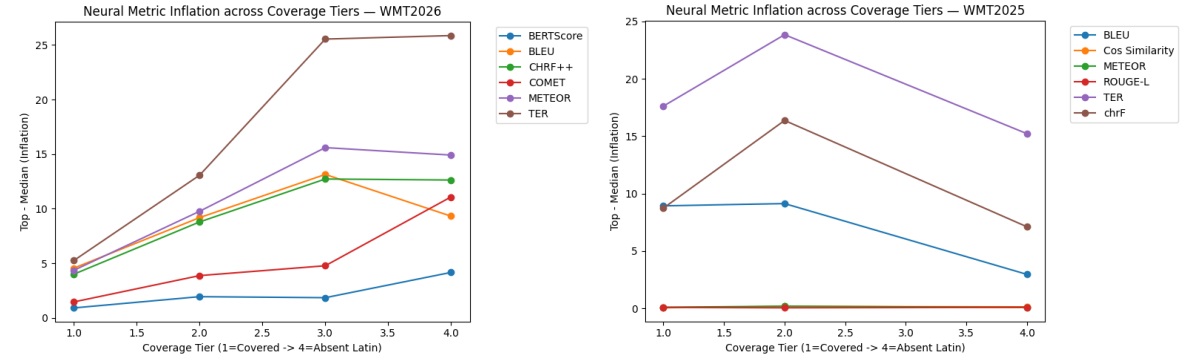

Figure 3: Top-minus-median inflation by coverage tier, all instruments overlaid. Left: WMT2026. Right: WMT2025.

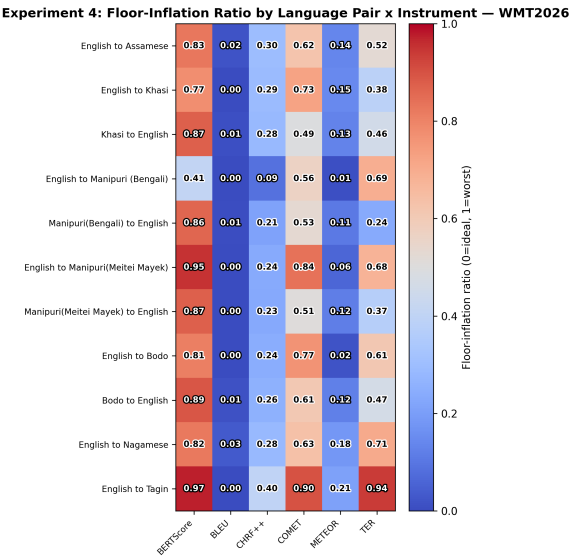

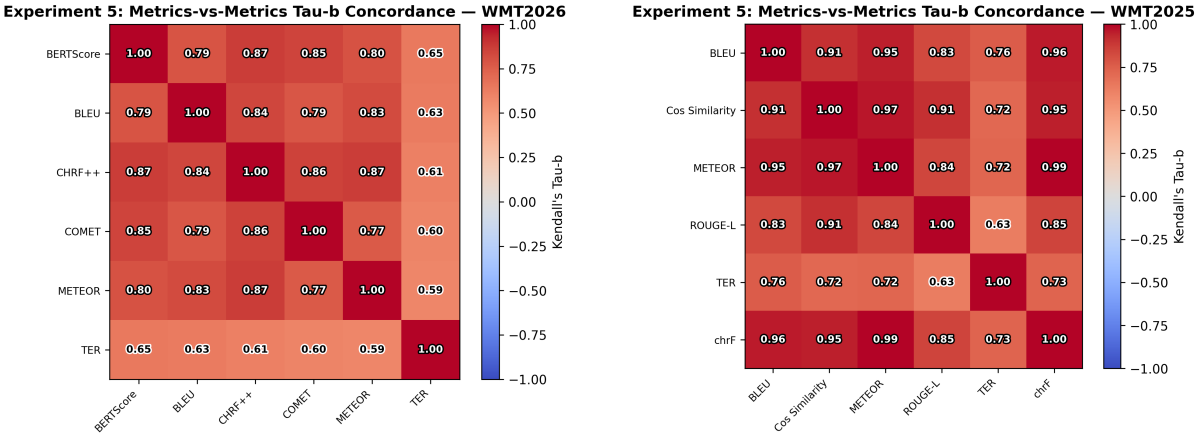

Figure 4: WMT26: floor-inflation ratio by language pair × instrument; blank cells indicate no degenerate submission for that pair.

### 5.5 Experiment 5: Metrics-vs-Metrics Concordance

We report internal concordance of the automatic-metric family only (Table 7: all pairwise instrument-instrument Kendall's $\tau$-b, system level, aggregated across all language pairs; WMT26: 6 metrics, 15 instrument pairs, over 20 language pairs; WMT25: 6 metrics, 15 instrument pairs, over 14 language pairs). While figure 2 established which metrics form a general consensus, figure 5 analyses these pairwise correlations to demonstrate that a metric's underlying computational family does not dictate its alignment with others. In both years, metric concordance is generally high ($\tau$-b mostly >0.75) but not uniform: TER is the least concordant instrument with every other metric in both releases (WMT26: $\tau$-b 0.59–0.65, Figure 5a; WMT25: 0.63–0.76, Figure 5b), consistent with it being an edit-distance rather than n-gram-overlap or embedding-

(a) WMT26

(b) WMT25

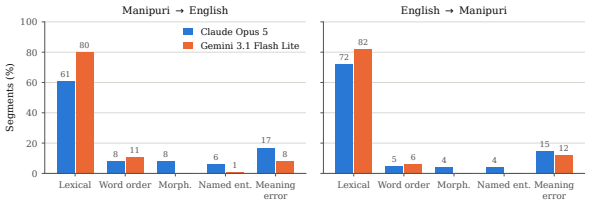
Figure 5: instrument-instrument Kendall's $\tau$-b concordance (metrics vs. metrics), system level.

based measure. The highest concordance in WMT26 reaches 0.87, tied between chrF++/BERTScore and chrF++/METEOR; in WMT25 it is METEOR/chrF (0.99), with Cosine-Similarity and the n-gram metrics (BLEU, METEOR, ROUGE-L, chrF) also mutually near 0.90–0.97. WMT26's embedding metrics (BERTScore, COMET) do not stand apart from the surface metrics here, both correlate with BLEU/METEOR/chrF++ at 0.77–0.87, comparable to the surface metrics' concordance with each other, so at the ranking-agreement level (unlike the floor-inflation results in §5.4) metric family does not predict internal disagreement; only TER consistently does.

### 5.6 LLM-as-a-Judge

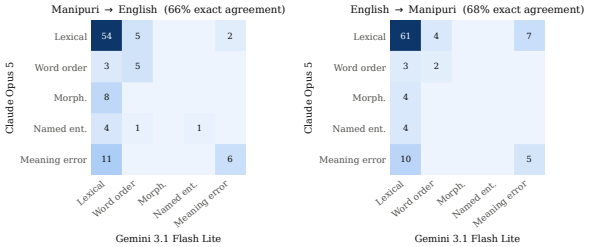
We extract the 100 most divergent examples of BLEU v/s COMET and analyse them. We understand the following.

**Root of Metric Divergence** From Figure 6a, we observe that *Lexical Variations*, Word-Order Variations and *Morphological Variations* constitute the highest number of cases in our error categorizations. Naturally, these constitute the most to the divergence seen in the BLEU and COMET scores.



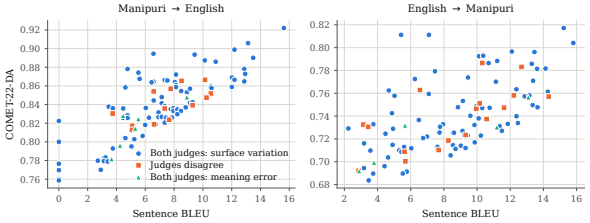
**Judge Agreement and Metric Analysis** In Figure 6b, we see *Claude* having more instances of categorizing into various error types, against *Gemini*, which often tries to club error types together. Meaning errors receive low BLEU scores. The judges agree on surface variation, and most such points lie above the diagonal in Figure 6c. Surface variation errors also hurt COMET and BLEU scores, and hence judges agree on them as well, with such points lying closer to the origin in general. Interestingly, we observe a larger spread of points, particularly in the upper half, for En→Mni in Figure 6c than for Mni→En. This suggests that for Manipuri translations, models struggle to match the references; however, they make up for it in the semantic space with high COMET scores.

## 6 Discussion



Our meta-evaluation shows that automatic metrics' assumptions diverge from their actual performance on low-resource Indic languages, making single-metric system ranking unreliable for non-pretrained scripts.

### 6.1 Impact of Script Coverage



The findings of Experiment 1 and Experiment 3 clearly indicate that script coverage plays a critical role in determining the consistency of neural metrics. Metrics such as BERTScore and COMET, which are based on embeddings, suffer from score compression, making it difficult to distinguish between systems for low-resource language pairs. Neural metrics show inflated scores when evaluating texts written in uncovered scripts such as Meitei-Mayek (Manipuri) and Tier 4 Latin scripts. Additionally, it should be noted that the language script was observed by automatic measures that employ language models (such COMET,

(a) Distribution of error categories identified by Claude and Gemini judges across both translation directions (mni→en and en→mni).

(b) Confusion matrix showing agreement and disagreement between Claude and Gemini judges on error classification verdicts.

(c) COMET and BLEU scores stratified by joint judge verdict, illustrating the relationship between automatic metrics and judge-assigned error categories.

Figure 6: Error analysis across three dimensions: error category distribution, inter-judge agreement patterns, and metric-verdict alignment.

etc.). For instance, the Meitei Mayek script of Manipuri would not have been exposed because it is a standalone script, subjecting it to script coverage bias, whereas the Bengali script used in Manipuri would have been seen due to exposure to Bengali/Assamese language, even though Manipuri language may or may not have been seen by the language model itself. This is our theory, and we hope to investigate it more in the future.

### 6.2 Metric Validity on Null Output

Agreement of the instrument does not mean that the instrument is valid. Experiment 4 highlights an important weakness of embedding-based scores, which overrate the degenerate or nearly worthless systems. BERTScore and COMET were unable to distinguish top systems from degenerate systems in Tier 3-Tier 4 pairs. In contrast, overlap scores such as BLEU and METEOR rated the degenerate systems nearly at the floor level, showing their higher validity when assessing null systems.

### 6.3 Metric Divergence with LLM Judges

Despite the resilience of surface statistics to NULL results, their problem lies in the lack of flexibility. Through our qualitative analysis of LLMs-as-judges, we have pinpointed the underlying causes of the prevalent mismatch between BLEU and COMET. High COMET and low BLEU scores for particular segments are mostly influenced by lexical variations, word-order variations, and morphological variations. All these variations ensure semantic accuracy; however, they heavily penalise BLEU, which focuses on a perfect match. Utilising LLMs as judges (Claude, in particular, since it appeared to have better classification than Gemini) helps us determine the difference between legitimate variations and translation errors.

## 7 Conclusion & Future Work

We apply the QRA apparatus to two editions of WMT Low-Resource Indic MT task, treating six metrics and two LLM judges as measuring systems rather than candidates for correlation with a human gold standard that does not exist for languages. Three findings hold. First, script coverage govern neural metrics behaviour, that is, moving from Manipuri Bengali script to Meitei Mayek shifts BERTScore and COMET score by 20 points, with language and context fixed and no metric preserves system ranking across the change, though the effect reverses in the opposite direction. Second, embedding metrics compress, whereas BERTScore separates systems least and retains 0.81 of the top system's score on degenerate output, whereas BLEU and METEOR sit near the floor. Third, QRA's Type I measure does not transfer across instruments; the rank-based alternative we propose answers a related question at the cost of magnitude information.

## Limitations

We report no correlation with human judgement, because none exists at scale for these languages. Our validity claims instead rest on conditions where the correct answer is known *a priori*, invariance under a change of script, and

near-zero scores for degenerate output, which show that certain instruments behave implausibly, but do not rank the instruments by fidelity to human preference. LLM-as-a-judge helps qualitatively identify whether metric discrepancies stem from word choice, morphology, or word order. They also provide natural-language explanations that make these differences easy to interpret. Finally, the released table gives system-level scores only, so our unit of analysis is the published ranking rather than the individual translation.

## Ethics Statement

We identify submissions with anomalous score patterns and report them as observations about metric behaviour, not participant conduct, making no claim about intent; affected teams are anonymised, and we notified the task organisers before submission. The languages studied are low-resource technically and minoritised socially, and our central finding, that neural metrics inflate scores for text in scripts outside their pretraining coverage, means published leaderboards may overstate the state of the art for precisely the languages least able to detect the error. We frame our recommendations toward more conservative reporting rather than toward discouraging work on these pairs, and caution against adopting LLM judges as an evaluation standard for languages whose coverage in the judge model is undocumented. We use only publicly released data in accordance with its terms, and release our digitised table, code, prompts and raw judge outputs for verification. No human subjects were involved.

# A Method

## A.1 QRA as a measurement apparatus

Meta-evaluation of MT metrics is conventionally posed as correlation with human judgment. That formulation presupposes a gold standard, and for the languages in this task, none exists at scale. We therefore adopt a measurement-theoretic apparatus in its place. The Quantified Reproducibility Assessment (QRA) framework (Belz et al., 2022; Belz, 2022), in the form given by Belz and Thomson (2026), takes its definitions from metrology rather than from NLP practice and, in doing so supplies something the correlation paradigm does not: a taxonomy of result types, each with a matching continuous-valued measure, reported at three fixed levels of granularity. It is this apparatus, rather than the reproducibility application for which it was designed, that we employ.

**Grounding.** QRA rests on the International Vocabulary of Metrology (Joint Committee for Guides in Metrology, 2012), under which reproducibility is the precision of a set of measured quantity values obtained under reproducibility conditions, and §2.24 of the VIM lists *different measuring systems* among those conditions. This is the clause on which our adaptation turns. We hold the measurand fixed, translation quality, and hold the objects fixed, the submitted systems, or in the adjudication study the individual segments, while varying the measuring system across the six automatic metrics and, in Experiment 5, the two judge models. What QRA then quantifies is the precision of a set of measurements taken by different instruments of the same quantity, which is a well-formed metrological question and a different one from the reproducibility question the framework was built to answer. We state the substitution explicitly here because it governs what the results in §5 can and cannot support: QRA measures the *agreement* of instruments, and agreement is not correctness. Experiments 3 to 5 supply the validity claims separately.

**Result types.** QRA distinguishes four types of evaluation results. **Type I** results are single numerical scores, such as a BLEU score or a mean quality rating. **Type II** results are sets of comparable numerical scores, such as the scores of all systems on one language pair. **Type III** results are categorical labels attached to text spans, such as marked-up translation errors. **Type IV** results are findings about differences between systems, such as the claim that one system outranks another. The distinction matters because relative claims can be stable where absolute ones are not, and because the four types require different measures.

**Measures.** For Type I results, QRA uses the bias-corrected coefficient of variation ($\mathrm{CV}^*$), chosen because it is scale-free and therefore comparable across studies. Given measured values $v_1, \ldots, v_n$ with sample mean $m$ and unbiased standard deviation $s^*$,

$$\mathrm{CV}^* \;=\; 100 \cdot \frac{s^*}{|m|}, \qquad s^* = c_n s, \tag{1}$$

where the correction factor $c_n$ of Holtzman (1950) removes the bias remaining in $s$ after Bessel's correction,

$$c_n \;=\; \sqrt{\frac{n-1}{2}}\,\frac{\Gamma\left(\frac{n-1}{2}\right)}{\Gamma\left(\frac{n}{2}\right)}. \tag{2}$$

Where normality is doubtful, Belz and Thomson (2026) provide the non-parametric alternative $c_n^*$ of Giles (2022),

$$c_n^* \;=\; \frac{8n(n-1)}{8n(n-1) - (n-1)(\kappa-3) - 2n}, \tag{3}$$

with $\kappa$ the sample kurtosis coefficient.

For Type II results QRA uses Pearson's $r$, Spearman's $\rho$ and Kendall's $\tau$, generalising to Kendall's $W$ where more than two sets of scores are compared. We report all three of $r$, $\rho$ and $\tau_b$ rather than selecting one, following the framework's rationale that each affords a different perspective on the same scores. Type II measures do not apply at the system level, where only a single score exists, nor at the study level, where score sets lie on incommensurable scales.

For Type III results, QRA uses Cohen's $\kappa$ for two label sets and Krippendorff's $\alpha$ for more, treating all labels from one measurement as issuing from a single rater. Automatic metrics emit no span-level labels, so Type III is reported as n/a for the metric analysis, a situation shared by all three worked examples in Belz and Thomson (2026), and is computed only over the judge error categories in Experiment 5.

For Type IV results QRA defines $P$, the proportion of identical pairwise system ranks across all pairs of measurements,

$$P = \frac{1}{|\mathcal{E}||\mathcal{S}|} \sum_{(E_i,E_j)\in\mathcal{E}} \sum_{(S_m,S_n)\in\mathcal{S}} \mathbb{1}\left[\sigma_{ij}^{mn}\right], \quad (4)$$

where $\sigma_{ij}^{mn}$ denotes the condition $\operatorname{sgn}(M_{E_i}(S_m) - M_{E_i}(S_n)) = \operatorname{sgn}\big(M_{E_j}(S_m) - M_{E_j}(S_n)\big)$, $\mathcal{E}$ is the set of distinct measurement pairs, $\mathcal{S}$ the set of distinct system pairs, and $M_E(S)$ the value returned by measurement $E$ for system $S$. $P$ is the measure that speaks most directly to shared-task practice, because it asks how often two instruments would produce the same published finding.

**Levels.** Every measure is reported at three levels: the *system* level, comparing values obtained for one system by different instruments; the *quality criterion* level, which in our instantiation is the language pair; and the *study* level, aggregating across pairs. Types II and IV do not apply at the system level, and Type II does not apply at the study level. We follow the QRA3 reporting template so that our tables are directly comparable with the assessments reported elsewhere.

**Instantiation.** Objects are the submitted systems; the measurand is translation quality; measuring systems are BLEU, METEOR, TER, chrF++, BERTScore and COMET, joined in Experiment 5 by two judge models; quality criteria are language pairs. As QRA requires, all scales are oriented so that higher is better and shifted to start at zero: TER is re-expressed as $100 - \text{TER}$, and we note where its unboundedness above leaves the resulting scale only nominally bounded below.

### A.2 Adapting Type I to cross-instrument comparison

Types II and IV transfer to cross-instrument use without modification, being defined over rankings and over sets of comparable scores, both of which are well formed when the measurements come from different instruments. Type I does not, and characterising the failure is a contribution of this paper.

**The failure.** CV* is a ratio of dispersion to central tendency, and is therefore interpretable only when the values entering it lie on a common scale with a common zero. This holds by construction in the reproducibility setting, where the same instrument is applied repeatedly. It does not hold across instruments. On our data BERTScore occupies an interquartile range of [81.9, 94.5] while BLEU occupies [7.4, 22.4], so the dispersion of a single system's six scores is dominated by the offsets between instrument scales rather than by any disagreement about that system's quality. The resulting study-level CV* of 100.4 sits far outside the framework's poor band for metrics (CV* $> 5$), but the number reflects only the fact that the instruments are differently calibrated.

The obvious remedy fails for a second and less obvious reason. Min–max normalisation of each instrument within a language pair maps the lowest-ranked system to zero on every instrument on which it is last. Because instruments largely agree at the bottom of the table, the same system is frequently last under most or all of them: across the 148 primary submissions in pairs with $n \geq 5$, 13 systems score zero on at least five of the six instruments, and five score zero on all six. For those five the normalised mean is exactly zero, so the denominator of Eq. 1 vanishes and CV* is undefined rather than merely large; for systems

last on five of six it reaches 257.4. Nineteen systems exceed $\mathrm{CV}^* = 100$ against a median of 14.1, so the aggregate is governed by a tail of floor effects rather than by any property of the instruments. Any normalisation that anchors the empirical floor at zero inherits the pathology.

**A rank-based Type I.** The measure retains the interpretation Type I is meant to carry: it asks how much the instruments disagree about where a given system stands. Let $\mathcal{I}$ be the instrument set with $|\mathcal{I}| = k$, let $\mathcal{S}_q$ be the systems submitted to language pair $q$ with $|\mathcal{S}_q| = n_q$, and let $r_i(s)$ denote the rank of system $s$ under instrument $i$, computed with ties averaged and 1 denoting the best system. The system-level measure is

$$\mathrm{CV}^*{}_{\mathrm{rank}}(s) \;=\; 100 \cdot \frac{c_k \cdot \mathrm{sd}\big(\{r_i(s)\}_{i\in\mathcal{I}}\big)}{\mathrm{mean}\big(\{r_i(s)\}_{i\in\mathcal{I}}\big)}, \quad (5)$$

aggregated to the quality-criterion level as the mean over $s \in \mathcal{S}_q$ and to study the level as the mean over pairs, following the framework's own aggregation convention for Type I.

Ranks share a scale across instruments by construction, which is the property of the shift-to-zero requirement exists to secure, and the mean rank is bounded below by 1, so the denominator cannot collapse. The measure retains the interpretation Type I is meant to carry: it asks how much the instruments disagree about where a given system stands.

**Remark on scale invariance.** $\mathrm{CV}^*$ is invariant to multiplication of its argument by a positive constant. Rescaling ranks to quantile positions $r_i(s)/(n_q{+}1)$, which one might adopt to make values comparable across pairs of unequal size, therefore leaves Eq. 5 unchanged. Comparability across pairs cannot be recovered by normalisation and must be obtained by design.

**Size control.** Rank dispersion is bounded by the number of systems, so $\mathrm{CV}^*{}_{\mathrm{rank}}$ is not directly comparable between a pair with fifteen submissions and one with five. We therefore report, in addition to the uncontrolled measure, a size-controlled variant in which each language pair is subsampled without replacement to a fixed $K$ systems, ranks are recomputed within the subsample, and the measure is averaged over $B$ draws. Comparing the two versions is itself informative: where the controlled and uncontrolled orderings coincide, the association between instrument disagreement and entrant count is substantive rather than an artefact of the measure's bounds. We report both, together with the correlation between quality-criterion-level $\mathrm{CV}^*{}_{\mathrm{rank}}$ and $n_q$.

### A.3 Statistical inference protocol

QRA specifies measures, but not inference, and the measures are point estimates computed on small samples. We therefore fix the following protocol in advance and apply it uniformly across Experiments 1 to 5.

**Interval estimation.** All reported values of $\mathrm{CV}^*$, $r$, $\rho$, $\tau_b$, $W$ and $P$ carry bias-corrected and accelerated bootstrap intervals with $B = 1000$ resamples. Resampling is over systems for system-level analyses and over segments where segment-level data exists. Where an experiment compares instruments, resampling is paired: the same resampled units are used for every instrument, so that intervals reflect uncertainty about the population rather than independent noise in each estimate.

**Comparing dependent correlations.** Several of our questions take the form: does instrument $X$ agree with a given reference judgment significantly better than instrument $Y$? The two correlations share a variable and are therefore dependent, and comparing them by inspecting overlapping intervals is invalid. We use the Williams test for the difference between dependent correlations sharing one variable (Williams, 1959).

**Comparing $P$ values.** Differences in $P$ between instrument pairs are assessed by a paired permutation test over system pairs with 10,000 permutations, since the underlying units, pairwise rank agreements, are not independent across instruments.

**Ties.** Eq. 4 scores a pair as agreeing when both measurements return $\mathrm{sgn} = 0$, so instruments that produce many ties accrue agreement by construction. This is immaterial among the automatic metrics, which almost never tie at four significant figures, but it is material for the judge scores, which are elicited on five-point scales. Left unaddressed it would

make the coarser instrument appear the more concordant. We therefore adopt the following rule and apply it throughout: a tie under both measurements counts as agreement, a tie under one and a difference under the other counts as disagreement. We use $\tau_b$ rather than $\tau_a$ for the same reason, and report the tie rate alongside every $P$ so that readers can assess the extent to which a given value is tie-driven.

**Multiple comparisons.** Each experiment generates a family of tests: one per instrument pair, or one per language pair. We apply the Holm–Bonferroni correction within each family and report both raw and adjusted $p$-values.

**Statistical power.** With three to fifteen systems per language pair, system-level correlation estimates are underpowered and their intervals are correspondingly wide. We report intervals throughout and do not interpret differences between instruments whose intervals overlap, including where a point estimate would suggest an ordering. Language pairs with fewer than five primary submissions are reported individually and excluded from aggregates. Where segment-level data is available, in Experiment 5, it carries the inferential weight; elsewhere our claims rest on the consistency of an effect across many language pairs rather than on its significance within any one.

**Preregistration of analysis choices.** Coverage-tier assignments (§4.3), the divergence-sampling rule and random seed (§4.6), the degeneracy threshold of BLEU $\leq$ 1.0 (§4.4), and the values of $K$ and $B$ in the size-controlled Type I are fixed before analysis and released with our code and digitised data, so that none can be adjusted to the observed effect.

## B Linguistic background for languages

The languages in the shared task are highly diverse in terms of typology, morphology, and orthography among Northeast Indian languages. These languages belong to three different language families, which posed challenges due to differences in their structural properties.

1. **Tibeto-Burman family**: The languages from these family are Manipuri, Bodo, Mizo, Kokborok, Karbi, and Tagin. These languages have inflectional and derivational morphology where the case, tense, aspect, and modality are marked through a large number of suffixes. Mostly, the syntax follows the Subject-Object-Verb order.

2. **Indo-Aryan family**: Languages from this family include Assamese and Nagamese (creole). While Assamese is one of the complex Indo-Aryan languages with inflectional morphology, Nagamese is an Indo-Aryan-based creole and lingua franca of Nagaland, known for its contact-induced simplification.

3. **Austro-Asiatic family**: Language from this family is Khasi, which, unlike the neighbouring SOV Tibeto-Burman languages, has SVO typology and analytic morphosyntax with prepositional case marking.

## C LLM-as-a-Judge Qualitative Examples

As an example of how segment-wise diagnosis is possible using our proposed model of LLM as a Judge, we include below some qualitative examples chosen from 100 cases that had very high COMET scores but relatively low BLEU scores. Here, the evaluators' task was to classify each divergence into one of the five predefined categories: Lexical Variation, Word Order Variation, Morphological Variation, Named Entity Variation, or Genuine Meaning Error.

Table 1 and Table 2 detail these classifications for the English-to-Manipuri (Bengali script) and Manipuri-to-English translation directions, respectively.

## D Additional Results (WMT2026)

Figures below use the WMT2026 results (20 language pairs, 6 metrics: BLEU, METEOR, TER, chrF++, BERTScore, COMET; primary submissions only).

Figures below use the WMT2026 results (20 language pairs, 6 metrics: BLEU, METEOR, TER, chrF++, BERTScore, COMET; primary submissions only).

Table 1: Examples of Manipuri (mni)→English (en) translations taken from WMT 2025. Error types and explanations were generated by an LLM and verified by a human.

| Source (mni) | Reference (en) | Translation (en) | Error type | Explanation |
|---|---|---|---|---|
| লমকোয়বসিংনা হায়দ্রবাদকি চৌমহল্লা পেলেসতা খোংনা চল্লি অমসুং নিজামগি মতমগি ইলিজেন্স অমসুং পুবারি অদু উবা ফংই। | Tourists stroll through Hyderabad's Chowmahalla Palace witnessing Nizam-era elegance and history. | Tourists walk through the Chowmahalla Palace in Hyderabad and witness the elegance and grandeur of the Nizam era. | Lexical Variation | The MT uses 'walk' instead of 'stroll' and 'grandeur' instead of 'history' to translate the source terms, which are acceptable lexical variations that maintain the original meaning. |
| চহি কয়াগি মতুংদা মিয়াম্না পাম্বা সিতকম্ অসি অনৌবা সিজনগিদমক্ হল্লক্লে। | Popular sitcom returns for new season after several years' hiatus. | After many years, the popular sitcom is back for a new season. | Word Order Variation | The MT and reference convey the same meaning, but the MT uses a different word order by placing the temporal phrase at the beginning of the sentence. |
| গুকেসকি মপা রজনিকান্তনা ভারতকি সেনিয়র গ্রেন্দমাস্তর অমদা ক্রেদিৎ পিখি। | Gukesh's father Rajnikanth gave credit to a senior Indian Grandmaster | Gukesh's father Rajnikant gives credit to one of India's senior grandmasters. | Morphological Variation | The MT renders the past-tense পিখি ('gave') as present 'gives', a tense/inflection mismatch; other differences (Rajnikant spelling, 'one of India's senior grandmasters') are trivial surface variants preserving meaning. |
| ব্রয়ান্ জোনসন্না মহাক্কি প্রমান্ লৈরবা ত্রাভেল্ রিকোভরি ত্রিকসিং সেয়র তৌরি। | Bryan Johnson Shares His Proven Travel Recovery Tricks | Brian Johnson shares his proven travel recovery tricks. | Named Entity Variation | The only substantive difference is the transliteration of the first name: reference 'Bryan' vs MT 'Brian'; the rest differs only in sentence-case and final period. |
| দিপিকা পাদুকোন্না নহা ওইরিবা মিওইসিংদা মতেং পাংনবা মেন্তেল্ হেল্থ ইনিসিয়েতিব হৌদোকখ্রে। | Deepika Padukone launches mental health initiative to support young individuals. | Deepika Padukone has launched the Mental Health Initiative to help young women. | Genuine Meaning | The source মিওইসিং means 'people/individuals' generally, but the MT narrows it to 'young women', introducing a gender that is not in the source; the rest matches the reference. |

## D.1 Experiment 1: Discriminative Power (CV*)

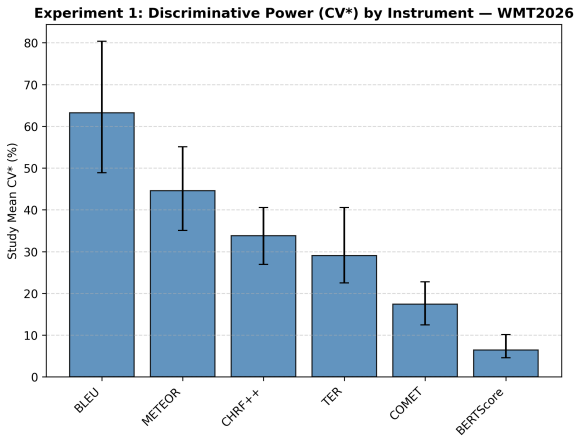

Figure 7: Study-level CV* per instrument across all WMT2026 pairs (95% CI). Higher = more discriminative.

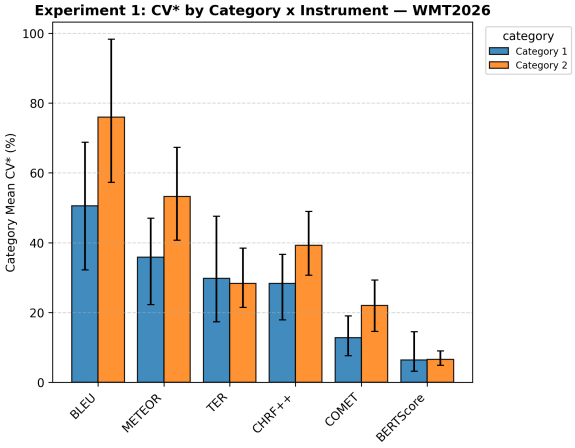

Figure 8: CV* by submission category (Category 1 vs. Category 2), per instrument.

## D.2 Experiment 2: Consensus Centrality

In the fig 7 surface metrics (BLEU, METEOR) show the highest CV*; neural metrics (COMET, BERTScore) the lowest, so they discriminate between systems less. This ordering holds across both submission categories.

In fig 9, 10, and table 4 metric agreement is high ($W > 0.8$) for most pairs but drops for Karbi, Tagin, and Kokborok. chrF++ and BERTScore are the most central metrics; TER agrees least with the rest.

Table 2: Examples of English (en)→Manipuri (mni) translations taken from WMT 2025. Error types and explanations were generated by an LLM and verified by a human.

| Source (en) | Reference (mni) | Translation (mni) | Error type | Explanation |
|---|---|---|---|---|
| Tourists visit Ajmer's Dargah seeking blessings at Rajasthan's famous Sufi pilgrimage site. | লমকোয়বসিংনা রাজস্থানগি মমিং লৈরবা সুফি তিরথ মফম্ অসিদা থৌজাল্ লৌদুনা অজমেরগি দারগাহদা চল্লি। | লমকোয়বশিংনা রাজস্থানগী মমিং চৎলবা সুফি লাই খুরুম্ফমদা থৌজাল ফংনবগীদমক অজমেরগী দর্গাদা লাকই। | Lexical Variation | The MT conveys the same proposition, differing only in word choice: 'মমিং চৎলবা' vs 'মমিং লৈরবা' for famous, 'লাই খুরুম্ফম' vs 'তিরথ মফম' for pilgrimage site, and 'লাকই' (come) vs 'চল্লি' (go), plus a spelling variant of Dargah. |
| Lok Sabha telecommunication policies debates to address 5G rollout challenges. | লোক্ সভা তেলিকম্যুনিকেসন্ পোলিসিসিংগি মতাংদা ৫জি রোল্ আউৎ চেলেন্জসিং কোকহন্নবা দিবেৎ তৌরি। | 5জি রোলআউট চেলেঞ্জশিং থেংননবা লোক সভা তেলিকম্যুনিকেসন পোলিসীশিংগী দিবেতশিং | Word Order Variation | The MT uses a different word order by placing the purpose clause at the beginning and uses a noun phrase structure instead of a full sentence, but the meaning remains identical. |
| Chelsea's 11 against Newcastle was the youngest in the league. | চেলসিনা ন্যুক্যাসলগা থেংনখিবা ১১ অদু লিগ অসিগি খ্বাইদগি নৌবা ওইখি। | ন্যুকেসলগী মায়োক্তা চেল্সিয়াগী 11 অসি লিগ অসিদা খ্বাইদগী নহা ওইরিবনি। | Morphological Variation | Same proposition; the clearest difference is the verb inflection (reference past ওইখি vs MT present/continuative ওইরিবনি), plus minor variants in the transliteration of Chelsea/Newcastle, the numeral script (১১ vs 11), and নৌবা vs নহা for 'young'. Competing label would be lexical_variation given those word-choice/spelling differences. |
| Pilgrims meditate at Bodh Gaya's temple discovering peace under Buddha's sacred tree. | তিরথ চৎপসিংনা বুদ্ধগি সেংলবা উগি মখাদা সান্তি থিদুনা বোধ গয়াগি মন্দিরদা ধ্যান্ তৌই। | তীর্থযাত্রীশিংনা বুদ্ধ গয়াগী লাইশংদা ধ্যান তৌদুনা বুদ্ধগী শেংলবা উগী মখাদা শান্তি ফংবা ঙম্লে। | Named Entity Variation | The MT renders "Bodh Gaya" as "বুদ্ধ গয়" instead of the reference's "বোধ গয়", a transliteration variant of the same place; other differences (তীর্থযাত্রীশিং vs তিরথ চৎপসিং, "শান্তি ফংবা ঙম্লে" for "discovering peace") are acceptable lexical/aspectual variation. |
| Wildlife Sanctuaries in Karnataka: are the greatest Haven for Nature Lovers | করনাতকাদা লৈবা বাইল্দলাইফ সেন্ত্রেলসিং: মহৌসাবু নুংসিজবসিংগি খ্বাইদগি চাউবা হেভননি। | কর্নাতকাগী ৱাইল্ডলাইফ সেঙ্কচুয়ারিশিং: মহৌশাগী ফজবশিংগী খ্বাইদগী চাওবা মফম ওইরি | Genuine Meaning | The MT renders "nature lovers" as "মহৌশাগী ফজবশিং" (nature's beautiful things/beauties) instead of people who love nature (reference: নুংসিজবসিং), so the beneficiary of the 'haven' is misrepresented; 'haven' is also flattened to the generic 'মফম' (place). |

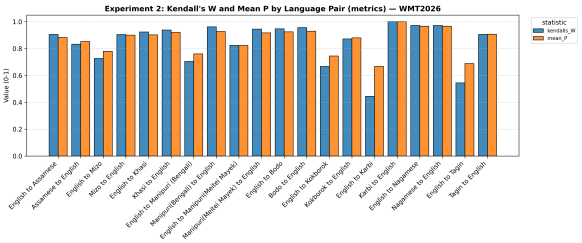

Figure 9: Kendall's W and mean pairwise agreement $P$ per language pair (metrics only).

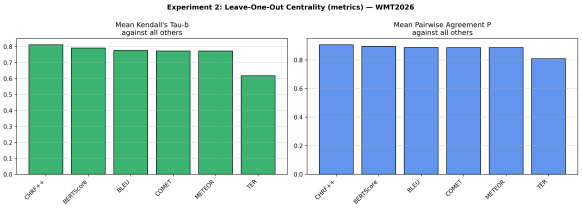

Figure 10: Leave-one-out centrality: mean Tau-b and $P$ of each instrument against all others.

| TER | 0.617 | 0.808 | TER | 0.704 | 0.851 |

### D.3 Experiment 3: Script Sensitivity & Coverage-Tier Inflation

In the table 5 BERTScore and COMET inflate Meitei-Mayek scores on English→Indic, but the effect disappears on Indic→English. In the fig 12, 11, and 13 Surface metrics inflate steadily from Tier 1 to Tier 4; BERTScore/COMET stay comparatively flat.

### D.4 Experiment 4: Null-Output Validity

As shown in Table 6 and Figure 14, BLEU and METEOR are near the ideal floor. BERTScore is the most concerning (ratio ≈ 0.81): degenerate output still scores close to the best system.

### D.5 Experiment:Metrics-vs-Metrics

Table 7 summarises the Kendall's $\tau$-b concordance between metric pairs for WMT25 and WMT26.

## E Additional Results (WMT2025)

In all the experiments on WMT 2025, we use the WMT2025 results (14 language pairs, 6 metrics: BLEU, ROUGE-L, METEOR, chrF, TER, Cosine-Similarity; primary submissions only; no BERTScore/COMET, and no dual-script Manipuri split this year).

Table 5: WMT2026 paired script shift (Meitei-Mayek − Bengali), mean [95% bootstrap CI]. Bold = CI excludes 0. No WMT2025 row exists: that year has no dual-script Manipuri split.

| Instrument | en→indic shift | indic→en shift |
|---|---|---|
| BLEU | −1.5 [−5.4, 1.9] | **−9.5 [−23.3, −1.1]** |
| METEOR | +3.6 [−6.2, 10.6] | **−16.8 [−40.0, −1.7]** |
| TER | +8.5 [−3.2, 18.7] | **+21.1 [0.9, 53.7]** |
| chrF++ | +3.0 [−8.9, 14.7] | **−13.3 [−31.8, −1.3]** |
| BERTScore | **+21.6 [11.9, 49.0]** | −2.9 [−7.4, 0.0] |
| COMET | **+23.3 [17.8, 35.4]** | **−12.8 [−27.5, −3.4]** |

| Instrument | WMT26 | WMT25 |
|---|---|---|
| BLEU | 0.007 | 0.029 |
| METEOR | 0.107 | 0.029 |
| ROUGE-L | – | 0.034 |
| Cos Sim. | – | 0.063 ($n$=1) |
| chrF++/chrF | 0.241 | 0.180 |
| TER | 0.504 | 0.424 |
| COMET | 0.614 | – |
| BERTScore | 0.809 | – |

Table 6: Mean floor-inflation ratio per instrument (0=ideal, 1=worst). $n$ = number of degenerate systems the ratio is averaged over; Cosine-Similarity (WMT25) has only $n$=1, so no CI could be computed (bootstrap requires $n \geq 3$). chrF++ (2026) and chrF (2025) use different pipelines and are not directly equated.

### E.1 Experiment 1: Discriminative Power (CV*)

Figure 15 BLEU, ROUGE-L, and METEOR show the highest CV*; chrF, TER, and Cosine-Similarity are lower and close to each other. Confidence Intervals (CIs) are wide given the smaller (14-pair) sample.

### E.2 Experiment 2: Consensus Centrality

In the figure 16 and 17, Metric agreement is very high across nearly all WMT2025 pairs ($W \geq 0.8$, with several at $W = 1.0$); Bodo→English has no metrics-only row since Cosine-Similarity is the only second metric available there. Cosine-Similarity and chrF are the most central instruments; TER agrees least with the rest.

### E.3 Experiment 3: Coverage-Tier Inflation

As shown in the figure 18 and 19, TER dominates both inflation and range by a wide margin at every tier (range peaks at Tier 2, ≈286); BLEU and chrF inflate moderately; ROUGE-

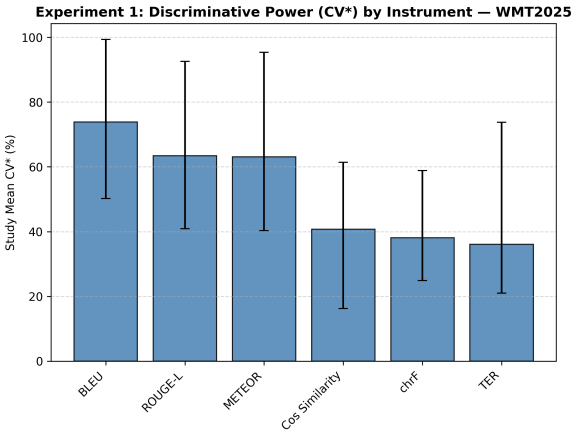

Figure 15: Study-level CV* per instrument across all WMT2025 pairs (95% CI). Higher = more discriminative.

| | WMT26 | WMT25 |
|---|---|---|
| $\tau$-b range | 0.59–0.87 | 0.63–0.99 |
| Lowest pair | METEOR–TER (0.59) | ROUGE-L–TER (0.63) |
| Highest pair | chrF++–BERTScore (0.87) | METEOR–chrF (0.99) |

Table 7: Metrics-vs-metrics Kendall's $\tau$-b concordance summary, system level, all pairs.

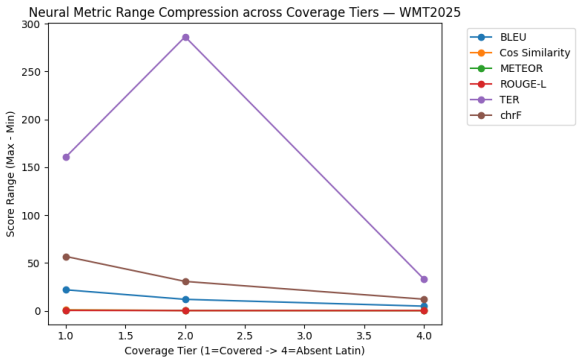

Figure 19: Raw score range (max−min) by coverage tier, per instrument.

L, METEOR, and Cosine-Similarity stay near zero throughout. No paired-script-shift figure is included here: WMT2025's Manipuri submissions are not split by script, so that comparison is unavailable for this year.

### E.4 Experiment 4: Null-Output Validity

In this figure 20, BLEU, METEOR, and ROUGE-L sit near the ideal floor. TER is the most concerning (ratio $\approx 0.42$, and 0.99 for English→Kokborok alone): degenerate output can score almost as high as the pair's best system.

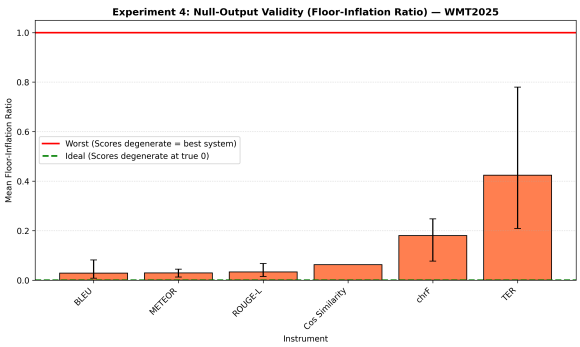

Figure 20: Mean floor-inflation ratio per instrument (0 = ideal, 1 = worst), 95% CI.

## F Prompts

We use the following prompts for our *LLM-as-a-Judge* protocol to evaluate the translations. Figure 21 refers to the system prompt provided to the judge model. Here it is asked to generate adequacy, fluency and semantic equivalence scores along with a certain confidence score which shows the judge's confidence in its own judgement. It also categorizes the errors present in the translations from the given categories in fig. 22 which has 5 different categories of errors - *Lexical variation*, *Word-order variation*, *Morphological variation*, *Named entity variation* and *Genuine meaning error*. We finally include the user prompt in fig. 23 for obtaining the *LLM-as-a-Judge* output.

## System Prompt

You are an expert bilingual annotator evaluating machine translation between $src_lang and $tgt_lang.
You are shown a source segment, a human reference translation, and a machine translation (MT) output. Judge the MT against the source, using the reference only as one acceptable rendering not as the single correct answer. A translation that differs from the reference in wording, word order, or morphology may still be fully correct.
Score each dimension on a 1-5 integer scale.
**Adequacy** — how much of the source meaning is preserved in the MT.

- 5: all meaning preserved, nothing added or lost.
- 4: nearly all meaning preserved; a minor nuance is lost.
- 3: most meaning preserved, one clear omission, addition, or distortion.
- 2: substantial meaning lost or wrong.
- 1: unrelated to the source, or meaning is inverted.

**Fluency** — how natural and grammatical the MT is as $tgt_lang text, judged on its own without looking at the source.

- 5: reads as though written by a native speaker.
- 4: fluent with a small awkwardness that does not impede reading.
- 3: understandable but visibly non-native; grammar or word-choice errors.
- 2: hard to read; frequent errors.
- 1: incomprehensible or not $tgt_lang.

**Semantic equivalence** — how close the MT is in meaning to the *reference*, ignoring surface form entirely. Two sentences that use different words, different word order, or different morphology but convey the same proposition are semantically equivalent.

- 5: identical meaning, differing only in surface form.
- 4: same meaning with a negligible difference in emphasis or specificity.
- 3: broadly the same meaning; one proposition differs.
- 2: partially overlapping meaning.
- 1: different meaning.

**Taxonomy**
**Confidence:** Also report confidence 1-5: how much you would stand behind this judgment as a whole, especially the error type. This is a claim about your own certainty, not about translation quality — a clearly bad translation you are sure about is confidence 5.

- 5: unambiguous. The difference is plain and exactly one label fits.
- 4: clear, with a small residual doubt.
- 3: defensible, but a second label fits nearly as well, or the reference itself looks questionable.
- 2: a guess between competing readings; you would not be surprised to be wrong.
- 1: you cannot properly assess this segment — the source or reference is unintelligible, truncated, or in an unexpected language.

Use the low end when you genuinely mean it. A run in which every segment is confidence 5 carries no information. In particular, drop to 3 or below when the source is ambiguous, when the reference and the MT are both defensible renderings of different readings, or when you lack the domain knowledge to tell a terminology error from a synonym.
**How to decide the error type:** Choose exactly one label — the one that best explains why the MT differs from the reference.

- If the MT and the reference mean the same thing, pick whichever surface category (1-4) accounts for the largest part of the difference. Do not pick "genuine meaning error" merely because the strings differ.
- Pick "genuine meaning error" only when the MT actually misrepresents the source: something is omitted, added, negated, or mistranslated such that a reader would be misinformed.
- If the MT is character-for-character identical to the reference, pick the surface category whose definition is closest to vacuous — use "lexical variation" and say in the explanation that there is no divergence.

**Output:** Return a single JSON object and nothing else. In `explanation`, give one or two sentences naming the concrete difference you based the error type on; if `confidence` is 3 or below, say there what the competing reading was. In `divergent_spans`, list the specific reference-vs-MT fragments that differ; leave it empty if nothing differs.
Judge only what is in front of you. Do not speculate about the system that produced the MT, and do not reward or penalise a translation for being longer or shorter than the reference.

Figure 21: System prompt used for evaluating machine translation quality using *LLM-as-a-Judge*.

**Error Type**

Error type (choose exactly one)

1. **Lexical variation** (`lexical_variation`) — a different but acceptable word or phrase choice: synonyms, a paraphrase, a transliteration or spelling variant, a different register, an idiom rendered literally or vice versa. Meaning is preserved.

2. **Word-order variation** (`word_order_variation`) — the same content words arranged differently: reordered clauses, active/passive alternation, fronting or extraposition, a different but valid constituent order. Meaning is preserved.

3. **Morphological variation** (`morphological_variation`) — the same lexemes carrying different inflection or affixation: tense, aspect, number, case, agreement, definiteness, honorific level, or a different derivational form of the same root. Meaning is preserved apart from the grammatical feature itself.

4. **Named entity variation** (`named_entity_variation`) — a difference confined to a proper name, number, date, measurement, currency, or other named entity: a different transliteration or spelling of a name, digits versus spelled-out numerals, a different date or unit format. The entity refers to the same thing.

5. **Genuine meaning error** (`genuine_meaning_error`) — the MT misrepresents the source: content is omitted or hallucinated, a relation is reversed, polarity or negation is wrong, or an entity refers to something different. A reader relying on the MT would be misinformed.

Figure 22: Error type taxonomy for machine translation evaluation.

**Evaluation Template**

Direction: $src_lang → $tgt_lang
Segment id: $seg_id
**SOURCE** ($src_lang):
$src
**REFERENCE** ($tgt_lang):
$ref
**MACHINE TRANSLATION** ($tgt_lang):
$mt
$scores
Evaluate the machine translation and return the JSON object.

## Abstract

While Large Language Models excel in natural language processing, efficiently extending their capabilities to spoken input remains a significant challenge. Existing methods for building SpeechLLMs often rely on computationally expensive full-model fine-tuning, or employ parameter-efficient projectors that suffer from inefficient token sequence lengths and costly full-model supervision. In this paper, we introduce Aligned Continuous Integrate-and-Fire, a highly efficient framework for zero-shot speech processing. Our method dynamically compresses continuous acoustic frames into the exact discrete token length of the target text utilizing explicit Dynamic Time Warping alignments. This allows our initial training stage to establish a robust acoustic-to-semantic bridge using lightweight distance metrics, entirely bypassing the computationally expensive LLM forward pass. For subsequent fine-tuning, we propose a memory-efficient knowledge distillation objective that targets a single LLM layer, performing competitively with full-model cross-entropy training at a fraction of the computational cost. Through extensive evaluations on Automatic Speech Recognition and Speech Translation, we demonstrate that our method achieves superior performance compared to prior parameter-efficient baselines.[1]

## 1 Introduction

Large Language Models (LLMs) have achieved unprecedented success in natural language processing (OpenAI et al., 2024; Comanici et al., 2025; Grattafiori et al., 2024; Qwen et al., 2025; Guo et al., 2025), yet a significant portion of high-performing open-weights LLMs remain text-only. While cascaded systems (speech recognition model followed by an LLM) offer a straightforward way to process spoken input, they suffer from error propagation and prevent end-to-end downstream fine-tuning. To natively equip LLMs with auditory capabilities, recent works connect a speech encoder to the LLM and fine-tune the system on speech-to-text data (Wu et al., 2023; Gong et al., 2024; Tang et al., 2024; Fathullah et al., 2024a; Hu et al., 2024; Das et al., 2025). Although effective, this paradigm is computationally expensive and prone to task-specific overfitting (Tang et al., 2024).

To improve efficiency, recent approaches freeze the LLM and train only a speech projector to map acoustic features to text embeddings (Fathullah et al., 2024b; Deng et al., 2025; Tan et al., 2025; Mohapatra et al., 2026). However, these methods still face significant limitations. Wav2Prompt (Deng et al., 2025) dynamically matches token lengths using a Continuous Integrate-and-Fire (CIF) module (Dong and Xu, 2020) but relies on expensive Cross Entropy (CE) supervision from the full LLM. SSR Tan et al. (2025) requires external alignment tools and extensive distillation training followed by full LLM fine-tuning. SpeechMapper (Mohapatra et al., 2026) avoids LLM forward passes but pads text embeddings to match the longer length of speech sequences, wasting computational resources on uninformative tokens and hindering both training and inference efficiency.

To overcome these limitations, we introduce **ACIF** (Aligned Continuous Integrate-and-Fire), a highly efficient framework for zero-shot speech processing that is trained exclusively on Automatic Speech Recognition (ASR) data. ACIF dynamically compresses continuous acoustic frames into the exact discrete token length of the target text. During our initial training phase (Stage 1), we supervise the CIF module using explicit token-level alignments generated via Dynamic Time Warping (DTW) (Sakoe and Chiba, 1978) directly from the speech and text embeddings. This allows the projector to learn a robust acoustic-to-semantic mapping through lightweight distance metrics (Mean Squared Error and cosine distance), bypassing the

[1] Our code: https://github.com/issam9/ACIF

*Proceedings of the Eleventh Conference on Machine Translation*, pages 304–317
October 28-29, 2026 ©2026 Association for Computational Linguistics

computationally expensive LLM forward pass.

For Stage 2 fine-tuning, standard full-model CE training on ASR data risks overfitting and incurs heavy computational costs. To address this, we propose a memory-efficient Knowledge Distillation (KD) objective that distills hidden states from a single LLM layer, performing competitively with full-model CE at a fraction of the cost. Through an analysis of KD layer depth, we reveal that ASR relies heavily on shallow, localized representations optimally captured at the first layer, whereas Speech Translation (ST) benefits from the abstract semantic representations developed in intermediate layers.

We evaluate ACIF on Automatic Speech Recognition (LibriSpeech, VoxPopuli, FLEURS) and zero-shot Speech Translation (Europarl-ST, CoVoST-2) using Llama 3.1 (8B) and Qwen 2.5 (7B) backbones. Our main contributions are:

- We propose ACIF, combining a CIF module with DTW-guided supervision to project continuous speech frames into exact LLM token representations.
- We demonstrate that our Stage 1 training establishes a high-quality semantic bridge with vastly greater efficiency than existing baselines, requiring no LLM forward passes.
- We introduce a highly memory-efficient, single-layer KD objective for Stage 2 fine-tuning that competes robustly with full-model CE training.
- We achieve superior zero-shot performance compared to prior methods, offering a substantially more lightweight and computationally efficient alternative for developing Speech-LLMs.

## 2 Related Works

### 2.1 Speech Large Language Models

While recent LLMs natively support multi-modal inputs (OpenAI et al., 2024; Comanici et al., 2025), a large portion of modern LLMs remain text-only, making the development of efficient audio adapters crucial. Previous works have equipped LLMs with auditory capabilities by connecting a speech encoder and fine-tuning the full model or utilizing LoRA adapters on task-specific datasets (Wu et al., 2023; Gong et al., 2024; Tang et al., 2024; Fathullah et al., 2024a; Hu et al., 2024; Das et al., 2025). Recent parameter-efficient approaches have moved beyond this by training only a lightweight projector and keeping the LLM entirely frozen (Fathullah et al., 2024b; Deng et al., 2025; Tan et al., 2025; Mohapatra et al., 2026). Closely related to our approach, Deng et al. (2025) introduced Wav2Prompt, which converts speech frames to text tokens using a CIF mechanism (Dong and Xu, 2020). Although this successfully avoids updating the LLM parameters, it still relies on CE supervision from the LLM during training, introducing significant computational overhead. Alternatively, Mohapatra et al. (2026) proposed SpeechMapper, which makes the LLM forward pass optional. However, SpeechMapper resolves the length mismatch between modalities by introducing padding tokens to the text embeddings, which renders training and inference inefficient. In contrast, our work trains a CIF module to project speech frames to the exact text token length. Furthermore, unlike Wav2Prompt which requires full LLM propagation for training, we supervise this projection using explicit token-level alignments generated via DTW.

### 2.2 Bridging the Modality Gap between Speech and Text

The goal of aligning acoustic and semantic representations is widely studied under the framework of bridging the modality gap. In speech-to-text tasks, representation misalignment has been shown to severely bottleneck performance (Liu et al., 2020; Wang et al., 2020). Various alignment strategies have proven effective to alleviate this issue (Inaguma et al., 2021; Ye et al., 2022; Fang et al., 2022; Ouyang et al., 2023; Zhang et al., 2025), with techniques relying on explicit word- or token-level boundaries yielding particularly strong results (Fang et al., 2022; Ouyang et al., 2023; Issam et al., 2025). Moving beyond static, pre-computed alignments, Issam et al. (2025) utilized DTW (Sakoe and Chiba, 1978) to dynamically generate alignments during the training of end-to-end speech translation models. We similarly rely on DTW to establish correspondence between acoustic and text representations. However, rather than training a task-specific encoder-decoder architecture with simple mean pooling, we project speech into the embedding space of a frozen LLM to specifically target zero-shot generalization. Additionally, we utilize trainable CIF weights to dynamically pool

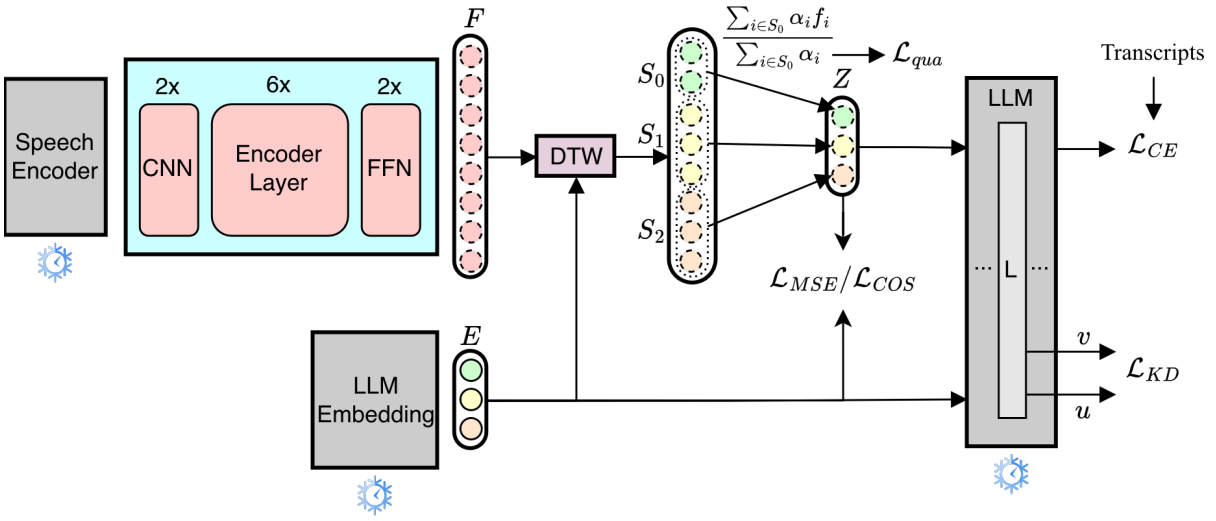

Figure 1: **Overview of the ACIF architecture.** The proposed projector consists of two convolutional layers, a 6-layer Transformer encoder, and a two-layer feed-forward network. The projected speech frames $F$ are aligned with the target text embeddings $E$ using DTW. An additional layer predicts continuous weights $\alpha_i$ to integrate each frame $f_i$ into its corresponding aligned token (Eq. 1). The resulting token-level speech embeddings $Z$ are optimized using normalized MSE ($\mathcal{L}_{\text{MSE}}$, Eq. 2) and mean-centered cosine distance ($\mathcal{L}_{\text{cos}}$, Eq. 3). Simultaneously, the $\alpha_i$ values are supervised via a quantity loss ($\mathcal{L}_{\text{qua}}$, Eq. 4) to ensure they sum to 1 over each text token's segment. During the fine-tuning stage, we incorporate either a standard cross-entropy loss ($\mathcal{L}_{\text{CE}}$) or a knowledge distillation loss ($\mathcal{L}_{\text{KD}}$), the latter being computed between the intermediate hidden states of the text and speech embeddings extracted at layer $L$ of the truncated LLM.

and integrate the continuous speech frames into exact, discrete token representations during training and inference.

## 3 Methodology

In this section, we present our methodology for efficiently bridging a pretrained speech encoder with a frozen LLM, as illustrated in Figure 1. We first introduce the ACIF projector and its training objectives (Section 3.1). To further optimize the projector, Section 3.2 details a memory-efficient fine-tuning strategy. Finally, Section 3.3 outlines how the trained projector dynamically integrates speech embeddings during inference.

### 3.1 ACIF: Aligned Continuous Integrate and Fire

Connecting a pretrained speech encoder to a frozen LLM requires a bridging projector that resolves the cross-modal gap. To enable the direct injection of speech representations into the LLM context, the projector must map acoustic features to the LLM embedding dimension, compress dense speech frame sequences to match the exact length of textual token sequences, and align the projected frames directly into the semantic embedding space of the LLM. To achieve this multi-step mapping efficiently, we design a lightweight projector architecture coupled with a dynamic alignment strategy.

Our projector consists of two 1D Convolutional Neural Network layers that perform initial temporal downsampling, and a 6-layer encoder that learns semantic alignment from speech to text. This is followed by two linear layers that map the downsampled features into the LLM hidden dimension, producing intermediate speech frame representations $F = [f_1, f_2, \ldots, f_{N'}] \in \mathbb{R}^{N' \times d}$, where $N'$ is the reduced sequence length. Concurrently, a single linear layer operates on these frames to predict a scalar weight $\alpha_i \in [0, 1]$ for each frame, representing its relative contribution toward forming a discrete token embedding.

During training, we compute an optimal alignment path between the intermediate frames $F$ and the target text token embeddings $E = [e_1, e_2, \ldots, e_M] \in \mathbb{R}^{M \times d}$ using DTW-Align (Issam et al., 2025) based on cosine distance. DTW partitions the $N'$ frames into $M$ contiguous segments, assigning a set of frames $S_j$ to each target token $j$. Instead of uniformly averaging the segment embeddings as in standard DTW-Align, we calculate a weighted average using the predicted alpha scores. For each target token $j$, the pooled representation $z_j$ is computed by multiplying the

aligned frame embeddings by their corresponding scalar weights and dividing the accumulated result by the sum of those weights:

$$z_j = \frac{\sum_{i \in S_j} \alpha_i f_i}{\sum_{i \in S_j} \alpha_i} \tag{1}$$

This token-level integration receives explicit positional signals from the alignment bounds itself, entirely eliminating the requirement for LLM forward passes to regularize the token compression.

The projector is optimized end-to-end using a joint objective comprising normalized MSE, mean-centered cosine distance, and a quantity loss. To ensure the MSE remains stable across different LLM backbones with varying embedding magnitudes, we divide the raw error by the mean squared magnitude of the target LLM embeddings. Given the pooled speech embeddings $Z = [z_1, \ldots, z_M]$ and target text embeddings $E = [e_1, \ldots, e_M]$, the normalized MSE is computed as:

$$\mathcal{L}_{\text{MSE}} = \frac{\sum_{j=1}^{M} \|z_j - e_j\|_2^2}{\sum_{j=1}^{M} \|e_j\|_2^2} \tag{2}$$

Furthermore, raw cosine similarity between embeddings can be inflated by a shared mean vector (Mu and Viswanath, 2018), which might dominate the pairwise similarity and obscure the semantic signal we aim to optimize for. We mitigate this by mean-centering the embeddings prior to computing cosine similarity, subtracting the mean of the target embeddings, $\mu_E = \frac{1}{M}\sum_{j=1}^{M} e_j$, from both the predicted and target vectors. This removes the dominant shared direction and yields a cosine loss that is more sensitive to true semantic discrepancies:

$$\mathcal{L}_{\cos} = \frac{1}{M}\sum_{j=1}^{M}\Big(1 - \cos(z_j - \mu_E, e_j - \mu_E)\Big) \tag{3}$$

where $\cos(\cdot,\cdot)$ denotes the cosine similarity operator.

Finally, the quantity loss applies an $L_1$ penalty between the accumulated scalar weights for each token and a target value of 1, enforcing that the predicted weights correctly match the exact target sequence length:

$$\mathcal{L}_{\text{qua}} = \frac{1}{M}\sum_{j=1}^{M}\left|\sum_{i \in S_j} \alpha_i - 1\right| \tag{4}$$

The overall objective is the weighted sum of these three components, $\mathcal{L}_{\text{total}} = \lambda_{\text{mse}}\mathcal{L}_{\text{MSE}} + \lambda_{\cos}\mathcal{L}_{\cos} + \lambda_{\text{qua}}\mathcal{L}_{\text{qua}}$.

### 3.2 Efficient Fine-tuning

Our projector can be efficiently fine-tuned using feedback from the LLM to further improve cross-modal embedding alignment. While the LLM itself could be jointly fine-tuned for downstream speech-to-text tasks, we freeze the LLM to preserve its general capabilities and prioritize computational efficiency. To fine-tune the projector, a standard approach is to incorporate a Cross Entropy loss alongside the alignment objectives (Deng et al., 2025; Mohapatra et al., 2026):

$$\mathcal{L}_{\text{total}} = \lambda_{\text{mse}}\mathcal{L}_{\text{MSE}} + \lambda_{\cos}\mathcal{L}_{\cos} + \lambda_{\text{qua}}\mathcal{L}_{\text{qua}} + \lambda_{\text{ce}}\mathcal{L}_{\text{CE}} \tag{5}$$

where $\lambda_{\text{ce}}$ governs the weight of the autoregressive language modeling loss.

However, while optimizing only the projector minimizes the number of trainable parameters, computing $\mathcal{L}_{\text{CE}}$ still requires a full forward pass through the multibillion-parameter LLM. This imposes a severe GPU memory bottleneck during training. We hypothesize that for zero-shot performance, the primary requirement is successfully mapping speech into the LLM's initial semantic space; thus, full-depth LLM propagation is unnecessary, and shallow feedback is sufficient to guide the representations.

Guided by this assumption, we propose an efficient alternative to standard CE loss by utilizing early-layer LLM representations (e.g., 1 layer) for fine-tuning. To enforce deeper semantic alignment without the full memory overhead, we introduce a KD objective utilizing the logit lens technique (nostalgebraist, 2020).

Specifically, the pretrained LLM is structurally pruned during training to retain only the first $L$ transformer layers. Both the target text embeddings $E$ and the pooled speech embeddings $Z$ are passed through this truncated network to extract their respective intermediate hidden states. These states are then mapped directly into the vocabulary space by applying the LLM's unembedding layer, yielding teacher text logits $\mathbf{u}$ and student speech logits $\mathbf{v}$.

The distillation loss $\mathcal{L}_{\text{KD}}$ is computed as the average Kullback-Leibler (KL) divergence between the teacher and student probability distributions over the vocabulary:

$$\mathcal{L}_{\text{KD}} = \frac{1}{M}\sum_{j=1}^{M} D_{\text{KL}}\Big(\text{softmax}(\mathbf{u}_j) \parallel \text{softmax}(\mathbf{v}_j)\Big) \tag{6}$$

where $M$ is the number of valid target tokens. In configurations where memory efficiency is paramount, $\mathcal{L}_{\text{KD}}$ safely replaces $\mathcal{L}_{\text{CE}}$, regularizing the projector by forcing the intermediate speech representations to mirror the predictive trajectory of the text embeddings at a fraction of the computational cost.

### 3.3 Inference Stage

At inference time, since target transcriptions are unavailable and DTW alignment cannot be applied, the CIF module dynamically collapses the variable-length sequence of speech frame embeddings into discrete token representations. It sequentially aggregates frame embeddings scaled by their predicted scalar weights, progressively accumulating acoustic evidence until the predefined firing threshold of 1 is reached. This threshold signifies the completion of a semantic token. To prevent information loss at token boundaries, the specific frame that breaches the threshold is fractionally partitioned: a remainder portion completes the current token embedding, while the surplus is carried over to initialize the subsequent token. Once all frames are processed, the module resolves any residual acoustic information left in the tail buffer. If the accumulated tail weight exceeds a half-token threshold ($w \geq 0.5$), it is deemed semantically meaningful and emitted as a valid final token. Crucially, this trailing embedding is divided by its accumulated weight to yield a weighted mean, normalizing its magnitude to match that of fully integrated tokens.

## 4 Experiments

### 4.1 Datasets

For model training, we exclusively utilize the LibriSpeech dataset (Panayotov et al., 2015), leveraging its paired audio and text transcriptions. We subsequently evaluate ASR performance on the standard LibriSpeech, Voxpopuli (Wang et al., 2021a) and FLEURS (Conneau et al., 2022) test splits. To assess zero-shot ST capabilities, we report results on select test sets from the Europarl-ST (Iranzo-Sánchez et al., 2020) and CoVoST-2 (Wang et al., 2021b) benchmarks. Specifically, we evaluate on the English-to-Spanish, German, Italian, and French directions from Europarl-ST, alongside the English-to-German and Chinese directions from CoVoST-2. Although our proposed alignment method is language-agnostic and applicable to any source language with sufficient ASR data, we restrict our evaluation to English-centric pairs to ensure direct comparison with prior work.

### 4.2 Backbones

For our acoustic representations, we use SeamlessM4T-v2-Large (Communication et al., 2023) as a speech encoder. Following SpeechMapper (Mohapatra et al., 2026), we specifically extract features from the 24th layer of the SeamlessM4T encoder. For the core language model, we experiment with Llama-3.1-8B-Instruct (Grattafiori et al., 2024) and Qwen2.5-7B-Instruct (Qwen et al., 2025). To preserve their pretrained capabilities and ensure computational efficiency, the weights of both the speech encoders and the LLMs remain strictly frozen during training.

### 4.3 Training Details

To optimize GPU memory and accelerate the training process, we pre-compute the acoustic features from the frozen speech encoder. Consequently, only the trainable projector and the frozen LLM embedding layer need to be loaded into memory. Target text transcriptions are normalized using the MMS normalization (Pratap et al., 2024). Specifically, we remove HTML tags, apply NFKC normalization, lowercase, and remove punctuation. Architecturally, the projector consists of two 1D convolutional layers (kernel size 5, stride 2), which reduce the temporal sequence length by a factor of 4. These are followed by 6 standard Transformer encoder layers with a hidden dimension of 1024. A final two-layer feed-forward network projects the representations through an intermediate dimension of 2048 into the specific LLM hidden dimension (4096 for Llama-3.1-8B and 3584 for Qwen2.5-7B).

We optimize the model using AdamW with a peak learning rate of $1 \times 10^{-4}$ and a cosine learning rate scheduler, incorporating a 10% linear warmup period. Training utilizes dynamic batching with a maximum batch size of 8192 speech frames and runs for 250k steps. This effectively matches the total volume of training data seen in SpeechMapper (Mohapatra et al., 2026), adjusting for their comparatively smaller batch size. During the subsequent fine-tuning stage, we maintain identical hyperparameters but reduce the learning rate to $1 \times 10^{-5}$ and the batch size to 1024 tokens and train for 20k steps. We strictly evaluate the final saved checkpoint in both stages.

During the initial training phase, the weights

for the loss components are set to $\lambda_{\text{mse}} = 0.01$, $\lambda_{\text{cos}} = 10.0$, and $\lambda_{\text{qua}} = 1.0$.[2] For the subsequent fine-tuning stage, we maintain these base hyperparameters while introducing the additional semantic objective: either standard cross-entropy ($\mathcal{L}_{\text{CE}}$) with $\lambda_{\text{ce}} = 1.0$, or knowledge distillation ($\mathcal{L}_{\text{KD}}$) with $\lambda_{\text{kd}} = 1.0$. When utilizing $\mathcal{L}_{\text{KD}}$, the pretrained LLM is pruned to retain only its first transformer layer.

Our models are implemented using PyTorch Lightning[3]. Due to the lightweight nature of the projector—comprising 96.6M trainable parameters—and our memory-efficient design, the entire training pipeline fits easily on a single 40GB A100 GPU. This low memory footprint even permits the concurrent training of multiple models on the same hardware. Training completes in approximately 6h30min on a single A100 GPU (or 10h30min on an NVIDIA RTX A5000), representing a drastic reduction in computational overhead compared to prior methods like SpeechMapper, which requires 4 days across 4 V100 GPUs.

### 4.4 Evaluation

For ASR evaluation, we report the Word Error Rate (WER) and Character Error Rate (CER) following the application of MMS text normalization (Pratap et al., 2024). For Speech Translation, we utilize the COMET[4] metric (Rei et al., 2022), which evaluates the generated hypothesis against both the source transcription and the reference translation. Additionally, we report case-sensitive, detokenized BLEU (Papineni et al., 2002) computed via SacreBLEU (Post, 2018) in our code repository. During the evaluation of the CoVoST-2 dataset, we filter out audio samples containing fewer than 1,000 or more than 480,000 acoustic frames. To ensure a fair comparison, we adopt closely identical prompt templates to SpeechMapper (Mohapatra et al., 2026) (see Appendix A). All text generation is performed using greedy decoding with a maximum generation length of 150 tokens, implemented via the HuggingFace Transformers library (Wolf et al., 2020).

[2]The disparity between $\lambda_{\text{cos}}$ and $\lambda_{\text{mse}}$ balances their initial gradient magnitudes: while the cosine loss is naturally bounded in $[0, 2]$, MSE between the randomly initialized projector output and the pretrained LLM embedding space is initially much larger and would otherwise dominate early optimization.

### 4.5 Baselines

Our primary baseline is SpeechMapper (Mohapatra et al., 2026), which similarly employs a two-stage training pipeline to achieve zero-shot speech capabilities. Their speech projector is architecturally heavier, consisting of two sequential blocks, each containing a single CNN layer and a 6-layer Transformer encoder. Within this structure, a linear layer in the first block projects the acoustic features to a hidden dimension of 2048, and a subsequent linear layer in the second block projects them to 4096, before a final linear layer maps the representations into the LLM's input space. Consequently, the SpeechMapper projector contains 277M trainable parameters, making it nearly three times larger than our lightweight 96.6M-parameter module. For a direct and fair comparison, we benchmark exclusively against their zero-shot experimental setup. This pipeline consists of Stage 1, which trains the projector independently without any forward passes through the LLM, and Stage 2, which incorporates the frozen LLM to fine-tune the projector using a cross-entropy objective.

## 5 Results

### 5.1 ASR Performance

Table 1 presents the ASR performance evaluated via WER and CER on the LibriSpeech (test-clean, test-other), VoxPopuli (VP), and FLEURS datasets. Our proposed ACIF alignment framework demonstrates significant improvements over the SpeechMapper baseline across multiple dimensions.

Most notably, our method exhibits vastly superior sample efficiency and alignment quality during the initial modality-bridging phase. Using the identical Llama 3.1 backbone, our Stage 1 model achieves a WER of 5.1 on the LibriSpeech clean split, nearly halving the 9.4 WER reported by SpeechMapper's Stage 1. This massive performance gap extends to the more challenging out-of-domain VP and FLEURS datasets, where our Stage 1 model improves upon SpeechMapper's Stage 1 WER by absolute margins of 8.8 and 13.0 points, respectively. This indicates that our alignment-guided CIF module establishes a highly accurate semantic mapping purely from the acoustic representations, without requiring expensive forward passes through the LLM.

Furthermore, during the Stage 2 fine-tuning phase, our KD objective consistently outperforms

| | | LS clean | LS other | VP | Fleurs |
|---|---|---|---|---|---|
| Seamless ASR | | **2.7 / 0.9** | **5.1 / 2.0** | **8.9 / 6.2** | **8.1 / 4.7** |
| Llama 3.1 | SpeechMapper Stage 1 | 9.4 / 6.5 | 12.0 / 7.9 | 25.0 / 19.7 | 30.2 / 27.6 |
| | SpeechMapper Stage 2 | 4.9 / 2.7 | 7.8 / 4.1 | 14.8 / 9.2 | 16.6 / 11.1 |
| Llama 3.1 | ACIF (stage 1) | 5.1 / 3.2 | 9.1 / 5.8 | 16.2 / 11.5 | 17.2 / 12.1 |
| | ACIF (stage 2) [CE] | 4.7 / 2.8 | 7.9 / 4.4 | 16.3 / 11.4 | 18.3 / 11.7 |
| | ACIF (stage 2) [KD] | 4.1 / 2.2 | 8.3 / 4.8 | 14.8 / 9.7 | 17.4 / 11.7 |
| Qwen 2.5 | ACIF (stage 1) | 3.7 / 1.7 | 7.3 / 3.7 | 15.2 / 9.2 | 17.9 / 10.4 |
| | ACIF (stage 2) [CE] | 4.9 / 2.5 | 9.1 / 4.8 | 18.3 / 12.0 | 21.6 / 13.5 |
| | ACIF (stage 2) [KD] | 3.8 / 1.8 | 7.2 / 3.7 | 15.0 / 9.1 | 17.2 / 10.1 |

Table 1: ASR performance (WER / CER) on LibriSpeech, VoxPopuli (VP), and FLEURS. The overall best results are highlighted in bold, while the highest SpeechLLM results are underlined. Baseline results for SpeechMapper are taken directly from the original paper (Mohapatra et al., 2026).

standard CE. For Llama 3.1, KD training yields a WER of 4.1, surpassing SpeechMapper's fully fine-tuned Stage 2 result (4.9 WER) on LibriSpeech test-clean. The stabilizing effect of the KD loss becomes especially critical when employing the Qwen 2.5 backbone. While standard CE fine-tuning leads to a noticeable degradation in performance compared to its Stage 1 baseline (e.g., WER increasing from 3.7 to 4.9 on test-clean), the KD objective successfully prevents this. Notably, applying KD safely maintains the performance reached during Qwen 2.5's Stage 1, yielding the best overall CERs on both VP (9.1) and FLEURS (10.1). Ultimately, these findings demonstrate that employing KD with only a single LLM layer is a highly robust, memory-efficient alternative to full-model CE supervision.

Finally, our best-performing configuration surpasses the zero-shot baseline of SSR (Tan et al., 2025) on both LibriSpeech evaluation splits. Specifically, our ACIF (Stage 2) [KD] model with a Qwen-2.5 backbone achieves 3.8 and 7.2 WER on test-clean and test-other, respectively, outperforming SSR's 5.0 and 8.1.

### 5.2 Zero-Shot Speech Translation Performance

Table 2 presents the zero-shot ST COMET scores on the Europarl-ST and CoVoST-2 evaluation sets. Consistent with our ASR findings, our ACIF method significantly outperforms the SpeechMapper baseline. Using the Llama 3.1 backbone, our Stage 1 model achieves substantial gains over SpeechMapper's Stage 1 across nearly all evaluation directions, with the exception of En-It. This improvement is particularly pronounced on the CoVoST-2 dataset, where our method outperforms the baseline by $+12.1$ COMET points on En-De and $+11.9$ points on En-Zh. Furthermore, while SpeechMapper suffers from performance degradation during its Stage 2 fine-tuning, our Stage 2 training consistently enhances the learned representations across both LLM backbones.

When comparing the Stage 2 optimization strategies, the results indicate that both CE and KD provide robust semantic alignment for zero-shot ST. For the Llama 3.1 backbone, KD yields the highest zero-shot performance on En-Es, En-Fr, and En-It directions, peaking at a COMET score of 79.1 on En-Es. Conversely, standard CE fine-tuning proves highly effective on the CoVoST-2 dataset, achieving the top zero-shot scores of 81.1 on En-De and 83.0 on En-Zh. Strikingly, unlike the representation degradation observed during Qwen 2.5 ASR fine-tuning, both CE and KD successfully stabilize and even slightly improve upon the Qwen 2.5 Stage 1 translation baseline. Ultimately, our best zero-shot configurations establish a highly effective semantic bridge. They closely trail the performance of the explicitly supervised cascaded baselines and consistently outperform the in-domain Seamless ST model on the Europarl-ST directions without requiring any translated text during training.

Finally, in comparison to Wav2prompt (Deng et al., 2025), which only reports BLEU on En–Es and En–Fr, we re-evaluate ACIF (Stage 2) [KD] with Llama 3.1 backbone using their exact decoding configuration (beam size of 5 and repetition penalty of 1.5). Under these settings, our method achieves 26.7 BLEU on En–Es and 21.0 BLEU on En–Fr, compared to 25.1 and 21.7, respectively. Notably, our approach performs competitively without requiring full LLM forward propagation or the 10 hours of in-domain Europarl-ST supervision utilized in Wav2prompt's ASR stage.

## 6 Analysis

### 6.1 Some Embeddings are Easier to Align

The geometry of the target embedding space may influence how easily a speech projector can learn the cross-modal mapping. Consequently, training the projector with identical hyperparameters across different LLM backbones may be suboptimal. In Figure 2, we evaluate the impact of training duration by varying the number of training steps for

| | | Europarl | | | | CoVoST2 | |
|---|---|---|---|---|---|---|---|
| | | **en-es** | **en-fr** | **en-de** | **en-it** | **en-de** | **en-zh** |
| | Transcripts + Qwen 2.5 7B (topline) | 83.53 | 79.87 | 80.55 | 79.2 | 83.3 | **87.3** |
| | Transcripts + Llama 3.1 8B (topline) | **84.4** | **80.92** | **82.87** | **81.03** | **85.9** | 87.1 |
| | Seamless + Qwen 2.5 7B (Cascaded) | 81.3 | 77.6 | 78.3 | 77.6 | 81.4 | 85.8 |
| | Seamless + Llama 3.1 8B (Cascaded) | 82.2 | 78.7 | 80.9 | 79.1 | 84.1 | 85.6 |
| | Seamless ST (in-domain) | 78.7 | 72.5 | 68.6 | 72.8 | 86.0 | 83.7 |
| Llama 3.1 | SpeechMapper (stage 1) (zero-shot) | 76.4 | 73.9 | 72.3 | 76.8 | 67.1 | 69.3 |
| Llama 3.1 | SpeechMapper (stage 2) (zero-shot) | 74.7±2.7 | 71.0±2.8 | 66.4±2.6 | 73.2±2.6 | 63.7±1.0 | 68.6±1.5 |
| Llama 3.1 | ACIF (stage 1) (zero-shot) | 78.3 | 75.7 | 77.8 | 76.1 | 79.2 | 81.2 |
| Llama 3.1 | ACIF (stage 2) [CE] (zero-shot) | 78.9 | 76.2 | 78.6 | 76.9 | 81.1 | 83.0 |
| Llama 3.1 | ACIF (stage 2) [KD] (zero-shot) | 79.1 | 76.3 | 78.4 | 77.1 | 80.9 | 82.8 |
| Qwen 2.5 | ACIF (stage 1) (zero-shot) | 76.6 | 73.3 | 75.8 | 73.9 | 78.6 | 82.4 |
| Qwen 2.5 | ACIF (stage 2) [CE] (zero-shot) | 77.4 | 73.8 | 75.9 | 74.1 | 78.3 | 82.9 |
| Qwen 2.5 | ACIF (stage 2) [KD] (zero-shot) | 77.0 | 73.7 | 76.2 | 74.3 | 78.6 | 82.4 |

Table 2: Speech translation performance (COMET scores) on the Europarl-ST and CoVoST-2 datasets. The overall best results are highlighted in bold, while the highest-performing zero-shot configurations are underlined. Baseline results for SpeechMapper are taken directly from the original paper (Mohapatra et al., 2026).

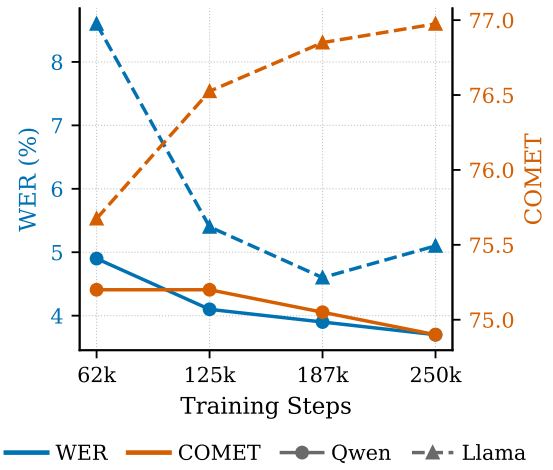

Figure 2: Impact of projector training duration on Librispeech test-clean (WER) and average Europarl-ST (COMET) performance. The Qwen 2.5 backbone achieves optimal alignment rapidly, while the performance of Llama 3.1 continues to steadily improve.

both Llama 3.1 and Qwen 2.5 backbones. We report WER on the LibriSpeech test-clean split and average COMET scores across Europarl-ST directions. The results highlight a clear difference in learning dynamics between the two models. While the projector aligned with Qwen achieves most of its performance early in training (within a quarter of the total steps), Llama steadily improves over longer training durations. This indicates that Qwen's target space is learned much faster by the projector.

Prior work has shown that pretrained language representations exhibit highly anisotropic structure and considerable redundancy, with much of the variance concentrated in a relatively small number of principal directions (Mu and Viswanath, 2018; Raunak et al., 2019). Such low effective dimensionality has been argued to simplify optimization in downstream learning tasks (Aghajanyan et al., 2021). Motivated by these observations, we examine whether differences in the geometry of the target embedding space can explain the projector learning dynamics observed above.

Figure 3 shows the cumulative variance explained by the principal components for both models, computed from over one million token embeddings extracted from the LibriSpeech training set. Qwen 2.5 exhibits a noticeably steeper eigenvalue decay than Llama 3.1. Specifically, Qwen requires only 857 principal components to explain 90% of the variance, whereas Llama requires 1,987 (more than twice as many), indicating that the variance of Qwen embeddings is concentrated in considerably fewer directions.

These geometric differences offer a plausible explanation for the training efficiency observed in Figure 2. The more concentrated variance spectrum of the Qwen embedding space suggests that its target representations are easier for the speech projector to learn, which is consistent with the substantially faster convergence observed during training. These results suggest that projector optimization is influenced not only by model size or architecture, but also by the geometry of the target embedding space. Consequently, training schedules and optimization hyperparameters should be adapted to the effective complexity of the target representation rather than transferred unchanged across LLM backbones.

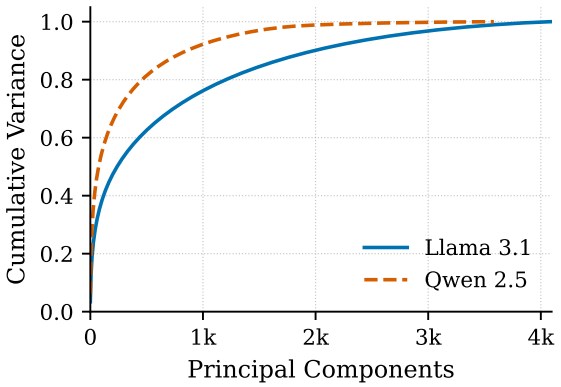

Figure 3: PCA eigenvalue decay of the target embedding spaces for Llama 3.1 and Qwen 2.5. Qwen 2.5 exhibits a substantially steeper decay, capturing 90% of the total variance in 857 principal components compared to 1,987 for Llama 3.1.

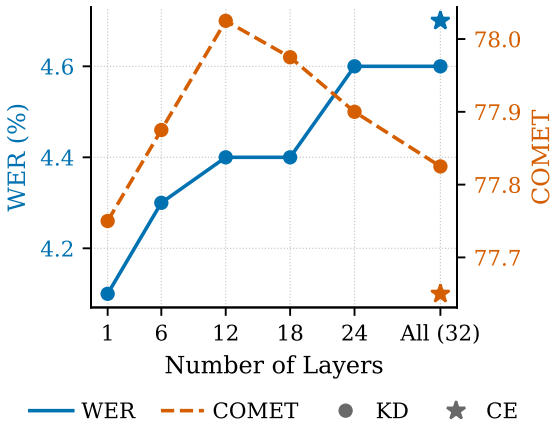

Figure 4: Impact of knowledge distillation layer depth on ASR and ST performance of Llama 3.1. WER on LibriSpeech (test-clean) steadily degrades as the number of distillation layers increases. Conversely, average COMET scores on Europarl-ST initially improve, reaching a peak at 12 layers before declining.

### 6.2 Impact of Distillation Depth

Our initial results demonstrate that KD using only the first layer of the LLM performs comparably to standard CE training with the full model. This raises an important question: how does increasing the distillation depth affect downstream performance? Figure 4 plots the WER on LibriSpeech and the average COMET score on Europarl-ST as we vary the target LLM layer $L$ for the $\mathcal{L}_{\text{KD}}$ objective. The isolated star markers represent the baseline performance using standard CE supervision across the full 32-layer LLM.

The results reveal a stark contrast between the optimal representations for ASR and ST. For ASR (the solid blue line), performance is strictly optimized at the shallowest depth. Distilling only the first LLM layer yields the lowest WER, and as the distillation depth increases, acoustic alignment steadily degrades. This suggests that the ASR task relies more heavily on the localized, surface-level representations found in early layers rather than the highly abstract representations formed deeper in the network.

Conversely, ST performance (the dashed orange line) benefits from intermediate semantic abstraction. Average COMET scores initially improve as the distillation depth increases, peaking at layer 12 before steadily declining. This indicates that the ST task requires the more complex semantic signals that develop at intermediate stages of the model. Importantly, for both tasks, distilling shallow or intermediate representations yields strictly better performance than mimicking the final layers (All 32). Furthermore, our optimal KD configurations (layer 1 for ASR, layer 12 for ST) outperform the full-model CE baselines. This confirms our hypothesis that mapping speech into the LLM's early or intermediate semantic spaces is sufficient for strong zero-shot performance, eliminating the need for full-model feedback. Finally, in Appendix B, we show that using cosine distance as an alternative to KL divergence is equally effective for zero-shot ASR and ST.

### 6.3 Sequence Length Alignment and Efficiency

During inference, ACIF relies solely on the predicted accumulation weights $\alpha$ to integrate acoustic frames into discrete token representations. This raises the question of how closely the length of these integrated embeddings matches that of the target reference text. As reported in Table 3, our ACIF mechanism dynamically aggregates acoustic frames into discrete speech representations that closely mirror ground-truth token lengths across both LLM backbones. Specifically, the average length ratio ($M_{\text{CIF}}/M$, where $M_{\text{CIF}}$ and $M$ denote the number of emitted ACIF tokens and target text tokens, respectively) remains tightly bounded between $0.994$ and $0.996$ with minimal variance ($\sigma \leq 0.033$). This demonstrates that the learned $\alpha$-accumulation accurately triggers at lexical boundaries without systematic under- or over-generation. Remarkably, $82\%$–$84\%$ of test sequences achieve

| | Stage | Comp. | Ratio | Exact (%) | $\leq \pm 1$ (%) | $\leq \pm 2$ (%) |
|---|---|---|---|---|---|---|
| Llama 3.1 | Stage 1 | 4.45× | **0.996**±0.032 | **84.1** | **97.8** | 99.3 |
| | Stage 2 [CE] | 4.45× | 0.995±0.033 | 82.1 | 97.1 | 99.2 |
| | Stage 2 [KD] | 4.45× | 0.994±0.032 | 82.7 | 97.1 | 99.2 |
| Qwen 2.5 | Stage 1 | 4.45× | 0.996±0.031 | 83.8 | 97.7 | **99.4** |
| | Stage 2 [CE] | 4.45× | 0.995±0.033 | 82.8 | 97.4 | 99.3 |
| | Stage 2 [KD] | 4.45× | 0.995±0.033 | 83.2 | 97.3 | 99.2 |

Table 3: Acoustic sequence compression and length alignment accuracy on LibriSpeech `test-clean`. **Comp.** denotes the dynamic CIF compression factor ($N'/M_{\text{CIF}}$). **Ratio** indicates the mean length ratio ($M_{\text{CIF}}/M \pm \sigma$). **Exact**, $\leq \pm\mathbf{1}$, and $\leq \pm\mathbf{2}$ report the percentage of utterances matching the target transcript length within 0, 1, and 2 token tolerances. Best overall results are in bold.

an exact length match with the reference token sequence, and over $97\%$ fall within a tight $\pm 1$ token tolerance ($> 99\%$ within $\pm 2$ tokens). Furthermore, this length calibration is strictly preserved throughout Stage 2 fine-tuning under both KD and CE objectives.

Crucially for computational efficiency, ACIF achieves an average dynamic downsampling rate of $4.45\times$ over the projected speech representations. Compounded with the initial $4\times$ reduction from the projector's convolutional layers, this yields an effective overall compression ratio of $\sim 17.8\times$ ($4\times4.45$) relative to the speech encoder's output. In contrast, SpeechMapper relies on a fixed $8\times$ reduction via consecutive frame averaging and strided convolutions. ACIF thus achieves more than double the temporal compression of prior work, substantially shortening the sequence length injected into the frozen LLM and mitigating quadratic self-attention overhead during inference.

## 7 Conclusion

In this paper, we introduced ACIF, a highly efficient framework that equips text-centric LLMs with zero-shot speech capabilities. By dynamically compressing acoustic frames into exact discrete token lengths via DTW-guided alignments, ACIF enhances both computational efficiency and downstream performance while eliminating the need for full LLM supervision. Our Stage 1 training establishes a robust acoustic-to-semantic bridge using lightweight distance metrics, entirely bypassing the LLM forward pass. For optional Stage 2 fine-tuning, we proposed a single-layer knowledge distillation objective that performs competitively with full-model cross-entropy supervision at a fraction of the memory cost. Ultimately, ACIF consistently outperforms parameter-efficient baselines on ASR and ST benchmarks, providing a lightweight, robust alternative for the future development of SpeechLLMs.

## Limitations

While ACIF demonstrates strong zero-shot capabilities, several limitations remain. First, our current training and evaluation pipelines are primarily English-centric. Future work should investigate the framework's scalability to a broader range of low-resource and typologically diverse languages. Second, our empirical evaluation focuses exclusively on Automatic Speech Recognition and Speech Translation. Exploring the applicability of ACIF to broader downstream tasks, such as spoken question answering or acoustic reasoning, remains an open area for investigation. Third, due to computational constraints, all models were trained using a single random seed. Although training converged reliably across configurations, reporting variance and confidence intervals across multiple seeds would provide a more complete assessment of performance stability. Finally, mapping continuous speech frames directly to discrete text token embeddings runs the risk of discarding valuable prosodic and paralinguistic cues inherent to spoken language. Future research should systematically analyze this information loss and explore alignment mechanisms that retain expressive acoustic features without compromising semantic alignment.

## Acknowledgments

The research presented in this paper was conducted as part of VOXReality project[5], which was funded by the European Union Horizon Europe program under grant agreement No 101070521.

## A Evaluation Prompts

For our evaluations, we format the inputs according to the specific chat templates of the underlying LLMs (e.g., Llama-3.1 or Qwen-2.5). The generalized prompt structure consists of a system message establishing the assistant's role, followed by a user message containing the projected acoustic embeddings and a task-specific instruction.

For ASR, we follow the instruction style of SpeechMapper to prompt verbatim transcription. For ST, the user instruction consists of a target-language-specific instruction which is a translation of "Can you translate the Speech content into [German/Spanish/French/Italian/Chinese] text?", followed by a formatting suffix: *"Output only the translation and nothing else."*. Table 4 details the exact system and user instructions used across all evaluations.

## B Cosine is as Effective as KL

Computing the standard KL divergence requires projecting hidden states through the LLM's unembedding matrix and applying a softmax operation, which introduces notable computational overhead during training. As a more efficient alternative, we experiment with defining our distillation objective, $\mathcal{L}_{\text{KD}}$, as the simple cosine distance between the intermediate hidden states of the speech representations $Z$ and the text embeddings $E$. Because the cosine distance is strictly bounded between 0 and 2, yielding intrinsically smaller numerical values than standard CE or KL losses, we scale this objective by a factor of $\lambda_{\text{kd}} = 10.0$. As demonstrated in Table 5, the cosine distance serves as a highly effective alternative to KL divergence. It achieves identical average COMET scores (77.8) across the Europarl-ST translation directions, while incurring only a marginal performance degradation of 0.1 WER on the LibriSpeech test-clean split.

| **Objective** | **LS clean** | **Europarl-ST** |
|---|---|---|
| Cosine | 4.2 / 2.3 | **77.8** |
| KL | **4.1 / 2.2** | **77.8** |

Table 5: Performance comparison between Cosine and KL distillation objectives on LibriSpeech (WER/CER) and Europarl-ST (COMET).

| Task | System Prompt | User Instruction (Appended after Speech Embeddings) |
|---|---|---|
| **ASR** | You are a helpful ASR transcription assistant. | Repeat the previous text between the quotes in its entirety just once and nothing else. Do not repeat the text multiple times or correct the text or add punctuation. End the text if you notice a phrase or a text is getting repeated. Ignore the words that do not make any sense. |
| **ST (de)** | You are a helpful translation assistant. | Können Sie den Inhalt der Rede in den deutschen Text übersetzen? Output only the translation and nothing else. |
| **ST (es)** | You are a helpful translation assistant. | ¿Puedes traducir el contenido del discurso al texto en español? Output only the translation and nothing else. |
| **ST (fr)** | You are a helpful translation assistant. | Pouvez-vous traduire le contenu du discours en texte français ? Output only the translation and nothing else. |
| **ST (it)** | You are a helpful translation assistant. | Puoi tradurre il contenuto del discorso in testo italiano? Output only the translation and nothing else. |
| **ST (zh)** | You are a helpful translation assistant. | 你能把演讲内容翻译成中文吗? Output only the translation and nothing else. |

Table 4: System prompts and user instructions used for zero-shot ASR and ST evaluation. The acoustic embeddings are inserted directly before the user instruction to form the final user message.

# IndicQE-APE: A Consolidated Benchmark for Quality Estimation and Automatic Post-Editing for Indic Languages

## Abstract

Indic quality estimation (QE) and automatic post-editing (APE) data is spread across separate releases, so no single resource supports training and evaluation across tasks and language pairs on one footing. We consolidate the WMT 2020–2024 shared-task lineage with an extended English-Malayalam resource into IndicQE-APE: 126,754 instances over nine directional pairs, with up to four label types aligned on the same segment, a direct assessment, a human post-edit, word-level tags and an error explanation, and a test set stratified over four difficulty axes. We benchmark six prompted LLMs and three COMET metrics on segment-level QE, and three systems on APE. Two of the axes are defined partly on direct assessment and select a compressed slice of it. Segments whose segment-level and token-level signals disagree are ranked below equally scored segments of the same language. Four-shot prompting costs every model at or below 3.4B both correlation and output-format compliance. Unedited MT beats every APE system we run on three of the four pairs. The benchmark[1] and code[2] are released.

## 1 Introduction

Reference-free evaluation of machine translation, scoring a translation without a human reference (QE) and repairing it (APE), remains an open problem for Indic and other low-resource languages for two compounding reasons. The data is fragmented: direct assessments, post-edits, word-level tags and explanations live in separate shared-task releases with incompatible schemas, splits and provenance, so training and evaluating across tasks and pairs means rebuilding the corpus first. In addition, evaluation on the data that does exist falls back on a single learned scalar whose behaviour across languages is rarely checked.

We address the first with a resource and the second with a measurement on it. IndicQE-APE unifies the WMT 2020–2024 QE and APE shared-task data for Indic pairs with an extended English→Malayalam resource into one release of 126,754 instances over nine directional pairs, sliceable by task and by language pair (Table 3). The label types are aligned on the same items: one instance may carry a direct assessment, a post-edit, word-level tags and an error explanation at once, so QE, APE and explainable QE can be studied without re-aligning corpora. Every test segment is flagged on each of four difficulty axes its labels can express. Appendix A places the release against the shared-task and metric literature it consolidates.

We report baselines for segment-level QE over all nine pairs and for APE over four. `CometKiwi-XL` (Rei et al., 2023) has the highest within-language segment correlation of the models we evaluate and the weakest cross-lingual agreement of the three trained metrics: its per-language offset moves against quality, where the offsets of the other two move with it, and pooling pairs costs it more than either. Within-language skill and cross-lingual comparability are separate properties, and a leaderboard that pools languages or compares raw scores across pairs inherits the offset. Of four difficulty axes, one costs a system anything once it is compared against segments of the same language carrying the same human score. Four-shot prompting costs every model at or below 3.4B both correlation and output compliance.

[2] https://github.com/surrey-nlp/IndicQE-APE

*Proceedings of the Eleventh Conference on Machine Translation*, pages 318–344
October 28-29, 2026 ©2026 Association for Computational Linguistics

These findings motivate two QE modelling directions we study on the benchmark: probing the hidden states of frozen instruction-tuned models (§4), and training a lightweight regression head on a COMET encoder to predict direct assessment (§5). The probe reads quality from intermediate layers; for the head the encoder's QE pretraining dominates, and it reaches parity with an off-the-shelf metric. The head saves per-instance predictions on all nine pairs, so the axis comparison is repeated on it, and it fails on the same axis as the prompted panel. *Contributions are:*

1. **IndicQE-APE**, a difficulty-stratified QE and APE benchmark over nine pairs with four aligned label types, an MQM layer, completed domain labels, corpus-level provenance and a standing duplication and leakage audit (§2).

2. **QE and APE baselines**: six prompted LLMs and three COMET metrics on segment-level QE over nine pairs (§3), and three systems on APE (§6), reported with output-format compliance alongside every correlation.

3. **Measurement on reference-free QE**: within-language correlation and cross-lingual comparability come apart, and the effect is a per-language offset that moves against quality. Of four difficulty axes only signal conflict survives a control matched on language and human score; the one that looks second-hardest without that control is measuring the range it selects (§3).

4. **Two QE modelling studies** on the benchmark: layer probing over frozen LLM states (§4) and a COMET-encoder regression head (§5), where encoder initialisation dominates.

## 2 The IndicQE-APE Benchmark

IndicQE-APE consolidates quality-estimation and post-editing data for Indic machine translation into one release. It is built test-first, stratified by difficulty, and carries up to four aligned label types.

**Consolidation and lineage.** The benchmark unifies WMT Direct-Assessment QE, domain-specific Indic QE, WMT and additional APE, and an extended English→Malayalam resource into 126,754 instances over nine directional pairs across Indo-Aryan and Dravidian scripts in both directions (en to {hi, mr, ta, te, gu, ml} and {et, ne, si} to en). Every instance records the source corpora it came from in a `sources` field and a human-readable `cadence_id`. Table 2 traces each corpus to its peer-reviewed release; the en→Indic DA backbone is the WMT 2022–2024 QE data, the X→en pairs are MLQE-PE, the post-edits are the WMT APE releases and Deoghare et al. (2024), and the en-ml layer extends the En→Ml QE release (Sindhujan et al., 2026). Eight of the nine pairs are Indic. The ninth, et-en, is Estonian, which is Uralic; it arrives with the MLQE-PE lineage on the same schema and serves as a non-Indic control carrying the same label types. Results are reported per pair throughout.

**Machine Translations and Annotation.** The hypotheses come from the upstream releases. The four WMT 2023–2024 en→Indic pairs were translated by a single multilingual system, NLLB-200-distilled-1.3B (NLLB Team, 2022), over source text from Anuvaad, the IITB corpus, NPTEL and SpokenTutorials (Blain et al., 2023; Zerva et al., 2024); en-mr by IndicTrans (Ramesh et al., 2022) over healthcare, cultural and news text (Zerva et al., 2022); and the three X→en pairs by per-pair fairseq Transformers over Wikipedia, the two lowest-resource of them under a semi-supervised backtranslation recipe (Fomicheva et al., 2022; Guzmán et al., 2019). The en-ml hypotheses are IndicTrans2 (Gala et al., 2023) over Anuvaad source text filtered by LaBSE similarity, sampled to spread the edit-rate distribution (Appendix L). Direct assessments are 0–100 FLORES-guideline judgements made against the source, $z$-normalised per annotator and averaged; the releases specify at least three annotators per segment, four for en-mr, and two independent panels for MLQE-PE, and the realised mean per pair is in Table 10. One MT system per group gives one hypothesis per source segment, so the benchmark supports segment-level meta-evaluation and no system-level ranking.

**Configuration.** The release is sliceable by named configuration. The nine-pair view is `full` (126,754), which holds every instance carrying a direct assessment, a post-edit, word tags or an explanation; the 2,163 en-hi segments annotated for MQM alone sit in `mqm` and nowhere else. `ape` (73,829) carries all seven post-edited pairs. Two configurations are scoped to en→Indic and do not contain the X→en pairs: `all` (100,366) and `qe-da` (85,586).

| | | Full dataset (instances carrying each label) | | | | | | | Eval (test) | |
|---|---|---|---|---|---|---|---|---|---|---|
| Pair | Script | Total | DA | PE | W-tag* | MQM | Expl. | Domain | QE | APE |
| en-hi | Devanagari | 21,092 | 15,136 | 9,983 | 9,982 | 2,327 | 1,999 | 19,301 | 1,881 | 1,536 |
| en-mr | Devanagari | 30,746 | 29,182 | 22,189 | 22,190 | 0 | 5,000 | 30,314 | 2,165 | 2,098 |
| en-gu | Gujarati | 9,109 | 9,109 | 0 | 0 | 0 | 0 | 8,996 | 1,090 | 0 |
| en-ta | Tamil | 16,262 | 9,002 | 10,838 | 10,838 | 0 | 2,645 | 14,886 | 2,038 | 1,448 |
| en-te | Telugu | 13,157 | 13,157 | 0 | 0 | 0 | 0 | 8,995 | 1,120 | 0 |
| en-ml | Malayalam | 10,000 | 10,000 | 10,000 | 10,000 | 0 | 10,000 | 10,000 | 1,436 | 1,436 |
| *X→en pairs (taken as-is from WMT20 MLQE-PE)* | | | | | | | | | | |
| et-en | – | 9,000 | 9,000 | 9,000 | 9,000 | 0 | 0 | 0 | 1,000 | 1,000 |
| ne-en | – | 8,649 | 8,649 | 8,332 | 8,612 | 0 | 0 | 0 | 1,000 | 962 |
| si-en | – | 8,739 | 8,739 | 3,487 | 8,679 | 0 | 0 | 0 | 1,000 | 380 |
| **Total** | | **126,754** | **111,974** | **73,829** | **79,301** | **2,327** | **19,644** | **92,492** | **12,730** | **8,860** |

Table 1: Composition of IndicQE-APE. *Total* is instances per pair; the label columns count instances carrying a direct assessment (DA), a human post-edit (PE), word-level OK/BAD tags (W-tag), a segment-level MQM score with typed spans (MQM; Lommel et al., 2014), an explanation (Expl., either kind) or a gold domain label. MQM covers en-hi only. *W-tag combines 38,616 real tags with 40,685 derived from MT and post-edit where no real tag exists, and no row carries both. The *Eval* columns come from one 13,032-segment challenge test, of which 12,730 carry a DA and 8,860 a post-edit; en-gu and en-te have no post-edits, so the APE column covers seven pairs.

| Source | Pairs | Released by |
|---|---|---|
| WMT22 QE | en-mr | Zerva et al. (2022) |
| WMT23 QE | en-hi/gu/ta/te | Blain et al. (2023) |
| WMT24 QE | en-hi/gu/ta/te (test) | Zerva et al. (2024) |
| MLQE-PE | et/ne/si-en | Fomicheva et al. (2022) |
| WMT22/23 APE | en-mr | Bhattacharyya et al. (2022) |
| WMT24 APE | en-hi, en-ta | Zerva et al. (2024) |
| Multilingual APE | en-hi, en-mr | Deoghare et al. (2024) |
| En→Ml QE | en-ml | Sindhujan et al. (2026) |

Table 2: Shared-task lineage of IndicQE-APE. Each source corpus is tagged per instance (`sources`, `cadence_id`); the upstream release sizes and this benchmark's re-curated per-pair totals differ, because instances are merged across corpora by a content-hash `uid`. The En→Ml row is the prior release of about half the en-ml segments; all 10,000 are carried here, the rest annotated by the same annotators under the same guidelines (Appendix L). Licensing is in §2.

| Configuration | Train | Valid. | Test | Total | Scope |
|---|---|---|---|---|---|
| `full` | 107,641 | 6,081 | 13,032 | 126,754 | nine pairs, every instance |
| `all` | 87,253 | 3,081 | 10,032 | 100,366 | en→Indic only |
| `qe-da` | 72,806 | 3,050 | 9,730 | 85,586 | en→Indic, DA-bearing |
| `ape` | 61,032 | 3,937 | 8,860 | 73,829 | seven post-edited pairs |
| `word-qe` | 65,241 | 4,553 | 9,507 | 79,301 | word-level OK/BAD tags |
| `explainable-qe` | 14,775 | 976 | 3,893 | 19,644 | error explanations |
| `mqm` | 1,708 | 143 | 2,639 | 4,490 | en-hi MQM layer |
| `challenge` | — | — | 13,032 | 13,032 | curated test only |

Table 3: Split sizes per released configuration, read from the released files. `challenge` is the curated difficulty-stratified test set, has no train split, and is the evaluation set for §3. Splits are source-disjoint, so no instance and no source sentence reaches two splits of a configuration.

**Difficulty-stratified design.** The evaluation set is built to a known composition. Difficulty is recorded on four axes. Each is a function of released columns alone, and every threshold but one is taken within language pair, so a segment is placed against its own pair's distribution. The exception is `A1`'s quality band, which is the same $[35, 75]$ on the 0–100 scale for every pair. `A1`, *annotator disagreement*, is a per-annotator DA standard deviation in the pair's top quartile with a mean in $[35, 75]$; `A2`, *edit effort*, is MT→post-edit token TER in the pair's top quartile; `A3`, *word error*, is BAD-tag density in the pair's top quartile or an error category of mistranslation, untranslated or addition; and `A4`, *signal conflict*, is a segment scored half a standard deviation above the pair's mean yet error-dense by the same margin, or scored in the pair's bottom 30% yet edited half a standard deviation less than its norm. `A4` selects a disagreement between two human signals. Appendix I gives a verified en-hi example of each axis and Appendix E the numeric cut every pair receives. The stratification is visible in the result: 59.8% of DA-bearing challenge segments carry at least one axis against 30.6% of the DA-bearing segments outside the test, and every one of the nine pairs is enriched. The axes overlap, so they ship as four flags: only 3,265 of the 7,616 flagged challenge segments sit on exactly one. en-gu and en-te arrive as direct assessments alone, so they are null on the three axes that need a post-edit or a word tag (Table 14).

**Labels and Domains.** Each segment carries up to four aligned label types (per-pair coverage in Table 1): a $z$-normalised direct-assessment (DA) score, a human post-edit, word-level OK/BAD tags, and an explanation, so the same items serve QE, APE and explainable QE without realignment. Explanations are of two kinds and the release records which: 8,951 human Translation Quality Remarks, all on en-ml, and 14,644 model-generated error descriptions on en-hi, en-mr, en-ta and en-ml (Appendix B). Every explanation outside en-ml is model-generated. We complete the domain metadata, which was inconsistently cased and absent for many rows, by normalising to a ten-domain taxonomy and inferring the missing labels with a word and character TF-IDF logistic-regression classifier on the source side, flagged by provenance (92,492 annotated and 34,262 inferred over the release; the challenge-test distribution is in Table 19). News, finance, tech and sports are gold-only en-ml labels and are never inferred onto other pairs. The three X→en pairs carry no gold domain, so all 26,388 of their labels are inferred, and the classifier is fitted and measured on English source text from the en→Indic pairs; we treat the X→en domain labels as unvalidated and condition no analysis on them. The classifier reaches 0.826 accuracy under five-fold cross-validation and beats prompted GPT baselines on a gold sample, by a margin confined to the classes that record provenance (Appendix B).

**Label coverage.** Label coverage is uneven across the pairs. 111,974 of the 126,754 instances carry a direct assessment. The remaining 14,780 come from the APE shared-task releases as source, MT and post-edit triples that were never DA-annotated, and they fall in en-ta (7,260), en-hi (5,956) and en-mr (1,564); they support APE and word-level tagging. In the other direction 73,829 instances carry a post-edit, so the QE and APE populations overlap and neither contains the other. IndicQE-APE releases no independent reference translations: every released target was produced by post-editing the MT. Where a corpus reference existed it was used in construction, as for en-ml (Appendix L). We treat the human post-edit as the reference, and every reference-based number we report is *human-targeted* in the sense of HTER (Snover et al., 2006).

**Provenance, deduplication and Splits.** An instance is identified by a `uid`, the hash of its normalised source and MT, so two corpora contributing the same segment produce one row: 234,446 corpus contributions collapse to 126,754 rows, and 77,505 of those rows carry more than one source. Every named configuration is then checked to be an exact view of that master table. The splits are built source-disjoint, and a regression check confirms that no exact instance and no source sentence reaches more than one of train, validation and test. The checks ship with the release (Appendix J), and `cadence_id` and `sources` carry the provenance.

**Word-level tags.** Word-level QE tags in the WMT lineage are produced by aligning the MT to its human post-edit and marking substituted or deleted MT tokens BAD (Specia et al., 2020). They are a deterministic function of (MT, post-edit), so any segment carrying a post-edit can be tagged under the same rule. Between the rule and an import of the MLQE-PE labels this takes coverage from 12,604 segments to 79,301 over seven of the nine pairs, 40,685 of the increase from the rule and 26,012 from the import. Real labels take precedence: 26,012 segments are imported from MLQE-PE for the X→en pairs, which also brings gap tags and source-side tags, and 40,685 are derived where no released label exists. en-gu and en-te have neither post-edits nor upstream tags and remain uncovered. Every row records which class it belongs to and the original columns are preserved, so a user may train on upstream-only, derived-only or the union. Re-deriving the released tags from MT and post-edit alone reproduces them at 0.963 Matthews correlation over 633,988 tokens. Agreement is lowest for en-ml and en-mr and highest for the X→en pairs, which is the order of morphological complexity. The per-pair figures, the tokenisation comparison and the morphological evidence are in Appendix B, and the per-segment confusion counts ship with the release.

**Availability and Licence.** The per-instance predictions behind every number here ship as an evidence bundle in a tagged release of that code. The English→Malayalam annotation protocol is documented in Sindhujan et al. (2025a) and Appendix L. Two licences apply and the per-row `sources` field says which. The three X→en pairs are MLQE-PE, redistributed under its CC0 1.0; everything else, including the English→Malayalam data, the 40,685 derived word-level tags, the MQM layer, the domains and the difficulty axes, is CC BY 4.0.

## 3 QE Baselines

We evaluate QE models on IndicQE-APE using 0-shot GEMBA-DA prompting (Kocmi and Federmann, 2023) for the instruction-tuned models and the COMET family as trained baselines.[3] All models are run on the same 13,032-segment challenge test, of which 12,730 carry a direct assessment and are the population for every correlation. The trained metrics score all of them. A prompted model scores only the segments it returns a usable score for, which at zero shots is between 12,552 and 12,730 segments; the residual is its non-compliance, reported alongside every correlation. Compliance is quoted two ways and the difference matters below 1: pooled over segments, which is what the 12,552 floor is, and macro over pairs, which is what a *parse* column reports. For each model we compute a within-language score, the macro correlation of model scores with human DA over the nine pairs (Pearson, Spearman, Kendall), and a cross-lingual score, the Pearson correlation across the nine pairs between the model's mean score for a pair and the mean human score for that pair. The cross-lingual score asks whether the model's numbers are comparable across languages. Table 4 reports both. We give all three coefficients for continuity with the QE shared tasks, with percentile bootstrap intervals over segments.

A prompted model returns text, so a score exists only once that text has been parsed, and the parsing rule is part of the measurement. We accept a reply as a score when it is unambiguously one: a bare number, or a number behind a label such as `Score:` or `Score (0-100):`. We reject prose and any reply carrying more than one number, and count the segment as non-compliant. Appendix M gives the failure modes a permissive parser produces on our four-shot outputs.

**Within-language accuracy does not make scores comparable across pairs.** `CometKiwi-XL` has the highest within-language Spearman of the models we evaluate (0.671) and, of the three trained metrics, the weakest agreement across languages: over the six en→Indic pairs its per-language means track the human per-language means at $r = 0.34$, against 0.91 for the weaker `XCOMET-XL` (Guerreiro et al., 2024) on the same population. Both figures come from the full-population pass of Table 17; that table's other block estimates the prompted models on the challenge test, and MetricX-24 (Juraska et al., 2024) sits with the trained metrics. Writing a model score as $m(x) = a_\ell + b_\ell\, q(x)$ for a segment $x$ in language $\ell$, within-language rank statistics are invariant to the per-language offset $a_\ell$ while the comparison of per-language means is governed by it, so comparability degrades when $a_\ell$ carries information other than quality. It does here: for `CometKiwi-XL` the offset correlates with quality at $-0.442$, where `CometKiwi-DA` is $+0.229$, `XCOMET-XL` $+0.433$ and `GPT-5.5` $+0.641$. Of the five systems in Table 5 it is the only one whose offset runs against quality and the only one whose bootstrap interval includes zero, so its raw coefficient is not identified at this sample size. Raw scores from such a metric should not be compared across pairs, and a leaderboard should average within-pair correlations.

| | within-language | | | cross-ling. |
|---|---|---|---|---|
| Model | P | $\rho$ | $\tau$ | $r$ |
| `BharatGPT-3B` | 0.134 | 0.098 | 0.075 | −0.46 |
| `Llama-3.2-3B` | 0.256 | 0.217 | 0.172 | 0.86 |
| `tiny-aya-fire` | 0.311 | 0.290 | 0.232 | 0.93 |
| `aya-expanse-32B` | 0.404 | 0.404 | 0.321 | 0.91 |
| `sarvam-m` | 0.455 | 0.440 | 0.344 | 0.91 |
| `GPT-5.5` | 0.627 | 0.623 | 0.461 | 0.94 |
| `CometKiwi-DA` | 0.625 | 0.621 | 0.452 | 0.78 |
| `CometKiwi-XL` | 0.680 | 0.671 | 0.497 | −0.21 |
| `XCOMET-XL` | 0.498 | 0.498 | 0.355 | 0.61 |

Table 4: QE over the nine pairs on the challenge test: zero-shot GEMBA-DA for the LLMs, the COMET family below the rule. Within-language columns are macro correlations over pairs. The cross-lingual column is the Pearson correlation between per-pair model means and per-pair human means over nine points, a diagnostic and not a ranking; it is computed on this table's population and so differs from the pooled column of Table 17, which uses the extended challenge test. Compliance is reported separately and never folded in (§3). Per-pair values are in Table 16.

The coefficient is a diagnostic. It rests on one point per language pair, moves from $-0.67$ on eight pairs to $-0.21$ on nine and $+0.12$ on the full population (Appendix H), and every interval is wide. WMT meta-evaluation averages within-pair correlations (Freitag et al., 2024). The claim rests on the per-language offsets and on the aggregation result below; the text quotes the scoped en→Indic values while the $r$ column of Table 4 pools all nine pairs and is correspondingly inflated (Appendix G).

[3] Model identifiers, sizes, serving stacks and decoding settings are in Appendix M, and the two prompt templates are printed there in full.

| Model | raw $r$ | bootstrap 95% CI | offset↔q. |
|---|---|---|---|
| `CometKiwi-XL` | $-0.208$ | $[-0.930, +0.320]$ | $-0.442$ |
| `CometKiwi-DA` | 0.783 | $[+0.554, +0.955]$ | 0.229 |
| `XCOMET-XL` | 0.607 | $[+0.037, +0.880]$ | 0.433 |
| `GPT-5.5` | 0.941 | $[+0.737, +0.991]$ | 0.641 |
| `sarvam-m` | 0.913 | $[+0.770, +0.991]$ | 0.595 |

Table 5: Cross-lingual agreement over nine pairs. *raw r* is the Pearson correlation between per-language model means and per-language human means, with a per-centile bootstrap interval over pairs; *offset↔q.* is the correlation between the fitted per-language offset $a_\ell$ and quality, where $m(x) = a_\ell + b_\ell\, q(x)$ is fitted per pair. No claim rests on *raw r* or on its interval; the last column carries them.

Appendix O replicates the effect with language held fixed, against annotation batch.

The same effect follows from aggregation alone. Pooling all nine pairs into one correlation instead of averaging per-pair Spearman costs `CometKiwi-XL` 0.117 (0.671 macro against 0.554 pooled), while `XCOMET-XL` loses 0.001 (0.498 to 0.497) and `CometKiwi-DA` gains 0.034. Pooling normally inflates a correlation. `CometKiwi-XL` is the only one that loses by more than rounding, because its per-language means are displaced against quality, so the variance pooling adds is variance it gets wrong.

**Where models fail.** `A1` and `A4` are defined partly on the direct assessment, and their segments sit in a narrow slice of it, holding 0.43 and 0.62 of their pair's remaining spread against 0.86 and 0.90 for `A2` and `A3`, which carry no score term. A rank correlation falls on a narrow range whether or not the segments are harder. Each axis is therefore compared against a control drawn from the rest of its own pair and matched to the flagged score histogram, inside the pair and only then averaged.

Measured against the rest of the pair, `A1` is the second-hardest axis at $-0.205$ and `A4` the hardest at $-0.284$ (Table 11). Measured against the matched control, `A1` is $-0.003$ $[-0.047, +0.037]$ and negative on four of its nine pairs, so its apparent difficulty was the compression of the score range. `A4` survives at $-0.146$ $[-0.270, -0.059]$, negative on all seven pairs that carry it and for all nine systems (Table 6). `A2` and `A3` come out flat to mildly positive, $+0.066$ and $+0.019$: heavy editing and dense word error leave a segment no harder to place among others the annotators scored the same.

The control leaves the disagreement between the two human signals, and $-0.146$ is a ceiling on it. One of `A4`'s two arms is carried by enough pairs to read, segments scored below par for their pair yet barely edited: 1,149 over four pairs, contrast $-0.070$, negative on every one. The other holds 123 segments over three pairs and is negative on two (Appendix D). On `A1` the segments differ from one another by no more than annotator noise, so the reliability of the DA mean is not estimable; on `A4` it is 0.534 and does not account for the contrast (Appendix P).

**What separates the pairs.** The released annotator scores separate the candidate explanations for the per-pair spread (Appendix Q). Label reliability does not explain it: per-pair ICC$(1, k)$ runs from 0.44 to 0.98 on the challenge test and does not predict per-pair correlation ($r = -0.16$, $p = 0.67$). Training exposure does not account for it either. CometKiwi is trained on the direct-assessment data our X→en pairs come from, so exposure would predict a direction gap for the trained metrics and none for the prompted ones; the gap is $+0.21$ against $+0.15$, and `tiny-aya-fire` at $+0.26$ exceeds two of the three trained metrics. Score spread tracks difficulty weakly: $r = +0.53$ ($p = 0.14$) between a pair's DA standard deviation and its mean correlation across systems. English to Telugu shows the pattern, with the smallest DA standard deviation of the nine pairs (14.0), the lowest-scoring pair for seven of the nine systems, and the lowest sentence-level correlation of any Indic pair at WMT 2023 and WMT 2024 (Blain et al., 2023; Zerva et al., 2024), while its reference-based MT quality is among the strongest here (Gala et al., 2023).

**Robustness to the prompt.** The headline uses one template at zero shots, so we check both choices (Table 7). Four-shot prompting lowers macro Spearman for four of the six prompted models and raises it for two, `aya-expanse-32B` by 0.055 and `GPT-5.5` by 0.003; the largest fall is `Llama-3.2-3B`, 0.217 to 0.027. A cell enters a macro only if the model returned a usable score on at least half of it, which costs `BharatGPT-3B` and `Llama-3.2-3B` five and four pairs and `tiny-aya-fire` two. Compliance falls under four shots as well, so the two conditions score different segments, but restricting both to the segments they both scored leaves every drop within 0.001 of its unpaired figure. Four-shot prompt-

| Model | A1 | A2 | A3 | A4 |
|---|---|---|---|---|
| GPT-5.5 | +0.015 | +0.040 | +0.001 | −0.224 |
| sarvam-m | +0.012 | +0.075 | +0.024 | −0.153 |
| aya-expanse-32B | +0.024 | +0.087 | +0.019 | −0.169 |
| tiny-aya-fire | −0.051 | +0.100 | +0.015 | −0.015 |
| Llama-3.2-3B | +0.039 | +0.076 | +0.005 | −0.041 |
| BharatGPT-3B | +0.014 | +0.047 | +0.036 | −0.092 |
| CometKiwi-DA | −0.044 | +0.079 | +0.035 | −0.165 |
| CometKiwi-XL | −0.032 | +0.064 | +0.054 | −0.140 |
| XCOMET-XL | −0.002 | +0.026 | −0.015 | −0.155 |

Table 6: Change in Spearman $\rho$ between a pair's flagged segments and a control drawn from the same pair with the same DA histogram, averaged over the pairs that carry the axis; negative means the flagged segments are ranked worse than equally-scored segments within language. Bold marks each system's worst axis: A4 is negative for all nine systems and worst for eight. Intervals and the unmatched comparison are in Table 11.

ing therefore degrades scoring itself. Both effects track capacity: the three models $\leq 3.4$B lose the most and comply least, failing on between 14% and 55% of segments, while aya-expanse-32B, the largest open model tested, gains. Which pairs fail is model-specific (Table 12). Both numbers are properties of one template. Constrained decoding, a per-model prompt or fine-tuning on the output format would raise compliance, and correlation with it. The prompt is held fixed, so the comparison bounds what an off-the-shelf template returns.

**Template choice.** The template matters less than the shot count and mainly to weak models. Per model the two differ by 0.026 in macro Spearman against 0.069 for the shot count, and SQM is the better of the two on 51 of the 94 cells both templates scored above the compliance floor. The divergence sits where the model is weakest: BharatGPT-3B at zero shots scores 0.098 under DA against 0.031 under SQM, whereas GPT-5.5's two templates agree to within 0.002. SQM is also the weaker on zero-shot compliance for two models, aya-expanse-32B parsing 0.872 (ne-en 0.47) and tiny-aya-fire 0.885 (si-en 0.62) against 0.981 and 1.000 under DA, all macro over pairs, so those SQM cells rest on a reduced population; aya-expanse-32B's 0.981 macro is the 0.986 pooled rate that sets the 12,552 floor above. We report GEMBA-DA throughout. sarvam-t is a translation model that follows neither prompt, parsing 0.003, so it is omitted from the QE evaluation and appears in §6 as an APE system.

| | macro $\rho$ | | | paired | 4-shot | |
|---|---|---|---|---|---|---|
| Model | 0-shot | 4-shot | Δ | Δ | pairs | parse |
| BharatGPT-3B | 0.098 | 0.001 | −0.098 | −0.098 | 4 | 0.447 |
| Llama-3.2-3B | 0.217 | 0.027 | −0.190 | −0.189 | 4 | 0.501‡ |
| tiny-aya-fire | 0.290 | 0.240 | −0.050 | −0.050 | 7 | 0.861 |
| aya-expanse-32B | 0.404 | 0.459 | +0.055 | +0.055 | 9 | 0.987 |
| sarvam-m | 0.440 | 0.421 | −0.019 | −0.019 | 9 | 1.000 |
| GPT-5.5 | 0.623 | 0.625 | +0.003 | +0.003 | 9 | 1.000 |
| *control: encoders, prompt-invariant* | | | | | | |
| CometKiwi-DA | 0.621 | 0.621 | 0.000 | — | 9 | — |
| CometKiwi-XL | 0.671 | 0.671 | 0.000 | — | 9 | — |
| XCOMET-XL | 0.498 | 0.498 | 0.000 | — | 9 | — |

Table 7: Effect of four-shot prompting. *pairs* is how many language pairs the four-shot macro averages: a cell counts only where the model returned a usable score on at least half of it (§3). Every zero-shot macro is over nine pairs, its lowest cell aya-expanse-32B on ne-en at 0.868. Δ compares each condition on every segment it scored; *paired* Δ restricts both to the segments they both scored. *parse* is the share of items returning a single GEMBA-DA score at four shots, over all nine pairs whether or not the cell enters the macro. ‡Llama-3.2-3B has no four-shot run on en-hi, so that pair is absent from its row rather than excluded by the rule. The encoders below the rule cannot see a prompt, so their columns must agree exactly; they are the internal check that the differences above come from prompting and not from the scoring code. Per-pair compliance is in Table 12.

## 4 Layer-Probing Quality Estimation

A quality score can also be read from a frozen model's hidden states instead of its generated text. We train the single-layer form of adaptive layer optimisation for QE (Sindhujan et al., 2025b), a regression head on the last-token hidden state of a frozen tiny-aya-fire at one layer, jointly over the six en→Indic pairs, and sweep the layer (Table 25, Appendix K).

Where the signal sits in the network does not follow language family. Averaged over pairs the best layer is −20 (0.527) and the two ends of the swept range are weakest, −5 nearest the output at 0.501 and −24 furthest from it at 0.496; the final layer is not swept. The weakest Indo-Aryan pair (en-hi) and the weakest Dravidian one (en-te) peak at that same depth, though the best layer is otherwise pair-dependent (Table 24). Picking the layer per pair raises the macro to 0.539, but that pick is made on the split the probe is then scored on and is an oracle over the six layers swept, so 0.527 at one fixed layer is the comparable figure. At that layer the probe recovers a signal for five of the six pairs (Spearman 0.45–0.64) and is weak on en-te (0.28). Length does not account for it: predicting

DA from source length, MT length or their ratio reaches macro Spearman 0.218 and sits below the probe on every pair.

Reading the states beats prompting the same weights. `tiny-aya-fire` scored by GEMBA-DA reaches macro Spearman 0.202 on these six pairs against 0.527 for the probe, which is ahead on every one of them. `GPT-5.5` reaches 0.578 on the same six, so a frozen 3.4B backbone with a trained read-out comes within 0.051 of the strongest prompted model and passes it on en-te (0.282 against 0.255).

The sweep saved per-layer aggregates, so the probe is reported at the pair level and the difficulty axes cannot be joined to it.

## 5 A Lightweight QE Head on COMET

The encoder baselines of §3 are used off the shelf. We also train a regression head over a COMET/CometKiwi encoder: it reads a source–hypothesis pair, funnels upper encoder layers and regresses a per-pair $z$-scored DA target under a Huber loss, with an option to add attention-derived adequacy features and a length ratio (Figure 1). Trained on the six en→Indic pairs of `qe-da` (72,806 segments) and evaluated on the matched challenge test (9,730), the funnel-only form reaches Spearman 0.596 and the form with the extra features 0.581. The features are worth −0.015 here and +0.005 on the ablation build below, and the bootstrap intervals overlap in both directions. The ablation varies one choice at a time on a five-pair build without en-ml, so its cells compare with each other; every ablation cell is a within-build contrast whose size is the claim (Appendix K).

Swapping only the backbone, the head inherits its encoder's QE knowledge in order: reference-free QE pretraining (CometKiwi, 0.580) beats reference-based pretraining (COMET-DA, 0.491) beats none (XLM-R-large, 0.440). That +0.140 gap (Williams $t$=20.5, $p < 0.001$, $n$=8,160) is the biggest gain of any substitution; the only other change that helps is the min–max target, at +0.040. Three choices move the score further than the encoder does, and all three are losses from removing something the reference configuration has: reading the last layer alone collapses the head at all three seeds; plain MSE costs 0.294 against the Huber reference, while CCC matches it; and the target must be scaled to the loss, a raw 0–100 target diverging where per-pair $z$ gives 0.585 and min–max $[0, 1]$ gives 0.625 (Table 21).

| System | $\rho$ (95% CI) | $r$ | $\text{acc}^*_{eq}$ |
|---|---|---|---|
| *Zero-shot COMET (en→Indic challenge test, $n$=9,730)* | | | |
| CometKiwi-DA | 0.588 | 0.596 | — |
| CometKiwi-XL | **0.608** | 0.597 | — |
| XCOMET-XL (QE) | 0.406 | 0.414 | — |
| *Trained head, six pairs ($n$=9,730) — the §5 lane* | | | |
| + CometKiwi, funnel only | 0.596 [.581,.610] | 0.580 | 0.708 |
| + CometKiwi, +features | 0.581 [.565,.596] | 0.577 | 0.704 |
| *Ablation build, five pairs ($n$=8,160), encoder swap* | | | |
| + XLM-R-large (no QE pretrain) | 0.440 [.421,.457] | 0.440 | 0.649 |
| + COMET-DA (ref-based) | 0.491 | 0.497 | — |
| + CometKiwi, CLS+funnel | 0.580 [.565,.595] | 0.590 | 0.709 |
| + CometKiwi, full features (ref) | 0.585 [.569,.600] | 0.600 | 0.707 |
| + CometKiwi, full, min–max target | 0.625 [.610,.640] | **0.662** | **0.727** |

Table 8: Regression QE over a COMET encoder on IndicQE-APE (within-language, segment-level, en→Indic challenge test), against the zero-shot COMET baselines on the same lane. The middle block is the six-pair lane §5 reports; the bottom block is the five-pair ablation build, whose cells compare with each other and not across blocks. $\text{acc}^*_{eq}$ is pairwise accuracy with tie calibration (Deutsch et al., 2023); intervals are percentile bootstrap over segments. Full ablation in Appendix K.

On the six-pair lane the head reaches parity: $\rho =$ 0.596 against 0.588 for zero-shot CometKiwi-DA on the same segments and 0.608 for CometKiwi-XL, a margin of 0.008 over the former that we do not read as an improvement. The head's saved predictions, with the X→en runs, cover all nine pairs, so the axis comparison of §3 can be repeated on a model trained here. It agrees on three of the four: `A4` is −0.176 funnel-only and −0.143 with features against a DA-matched control, negative on every pair for both, and `A2` and `A3` are positive. On `A1` the two estimators part, the head giving −0.084 and −0.050 against the panel's −0.003, but en-gu at −0.41 and en-ml at −0.24 carry almost all of it against +0.16 on ne-en, so we read it as unstable. The head's own offset runs the same way as `CometKiwi-XL`'s, at −0.11 to −0.05 against −0.442, though on the ablation build's five pair means neither its size nor its sign is established ($p > 0.85$). Run unchanged on the three X→en pairs the pipeline gives 0.655 funnel-only and 0.668 with the extra features, 0.059 and 0.087 above the matching en→Indic figure. The lower en→Indic number is a property of those pairs.

## 6 Automatic Post-Editing

The benchmark's post-edits support automatic post-editing directly, with the human post-edit as

| Model | Pair | char-TER↓ | chrF++↑ | CometKiwi↑ |
|---|---|---|---|---|
| do-nothing | en-hi | 44.5 | 55.4 | — |
| | en-mr | **26.1** | **74.8** | — |
| | en-ta | **43.4** | **64.2** | — |
| | en-ml | **31.1** | **78.1** | — |
| `sarvam-m` | en-hi | 37.6 | 58.9 | 0.819 |
| | en-mr | 36.5 | 63.9 | 0.743 |
| | en-ta | 54.5 | 54.1 | 0.826 |
| | en-ml | 44.7 | 60.0 | 0.862 |
| `sarvam-t` | en-hi | **34.4** | **62.5** | **0.829** |
| | en-mr | 42.5 | 59.0 | **0.757** |
| | en-ta | 63.0 | 49.1 | **0.841** |
| | en-ml | 49.0 | 53.4 | **0.872** |
| `tiny-aya-fire` | en-hi | 46.7 | 55.5 | 0.782 |
| | en-mr | 36.7 | 70.6 | 0.697 |
| | en-ta | 57.0 | 56.5 | 0.771 |
| | en-ml | 37.8 | 71.1 | 0.802 |

Table 9: APE quality per model and pair on the en→Indic APE test (↓/↑ = lower error / higher similarity), every cell on the same rows (en-hi 1,536, en-mr 2,098, en-ta 1,448, en-ml 1,436). *do-nothing* is the unedited MT scored against the human post-edit; bold marks the best row per pair and metric. char-TER and chrF++ are reference-based against the post-edit, CometKiwi reference-free against the source. CometKiwi is blank for do-nothing because the zero-shot pass scored DA-bearing rows only, which covers these four pairs unevenly; on the rows it does cover the unedited MT scores 0.769, 0.688, 0.757 and 0.815.

the reference. Table 9 reports three open systems, `sarvam-m`, the dedicated translator `sarvam-t`, and `tiny-aya-fire`, on the four en→Indic pairs with system outputs, scored with the reference-based surface metrics char-TER and chrF++. Post-editing systems were run for these four pairs only: en-gu and en-te carry no human post-edits, and the three X→en pairs carry post-edits with no system outputs produced for them here (Table 1). All three run zero-shot from the prompt in Appendix M, untrained on the benchmark. `sarvam-m` and `tiny-aya-fire` are given the source and the MT and asked to edit it; `sarvam-t` is a translation model and is run in retranslation mode, from the source alone. Appendix N repeats the table under word-level TER and BLEU.

The first block of Table 9 is the unedited MT, and on three of the four pairs it is the best row in the table. Leaving en-mr alone gives char-TER 26.1 against 36.5 for the best system, en-ta 43.4 against 54.5, en-ml 31.1 against 37.8, and the same three on chrF++. Only on en-hi does any system improve on doing nothing, and en-hi is the one pair whose post-edits almost always change something: on its APE test rows 0.5% of post-edits leave the MT untouched, against 12.2% for en-mr, 29.1% for en-ta and 30.8% for en-ml.

The reference-free view says the opposite. CometKiwi rates every system above the unedited MT in eleven of twelve cells, and orders them identically on all four pairs, `sarvam-t` above `sarvam-m` above `tiny-aya-fire`, while chrF++ gives that order on en-hi and reverses it on the other three. The cause is the reference. A post-edit is produced by editing the MT, so the MT is by construction close to it, and a surface metric against post-edits measures residual repair effort (§2). `sarvam-t` retranslates from the source, so it departs from the post-edit however good its output is. The penalty scales with how conservative the post-edits are, and the table shows it: `sarvam-t` is the best system on en-hi, the one pair whose post-edits almost always change something, and the worst on each of the other three. Post-edit-anchored references reward conservative editing, and where post-edits are often no-ops the unedited MT cannot be beaten. The two surface metrics also disagree with each other on en-mr and en-ta, where `sarvam-m` needs fewest edits but `tiny-aya-fire` retains the most $n$-grams.

The negative result is scoped to prompting. `ape` ships 61,032 training triples that none of these three systems saw, and a system fitted on them would learn to edit conservatively, which is what the post-edit reference rewards. The do-nothing row is the baseline such a system has to clear.

## 7 Conclusion

IndicQE-APE consolidates the WMT 2020–2024 Indic QE and APE lineage with an extended English→Malayalam resource into one benchmark of 126,754 instances over nine directional pairs, with up to four label types aligned on the same items, a constructed difficulty-stratified test set, verified provenance and no train/test leakage. On it, within-language QE accuracy does not imply cross-lingual comparability, and of four difficulty axes one survives a control matched on language and human score, the axis holding segments whose segment-level and token-level signals disagree, which costs every one of the nine systems we evaluate. For anyone using reference-free QE across languages, raw scores are not comparable between pairs. Of the five systems we fit per-language offsets for, the one with the best within-language correlation is the only one whose offset

runs against quality, and of the three trained metrics it is the only one that loses more than rounding when pairs are pooled. Pooling pairs into one correlation, or ranking systems on scores drawn from different pairs, inherits that. APE carries a separate warning. The unedited MT beats every post-editing system we run on three of the four pairs under all four surface metrics, while a reference-free metric ranks those systems above it. Post-edit references reward conservative editing, and an APE result reported against them needs a do-nothing row.

The `word-qe` and `explainable-qe` configurations are released with no baseline, and word-level QE over agglutinative targets will need the subword tagging our whitespace alignment leaves out. English to Telugu is the lowest-scoring pair for seven of the nine systems, and its narrow score range accounts for part of that. And nothing we ran handles the segments where the human score and the surface evidence disagree: across seven trained configurations that vary the encoder, the loss and the target scale, every one of them fails on it.

## Limitations

Provenance is heterogeneous: the direct assessments come from several WMT editions and annotation batches. Domain labels are partly inferred ($3{,}756$ of $12{,}730$ challenge items) by a classifier at $0.826$ accuracy, and the X→en labels are inferred outside the language it was fitted on, so we condition no analysis on them. Every explanation outside en-ml is model-generated. Post-edits, not independent references, are the reference throughout, so reference-based numbers measure residual repair effort. en-gu and en-te carry no post-edits, and `all` and `qe-da` omit the X→en pairs, so a nine-pair evaluation must come from `full`.

One machine translation per source segment supports segment-level meta-evaluation and no system-level ranking. The cross-lingual coefficient rests on at most nine points and is weakly identified. Prompted models are scored on different populations, so a correlation and a compliance rate belong together (§3). The MQM layer covers en-hi alone, and under a third of its DA-paired segments carry trustworthy error spans; its two batches differ in range and the DA↔MQM agreement is estimated on the narrower. Just over half the word tags we derive ourselves under the upstream rule. The rule is validated, at $0.937$ and $0.974$ Matthews correlation against real labels. The tags themselves are post-edit-derived, agree least for en-ml and en-mr, and are less error-dense than the real pool. Gap and source-side tags exist only for X→en, tags are impossible for en-gu and en-te, and all of them are coarse for agglutinative targets.

Two of the four are defined partly on the direct assessment, so what they select is partly a property of the annotation. The matched control removes the score range and leaves the label noise, and the attenuation correction applies on three pairs. Of `A4`'s two arms only the larger is readable, and its size halves without en-ml, though its sign holds. Two of the three results scale differently with more data. The cross-lingual claim would be settled, in either direction, by pairs: nine points cannot support a coefficient, and the per-language offsets it rests on are estimated per pair, so they neither strengthen nor weaken as pairs are added. `A4` is the opposite, resting on seven pairs of which one small cell dominates the size, so independently annotated pairs would tighten it or break it. The MQM result is the least secure: it holds language fixed across two annotation batches of one pair, and a second language with expert annotation would be the test of it.

The probe is one layer over one backbone and saved no per-instance predictions, so the axes cannot be joined to it. The head's cross-lingual coefficient rests on five pair means and is not significant, and its ablation runs on a five-pair build that predates a late data fix, so the six-pair lane does not confirm it. The APE evaluation is prompted, covers four of seven post-edited pairs and trains nothing, so it sets a do-nothing baseline.

## Ethics Statement

The dataset consolidates publicly released shared-task corpora, redistributed under the terms given in §2. Appendix L records how the English→Malayalam data was produced: who annotated it, under what guidelines, through what quality control, and through commercial annotation agencies that recruited and paid their own annotators. The benchmark is released publicly with corpus-level provenance so that each instance can be traced to its source. QE and APE are evaluation and assistance technologies for translation and carry limited dual-use risk; the main ethical consideration is that a QE score should be treated as comparable across languages only where it is (§3).

## Acknowledgements

IndicQE-APE was made possible by its data sponsors and collaborating institutions: the People-Centred AI Institute, University of Surrey; Computation for Indian Language Technology (CFILT), IIT Bombay; and the European Association for Machine Translation (EAMT). We further thank the upstream data providers whose released corpora this benchmark consolidates: the WMT Quality Estimation shared tasks (2020, 2022, 2023, 2024) and the WMT Automatic Post-Editing shared tasks, the MLQE-PE dataset, and the annotation teams behind the English-Hindi MQM and English–Malayalam QE data. We acknowledge the efforts of Rajen Chatterjee (Apple Inc., US) towards creating the APE data. We also thank the data annotation agencies Zibanka Media and Techliebe for their help with human data annotation over the years.

## A Related Work

**Reference-free and reference-based metrics.** Learned metrics estimate quality from source and hypothesis without a reference. COMET and its reference-free variant CometKiwi (Rei et al., 2020, 2022) are trained on human direct assessments and set current practice at the WMT metrics and QE tasks (Freitag et al., 2024). These metrics return a scalar and do not expose the per-language behaviour of that scalar. That behaviour is what §3 measures. TER and its human-targeted form HTER (Snover et al., 2006), CharacTER (Wang et al., 2016), and chrF (Popović, 2015) with chrF++ (Popović, 2017) provide reference-based surface baselines. For Indic pairs specifically, IndicMT Eval meta-evaluates these metrics against MQM-style human annotation over five Indian languages and finds their agreement with human judgement weak (Sai B et al., 2023).

**The quality-estimation shared tasks.** The WMT QE shared tasks are the primary source of direct-assessment data for these pairs. WMT 2020 introduced the multilingual QE setting with the MLQE-PE dataset (Specia et al., 2020; Fomicheva et al., 2022), which supplies our X→en pairs (et-en, ne-en, si-en). WMT 2022 added English-Marathi (Zerva et al., 2022); WMT 2023 added en-hi, en-gu, en-ta and en-te (Blain et al., 2023); and WMT 2024 added new test sets and asked whether LLMs close the QE gap (Zerva et al., 2024). IndicQE-APE consolidates these releases; §2 gives the lineage and per-pair counts.

**The post-editing shared tasks.** The WMT APE shared tasks provide the post-editing data: en-mr in 2022 and 2023 (Bhattacharyya et al., 2022, 2023) and en-hi/en-ta in 2024 (Zerva et al., 2024). Our English→Malayalam QE and APE data extends the recent En→Ml release (Sindhujan et al., 2026).

**What this release adds.** The sources it consolidates are single-task and single-edition. MLQE-PE (Fomicheva et al., 2022) supplies direct assessments, post-edits and word-level tags for its pairs, with no explanations, no MQM and no difficulty structure; the WMT QE editions (Zerva et al., 2022; Blain et al., 2023; Zerva et al., 2024) each add pairs and a test set and are released separately on incompatible schemas; the APE editions (Bhattacharyya et al., 2022, 2023) supply post-edits without the DA layer. IndicMT Eval (Sai B et al., 2023) is the closest Indic resource in spirit, and it meta-evaluates reference-based metrics against MQM annotation and supplies no QE training data. IndicQE-APE differs in four ways: the label types are aligned on the same items, the test set is constructed by difficulty axis, every row carries corpus-level provenance and the label provenances are separate columns, and the compo-

sition and hygiene claims ship as scripts that fail on drift.

**Prompting and probing.** Instruction-tuned LLMs can be prompted to emit a quality score (Kocmi and Federmann, 2023), which we use as the prompted-QE baseline. An alternative reads quality from a model's internal representations: adaptive layer optimisation for QE selects and weights hidden layers of a frozen LLM (Sindhujan et al., 2025b), which we take up in §4.

## B Construction Detail

**Tokenisation.** IndicNLP tokenisation (Kunchukuttan, 2020) reproduces the shipped `mt_tokens` at 0.960 exact-sequence agreement (1.000 on en-ml), where Moses, the default in the standard corpus-builder recipe, reaches 0.660 and falls to 0.313 on Malayalam. Every tag sequence is released with the tokenisation it indexes (`mt_tokens`, `source_tokens`). The imported source tags index MLQE-PE's tokenised source, and our `source` field is detokenised.

**Subword segmentation.** Tokenisation above is the *word* layer, the one the released tags index. Underneath it every trained model in this paper reads a subword vocabulary, and the cost of a word in that vocabulary varies across these scripts. Measured on the challenge test under the XLM-R SentencePiece model, which CometKiwi-DA, `CometKiwi-XL`, `XCOMET-XL` and the head of §5 all share, a target word costs 1.59 pieces in Hindi, 1.98 in Marathi, 2.00 in Gujarati, 2.43 in Tamil and Telugu and 2.55 in Malayalam, against 1.37–1.41 for the English targets of the X→en pairs: 2.16 against 1.40 by direction. The order is the one the derived tags follow. Across the seven pairs carrying real tags, fertility and the agreement of the derived tags rank at Spearman $-0.927$ ($p = 0.003$), so the tag layer is coarsest where a whitespace token packs the most subwords, and the morphological reading above has a measured counterpart. This is also why the release ships the tokenisation each tag sequence indexes: a user working at the subword level must re-align, and the alignment is theirs to choose. Reproduce with `analysis/subword_fertility.py`. The prompted models carry six different vocabularies and are not measured here; what their model cards state about language coverage is in Appendix M.

**Validating the derived word-level tags.** We re-derive from MT and post-edit alone every real released tag we can, which is 33,119 of the 38,616 tagged segments and 633,988 tokens. Of the 5,497 left out, 5,473 carry no post-edit to derive from, almost all of them si-en, where MLQE-PE ships 8,650 tag sequences against 3,487 post-edits. The other 24 are en-ml rows whose shipped tag sequence and shipped tokenisation differ in length, so gold and derived tags cannot be aligned; they are left out of the agreement figures and flagged in the release. We report Matthews correlation (MCC), the word-level statistic used at the WMT QE task, alongside accuracy and BAD $F_1$; the gold BAD rate is 0.370. Corpus MCC is 0.963 (accuracy 0.983, BAD $F_1$ 0.977). The two provenance classes separate: against upstream MLQE-PE labels the derived tags reach MCC 0.974, and against the en→Indic shipped tags 0.937. Per pair, agreement is weakest for en-ml (MCC 0.898) and en-mr (0.929) and highest for the X→en pairs (0.969–0.973), which is the order of morphological complexity. Malayalam has the highest type-token ratio of the Indian languages measured by Kumar et al. (2007), 26.5% against 10.8% for Marathi and 4.2% for Hindi, and Marathi is the most agglutinative of the Indo-Aryan languages here (Kunchukuttan and Bhattacharyya, 2016; Subbārāo, 2012). A whitespace token in an agglutinative language carries what English spreads over several words (Chung and Gildea, 2009), so one wrong morpheme condemns the whole token; separating a wrong form of the right lemma from a wrong word needs a sub-word layer (Popović and Ney, 2011). The derived tags share the construction rule and the provenance class of the released ones, and they remain post-edit-derived. Per-segment confusion counts are released so any of these figures can be recomputed without re-running the derivation. These figures validate the derivation; no word-level QE system is reported.

**Domain completion.** The domain classifier of §2 is a word and character TF-IDF logistic regression on the source side. Five-fold cross-validation on the 89,399 annotated segments with a distinct source sentence, of the 92,492 annotated, gives $0.826 \pm 0.001$ accuracy and $0.805 \pm 0.003$ macro F1; the fold is taken on the source because rows are unique by source and MT, so a source can recur against different hypotheses and would otherwise leak. On a shared 500-segment gold

sample it scores 0.804 against 0.566–0.618 for three prompted GPT configurations (gpt-4o-mini zero-shot, gpt-5.4-nano zero- and six-shot). The gap is confined to the provenance-defined classes (tourism, education, general, other; F1 +0.19 to +0.34) and closes on the topic-transparent ones (health +0.03, legal +0.01): a content-only judge cannot recover a label that records which corpus a row came from.

**Word-tag provenance columns.** `wtag_provenance` ∈ {upstream, mlqe-pe-upstream, derived} is a released column, with real and derived tags in separate fields and never both on one row. The X→en pairs additionally carry MLQE-PE gap tags (`wtag_gaps`) and source-side tags (`source_tags`). The MLQE-PE import covers 98.6% of the X→en rows; the remainder, plus 351 upstream segments whose duplicate copies carry conflicting tags, are left to derivation or to no tag.

**Error explanations.** The synthetic explanations cover 1,999 en-hi, 5,000 en-mr, 2,645 en-ta and 10,000 en-ml segments. Each is a free-text English description of MT errors, accompanied by a list of MQM-style error categories. They were carried over from the ALOPE-RL data released by Sindhujan et al. (2026) and were generated by prompting an LLM to produce a detailed natural-language description of a given translation, based on the corresponding TQRs (for en-ml) or WTags (for en-hi, en-mr and en-ta). DeepSeek-V4-Pro generated the explanations for all en-hi, en-mr and en-ta segments and for 5,000 of the en-ml segments; DeepSeek-V3 was used for the remaining 5,000 en-ml segments. The en-ml rows additionally include descriptions and error categories for the same segments generated by Gemini 2.5 Pro, stored in `synthetic_description_gemini` and `error_categories_gemini`, which Sindhujan et al. (2026) originally used to compare the Gemini and DeepSeek explanations and isolate the impact of explanation quality. These columns sit outside the explanation counts of Table 1, which counts a segment once, however many descriptions it holds. The synthetic explanations were not validated against human judgement and do not constitute typed, localised error annotations: the en-hi MQM layer of Appendix O is the only such annotation in the benchmark.

**Annotator agreement.** The release carries the individual annotator scores behind every mean (`da_scores`, `n_annotators`), so agreement can be recomputed. It is available for 111,545 of the 126,754 instances, at a mean of 3.5 annotators each. The scores carry no annotator identifiers, so raters are interchangeable; we report Krippendorff's $\alpha$ on the interval scale and a one-way random-effects ICC, both of which are defined for that design. Because a model is trained and evaluated against the *mean* score, we also report ICC$(1, k)$, the reliability of that mean, which bounds how well any model can correlate with the target under classical attenuation. The bound is conservative: ICC(1) charges all within-segment variance to noise, and with uncrossed raters that includes systematic differences in how annotators use the scale, so an observed correlation can exceed it, as `CometKiwi-XL` does on en-mr (Table 23).

Agreement varies more across the consolidated sources than across languages (Table 10). The new en-ml data has the highest agreement in the benchmark ($\alpha = 0.955$), and en-te is close behind (0.910). At the other end, en-mr reaches $\alpha = 0.080$, so a single Marathi annotator carries almost no signal, and even the four-annotator mean has a reliability of 0.247. en-mr is also the largest pair at 30,746 instances. This is a property of the upstream annotation campaigns.

Agreement does not predict difficulty. en-te has near-ceiling agreement and is the lowest-scoring pair for seven of the nine systems (§3), so its difficulty is something other than annotation noise. Range is the more likely part of the explanation: its DA scores have the smallest standard deviation of the nine pairs on the challenge test, 14.0 against 25.1 for en-ml (Appendix Q).

## C QE Meta-Evaluation

Table 11 gives each axis in full, against both controls, and Table 12 the per-pair four-shot compliance behind Table 7. The per-pair correlations are in Appendix F and the cross-lingual fits in Table 5.

## D The Axes Pair by Pair

Table 13 breaks the matched contrast of §3 down to the pair, averaged over the nine systems. `A4` is negative on all seven pairs, and the size is uneven: −0.598 on en-ml against −0.061 to −0.088 on the three en→Indic pairs whose `A4` cells are large. Dropping en-ml, whose `A4` cell is 34 seg-

| Pair | $n$ | $k$ | $\alpha$ | ICC(1) | ICC(1,$k$) | SD |
|---|---|---|---|---|---|---|
| en-hi | 15,102 | 4.00 | 0.218 | 0.218 | 0.528 | 11.5 |
| en-mr | 28,999 | 3.95 | 0.080 | 0.077 | 0.247 | 16.1 |
| en-ta | 8,790 | 3.00 | 0.574 | 0.574 | 0.802 | 7.6 |
| en-te | 13,157 | 3.00 | 0.910 | 0.910 | 0.968 | 2.2 |
| en-gu | 9,109 | 3.00 | 0.540 | 0.540 | 0.779 | 10.3 |
| en-ml | 10,000 | 3.00 | 0.955 | 0.955 | 0.985 | 4.4 |
| et-en | 9,000 | 3.67 | 0.770 | 0.751 | 0.917 | 10.5 |
| ne-en | 8,649 | 3.66 | 0.744 | 0.733 | 0.909 | 8.9 |
| si-en | 8,739 | 3.67 | 0.783 | 0.764 | 0.922 | 10.0 |
| **pooled** | 111,545 | 3.54 | 0.690 | 0.677 | 0.881 | 10.2 |

Table 10: Agreement on the direct assessments. $n$ is instances with at least two annotators, $k$ the mean number of annotators. $\alpha$ is Krippendorff's interval alpha and ICC(1) a one-way random-effects coefficient, both for a single rater; ICC(1,$k$) is the reliability of the mean, which is the label models predict. SD is the mean within-segment standard deviation on the 0–100 DA scale, which is the same quantity without a normalising denominator.

| Axis | Pairs | Flagged | $\rho$ on | $\rho$ ctl | Plain | Matched (95% CI) | Neg. |
|---|---|---|---|---|---|---|---|
| A1 | 9 | 4,832 | 0.239 | 0.241 | $-0.205$ | $-0.003$ [-0.047, +0.037] | 4/9 |
| A2 | 7 | 3,477 | 0.418 | 0.352 | $+0.023$ | $+0.066$ [+0.011, +0.122] | 2/7 |
| A3 | 7 | 3,879 | 0.363 | 0.344 | $-0.032$ | $+0.019$ [+0.005, +0.032] | 2/7 |
| A4 | 7 | 1,320 | 0.234 | 0.366 | $-0.284$ | $-0.146$ [-0.270, -0.059] | 7/7 |

Table 11: Each difficulty axis over the nine systems and the pairs that carry it. *$\rho$ on* is the correlation on the flagged segments and *$\rho$ ctl* on the DA-matched control. *Plain* contrasts the flagged segments with all the remaining segments of the same pair, *Matched* with the control that shares their score histogram; the interval is a bootstrap over pairs and the last column counts the pairs on which the matched contrast is negative. `A1` loses its entire effect to the control and `A4` about half of one, which it keeps on every pair.

ments, moves the mean from $-0.146$ to $-0.071$; dropping any other pair leaves it between $-0.154$ and $-0.165$. The claim this paper makes is the sign and its consistency.

`A1` is the mirror image. Its mean is zero because the pairs disagree: $-0.12$ on en-gu and $-0.11$ on en-ml against $+0.09$ on ne-en. Splitting by pair shows there is no effect to explain.

`A4` has two arms, and they fall on almost disjoint pairs. The arm holding segments scored below par for their pair yet barely edited is carried by en-hi, en-mr, en-ta and et-en, 1,149 segments in all, and its matched contrast is $-0.070$, negative on every one of them. The converse arm, scored well yet error-dense, is carried by en-ml, ne-en and si-en, and at 123 segments over three pairs it is negative on two of the three, with the en-ml cell doing all the work. Those two figures cover the cells large

| Model | en-hi | en-mr | en-ta | en-te | en-gu | en-ml | et-en | ne-en | si-en |
|---|---|---|---|---|---|---|---|---|---|
| `BharatGPT-3B` | 0.978 | 0.966 | 0.492 | 0.013 | 0.604 | 0.058 | 0.086 | 0.591 | 0.232 |
| `Llama-3.2-3B` | — | 0.851 | 0.885 | 0.409 | 0.779 | 0.088 | 0.000 | 0.063 | 0.931 |
| `tiny-aya-fire` | 0.997 | 0.996 | 1.000 | 0.998 | 0.967 | 0.469 | 1.000 | 0.972 | 0.348 |
| `aya-expanse-32B` | 0.993 | 0.986 | 0.999 | 0.995 | 0.997 | 0.999 | 0.980 | 0.999 | 0.932 |
| `sarvam-m` | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 |
| `GPT-5.5` | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 |

Table 12: Output-format compliance under four shots, by pair: the share of segments returning a single GEMBA-DA score, counting a bare number or a labelled number and rejecting prose and multi-number replies (§3). Failure is model-specific by pair and not predicted by the macro rate: `BharatGPT-3B` holds above 0.96 on en-hi and en-mr but returns 0.013 on en-te, while `sarvam-m` and `GPT-5.5` comply everywhere. At zero shots no cell falls below 0.998 except `aya-expanse-32B`'s, which reach down to 0.868 on ne-en, so the failure is specific to the four-shot prompt. `Llama-3.2-3B` was not run on en-hi. `sarvam-t` is a translation model, complies at 0.003, and is omitted from the QE evaluation. A correlation computed over a low compliance rate rests on a self-selected subset, so we report the two separately.

enough to estimate, 1,272 of `A4`'s 1,320 segments; the remaining 48 sit in arm cells below the thirty-segment floor. The consistent half of `A4` is the barely-edited arm. A release recording an unedited segment as its own post-edit does not explain it: across its four pairs the share of the arm whose post-edit is identical to the MT runs from none at all on et-en and 1% on en-hi to 94% on en-ta, and the contrast is the same size at both ends.

| | `A1` | | `A2` | | `A3` | | `A4` | |
|---|---|---|---|---|---|---|---|---|
| Pair | $n$ | $\Delta\rho$ | $n$ | $\Delta\rho$ | $n$ | $\Delta\rho$ | $n$ | $\Delta\rho$ |
| en-hi | 478 | $+0.054$ | 420 | $+0.191$ | 622 | $+0.019$ | 381 | $-0.070$ |
| en-mr | 982 | $-0.014$ | 929 | $+0.119$ | 704 | $+0.027$ | 349 | $-0.088$ |
| en-ta | 723 | $-0.000$ | 726 | $+0.090$ | 757 | $+0.033$ | 375 | $-0.061$ |
| en-gu | 404 | $-0.115$ | — | — | — | — | — | — |
| en-te | 538 | $+0.016$ | — | — | — | — | — | — |
| en-ml | 523 | $-0.108$ | 712 | $-0.053$ | 957 | $+0.036$ | 34 | $-0.598$ |
| et-en | 379 | $+0.042$ | 303 | $-0.014$ | 304 | $-0.012$ | 73 | $-0.102$ |
| ne-en | 288 | $+0.092$ | 283 | $+0.060$ | 273 | $+0.037$ | 53 | $-0.036$ |
| si-en | 517 | $+0.009$ | 104 | $+0.070$ | 262 | $-0.005$ | 55 | $-0.068$ |

Table 13: Matched contrast per pair and axis, averaged over the nine systems, with the number of flagged segments beside it. A dash is a label the pair does not carry. Only `A4` holds one sign across every pair.

## E Axis Thresholds by Pair

Every threshold in §2 except `A1`'s $[35, 75]$ quality band is taken within language pair, over the whole release, so a segment's flag does not depend on which split it landed in. Table 15 gives the resulting numeric cut for each pair, so any flag can be recomputed from the released columns without running

| Pair | Segments | A1 | A2 | A3 | A4 |
|---|---|---|---|---|---|
| en-hi | 1,881 | 478 | 420 | 622 | 381 |
| en-mr | 2,165 | 982 | 929 | 704 | 349 |
| en-ta | 2,038 | 723 | 726 | 757 | 375 |
| en-gu | 1,090 | 404 | — | — | — |
| en-te | 1,120 | 538 | — | — | — |
| en-ml | 1,436 | 523 | 712 | 957 | 34 |
| et-en | 1,000 | 379 | 303 | 304 | 73 |
| ne-en | 1,000 | 288 | 283 | 273 | 53 |
| si-en | 1,000 | 517 | 104 | 262 | 55 |

Table 14: Segments on each difficulty axis, per pair, on the DA-bearing challenge test (12,730 segments over nine pairs). A dash is a label the pair does not have, not an axis it scores zero on: en-gu and en-te ship as direct assessments with no post-edits, word tags or error categories. A segment may sit on more than one axis. The domain composition of the same test set is in Table 19.

| | Top quartile | | | $\mu + \sigma/2$ | | A4 lower arm | |
|---|---|---|---|---|---|---|---|
| Pair | da_std | TER | bad | DA | bad | DA $p_{30}$ | TER $\mu - \sigma/2$ |
| en-hi | 12.74 | 0.67 | 0.50 | 85.73 | 0.48 | 79.25 | 0.33 |
| en-mr | 18.99 | 0.30 | 0.21 | 74.96 | 0.25 | 66.50 | 0.11 |
| en-ta | 8.58 | 0.50 | 0.38 | 91.81 | 0.39 | 81.67 | 0.05 |
| en-gu | 12.73 | — | — | 91.61 | — | 78.33 | — |
| en-te | 2.36 | — | — | 83.49 | — | 71.67 | — |
| en-ml | 4.71 | 0.31 | 0.40 | 86.48 | 0.36 | 56.67 | −0.08 |
| et-en | 11.40 | 0.62 | 0.36 | 78.57 | 0.34 | 48.67 | 0.36 |
| ne-en | 10.50 | 0.92 | 0.74 | 47.83 | 0.67 | 25.00 | 0.61 |
| si-en | 11.43 | 0.91 | 0.71 | 64.81 | 0.65 | 28.00 | 0.59 |

Table 15: The numeric cut each pair receives, over the whole release. The first three columns are the top-quartile cuts that define A1, A2 and A3; the next two the half-standard-deviation cuts of A4's upper arm; the last two the bottom-30% and low-edit cuts of its lower arm. A dash marks a signal the pair does not have.

our code. The cuts differ enough between pairs to matter: the direct assessment at which a segment enters the bottom 30% of its pair is 79.2 for en-hi and 25.0 for ne-en, so an axis defined on a corpus-wide cut would be a statement about the pair.

A4's lower arm needs a token TER half a standard deviation below its pair's mean, and on en-ml that cut falls at $-0.08$, because 44.4% of its post-edits leave the MT untouched and the remainder are heavily edited, giving a mean of 0.204 against a standard deviation of 0.563. No segment can satisfy it, so en-ml's A4 is entirely the upper arm. The same threshold behaves differently again on en-ta, where it falls at 0.05 and selects the zero-edit segments almost exclusively. The arm is defined relative to each pair, and it picks out a property of the pair's edit distribution as much as of the segment.

## F Per-Pair QE Decomposition

Table 16 gives the full per-pair breakdown behind the macro columns of Table 4: nine systems on all nine pairs of the challenge test. The trained metrics cover every DA-bearing segment and the prompted models only the ones they comply on, so the cells within a row share a population and those across rows do not. BharatGPT-3B scores near zero throughout, never above 0.16 and negative on si-en, and follows neither pattern below. Telugu carries the lowest column mean, 0.119 against 0.274–0.364 for the other en→Indic pairs; the exceptions are BharatGPT-3B, lowest on si-en at $-0.091$, and Llama-3.2-3B, lowest on en-mr by 0.006. We leave it open. The X→en directions score above the en→Indic directions on average for every system that scores above chance, which is consistent with the direction split of Appendix G.

**What holds independently of the pair.** Table 16 varies both the system and the pair, so it can be asked whether anything about a system survives changing the pair. The ordering does, largely. Ranking the nine systems inside each pair and comparing the nine rankings gives Kendall's $W = 0.880$, with a mean pairwise Spearman between rankings of 0.865: lowest 0.533 between en-ml and et-en, highest 0.967 between et-en and si-en, and en-ml is one of the two pairs in four of the five lowest. BharatGPT-3B and Llama-3.2-3B are in the bottom three everywhere, CometKiwi-XL and GPT-5.5 in the top four everywhere, and every system holds its band across the pairs. A leaderboard built on any single pair here would order the panel roughly as the macro does; it would not transfer the *level*, which is what §3 is about. Domain transfers less well than that, and less well than it appears. Averaging within pair and then over pairs, so that no domain correlation pools segments from different languages, the ten domains span 0.221 (finance 0.339 against sports 0.118). Six of the ten sit in one pair alone: news, finance, tech, sports, education and other are en-ml gold labels (§2), so their cells are that pair wearing a domain's name. Over the four domains that more than one pair carries, the span falls to 0.101, health 0.338 against legal 0.237, against 0.245 across the six en→Indic pairs themselves. On this evidence

| Model | en→Indic | | | | | | X→en | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | en-hi | en-mr | en-ta | en-gu | en-te | en-ml | et-en | ne-en | si-en | macro |
| BharatGPT-3B | 0.089 | 0.085 | 0.107 | 0.101 | 0.027 | 0.130 | 0.153 | 0.073 | −0.091 | 0.075 |
| Llama-3.2-3B | 0.183 | 0.081 | 0.182 | 0.082 | 0.087 | 0.122 | 0.380 | 0.225 | 0.208 | 0.172 |
| tiny-aya-fire | 0.204 | 0.186 | 0.227 | 0.215 | 0.039 | 0.107 | 0.497 | 0.369 | 0.244 | 0.232 |
| aya-expanse-32B | 0.294 | 0.322 | 0.425 | 0.247 | 0.094 | 0.336 | 0.504 | 0.332 | 0.337 | 0.321 |
| sarvam-m | 0.311 | 0.411 | 0.427 | 0.294 | 0.137 | 0.382 | 0.472 | 0.355 | 0.306 | 0.344 |
| GPT-5.5 | 0.399 | 0.529 | 0.488 | 0.485 | 0.180 | **0.467** | 0.605 | 0.544 | 0.452 | 0.461 |
| CometKiwi-DA | 0.350 | 0.546 | 0.488 | 0.452 | 0.175 | 0.405 | 0.623 | 0.565 | 0.464 | 0.452 |
| CometKiwi-XL | **0.450** | **0.565** | **0.574** | **0.522** | **0.214** | 0.374 | **0.660** | **0.603** | **0.513** | **0.497** |
| XCOMET-XL | 0.187 | 0.404 | 0.359 | 0.399 | 0.117 | 0.247 | 0.608 | 0.471 | 0.403 | 0.355 |
| mean | 0.274 | 0.348 | 0.364 | 0.311 | **0.119** | 0.285 | 0.500 | 0.393 | 0.315 | |

Table 16: Per-pair Kendall $\tau$ against human DA for every system in Table 4, on the challenge test. The trained metrics cover all 12,730 DA-bearing segments and the prompted models the 12,552 to 12,730 they comply on. Prompted models above the rule, trained metrics below. Bold marks the best system per column, and the lowest column mean. `sarvam-t` is omitted from the QE evaluation (compliance). Telugu carries the lowest column mean, and the X→en directions score above the en→Indic ones on average for every system that scores above chance.

the pair a segment is in matters more than the domain it is about, and we draw no domain conclusion from the single-pair labels. Reproduce with `analysis/model_order_and_domain.py`.

## G Direction Scope in Cross-Lingual Correlation

The cross-lingual score of §3 is a correlation across language pairs between per-pair model means and per-pair human means, with one point per pair. IndicQE-APE contains two translation directions whose human scores occupy separate ranges: mean DA is 67.9–83.6 over the six en→Indic pairs and 37.8–64.9 over the three X→en pairs. Pooling them places two clusters on the scatter, so a model that does no more than register that X→en is the harder direction earns a large coefficient without ordering anything within either direction.

Table 17 measures the size of that effect. For six of the ten systems the pooled and scoped coefficients differ by more than 0.4, and for four of them by more than 0.85: `aya-expanse-32B` moves from +0.92 pooled to −0.22 scoped, `Llama-3.2-3B` from +0.81 to −0.27, `tiny-aya-fire` from +0.94 to +0.08, and a reference-based MetricX-24 from −0.93 to −0.04. Under the scoped estimate only two systems have a bootstrap interval that excludes zero, `sarvam-m` and `XCOMET-XL`.

**Why the directions cannot be paired.** No language appears in both directions here, so direction is confounded with language throughout, and et-en is the one pair that separates two things direction otherwise conflates. It is low-resource and carries the same label types, and it is Uralic, so a result that holds on the six en→Indic pairs and breaks on et-en is a candidate artefact of Indic script or morphology, while one that holds on et-en too is not. The confound cannot be removed with this data. The upstream releases fixed the directions, and IndicQE-APE consolidates them, so building the missing arm of any pair, hi-en say, means a fresh direct-assessment campaign. Until one exists, a direction effect and a language effect are the same effect measured twice, and we read the two directions apart.

The cross-lingual coefficients quoted in the body of this paper are therefore scoped to en→Indic. More generally, a cross-lingual coefficient estimated from one point per language pair is weakly identified at the number of pairs any current Indic benchmark provides, and pooling translation directions inflates it in a direction that is easy to mistake for skill. We report the coefficients as the established summary.

## H Direct Assessment on the Full Population

Table 18 reports segment-level Spearman correlation with human direct assessment away from the challenge test, on the 81,315 DA-bearing rows this scoring pass covers, with zero-edit rows included.

| System | pooled ($k$=9) | en→Indic ($k$=6) | 95% CI |
|---|---|---|---|
| *GEMBA-DA prompted, challenge test* | | | |
| `BharatGPT-3B` | −0.45 | −0.46 | [−1.00, +0.40] |
| `Llama-3.2-3B` | 0.81 | −0.27 | [−0.93, +0.82] |
| `tiny-aya-fire` | 0.94 | 0.08 | [−0.93, +0.89] |
| `sarvam-m` | 0.91 | **0.84** | [+0.42, +0.98] |
| `GPT-5.5` | 0.94 | 0.52 | [−0.54, +1.00] |
| `aya-expanse-32B` | 0.92 | −0.22 | [−0.95, +0.79] |
| *trained metrics, full-population pass (81,315)* | | | |
| `CometKiwi-XL` | 0.12 | 0.34 | [−0.28, +1.00] |
| `XCOMET-XL` | 0.73 | **0.91** | [+0.74, +1.00] |
| MetricX-24 (QE) | −0.94 | −0.38 | [−1.00, +0.51] |
| MetricX-24 (ref) | −0.93 | −0.04 | [−0.98, +0.95] |

Table 17: Cross-lingual Pearson correlation, pooled over all pairs against scoped to the six en→Indic pairs, with a percentile bootstrap interval over pairs for the scoped estimate. MetricX-24 is an error score, so its sign is reversed relative to the others; its reference-based mode covers seven pairs pooled and four scoped, because en-gu and en-te carry no post-edits. The two blocks are computed on different populations and are not directly comparable to each other. Bold marks the two systems whose scoped interval excludes zero. Source: `scripts/xling_direction_scope.py`.

That is a subset of the 111,974 DA-bearing rows of Table 1. Four pairs are covered in full and five are scored short: en-hi 4,027 of 15,136, en-mr 20,625 of 29,182, en-ta 3,578 of 9,002, ne-en 8,332 of 8,649 and si-en 3,487 of 8,739. All three metrics cover the same rows, so the columns are comparable with each other. `CometKiwi-XL` scores highest on this axis. MetricX-24 shows a large asymmetry between translation directions: its mean error is 3.0–3.7 on en→Indic against 6.9–10.3 on X→en, in the same direction as the zero-edit rates (1.4–45% on en→Indic against 0% on X→en). MetricX runs reference-free here and never sees a post-edit, so the zero-edit rate acts on it only as a proxy for how much repair the MT needed, and the two together say the en→Indic hypotheses are the better ones. That is a further reason to hold the two directions apart (Appendix G).

## I Benchmark Distributions

**Worked examples of each axis.** Table 20 shows one verified en-hi segment on each of the four axes, with the signal that places it and one unflagged segment for reference. The `A4` example makes the axis concrete. Its direct assessment of 77.8 sits inside the bottom 30% of the en-hi distribution, whose mean is 81.2, while the post-editor changed under a third of its tokens against a pair mean of 0.514: the DA says the segment is below par for this pair, the edit record is that little needed doing, and the axis selects that disagreement.

| Pair | `CometKiwi-XL` | `XCOMET-XL` | MetricX |
|---|---|---|---|
| en-hi | 0.467 | 0.080 | −0.255 |
| en-mr | 0.632 | 0.443 | −0.420 |
| en-ta | 0.640 | 0.243 | −0.433 |
| en-ml | 0.499 | 0.379 | −0.434 |
| en-gu | 0.678 | 0.462 | −0.435 |
| en-te | 0.395 | 0.281 | −0.294 |
| et-en | 0.772 | 0.700 | −0.679 |
| ne-en | 0.706 | 0.562 | −0.591 |
| si-en | 0.702 | 0.568 | −0.584 |

Table 18: Segment-level Spearman $\rho$ against human DA on the 81,315 DA-bearing rows the full-population pass covers, of the 111,974 in the benchmark, zero-edit rows included. MetricX-24 is an error score, so a negative correlation is the correct direction; CometKiwi-XL and `XCOMET-XL` are quality scores. MetricX-24 is shown in QE mode so that all nine pairs are covered; its reference-based mode exists only for the seven pairs with post-edits and is not applicable on en-gu/en-te. Zero-edit rates differ sharply by direction, and the two directions should not be pooled into one correlation.

**Domain composition.** Table 19 gives the domain distribution of the same challenge test.

| Domain | Count | Share |
|---|---|---|
| general | 4,477 | 35.2% |
| tourism | 2,117 | 16.6% |
| legal | 1,834 | 14.4% |
| health | 1,834 | 14.4% |
| other | 800 | 6.3% |
| education | 589 | 4.6% |
| news | 518 | 4.1% |
| finance | 332 | 2.6% |
| tech | 132 | 1.0% |
| sports | 97 | 0.8% |
| Total | 12,730 | 100% |

Table 19: Domain composition of the DA-bearing challenge test, nine pairs. 8,974 labels are annotated and 3,756 inferred; news, finance, tech and sports are gold-only en-ml domains and are never inferred onto another pair.

## J Duplication and Split-Hygiene Checks

The release ships two read-only verification scripts. `verify_tab_composition.py` re-derives every per-pair and per-label count of Table 1 from the live repository and fails on drift. `audit_duplication.py` checks that each task configuration drawn from the master table is an

| Axis | Example (English source; Hindi MT; IAST; note) | DA | Signal that places it | All axes |
|---|---|---|---|---|
| `no axis` | **EN** Raja and Chhaya fall in love and decide to get married.<br>**HI** राजा और छाया प्यार में पड़ जाते हैं और शादी करने का फैसला करते हैं।<br>*rājā aura chāyā pyāra meṃ para jāte haiṃ aura śādī karane kā phaisalā karate haiṃ*\|<br>faithful; *fall in love* → प्यार में पड़ना is correct. | 98 | DA 98, da_std 2 | — |
| `A1` | **EN** A hole is shown in the mouth.<br>**HI** मुंह में छेद दिखाया गया है।<br>*muṃha meṃ cheda dikhāyā gayā hai*\|<br>the translation is sound; the annotators simply split. | 68 | da_std 40; scores [95, 100, 76, 0] | `A1` |
| `A2` | **EN** Blown through the opening at the end of the neck.<br>**HI** गर्दन के अंत में छिद्र के माध्यम से बहता है।<br>*gardana ke aṃta meṃ chidra ke mādhyama se bahatā hai*\|<br>*blown* mistranslated as बहता है ('flows'); the post-edit rewrites it. | 78 | TER 0.67, the pair's top quartile | `A2`, `A3` |
| `A3` | **EN** The terracotta human head with a pointed headdress.<br>**HI** टेराकोटा (terracotta) मानव सिर एक नुकीले शीर्ष के साथ।<br>*ṭerākoṭā (terracotta) mānava sira eka nukīle śīrṣa ke sātha*\|<br>*headdress* → शीर्ष ('top'); *terracotta* left untranslated. | 80 | BAD-tag density 0.85 | `A2`, `A3` |
| `A4` | **EN** Plus we avoided a lot of confusion and wrote a cleaner code.<br>**HI** इसके अलावा हमने बहुत भ्रम से बचा और एक क्लीनर कोड लिखा।<br>*isake alāvā hamane bahuta bhrama se bacā aura eka klīnara koḍa likhā*\|<br>below par for en-hi on the holistic score, yet the post-editor changed little. | 78 | DA 78 against a pair mean of 81.2, TER 0.29 against 0.514 | `A3`, `A4` |

Table 20: Verified en-hi segments from the `challenge` config, one on each difficulty axis and one on none, with the signal that places each. `da_std` is the standard deviation of the annotator scores, TER is MT→post-edit token TER, and BAD-tag density the fraction of word-level BAD tags. The last column lists every axis the segment carries, because the axes overlap: the `A2` exemplar is also error-dense and the `A4` one also carries `A3`. Thresholds are taken within pair, so `A4`'s direct assessment of 78 is in the bottom 30% of en-hi, whose mean is 81.2, while its TER of 0.29 is well under the pair's 0.514: the score says below par, the edit record says little needed doing.

exact view of it, so a configuration cannot be built from a stale snapshot or acquire rows of its own. `mqm` is the one exception and is checked separately: 2,327 of its 4,490 rows are the DA-paired MQM segments of `full` and the other 2,163 are MQM-only, outside the 126,754, which is why Table 1's MQM column reads 2,327 against Table 3's 4,490. The audit also checks that no exact instance and no source sentence crosses a train, validation or test boundary. The second is a regression test on the split builder, which enforces source-disjointness by construction. Both pass on the current release, whose master `full` configuration holds 126,754 rows. `uid` is a hash of the normalised source and MT, so distinct rows have distinct identifiers by construction; what the merge establishes is that segments shared between corpora were collapsed.

## K Layer-Probing and COMET-Regression: Protocol and Full Results

**Layer-probing (§4).** The probe of §4 uses a 4-bit QLoRA backbone, trains on the `all` split against DA and is evaluated on the matched `challenge` split. Layers $\{-5, -7, -11, -16, -20, -24\}$ are swept; Table 24 gives the Spearman over all segments for every pair and layer behind the best-layer summary of Table 25.

**COMET-regression (§5).** The hybrid head funnels upper encoder layers ($[12, 16, 20, -1]$ on a 24-layer encoder), optionally adds TSA / TSE attention features and a length ratio, and regresses per-pair $z$-scored DA under a Huber loss ($\delta$=1). Training: joint over five en→Indic pairs (en-hi, en-mr, en-ta, en-gu, en-te; 64,416 segments), batch

| Ablation (one axis from the reference) | $\rho$ | $r$ | $\text{acc}^*_{eq}$ | RMSE |

Table 21: Full comet-QE ablation on the en→Indic challenge test (within-language, segment-level). $\text{acc}^*_{eq}$ is pairwise accuracy with tie calibration (Deutsch et al., 2023). One axis is varied from the CometKiwi reference. Correlation and pairwise accuracy order the converged runs alike except for two adjacent swaps within 0.006 Spearman. †RMSE is on the $[0, 1]$ target scale and not comparable to the $z$-scale rows. ‡run that collapsed to near-mean prediction at one seed. §run that produced a near-constant score at the seed shown; for InfoXLM this is a seed effect and not a property of the encoder. A constant score sends $\text{acc}^*_{eq}$ to the gold tie rate (0.006), which separates it from the merely weak runs at 0.52–0.53; the correlations do not make that distinction.

| Configuration | $s$=42 | $s$=43 | $s$=44 | $s$=42′ | |
|---|---|---|---|---|---|
| *(a) The four collapsed runs, reseeded* | | | | | |
| E3 funnelling: none | 0.097 | 0.096 | 0.097 | — | collapses at every seed |
| E1 encoder: InfoXLM | −0.001 | 0.525 | 0.229 | — | unstable |
| E2 features: A0+TSA | 0.085 | 0.557 | 0.575 | 0.537 | recovers |
| E4 loss: Huber 0.5 | 0.089 | 0.566 | 0.556 | 0.574 | recovers |
| *(b) Additional arms (single seed)* | | | | | |
| Six pairs, A0 | 0.596 | — | — | — | headline population |
| Six pairs, reference | 0.581 | — | — | — | |
| X→en repro, reference | 0.668 | — | — | — | external check |
| X→en repro, A0 | 0.655 | — | — | — | |

Table 22: Seed stability and additional arms, test Spearman. (a) Each configuration that collapsed to near-mean prediction was run at three seeds; $s$=42′ is a fourth run at the first seed. Only *E3 funnelling: none* collapses at all three, so it is the one collapse attributable to the configuration; the other two recover, and their low values are not properties of those settings. (b) A0 is the funnel-only configuration and *reference* adds the attention features and the length ratio. The six-pair arms are the two figures §5 reports; the X→en arms run the same two configurations on MLQE-PE passthrough pairs, as an external check on the training pipeline. Rows in (a) marked $s$=43 or $s$=44 are on the released 8,294-row five-pair test and the rest on the earlier 8,160-row build (Appendix K).

| Zero-shot ($\rho$) | gu | hi | ml | mr | ta | te | all |
|---|---|---|---|---|---|---|---|
| CometKiwi-DA | 0.62 | 0.49 | 0.58 | 0.74 | 0.68 | 0.25 | 0.588 |
| CometKiwi-XL | 0.70 | 0.62 | 0.54 | 0.76 | 0.76 | 0.31 | 0.608 |
| XCOMET-XL | 0.56 | 0.27 | 0.36 | 0.58 | 0.51 | 0.17 | 0.406 |

Table 23: Zero-shot COMET per-pair Spearman on the en→Indic challenge test ($n$=9,730). en-te is the hardest pair for every metric, echoing the LLM pattern of §3.

$8 \times$ gradient-accumulation 2, max length 256, 4 epochs, learning rate $3 \times 10^{-5}$, selection on dev Pearson; evaluated on the 8,160-segment challenge test. That build predates a late data fix and is short 28 en-hi, 41 en-mr and 65 en-ta rows against the released five-pair test of 8,294; the reseeded runs of Table 22 use the released build, so a row there can span both. The 134 rows do not move a cell: *E3 funnelling: none* gives 0.097 on the shorter build and 0.096 and 0.097 on the longer one. The six-pair runs of §5 add en-ml and use the released data throughout (72,806 train, 9,730 test). Each design axis is varied alone from the CometKiwi reference (Table 21). Per-instance test predictions (`item_id`, language pair, gold, prediction) are saved for every run, from which the per-pair, per-axis and cross-lingual analyses of §5 are computed. The COMET-regression code is in `experiments/comet_qe/`.

**Pairwise accuracy against correlation.** Correlation and pairwise accuracy with tie calibration give the converged runs the same broad order (Table 21). They swap two adjacent pairs, A0 against A3 and Huber against CCC, and in both the two runs are within 0.006 Spearman of each other. They part on the failed runs. A run that produces a constant score has its $\text{acc}^*_{eq}$ fall to 0.006, the rate at which the human labels themselves tie. Runs that reach 0.52 to 0.53 sit above the tie rate and near chance on ordering. Spearman puts both kinds in the same band (−0.001 to 0.097). The two have different causes, a training failure against a weak configuration, and the first is the one likely to go away at another seed, which is what the reseeding below tests.

**Seed stability.** Four of sixteen runs collapsed to near-mean prediction. A single seed cannot separate an unhelpful setting from an unlucky initialisation, so each was run at three seeds and a collapse is reported only where it holds at all three. Removing multi-layer funnelling collapses at every seed, to within 0.001 (0.097, 0.096, 0.097), so the claim in §5 that funnelling is necessary rests on all three.

| `tiny-aya-fire` $\rho$, all segments | $-5$ | $-7$ | $-11$ | $-16$ | $-20$ | $-24$ |
|---|---|---|---|---|---|---|
| en-gu | 0.635 | **0.662** | 0.630 | 0.647 | 0.643 | 0.605 |
| en-hi | 0.436 | 0.412 | 0.436 | 0.430 | **0.449** | 0.402 |
| en-ml | 0.431 | 0.462 | **0.515** | 0.505 | 0.499 | 0.512 |
| en-mr | 0.653 | **0.666** | 0.659 | 0.661 | 0.644 | 0.614 |
| en-ta | 0.628 | 0.642 | 0.625 | **0.662** | 0.643 | 0.610 |
| en-te | 0.223 | 0.261 | 0.229 | 0.249 | **0.282** | 0.233 |
| mean | 0.501 | 0.517 | 0.516 | 0.526 | **0.527** | 0.496 |

Table 24: Layer-probing sweep behind Table 25: Spearman over all segments, per pair and layer (`tiny-aya-fire`, challenge split). Averaged over pairs the signal peaks at layer $-20$ and the two ends of the swept range, $-5$ and $-24$, are weakest; the best layer is pair-dependent. Layers are counted back from the output, so $-24$ is the furthest from it and the final layer is not swept.

| Pair | Best layer | $\rho$ | $r$ |
|---|---|---|---|
| en-gu | $-7$ | 0.662 | 0.663 |
| en-hi | $-20$ | 0.449 | 0.635 |
| en-ml | $-11$ | 0.515 | 0.518 |
| en-mr | $-7$ | 0.666 | 0.662 |
| en-ta | $-16$ | 0.662 | 0.658 |
| en-te | $-20$ | 0.282 | 0.329 |
| macro | — | 0.539 | 0.577 |

Table 25: Single-layer probe (`tiny-aya-fire`) on IndicQE-APE: the best layer per pair and its segment-level correlation with human DA on the challenge split. The layer is chosen by $\rho$ on the same split it is scored on, so the macro of 0.539 is an oracle over the six layers swept; one layer fixed across pairs ($-20$) gives 0.527 (Table 24), and that is the figure §4 compares against. Full layer sweep in Table 24.

The InfoXLM encoder is unstable: its three seeds give $-0.001$, 0.525 and 0.229, a spread of 0.526, so we report the spread and rest the encoder ordering elsewhere. The remaining two recover at other seeds (0.537 and 0.574), so those settings carry no collapse (Table 22).

**No design choice escapes `A4` (§5).** The ablation build gives seven trained configurations that differ in encoder, loss and target scale, and every one of them is worse on `A4` than on a DA-matched control, on each of the three pairs the build carries the axis on. The contrast runs from $-0.095$ for the MSE loss to $-0.129$ for the CCC loss, and the min–max target, the strongest configuration by overall correlation, sits at $-0.099$. Changing what the head reads, what it is penalised by and what scale it predicts on all leave the axis intact.

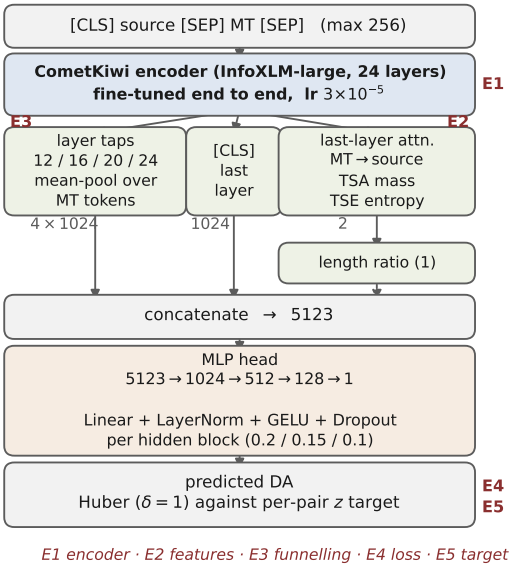

Figure 1: The regression head over a COMET encoder, and the five axes varied in Table 8. The encoder is fine-tuned with the head, not frozen. TSA is the MT-to-source attention mass and TSE its entropy.

## L The English–Malayalam Annotation

English–Malayalam is the only pair in IndicQE-APE whose annotation is new, so it is the only one whose protocol is ours to report. It was produced under a one-year project funded by the European Association for Machine Translation. The curation and annotation process is documented in the project report (Sindhujan et al., 2025a). About half of the segments were first released as the En→Ml QE dataset of Sindhujan et al. (2026), which pairs direct assessments with free-form Translation Quality Remarks; the same annotators completed the rest under the same guidelines. All 10,000 are released here.

**Source text and machine translation.** Source segments are drawn from the Anuvaad parallel corpus, which is domain-labelled at source, so the en-ml domain labels are gold for every row. The released mix is news (2,227), finance (2,151), tech (2,000), legal (1,892) and sports (1,730). Candidate segments were filtered on Language-agnostic BERT Sentence Embedding similarity at a threshold of 0.8, so the pairs entering translation are ones the source corpus itself aligns confidently. Hypotheses were produced by IndicTrans2 (Gala et al., 2023). Segments were then selected to

spread the Translation Edit Rate between the hypothesis and the corpus reference, so the resulting DA distribution covers the range: on the challenge test en-ml's DA standard deviation is 25.1, second only to et-en's 27.9 and above the 14.0–18.3 of the other en→Indic pairs (Table 30). Before annotation began, a native Malayalam speaker fluent in English reviewed a 25-segment sample to surface the error types the guidelines would need to cover.

**Who annotated it.** Annotation was carried out by a commercial annotation agency, which recruited and paid its annotators under its own terms; no crowdsourcing platform and no per-task micropayment was used. Every segment was scored by three annotators, all native speakers of Malayalam and fluent in English, and the release carries all three scores per segment (`da_scores`) rather than only their mean. Post-editing was done by a separate evaluator who took no part in the direct assessment, so the post-edit is not the same person's second look at their own score.

**Guidelines and quality control.** Both tasks ran the same way. A pilot of 500 segments was annotated first and reviewed against the guidelines; the guidelines were revised on what that pilot exposed, and only then did the main batches of 3,750 segments begin. Throughout, random samples from each delivered batch were validated in weekly meetings, discrepancies were put to all three annotators together, and the affected segments were re-annotated and re-checked in the following meeting. The post-editing brief was to make the minimum edit that carries the meaning of the source, which makes the post-edit a repair of the hypothesis (§2). 44.4% of en-ml post-edits leave the hypothesis untouched, the highest zero-edit rate of the four APE pairs, which follows from a minimum-edit brief on filtered source text.

**What the effort bought.** en-ml has the highest annotator agreement in the benchmark, $\alpha = 0.955$ and $\mathrm{ICC}(1,k) = 0.985$ against a pooled 0.690 and 0.881 (Table 10), so the iterative-guidelines protocol is visible in the numbers. It does not make the pair easy. en-ml is mid-table for the strongest prompted models and near the bottom for others, second-lowest of nine for `tiny-aya-fire` and `CometKiwi-XL` (Table 16), so the pair with the highest agreement is among the harder ones. That is one case for the claim of Appendix Q that label reliability does not predict difficulty.

| | Identifier | Size | Served by | Undeclared pairs |
|---|---|---|---|---|
| `BharatGPT-3B` | `CoRover/BharatGPT-3B-Indic` | 3.0B | transformers | et/ne/si-en |
| `Llama-3.2-3B` | `meta-llama/Llama-3.2-3B-Instruct` | 3.2B | transformers | all but en-hi |
| `tiny-aya-fire` | `CohereLabs/tiny-aya-fire` | 3.4B | transformers | en-ml, si-en |
| `sarvam-m` | `sarvamai/sarvam-m` | 24B | vLLM | et/ne/si-en |
| `aya-expanse-32B` | `CohereLabs/aya-expanse-32b` | 32B | vLLM | all but en-hi |
| `GPT-5.5` | `gpt-5.5-2026-04-23` | — | OpenAI API | not published |
| `sarvam-t` | `sarvamai/sarvam-translate` | 4B | vLLM | et-en, si-en |

Table 26: Models evaluated, with the size each model card states. `sarvam-t` is a dedicated translation model and appears in the APE evaluation only (§6); it does not follow either QE template. Sizes for the closed model are not published. *Undeclared pairs* are those with a language outside the model card's `language` field, read in September 2026; English is in every list, so for en→Indic it is the target that decides. `sarvam-t` is the one model every pair it is actually run on is declared for, since its four APE pairs exclude et-en and si-en. Discussed below.

**Error remarks.** Annotators were also asked for a short description of the errors they saw. All 10,000 segments carry one, and they are released as human Translation Quality Remarks. The remarks are brief and were written to no typed error taxonomy, so they are weak supervision for explainable QE.

## M Experimental Settings

Every setting below is read from the `_meta` block that each result file carries, so it records what the run used.

**Prompted models.** Table 26 lists the identifiers. Decoding is identical for all of them and for both templates and both shot counts: greedy, temperature 0.0, top-$p$ 1.0, at most 512 new tokens, seed 0. An earlier pass capped generation at 8 tokens and was discarded, because a cap that short truncates a reasoning preamble mid-number and turns a compliance failure into a wrong score. Few-shot examples are drawn from the training split of the same language pair, fixed across segments, and identical across models. Open models run under vLLM at 24B and above and under `transformers` below; the closed model runs through the OpenAI API at a pinned dated snapshot.

**Declared language coverage.** Five of the six prompted models publish a language list and none of the five covers all ten languages of the benchmark; `GPT-5.5` publishes none. A natural reading of the four-shot result is that the models fail where they were never trained. It holds for one model. `tiny-aya-fire` lists neither Malayalam nor Sinhala, and those two are exactly its two

four-shot compliance failures: it parses 0.990 of the seven pairs it declares and 0.408 of the two it does not, and no other cell falls below 0.967. Elsewhere the split does nothing. `BharatGPT-3B` declares Telugu and Malayalam, and en-te at 0.013 and en-ml at 0.058 are its two worst cells. `sarvam-m` correlates *better* on the three pairs it does not declare than on the six it does (0.481 against 0.420, zero-shot macro Spearman), and those three are the X→en pairs, so it is the direction split of Appendix G. `aya-expanse-32B` and `Llama-3.2-3B` declare only English and Hindi of the ten, so for them the split is one pair against eight, and `Llama-3.2-3B` has no four-shot en-hi run, which leaves it no declared cell at all. A model card states the languages a vendor claims to support, and the zero-shot condition this paper reports throughout falls nowhere below 0.868 compliance on any pair for any model. Table 26 gives the coverage. Reproduce with `analysis/model_language_coverage.py`.

**Trained metrics.** `CometKiwi-DA` is `Unbabel/wmt22-cometkiwi-da`, `CometKiwi-XL` is `Unbabel/wmt23-cometkiwi-da-xl` and `XCOMET-XL` is `Unbabel/XCOMET-XL`, all run reference-free through `unbabel-comet` 2.2.2 at default batch size. MetricX-24 is `google/metricx-24-hybrid-xl-v2p6`. The COMET-encoder head of §5 is built on the CometKiwi encoder extracted from the first of these; its training hyper-parameters are in Appendix K.

**Surface metrics.** chrF++, word-level TER and BLEU come from `sacrebleu` 2.4.2 (Post, 2018) at corpus level, chrF++ as `corpus_chrf(word_order=2)`. The signatures are

```
chrF2++|nc:6|nw:2|space:no|v:2.4.2
TER|norm:no|punct:yes|
asian:no|case:mixed|v:2.4.2
BLEU|nrefs:1|case:mixed|
eff:no|tok:13a|smooth:exp|v:2.4.2
```

char-TER is ours and is not a sacreBLEU metric: it is the total Levenshtein distance in characters between hypothesis and reference, divided by the total reference length in characters and micro-averaged over the corpus. We make it the primary edit metric because the `13a` word tokeniser charges a whole-word edit for a one-character inflection, which inflates TER and deflates BLEU on agglutinative targets. Appendix N gives the word-level numbers against a shared-task table.

**Hardware.** Open models were served on one GPU per job on a Slurm cluster, an NVIDIA L40S (48 GB) for models up to 24B and an A100 (80 GB) for the 32B model. The layer probe is a 4-bit QLoRA backbone on one L40S. The COMET-encoder head trains on one GPU in `fp16`. All analysis is CPU-only and runs from saved per-instance predictions, so every number in this paper can be recomputed without a GPU. Those predictions are released as an evidence bundle beside the code: one record per scored segment carrying the identifier and either the parsed score or, for a prompted model, the raw reply the parser saw; the regression head's per-instance predictions; and the aggregate tables the generators splice from. A manifest maps each file to the table it backs, and every identifier is a `uid` in the released dataset, so the two join on one column.

**Why the parser is strict.** Taking the first or nearest number from any reply reports full compliance and returns a value for every segment, but on our four-shot outputs it reads the range in `Score (0-100): 88` as 0, the enumerator of a prose answer beginning `1.` as 1, and the first entry of a four-number reply, which is a score for one of the prompt's own examples, as the score for the test segment. The strict rule of §3 rejects all three and counts the segment as non-compliant instead.

**The two prompt templates.** Both follow GEMBA (Kocmi and Federmann, 2023). `{src_name}` and `{tgt_name}` are the language names in English. Few-shot examples repeat the user block with its answer before the test segment's user block.

**GEMBA-DA**, system:

```
Score the following translation from
{src_name} to {tgt_name} on a
continuous scale from 0 to 100, where
a score of zero means "no meaning
preserved" and a score of one hundred
means "perfect meaning and grammar".
Reply with only the integer score and
nothing else.
```

**GEMBA-SQM**, system:

```
Score the following translation from
{src_name} to {tgt_name} on a
continuous scale from 0 to 100 that
starts with "No meaning preserved",
goes through "Some meaning
```

```
preserved", then "Most meaning
preserved and few grammar mistakes",
up to "Perfect meaning and grammar".
Reply with only the integer score and
nothing else.
```

User block, both templates:

```
{src_name} source: "{source}"
{tgt_name} translation: "{mt}"
Score (0-100):
```

The two differ in whether the system message names the intermediate points of the scale. Both close with the same instruction to return a bare integer, so the compliance rates of §3 measure instruction-following.

**The APE prompts.** §6 runs two tracks at zero shots, both under the decoding settings above. The post-editing track gives the model the MT to repair:

**Post-edit**, system:

```
You are an expert post-editor. Given
a source sentence and a machine
translation, produce a corrected
translation that is fluent, accurate,
and faithful to the source. Reply
with only the corrected translation,
no explanation.
```

User block:

```
Source ({src_name}): {source}
Machine translation ({tgt_name}):
{mt}
Corrected translation ({tgt_name}):
```

The retranslation track is for a dedicated MT system, which is not an instruction-following model and is not shown the MT. Its format follows the `sarvam-t` model card, a system message of `Translate the text below to {tgt_name}.` with the source as the user block. The output is scored exactly as a post-edit would be, which makes the `sarvam-t` row of Table 9 comparable to the other two.

## N APE under Word-Level Metrics

Table 27 repeats Table 9 under the two metrics the APE shared tasks report. The conclusion holds under either choice: the unedited MT wins on en-mr, en-ta and en-ml under all four surface metrics and loses on en-hi under all four. What changes is the size of the gap. On en-ta the unedited MT is 17.8 TER points ahead of the best system under word-level scoring and 11.1 ahead under charTER, which follows from the `13a` tokenisation (Appendix M).

| Model | Pair | TER↓ | BLEU↑ |
|---|---|---|---|
| do-nothing | en-hi | 55.1 | 36.9 |
| | en-mr | **34.2** | **61.6** |
| | en-ta | **56.2** | **53.5** |
| | en-ml | **38.7** | **60.9** |
| `sarvam-m` | en-hi | 47.6 | 38.5 |
| | en-mr | 51.1 | 38.1 |
| | en-ta | 74.7 | 26.3 |
| | en-ml | 62.7 | 29.8 |
| `sarvam-t` | en-hi | **43.6** | **42.4** |
| | en-mr | 59.1 | 28.6 |
| | en-ta | 86.0 | 18.1 |
| | en-ml | 71.2 | 20.6 |
| `tiny-aya-fire` | en-hi | 56.0 | 34.7 |
| | en-mr | 46.1 | 50.7 |
| | en-ta | 74.0 | 36.7 |
| | en-ml | 48.5 | 49.6 |

Table 27: APE under word-level sacreBLEU TER and BLEU, on the same rows as Table 9. Bold marks the best of the four rows per pair and metric. Signatures are in Appendix M.

## O English–Hindi MQM Layer

Language is one way to group segments, and if the effect above is a property of these metrics, it should appear under another grouping with the same structure. The en-hi MQM layer supplies one. MQM (Lommel et al., 2014) scores a segment by weighting typed, localised error spans, and is the protocol WMT adopted for metric meta-evaluation after Freitag et al. (2021) showed crowd-sourced DA to disagree with expert judgement on system rankings. Our layer is annotated in two batches with different quality profiles: an EAMT re-annotation of segments already in the benchmark and the WMT24 general-MT test set, new here. On the test split the EAMT batch averages 97.56 and the WMT24 batch 90.55; over the whole layer the EAMT batch averages 98.35. Both are en-hi, so language is held fixed and only the batch varies. Scoring the three COMET metrics against MQM gold and splitting by batch reproduces the pattern (Table 28). For `CometKiwi-XL` the pooled Spearman is 0.116 against 0.276 and 0.219 within the two batches, and for `XCOMET-XL` it is 0.029 against 0.243 and 0.052. A pooled correlation below *both* of its parts requires the metric to order the groups against the human ordering, and that is what happens: humans rate the EAMT batch above the WMT24 batch, while both XL metrics score the WMT24 batch higher. `CometKiwi-DA` orders

the two batches correctly and shows no such collapse (0.330 pooled against 0.307 and 0.375); it is also the system that was well behaved across languages. The effect is therefore a per-*group* offset: the same two systems misplace whole groups of segments relative to each other, whether the groups are languages or annotation batches, and the misplacement runs against quality in both cases. This also rules out range restriction as the explanation for the low pooled figures. Range restriction would predict the near-ceiling EAMT batch (gold standard deviation 1.96) to correlate *worse* than the spread WMT24 batch (7.54); it correlates better for two of the three metrics. On the 2,327 segments carrying both a human DA score and an MQM score, the two human signals agree moderately (r @ 0.573, rho @ 0.518, tau @ 0.366).

**Span coverage.** Every MQM segment carries a score, and a minority carry localised error spans. Of the 2,327 scored segments, 549 have spans and 160 score exactly 100 and correctly have none; the remaining 1,618 score below 100, so errors exist, and their offsets were never recorded upstream, where only 33.9% of the source annotation records carry severity and character offsets. An empty span list therefore means two opposite things, so the release exposes `mqm_spans_complete`: true for the 709 segments whose span information is trustworthy, false for the 1,618 where a penalty implies unlocalised errors. Span-level work should use the former; segment-level scoring can use all 2,327. These counts are for the DA-paired subset. Over the whole `mqm` configuration the span base is larger: 1,895 of 4,490 segments carry trustworthy span information. That figure is the 1,728 segments holding at least one span plus 167 scored exactly 100. The WMT24 batch is better localised than the EAMT batch (1,116 of 2,016 carry spans, against 612 of 2,474).

**Two annotation batches.** Provenance is recorded in `mqm_source` and matters for any analysis that uses the layer. The EAMT-QE batch re-annotates segments already in the benchmark and supplies every DA-paired row, and its MQM scores span only 91.2–100 with mean 98.35: it is a near-ceiling sample. The WMT24 general-MT batch is new to the benchmark, carries no DA, and spans 57.1–100 with mean 90.55. The DA↔MQM correlation above is computed entirely within the narrower half, so it characterises that batch (Table 28). Across the `mqm` configuration 1,728 of 4,490 segments carry at least one error span (38.5%), with 1,645 minor, 1,033 major and 7 neutral spans and a mean of 0.60 spans per segment. The span typing supports error-type-conditioned QE analysis that a single DA scalar cannot, which we leave to future work. Numbers are reproduced by `analysis/mqm_provenance_split.py`.

**Metrics against MQM gold.** Table 28 scores the three pretrained COMET metrics against `mqm_score` on the 2,639-segment test split, split by annotation batch. This is the evidence for the per-group offset result of §3: for `CometKiwi-XL` and `XCOMET-XL` the pooled figure falls below both batch-internal figures, which requires the metric to order the batches against the human ordering. The layer also lets the two human protocols be compared directly. On the 476 segments of the test split that carry both an MQM and a DA score, `XCOMET-XL` agrees better with MQM ($\rho = 0.248$) than with DA (0.152), while both CometKiwi variants agree better with DA (`CometKiwi-DA` 0.365 against 0.320, `CometKiwi-XL` 0.460 against 0.342). XCOMET is trained on MQM-style error spans, so the direction is the expected one and checks that the MQM layer measures what it claims. The layer also lets the two human protocols be compared directly. On the 476 segments of the test split that carry both an MQM and a DA score, `XCOMET-XL` agrees better with MQM ($\rho = 0.248$) than with DA (0.152), while both CometKiwi variants agree better with DA (`CometKiwi-DA` 0.365 against 0.320, `CometKiwi-XL` 0.460 against 0.342). XCOMET is trained on MQM-style error spans, so the direction is the expected one.

## P Axis Difficulty against Label Reliability

A correlation is bounded by the reliability of its target, so an axis defined on the label could look hard because that target is noisy. Table 29 measures it from the released per-annotator scores: segments on no axis at all carry $\alpha = 0.891$ and a reliability of 0.967 for the mean, `A2` and `A3` sit near 0.75, `A4` at 0.534, and on `A1` the mean within-segment spread exceeds the spread between segments, so the coefficients go negative and the reliability is not estimable. `A4` is estimable, and the ceiling it implies does not account for its contrast. A reliability of 0.534 caps an attainable correlation at $\sqrt{0.534} = 0.731$, and the systems reach 0.234 there. Correcting each side of the compar-

| Metric | pooled | EAMT ($n$=623) gold sd 1.96 | WMT24 ($n$=2,016) gold sd 7.54 |
|---|---|---|---|
| `CometKiwi-DA` | 0.330 | 0.307 | 0.375 |
| `CometKiwi-XL` | **0.116** | 0.276 | 0.219 |
| `XCOMET-XL` | **0.029** | 0.243 | 0.052 |

Table 28: Segment-level Spearman against `mqm_score` on the en-hi `mqm` test split, by annotation batch. Language is constant, so only the batch varies. Bold marks the two systems whose pooled correlation is lower than *both* of its parts, which happens only when the metric orders the groups against the human ordering: humans rate EAMT above WMT24 (mean 97.56 against 90.55) while both XL metrics score WMT24 higher. Range restriction is not the explanation, since the narrower EAMT batch correlates better than the wider WMT24 batch for two of three metrics. Reproduce with `analysis/mqm_provenance_split.py`.

ison by its own ceiling is possible on the three X→en pairs, where the flagged set and its matched control both admit one: the two ceilings come out within 0.004 of each other on all three, correcting for them moves the contrast by $-0.009$, and it stays negative on each. On the four en→Indic pairs the compressed score range leaves ICC$(1,k)$ unestimable on the flagged set and on its matched control alike, so no correction can be made. Reproduce with `analysis/axis_reliability.py`.

| Segments | $n$ | within SD | between SD | $\alpha$ | ICC(1,$k$) |
|---|---|---|---|---|---|
| all | 12,730 | 13.2 | 22.0 | 0.598 | 0.851 |
| `A1` | 4,832 | 21.9 | 10.9 | $-0.045$ | — |
| `A2` | 3,477 | 17.8 | 19.5 | 0.414 | 0.736 |
| `A3` | 3,879 | 16.6 | 20.4 | 0.477 | 0.782 |
| `A4` | 1,320 | 19.4 | 14.6 | 0.219 | 0.534 |
| no axis | 5,114 | 5.2 | 22.9 | 0.891 | 0.967 |

Table 29: Label reliability by difficulty axis on the DA-bearing challenge test. *within SD* is the mean within-segment standard deviation of the annotator scores and *between SD* the standard deviation of the segment means, both on the 0–100 DA scale, so *between SD* already carries the annotator error. $\alpha$ is Krippendorff's interval alpha and ICC(1,$k$) the reliability of the mean, which is the label systems are scored against. Removing the annotator error leaves almost no variance between segments on `A1` and a standard deviation of 10.9 on `A4`, which is why the coefficients go negative on the first and not the second.

## Q Pair-Level Factors

Table 30 gives the per-pair quantities behind §3: the reliability of the DA mean, the spread of that mean, and the segment-level correlation of a representative system from each family. Three candidate explanations are tested against them. *Label reliability* predicts that pairs with a less reliable target are harder for every system alike. It does not hold: across the nine pairs the correlation between ICC$(1,k)$ and per-pair Spearman is $-0.16$ ($p = 0.67$) averaged over systems, and no individual system reaches significance. en-ml has the most reliable labels in the benchmark (ICC$(1,k) = 0.976$) and is second lowest of the nine on `CometKiwi-XL`. *Training exposure* predicts that the X→en advantage is larger for metrics trained on MLQE-PE than for prompted models that never saw those labels. The gap is $+0.18$ (`CometKiwi-DA`), $+0.17$ (`CometKiwi-XL`) and $+0.27$ (`XCOMET-XL`) for the trained metrics, against $+0.14$ (`GPT-5.5`), $+0.15$ (`aya-expanse-32B`), $+0.26$ (`tiny-aya-fire`) and $+0.06$ (`sarvam-m`) for the prompted ones. Exposure may contribute, and it cannot account for a gap that appears at the same size in systems with no exposure at all. *Target spread* is the only one that survives, and weakly: $r = +0.53$ ($p = 0.14$) between a pair's DA standard deviation and its mean correlation, $+0.41$ using the interquartile range. Reproduce with `analysis/pair_factors.py`.

| Pair | $n$ | ICC(1,$k$) | DA SD | IQR | `CometKiwi-XL` | `GPT-5.5` |
|---|---|---|---|---|---|---|
| en-hi | 1881 | 0.787 | 14.7 | 15.8 | 0.618 | 0.547 |
| en-mr | 2165 | 0.435 | 15.5 | 22.5 | 0.762 | 0.715 |
| en-ta | 2038 | 0.558 | 16.6 | 24.0 | 0.762 | 0.662 |
| en-gu | 1090 | 0.670 | 18.3 | 31.7 | 0.704 | 0.645 |
| en-te | 1120 | 0.882 | 14.0 | 17.7 | 0.306 | 0.255 |
| en-ml | 1436 | 0.976 | 25.1 | 53.7 | 0.539 | 0.641 |
| et-en | 1000 | 0.902 | 27.9 | 50.3 | 0.859 | 0.799 |
| ne-en | 1000 | 0.892 | 16.5 | 20.7 | 0.792 | 0.720 |
| si-en | 1000 | 0.829 | 20.8 | 31.4 | 0.701 | 0.619 |

Table 30: Per-pair factors on the QE-DA challenge test. ICC(1,$k$) is the reliability of the DA mean, DA SD and IQR the spread of that mean over segments, and the last two columns segment-level Spearman for the strongest trained metric and the strongest prompted model.

# Text-Only vs. Image-Aware VLM Judges for Manga Translation Evaluation

**Subaru Kimura** **Jun Suzuki**
**Tohoku University**
is-failab-research@grp.tohoku.ac.jp

## Abstract

In manga translation, visual context outside speech-bubble text, including speaker identities, referents, and scene tone, is depicted in page images, making it natural to refer to images during translation evaluation. However, most conventional manga translation evaluations rely solely on text-only automatic metrics, leaving the impact of image input insufficiently explored. We propose a practical validation framework that employs the same vision-language model (VLM) as both a text-only judge (TOJ) and an image-aware judge (IAJ) to investigate evaluation divergences associated with image-aware evaluation procedures. We use a Japanese-English manga dataset of official translations aligned at the page and speech-bubble levels. First, adding page images to TOJ improved the primary VLM's detection of deliberately injected, visually dependent degradations. Second, we analyzed evaluation divergences between TOJ and IAJ, finding different error counts and error-category distributions. Human verification did not reveal a consistent preference between TOJ and IAJ.

## 1 Introduction

Machine translation research has advanced with the central goal of accurately converting text between languages at the sentence or document level. In practice, however, what should be translated and which expressions are appropriate depend on the communicative situation, medium, and non-verbal information available to readers, which may not be captured by source and target text alone.

Recent work has advanced both automatic translation evaluation (Lavie et al., 2025) and multimodal translation research incorporating visual context (Feng et al., 2025). Manga translation is a prime example: page images depict not only dialogue text, but also speakers, referents, and characters' emotional states.

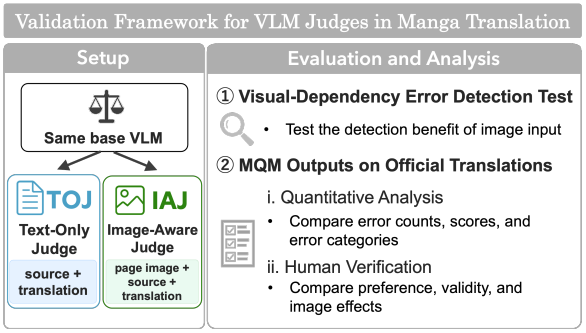

Figure 1: Overview of the proposed validation framework.

In manga translation quality evaluation (TQE), certain mistranslations, such as misidentifying speakers, pronouns, or object referents, or mismatching the tone of depicted scenes, can be difficult or impossible to identify reliably from source and target text alone and may require referencing page images. In addition, in literary and manga translation, trade-offs exist between literal fidelity, naturalness, character persona, and visual context adaptation, such that a single reference translation cannot always serve as the unique ground truth. Therefore, in manga TQE, including available page images in the input is natural to prevent information loss and evaluate appropriately.

Because VLMs can handle images and text simultaneously, an image-aware judge has the potential to detect visually dependent errors and incorporate context into evaluation that text alone cannot recover. However, providing images does not necessarily make a VLM judge universally more accurate. Errors in visual recognition or misinterpretations stemming from viewing images may also arise. The goal of this paper is not to assert that IAJ is uniformly superior to TOJ, but to investigate how VLM judge behavior changes under image-aware evaluation procedures.

Robust validation would ideally involve large-scale human correlation studies that account for di-

*Proceedings of the Eleventh Conference on Machine Translation*, pages 345–367
October 28-29, 2026 ©2026 Association for Computational Linguistics

versity across works, languages, and models. However, human evaluation of manga translation demands domain expertise, and suitable evaluation data are scarce, making such validation difficult to conduct at scale.

To address this difficulty, we propose a practical validation framework that compares the same underlying VLM under two conditions: **Text-Only Judge** (TOJ), which evaluates source and target text, and **Image-Aware Judge** (IAJ), which incorporates page images into the evaluation and, in our default setting, additional visual-grounding instructions. We use a Japanese-English manga dataset of official translations comprising 180 pages aligned at the speech-bubble level with page images. Using this framework, we investigate three research questions: whether image input improves the detection of degraded translations requiring visual context, how automatic evaluations of TOJ and IAJ differ, and whether human verification reveals a consistent preference between their fine-grained outputs.

The overview of the proposed validation framework is shown in Figure 1.

This paper makes four main contributions:

- **Validation framework for VLM judges:** We present a practical validation framework for manga translation evaluation using VLM judges that separately examines the effect of image input on detecting visually dependent errors and differences in evaluation characteristics between TOJ and IAJ on official translations.
- **Manga translation dataset based on official translations:** We transcribe Japanese source text and official English translations from manga pages publicly distributed by the rights holder, and construct an evaluation dataset of 180 pages aligned at the speech-bubble level with page images.
- **Benefit from image input:** In a degraded translation detection benchmark requiring visual context, simply adding page images to TOJ enables the primary VLM to detect more degraded translations.
- **Analysis of evaluation differences and human verification between TOJ and IAJ:** Comparing automatic evaluations of TOJ and IAJ on official translations, we show distinct trends in error counts, model-reported scores, and error-category distributions. Furthermore, human verification by 6 annotators on 40 sampled pages with TOJ/IAJ output differences reveals no consistent preference for either TOJ or IAJ. Post-task feedback suggests several directions for refining the human evaluation protocol, including prioritizing competing evaluation perspectives, defining boundary cases, and providing concrete examples of image effects.

## 2 Related Work

### 2.1 Machine Translation Evaluation and Large Language Model Judges

In automatic machine translation (MT) evaluation, following lexical overlap metrics with reference translations like BLEU (Papineni et al., 2002) and chrF (Popović, 2015), learned metrics such as COMET (Rei et al., 2020) and MetricX (Juraska et al., 2023) have been developed. Furthermore, large language model (LLM)-based metrics like G-Eval (Liu et al., 2023) and GEMBA (Kocmi and Federmann, 2023b) have enabled reference-free evaluation.

In human evaluation frameworks, Direct Assessment (DA) (Graham et al., 2013), Error Span Annotation (ESA) (Kocmi et al., 2024), and Multidimensional Quality Metrics (MQM) (Lommel et al., 2014; Freitag et al., 2021) have been widely adopted. Recently, LLM-as-a-Judge using MQM-based evaluation has gained traction (Fernandes et al., 2023; Kocmi and Federmann, 2023a; Agrawal et al., 2024), and has shown efficacy in document-level, context-aware translation evaluation (Yan et al., 2025; Semenov et al., 2025).

Building on the established efficacy of LLM judges in MQM evaluation, this study investigates the efficacy of VLM judges in MQM evaluation. We focus on differences between text-only and image-aware judges using the same underlying VLM. This enables realistic, albeit bounded, validation of image input effects in automatic manga translation evaluation, which was previously difficult to verify.

### 2.2 Multimodal Translation and Manga Translation

As multimodal machine translation research progresses, translation methods leveraging visual context in manga translation have been proposed (Hinami et al., 2021; Lippmann et al., 2025). In partic-

ular, Hinami et al. framed manga translation as a context-dependent multimodal task, showing that human evaluations viewing manga images rank translations differently than BLEU scores. This provides an early example highlighting the limitations of evaluating manga translation using text-only metrics alone. However, existing manga MT research focuses primarily on translation model development, leaving manga-specific TQE using page images, source text, and candidate translations underexplored.

Meanwhile, in the broader multimodal translation domain, studies leveraging VLM judges to analyze visual ambiguity in translation datasets have begun to emerge (Betala et al., 2025). However, because it remains unclear whether models supplied with images actually use visual information, or what image input improves and changes, VLM judges themselves require rigorous validation.

Additionally, MangaVQA (Baek et al., 2026) demonstrates that recent VLMs possess foundational visual understanding capabilities for manga pages. However, comprehending manga is necessary, but it is not equivalent to accurately evaluating translation quality. Furthermore, even a single misrecognition can alter translation evaluation decisions.

Accordingly, we use the proposed validation framework to examine the impact of image input on VLM judges' detection of visually dependent errors and output characteristics in manga translation evaluation.

## 3 Experimental Setup

### 3.1 Automatic Evaluation Design

The evaluation unit is page-level. A single page is represented as a triplet $x = (I, s_{1:n}, t_{1:n})$, consisting of Japanese page image $I$, Japanese source segment sequence $s_{1:n}$, and English translation segment sequence $t_{1:n}$. Here, $n$ denotes the number of speech bubbles (segments) on a page, varying by page. TOJ takes $(s_{1:n}, t_{1:n})$ as input and uses a default MQM-style prompt. Our default IAJ (IAJ-full) takes $(I, s_{1:n}, t_{1:n})$ as input and adds a visual-grounding instruction and a `visual_caption` output requirement to the default prompt. Note that the input image $I$ provided to IAJ is **only the Japanese page image**; the English target page image is not provided to the judge. Both conditions employ MQM-style evaluation with our custom 10-category taxonomy, outputting an auxiliary model-reported score $S_p \in [0, 100]$ per page and a structured list of errors for each mistranslation location. Here, $S_p$ is the integer score output in the JSON field `quality_score`. We define the corresponding model-reported score deficit as $D_p^{\text{judge}} = 100 - S_p$. Separately, we compute fixed-weight penalties $D_p^{\text{MQM}}$ from the three reported severity labels—`neutral`, `minor`, and `major`. Each error item consists of the corresponding segment index, error category, severity, and a natural language explanation.

Our MQM-style evaluation prompt adapts MQM-Chat (Li et al., 2025) (which defines 7 error types for dialogue translation, including ambiguity, slang/loanwords, and dialogue consistency), redefining and expanding categories to match manga translation characteristics (segment-level bubbles, personal reference ambiguity, tone/emotion, and visual scene alignment) into our custom 10-category taxonomy (full prompt in Appendix A).

### 3.2 Dataset

As the evaluation target, we use Volume 1 of *Give My Regards to Black Jack*, by Shuho Sato. In this study, we transcribed Japanese source text and English translation text from publicly available manga images, establishing 180 pages with unique 1:1 segment alignment at the bubble level verified via optical character recognition (OCR) and human inspection (dataset statistics in Appendix B).

The evaluation data are publicly available at `https://huggingface.co/datasets/joddy/gmr2bj_manga_mt_ja_en` for reproducibility. Details of released dataset contents are provided in Appendix C.

### 3.3 Models

The primary evaluation model is `gemini-3-flash-preview` (Google, 2025). This selection is based on pilot study findings showing that this model balances manga page image comprehension and structured output stability effectively. Furthermore, MangaVQA reports strong performance of Gemini-family models on manga page understanding (Baek et al., 2026), which motivated our use of a Gemini-family VLM in this study. We employ the same model under both TOJ and IAJ conditions to analyze differences between text-only and image-aware evaluation.

In this paper, we primarily report results for the main evaluation model. To verify that gains

| Degradation Type | Description |
|---|---|
| `speaker_or_addressee` | Confuses speaker or addressee, shifting subjects or honorifics |
| `referent_or_object` | Translates referenced objects/entities in image as something else |
| `tone_emotion_or_style` | Translates with tone or style contradicting facial expression or scene |
| `action_or_state` | Translates with actions or physical states contradicting depicted artwork |

Table 1: Degradation operation types used in Experiment 1 to create translations contradicting manga page image content.

from image-aware procedures are not unique to the primary model, we also perform automatic MQM evaluation with `gpt-5.4-mini` (OpenAI, 2026a) and `qwen3-vl-32b-instruct` (Qwen Team, 2025) as a robustness check. Experiment 1 evaluates 75 degraded translations, and Experiment 2 evaluates 180 official translation pages.

## 4 Experiment 1: Degraded Translation Detection

### 4.1 Creation of Degraded Translations

To intentionally generate "translation errors that cannot be decisively identified without viewing page images," we designed four types of degradation operations shown in Table 1. These four degradation types are benchmark-construction categories and are distinct from the ten MQM error categories used by the judges. Using `gemini-2.5-pro` (Gemini Team, 2025) and `gemini-3-flash-preview`, we generated degraded translation candidates contradicting image content across these four types, selecting a total of 75 benchmark instances through human vetting. Across the entire process, 75 final instances were adopted from over 900 generated candidates, yielding an overall adoption rate of approximately 8%. We note that the number and variety of highly visually dependent degradations that can be constructed from a single 180-page volume are inherently limited. Prompts used for candidate creation are detailed in Appendix A.

### 4.2 Metrics

In Experiment 1, we post-hoc evaluate whether error explanations output by TOJ/IAJ as MQM-style judges using our custom 10-category taxonomy semantically capture the pre-designed degradation intent.

For each degraded translation, `gpt-5.6-luna` (OpenAI, 2026b) classifies the relationship between the judge's error explanation and the degradation intent into {`same`, `related`, `different`}, counting `same` as a semantic match. We term this proportion the **semantic match rate** (prompts in Appendix A). This is an instance-level detection rate: the proportion of the 75 degraded translations for which at least one reported error is classified as `same`. It is not conventional overall accuracy, error-level recall, or MQM accuracy. This metric does not assess the precision of the reported errors. Reported errors that do not match the injected degradation may still identify genuine translation issues and therefore cannot automatically be treated as false positives. Without independent annotations of these additional errors, we cannot reliably compute precision or an F1 score. We also report the mean number of error flags per degraded translation, computed from the 75 fixed MQM outputs independently of the five semantic match runs. During exploratory stages, we experimented with rule-based metrics, but selected semantic match as an LLM-based evaluation method capable of accounting for paraphrastic variation. We formulate semantic matching as a natural language inference (NLI)-like classification task that can accommodate paraphrased explanations. Its validity remains limited by the lack of independently annotated gold labels.

### 4.3 Compared Evaluation Conditions

The prompt used for our default IAJ (IAJ-full) adds a visual-grounding instruction and a `visual_caption` requirement to TOJ's base prompt. The difference between TOJ and IAJ-full encompasses not only image presence, but also the combined effect of input modality and visual grounding procedures. To disentangle this confounding factor, Experiment 1 introduces **IAJ-minimal** (adding only page images to TOJ) and **IAJ-blank** (replacing IAJ-full images with a blank image).

### 4.4 Results

Because semantic match judgments can vary across runs, we repeated semantic match classification five times using the same fixed MQM outputs, without re-running the underlying VLM judges. We report the mean and range in Table 2.

| Condition | Page Image | Grounding | Mean (%) | 5-run Range (%) | Mean flags |
|---|---|---|---|---|---|
| TOJ | None | None | 57.9% | 56.0–58.7% | 1.11 |
| IAJ-blank | Blank image | Yes | 52.0% | 50.7–53.3% | 1.03 |
| IAJ-minimal | Actual page | None | 81.6% | 80.0–82.7% | 1.40 |
| IAJ-full | Actual page | Yes | 80.5% | 78.7–82.7% | 1.20 |

Table 2: Experiment 1 results. Semantic match rates are summarized by their mean and range across five runs. Mean flags denotes the average number of reported errors per instance.

IAJ-minimal achieved a mean rate of 81.6%, and IAJ-full achieved 80.5%; both had higher semantic match rates than TOJ's 57.9%. Conversely, IAJ-blank achieved a mean rate of 52.0%, dropping below both IAJ-full and TOJ. The pure contrast of image presence (TOJ vs. IAJ-minimal) yielded a 5-run mean difference of +23.7 percentage points. Comparing identical degraded translations between TOJ and IAJ-minimal and testing aggregated differences grouped by source page revealed that IAJ-minimal's gain was statistically significant across all 5 runs. Significance test details are shown in Appendix D. This ablation result shows, on this constructed benchmark, that providing page images increases the semantic match rate compared to TOJ, whereas substituting actual images with blank images degrades the semantic match rate. This provides evidence that page images help detect degraded translations requiring visual context on this constructed benchmark.

The slightly higher semantic match rate of IAJ-minimal over IAJ-full does not necessarily imply that IAJ-minimal is a more accurate judge. Semantic match measures whether an error explanation matching the degradation intent is contained in the MQM output, not overall MQM precision. IAJ-minimal produced more error flags overall than IAJ-full, which may have driven up the semantic match rate. Furthermore, we note that the additional prompt in IAJ-full was added to the base prompt because preliminary qualitative checks showed it aided MQM precision prior to scaling experiments.

We illustrate one representative degraded translation contradicting manga image content that was detected by IAJ-full but missed by TOJ. This example concerns a visually dependent degradation involving a referent. Additional examples of visually dependent degradations are provided in Figure 3 in Appendix E.

### 4.5 Robustness Across Other VLMs

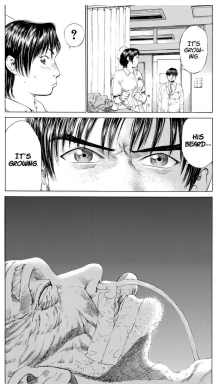
To verify whether divergences manifest across models, we evaluated TOJ and IAJ-full conditions using `gpt-5.4-mini` and `qwen3-vl-32b-instruct` (Table 3).

In both models, IAJ-full achieved a higher semantic match rate than TOJ, though the rates varied considerably by model. These results show that the directional divergence between TOJ and IAJ-full is not unique to the primary model, while indicating that absolute semantic match rates and gain magnitudes depend on the underlying VLM.

## 5 Experiment 2: TOJ/IAJ Evaluation Characteristics and Human Verification

In Experiment 2, we deliberately evaluate original official translations using automatic MQM-style evaluation to quantitatively and qualitatively analyze output differences between TOJ and IAJ-full. Hereafter, references to IAJ imply IAJ-full unless noted otherwise. When treating official translations as a provisional reference baseline, errors reported by judges can be interpreted as provisional false positives relative to the official translation or as overflagging relative to that baseline. However, official translations are not absolute ground truth; they may contain actual translation errors or room for improvement, and alternative valid translations exist. Furthermore, discrepancies between choices made in official translations and evaluation aspects prioritized by TOJ/IAJ can cause judges to flag errors in official translations. Thus, evaluating official translations allows us to analyze the evaluation characteristics of TOJ and IAJ.

### 5.1 Quantitative Analysis Design



By analyzing differences in MQM-style outputs between TOJ and IAJ-full, we quantitatively elucidate differences in their evaluation characteristics. Errors in MQM-style outputs are categorized into TOJ-only, IAJ-only, and common, analyzing output divergences. We match TOJ and IAJ flags

| MQM Judge | Semantic match rate | | | Mean flags | |
|---|---|---|---|---|---|
| | TOJ | IAJ-full | Difference | TOJ | IAJ-full |
| `gemini-3-flash-preview` | 57.9% (56.0–58.7) | 80.5% (78.7–82.7) | +22.7 pp | 1.11 | 1.20 |
| `gpt-5.4-mini` | 24.8% (24.0–25.3) | 30.7% (30.7–30.7) | +5.9 pp | 1.05 | 0.89 |
| `qwen3-vl-32b-instruct` | 45.6% (44.0–48.0) | 59.2% (57.3–61.3) | +13.6 pp | 1.43 | 1.53 |

Table 3: Experiment 1 cross-model comparison. Semantic match rates are five-run means with ranges in parentheses. Differences are IAJ-full minus TOJ, computed before rounding. Mean flags is defined as in Table 2.

bj_vol1_113 (JA)

bj_vol1_113 (EN)

**Degraded segment**
type: `referent_or_object`
JP "ヒゲが……"
EN (original) "HIS BEARD–"
EN (degraded) "MY BEARD–"

**Degradation intent**
"The possessive 'HIS' was changed to 'MY', shifting the referent of the beard from the patient to the speaker (the doctor)."

**IAJ-full error explanation**
"The doctor is observing the patient's beard, not his own. The use of the first-person possessive 'MY' is a reference error that misidentifies whose beard is being discussed."

Figure 2: Representative example (`bj_vol1_113`) of degraded translation contradicting manga image content missed by TOJ but detected by IAJ-full. Left: JA/EN page images; Right: degraded segment, degradation intent, and IAJ-full error explanation. The EN page image is shown for illustration only and was not provided to IAJ. The patient's beard and the doctor's face clarify the referent error changing "HIS" to "MY". *Give My Regards to Black Jack / SHUHO SATO*

at the segment level using a rule-based procedure, classifying corresponding flags as common and non-corresponding flags as TOJ-only or IAJ-only. This heuristic matching combines explanation token set Jaccard similarity and string similarity with `error_category` and `severity` alignment. The objective is to mechanically link obviously identical flags to aggregate output differences quantitatively. Therefore, this classification does not guarantee strict semantic identity, and results should be interpreted as diagnostic statistics describing TOJ and IAJ output divergences. Matching methodology details are provided in Section G of the Appendix.

### 5.2 Qualitative Analysis Design

To qualitatively analyze TOJ and IAJ-full evaluations, we conduct human verification involving 6 Japanese annotators from the same laboratory (non-authors). Annotators were native Japanese speakers familiar with reading manga and possessing backgrounds in language processing research. All annotators were master's or doctoral students at Tohoku University and had no prior experience in professional translation or MQM annotation. Standardized English proficiency test scores were not collected. While using professional Japanese-to-English manga translators would be ideal, recruiting and executing verification with multiple professional translators presents substantial practical hurdles.

For human verification targets, from the candidate set of 116 pages among 180 pages having at least one unique flag in TOJ or IAJ, we selected 40 pages via simple random sampling. Sampling from pages with output differences allows for a clearer analysis of evaluation characteristic divergences between TOJ and IAJ. The selected 40 pages comprised 12 pages with unique flags in TOJ only, 4 pages in IAJ only, and 24 pages with unique flags in both. For these 40 pages, evaluators compared TOJ and IAJ flags for the same page.

The main judgment asked evaluators which judge's flags were superior, with three response options: `prefer_IAJ` / `prefer_TOJ` / `tie`. Additionally, evaluators reported confidence, page-level output validity ratings for TOJ/IAJ, image effect on IAJ flags, and usefulness of image information in translation evaluation. Each validity

rating covered the complete flag set produced by one judge for one page; thus, the denominator was 40 pages $\times$ 6 annotators $=$ 240 ratings per judge. Evaluators received descriptions for each option but were not instructed on a rigid priority hierarchy when source fidelity, naturalness, and visual consistency conflicted. When 4 or more of 6 evaluators selected the same main judgment, it was classified as strict majority; otherwise, it was classified as `no_majority`. For operational protocol details, annotation user interface (UI), and instructions, see Appendix F.

## 5.3 Quantitative Analysis of MQM-style Evaluation

### 5.3.1 Overview of Automatic Evaluation across 180 Pages

Table 4 shows automatic evaluation results across all 180 official translation pages for TOJ and IAJ-full, including error-flag counts and model-reported score statistics. For gemini-3-flash-preview, IAJ-full yielded fewer mean error flags per page than TOJ (1.77 $\rightarrow$ 1.46), and a lower mean model-reported score deficit ($100 - S_p$) (10.24 $\rightarrow$ 8.08). Each reported error is assigned one of three severities: `major`, `minor`, or `neutral`. Prompts define `major` as errors substantially distorting meaning, `minor` as errors with limited impact, and `neutral` as reported issues with constrained effect. In this paper, all three severities are included in error flag counts. Major flags were fewer than minor flags, with major-free pages accounting for 147/180 (81.7%) in TOJ and 158/180 (87.8%) in IAJ-full. Conversely, minor errors occurred at 1–2 items per page across most pages for both judges. While this does not directly show that IAJ-full produced more accurate evaluations, it shows that image-aware procedures alter judge output volume and reported scores.

As a fixed-weight scoring analysis based on MQM severity labels, we assigned weights of 0, 1, and 5 to neutral, minor, and major, respectively, and calculated penalty points per 100 words of the official English translation. For the primary evaluation model, TOJ yielded 5.80 penalty points, compared with 4.57 for IAJ-full; thus, the tendency for IAJ-full to incur fewer penalties was reproduced in the fixed-weight MQM aggregation. This result is consistent with the comparison based on the judge-reported `quality_score`; the page-level Spearman correlations between the two measures were 0.762 for TOJ and 0.717 for IAJ-full. The auxiliary models showed differences in the same direction, while fixed-weight scoring and sensitivity analyses are provided in Appendix G.

Thus, automatic comparison across 180 pages showed that IAJ-full produced fewer flags and smaller auxiliary score deficits than TOJ. Auxiliary models exhibited a similar directional trend: IAJ-full produced fewer total error flags and smaller auxiliary mean score deficits than TOJ. Auxiliary model results for Experiment 2 are detailed in Appendix H.

| Metric | TOJ | IAJ-full |
|---|---|---|
| *All 180 Pages* | | |
| Total error flags | 318 | 262 |
| Mean / page | 1.77 | 1.46 |
| Major error flags | 36 | 24 |
| Mean major / page | 0.20 | 0.13 |
| Minor error flags | 268 | 233 |
| Mean minor / page | 1.49 | 1.29 |
| Neutral error flags | 14 | 5 |
| Mean neutral / page | 0.08 | 0.03 |
| Mean quality_score | 89.8 | 91.9 |
| Mean score deficit ($100 - S_p$) | 10.24 | 8.08 |
| *Page-Level Error Distribution* | | |
| 0-error pages | 20 (11.1%) | 31 (17.2%) |
| 1+ error pages | 160 (88.9%) | 149 (82.8%) |
| 0-major pages | 147 (81.7%) | 158 (87.8%) |
| 0-error in both judges | 19 (10.6%) | |

Table 4: Automatic evaluation results reported by judges on official translations across 180 pages (based on `gemini-3-flash-preview`). The table includes total error flags, severity counts, mean model-reported `quality_score`, and mean score deficit ($100 - S_p$). Total error flags include `major`, `minor`, and `neutral`.

### 5.3.2 Structural Analysis of Judge Output Divergence

To examine TOJ and IAJ-full output differences in detail, we categorized errors across all 180 pages into TOJ-only, IAJ-only, and common. Overall, TOJ-only = 152, IAJ-only = 96, and common = 166, showing TOJ produced more unique flags. We define TOJ-only share as TOJ-only/(TOJ-only + IAJ-only). In `tone_and_emotion` (65.5%), `omission_or_addition` (64.6%), `terminology_and_named_entities` (62.5%), and `naturalness_and_register` (61.2%), TOJ-only flags were more frequent than IAJ-only flags, suggesting that TOJ often flags fine-grained differences in naturalness, style, and fidelity. In contrast, `reference_and_disambiguation` and

| Category | TOJ-only | IAJ-only | TOJ-only Share |
|---|---|---|---|
| Overall | 152 | 96 | 61.3% |
| meaning_accuracy | 42 | 32 | 56.8% |
| naturalness_and_register | 30 | 19 | 61.2% |
| omission_or_addition | 31 | 17 | 64.6% |
| tone_and_emotion | 19 | 10 | 65.5% |
| terminology_and_named_entities | 20 | 12 | 62.5% |
| reference_and_disambiguation | 4 | 4 | 50.0% |
| action_and_state | 1 | 1 | 50.0% |
| speaker_and_dialogue_consistency | 0 | 0 | – |
| colloquial_and_cultural_expression | 3 | 0 | 100.0% |
| other | 2 | 1 | 66.7% |

Table 5: Breakdown of TOJ/IAJ unique error flags by MQM category across 180 pages.

`action_and_state` showed nearly equal TOJ-only and IAJ-only shares, indicating IAJ-full also produced unique flags regarding visual reference resolution and action understanding. Category breakdowns for TOJ-only / IAJ-only are presented in Table 5.

Furthermore, comparing 54 segment locations where both judges flagged the same page segment but could not be matched as common, 37 instances (68.5%) differed in `error_category`. This indicates that even when targeting the same segment, TOJ and IAJ frequently conceptualize issues from different perspectives.

#### 5.3.3 Retention of TOJ Flags in IAJ-full

We define coverage as the proportion of error candidates flagged by TOJ that are retained as identical flags in IAJ-full. Across 160 pages with 1+ TOJ flag (totaling 318 TOJ flags), 166 flags (52.2%) were retained in IAJ-full. On 45 pages (28.1%), IAJ-full retained zero TOJ flags. This indicates that while IAJ-full incorporates flags overlapping with TOJ, it also does not retain some flags reported by TOJ. Detailed coverage distribution statistics are provided in Table 13 in Appendix I.

### 5.4 Qualitative Analysis via Human Verification

#### 5.4.1 Main Judgment and Agreement among 6 Annotators

Table 6 summarizes the 240 judgments from 6 annotators over 40 pages. Preferences were dispersed, and agreement was limited despite predominantly medium or high confidence. Among the 14 pages without a majority, 12 had a 3–2–1 split and two a 3–3 split; most disagreements were therefore not clean binary divisions.

Annotators also showed distinct tendencies: one chose `tie` on 27 pages, another preferred TOJ on 24, and another preferred IAJ on 17. Low agreement thus cannot be explained merely by hesitation. Possible factors include small differences between outputs, differing criteria or tie thresholds, and characteristics of the sampled pages, but these results do not isolate their contributions.

| Metric | Value |
|---|---|
| Annotators / Verified Pages | 6 / 40 |
| *Individual votes* ($n = 240$) | |
| Prefer IAJ / TOJ / Tie | 73 / 87 / 80 |
| Percentage | 30.4 / 36.3 / 33.3% |
| Medium or high confidence | 228 (95.0%) |
| Mean Pairwise Agreement | 0.512 |
| Fleiss' $\kappa$ | 0.266 |
| Strict Majority - unanimous | 5 / 40 |
| Strict Majority - non-unanimous | 21 / 40 |
| Any majority | 26 / 40 (65.0%) |
| `prefer_IAJ` Consensus | 7 |
| `prefer_TOJ` Consensus | 12 |
| `tie` Consensus | 7 |
| `no_majority` | 14 / 40 (35.0%) |

Table 6: Experiment 2: Main judgment agreement and page-level consensus among 6 annotators over 40 TOJ/IAJ-full MQM outputs.

#### 5.4.2 Page-Level Output Validity and Reasons for Tie

Table 7 summarizes ratings of each judge's complete page-level flag set, not individual errors. Both judges were often rated valid, with similar valid rates, whereas IAJ received more unclear ratings. The dominant tie reason was that both sets were valid, rather than both invalid. Rating definitions are provided in Appendix F.

#### 5.4.3 Usefulness of Image Information and Effect on IAJ

Perceived image usefulness and observed effects on IAJ flags address different questions (Table 7).

| **Output validity** ($n = 240$ **each**) | **TOJ Count (%)** | **IAJ Count (%)** |
|---|---|---|
| Valid | 168 (70.0) | 172 (71.7) |
| Partially valid | 46 (19.2) | 28 (11.7) |
| Invalid | 15 (6.3) | 12 (5.0) |
| Unclear | 11 (4.6) | 28 (11.7) |
| Valid or partially valid | 214 (89.2) | 200 (83.3) |
| **Tie reason** ($n = 80$) | | **Count (%)** |
| Both valid | | 58 (72.5) |
| Both partially valid | | 10 (12.5) |
| Difference too small | | 10 (12.5) |
| Both invalid | | 1 (1.3) |
| Other | | 1 (1.3) |

| **Image usefulness** ($n = 240$) | **Count (%)** |
|---|---|
| Helpful or essential | 124 (51.7) |
| Not needed | 109 (45.4) |
| Unclear | 7 (2.9) |
| **Image effect** ($n = 240$) | **Count (%)** |
| No observable effect | 137 (57.1) |
| Any positive effect | 55 (22.9) |
| Any negative effect | 26 (10.8) |
| Unclear | 24 (10.0) |

Table 7: Experiment 2 human ratings. Left: output validity and reasons for ties. Right: perceived image usefulness and observed effects on IAJ outputs. Values are counts with percentages in parentheses. IAJ denotes IAJ-full. Positive effects include valid detection, overflagging prevention, or rationale strengthening; negative effects include visual misrecognition/overinterpretation or missed textual issues. Effects are counted per response, with two responses reporting both positive and negative effects.

Judgments of potential usefulness were nearly evenly divided, whereas most responses reported no observable effect on IAJ flags. Positive and negative effects were both reported, indicating instance-dependent benefits and occasional adverse effects rather than consistent improvement. Image effects allowed multiple selections; full option definitions appear in Appendix F.

#### 5.4.4 Post-Task Feedback

As post-task feedback upon completing annotations, evaluators answered 5-point scale items regarding overall task difficulty, rubric sufficiency, priority clarity when criteria conflict (source fidelity vs. target naturalness vs. visual consistency), main label clarity, and usefulness of concrete examples. Additionally, evaluators picked the single annotation field that caused the most hesitation across 40 pages, and selected multiple-choice options for explanations or examples that would aid judgment in future iterations (e.g., priority rules, boundary case examples, image effect examples, severity rules, concrete label examples). Across 6 annotators' post-task feedback, median task difficulty was 4.0/5, while rubric sufficiency and main label clarity medians were both 4.0. In contrast, priority clarity when criteria conflict received a median of only 2.5. Usefulness of concrete label examples or boundary cases had a median of 4.0, and 4 of 6 annotators picked image effect classification as the hardest field. Additional guidance covering priority rules, boundary examples, image effect examples, severity examples, and label examples was requested by 3 annotators each. Thus, future evaluation designs should consider providing explicit priority rules and concrete benchmark examples when evaluation perspectives conflict. However, causal improvements in agreement or accuracy from adding guidelines remain unverified.

## 6 Discussion

We briefly summarize key insights derived from experimental results.

**Does Adding Page Images Aid Visually Dependent Error Detection?** In Experiment 1, for 75 degraded translations designed to be difficult to judge without images, IAJ-minimal (adding only page images to TOJ) achieved a higher mean semantic match rate than TOJ, with the difference being statistically significant across all 5 runs. These results provide evidence that, on this constructed benchmark, inputting page images aids the detection of visually dependent degradations.

**How Does Image-Aware Procedure Alter Judge Evaluation Characteristics?** In Experiment 2, IAJ-full produced fewer flags and smaller auxiliary score deficits derived from model-reported scores than TOJ, exhibiting divergences in unique flag counts and error category assignments for identical segments. This indicates that IAJ-full does not merely add flags: some flags reported by TOJ are not retained, and errors are reported from distinct angles.

**Can Human Verification Stably Arbitrate TOJ vs. IAJ Differences?** Human verification

showed no consistent preference trend favoring either TOJ or IAJ. Page-level output validity ratings for both conditions did not differ markedly, and `both_valid` was the dominant reason for `tie` judgments. This pattern is consistent with the difficulty of ranking two flag sets both judged valid overall, although the present results do not isolate the cause of disagreement. Evaluator perceptions of potential image usefulness split evenly, while observed image effects on actual IAJ flags showed no effect in 57.1%, positive effects in 22.9%, and negative effects in 10.8%. Thus, human verification found no uniform preference for IAJ-full, indicating that the image-aware evaluation procedure does not yield uniformly preferred evaluations across all pages. Post-task feedback showed that annotators sometimes had difficulty choosing between judge outputs when different evaluation criteria favored different outputs. The limited agreement may partly reflect differences in how annotators prioritize source fidelity, target-language naturalness, and visual consistency when comparing judge outputs. Our protocol did not prescribe a strict priority among these criteria, leaving room for differing judgments. However, the present results cannot determine whether disagreement primarily reflects small differences between judge outputs, differing priorities among evaluation criteria, or characteristics of the manga title and sampled pages.

**What Is Required for Practical VLM Judge Evaluation?** Future work should calibrate evaluators after sharing priority rules for conflicting evaluation perspectives, common criteria, boundary cases, and concrete examples of image effects. However, whether adding such explanations or calibration improves agreement or judgment stability remains unverified. Practical use also requires additional validation across multiple works, other language pairs, and models.

## 7 Conclusion

This study presents a validation framework for manga translation VLM judges that separately evaluates detection gains for visually dependent errors and characteristic output changes induced by image-aware procedures. To accomplish this, we built an open evaluation dataset of 180 pages from transcribed official Japanese and English manga, aligned at the speech-bubble level with page images. In Experiment 1, we found that adding page images aids in detecting visually dependent errors on this constructed benchmark, providing evidence for a baseline benefit of utilizing VLM judges. In Experiment 2, while IAJ-full exhibited different error volume and evaluation perspectives from TOJ, human preference judgments across 6 annotators showed no consistent superiority. These findings suggest that IAJ merits further investigation for manga translation evaluation, but do not support replacing TOJ with IAJ universally. Through our proposed validation framework, we present a practical validation approach for settings where large-scale human correlation studies are difficult. Our framework provides a starting point for extending VLM judge evaluation to other visually dependent translation domains, such as subtitles, advertisements, and instruction manuals.

## Limitations

- The evaluation target is restricted to a single manga work and language pair (ja→en). Generalizability to other works, genres, or language pairs remains unverified; we do not claim identical effect sizes or output characteristics hold across manga broadly. Copyright constraints surrounding redistributable official parallel manga data exacerbate this limitation.

- Degraded translations in Experiment 1 were intentionally created and selected to require visual information, and do not reflect the natural distribution of manga translation errors. Therefore, detection rates in Experiment 1 should not be interpreted as operational error detection rates or representative values for manga translation errors as a whole.

- Experiment 2 compares TOJ with IAJ-full; therefore, observed differences cannot be attributed solely to image presence because IAJ-full also modifies the evaluation instructions.

- The 5 runs in Experiment 1 repeat semantic-match classification of fixed MQM outputs, rather than MQM judge execution under identical conditions. MQM judge execution used `temperature=0.1`, but lowering the temperature does not guarantee identical outputs under repeated execution. Therefore, observed differences among TOJ, IAJ-minimal, IAJ-full, and IAJ-blank may partly reflect single-run MQM-output variability, in addition to differences in image input and evaluation instructions.

- Semantic match evaluation relies on LLM judge precision. While authors performed spot-checks, alignment against independent multi-annotator gold labels and systematic verification of meta-evaluator precision were not conducted. Consequently, reported semantic match rates may contain meta-evaluator judgment noise.

- We did not validate the judges' error localization, categories, severity labels, or explanations against independent MQM annotations by experienced translation experts. Human verification in Experiment 2 assessed judge outputs rather than independently annotating translation errors. Thus, our findings concern detection of injected degradations and differences in judge outputs, and do not establish overall MQM accuracy.

- Common flag matching between TOJ and IAJ-full employs a rule-based heuristic based on explanation similarity, category, and severity, without human alignment validation. Therefore, unique flag counts and coverage rates may reflect heuristic matching errors.

## Ethical Considerations

**Content Safety.** The evaluated work is a general-audience medical drama containing medical depictions (surgeries, death), but review of the 180 evaluated pages revealed no explicit hate speech, discrimination, or explicit violence.

## Acknowledgments

We thank Shuho Sato and Sato Manga Works Ltd. for making *Give My Regards to Black Jack* available under a generous reuse policy, which enabled this study and the release of the accompanying dataset. This work was partly supported by JST Moonshot R&D Grant Number JPMJMS2011-35 (fundamental research), by JSPS KAKENHI Grant Number JP26H02511, and by JST BOOST Japan Grant Number JPMJBS2421.

## A Prompts

Complete templates for primary prompts used in this study are shown below. In actual execution, placeholders `{...}` were populated at runtime.

**Degraded Translation Candidate Generation Prompt** To generate degraded translation candidates, page images, source text, and official translations were input with the following prompt. Degradation types were substituted at runtime as `{degradation_types}`. At runtime, the full-page source and official target text were substituted into `{source_full}` and `{translation_full}`, respectively. `{pairs}` contained bubble-level source-target pairs.

> You are generating natural but visually contradictory degradation candidates for manga translation evaluation.
> The source language is Japanese and the target language is English.
> For each of these degradation types, return up to 3 candidates in descending order of plausibility: `{degradation_types}`.
> Each candidate must change exactly one segment if possible and should only be clearly wrong when considering the image.
> Do not create candidates that are clearly wrong from the source text alone. Avoid obvious text-only mismatches such as changing explicit names, countries, numbers, occupations, or key terms that are directly stated in the source text.
> Also avoid candidates that become clearly wrong after reading neighboring text segments on the same page.
> Prefer subtle changes where the source text and translation can still look plausible in isolation, but the page image makes the error clear.
> Aim for candidates that remain plausible to a text-only judge, while still being strong enough to force a vision-aware judge to name a concrete translation error.
> Accepted patterns: omitted Japanese subjects resolved differently by the image; gender-neutral references resolved by the depicted character; short replies whose tone depends on expression; object mismatch should target ambiguous references or generic words whose concrete referent is only visible in the image.
> Rejected patterns: replacing an explicit source word with another term; adding a new action or proposition not licensed by the source or neighboring text; changing speaker/addressee when the page text already fixes it; making object/action changes that are already wrong without the image.
> Type-specific constraints: avoid speaker/addressee changes when neighboring text already makes the addressee clear; avoid strong interjections whose tone is obvious from text alone; avoid count changes or lexical narrowing that already create a clear text-only meaning difference; avoid action changes when the source text already states the action or physical state.
> The degraded_text must be the rewritten translation segment only, in the same target language as the original translation. Do not output Japanese source text.
> Return metadata:
> - edit_description
> - visual_evidence_note
> Only return JSON.
>
> <input>
> <page_source_full>
> {source_full}
> </page_source_full>
> <page_translation_full>
> {translation_full}
> </page_translation_full>
> {pairs}
> </input>

**Common Prompt for MQM Judges** In TOJ, `{vision_instruction}` and `{evaluation_procedure}` are left empty. In IAJ-minimal, only page images are added. In IAJ-full, additional instructions described below are embedded in `{vision_instruction}` and

{evaluation_procedure}. IAJ-blank uses the IAJ-full prompt with page images replaced by a blank image. MQM judge execution used temperature=0.1.

You are an annotator for the quality of manga translation.
Your task is to identify translation errors on a single manga page and assess the overall quality.

{vision_instruction}
{evaluation_procedure}
<input>
<source_language>{src_lang}
</source_language>
<target_language>{tgt_lang}</target_language>
<page_source_full>
{source_full}
</page_source_full>
<page_translation_full>
{translation_full}
</page_translation_full>
{pairs}
</input>

First read the page as connected discourse, then evaluate individual segments.
Evaluate each source/translation segment pair carefully.
Also consider consistency, coherence, and fluency across neighboring segments on the same page.

Use the following error categories:
- meaning_accuracy: Errors where the translation conveys a meaning that is substantially different from the source. Use this category only when no more specific category better explains the error.
- omission_or_addition: Errors where the translation omits source information that should be conveyed, or adds meaning that is not supported by the source.
- reference_and_disambiguation: Errors where the translation incorrectly resolves, over-specifies, or fails to appropriately preserve underspecified reference in the source.
- speaker_and_dialogue_consistency: Errors where the translation is inconsistent with who is speaking, who is being addressed, or how the utterance fits into the local dialogue context on the page.
- tone_and_emotion: Errors where the translation fails to match the emotional tone, intensity, interpersonal stance, or expressive force conveyed by the source and page context.
- action_and_state: Errors where the translation misrepresents an action, posture, physical state, ongoing event, or target of action.
- terminology_and_named_entities: Errors involving incorrect, inconsistent, or contextually inappropriate translation of specialized terms, role labels, names, titles, organizations, locations, or other named entities.
- naturalness_and_register: Errors where the translation is grammatically awkward, stylistically unnatural, or mismatched in register, formality, or social tone for the local context. Do not penalize a translation merely for being colloquial, slangy, or non-literal if it naturally conveys the source nuance in context.
- colloquial_and_cultural_expression: Errors where the translation fails to appropriately render colloquial, stylized, era-specific, socially marked, or culturally grounded expression. Natural slang, casual phrasing, and expressive wording are acceptable when they help preserve the source nuance rather than flatten it into overly formal or literal English.
- other: Errors that materially affect translation quality but cannot be adequately explained by any category above. Use sparingly.

For each error: identify the primary segment_index, optionally context_segment_indices, error_span, explanation, exactly one error_category, severity (major/minor/neutral), and improvement string.

Severity guideline: major = meaning substantially distorted; minor = meaning mostly preserved but suboptimal; neutral = limited impact.

Scoring guideline: Start from 100; subtract more for major than minor/neutral; keep scoring internally consistent across pages; do not double-count cross-segment issues (count a cross-segment issue as one error, not multiple duplicated errors).

Important constraints:
- Only annotate errors that are supported by the source text and translation.
- Do not invent missing context that is not justified by the input.
- Do not over-penalize stylistic variation unless it is clearly unnatural, misleading, or contextually inappropriate.
- Prefer translations that preserve source nuance, voice, and interpersonal texture, not just grammar or dictionary-level literalness.
- If the error is an omission, set “error_span”: “” and describe the missing content in “explanation”. For omission errors, set improvement to the missing phrase or sentence.
- If an issue mainly appears when reading neighboring segments together, anchor it to the most affected segment_index, include the relevant neighbors in context_segment_indices, and explain the cross-segment context in explanation.
- Do not report the same underlying issue multiple times. Merge it into one error anchored to the most affected segment.
- If there is no error, return an empty errors array.

Output requirements:
- Respond with valid JSON only.
- Do not include any text before or after the JSON.
- Use plain text strings without Markdown.

**MQM Judge JSON Schema** The following JSON schema was inserted at runtime.

```
{
  "$defs": {
    "MQMError": {
      "properties": {
        "segment_index": {
          "minimum": 0,
          "title": "Segment Index",
          "type": "integer"
        },
```

```
        "context_segment_indices": {
          "items": {
            "minimum": 0,

  "type": "object"
}
```

**Additional Instructions for IAJ-full and IAJ-blank** In IAJ-full and IAJ-blank, `{vision_instruction}` and `{evaluation_procedure}` in the common prompt are populated as follows:

> [vision_instruction]
> Evaluate the translation with reference to the original manga image. Understand the visual content of the page carefully and use it to assess whether the translation is consistent with the depicted scene and context. Before judging translation quality, first form a concise internal caption of the page. Then identify the visible facts that matter for translation evaluation (who is present, who is likely speaking or being addressed, what object or person a referring expression points to, what action_or_state/emotional stance is depicted). Include the concise caption in the JSON field visual_caption.
>
> [evaluation_procedure]
> - Step 1 (visual grounding): Form a concise internal caption and extract only translation-relevant visual facts.
> - Step 2 (MQM evaluation): Evaluate translation quality using source text, translation text, page-level discourse, and the grounded facts from Step 1.

**Semantic Match Classification Prompt** Judge output error lists and degradation intents were input to an LLM (`gpt-5.6-luna`) to classify semantic match as `verdict` $\in$ {`same`, `related`, `different`}. An instance was counted as detected when at least one reported error received `verdict=same`; the proportion of detected instances was aggregated as the semantic match rate. `gpt-5.6-luna` was executed with `reasoning_effort=medium`.

> You are judging whether MQM errors semantically catch an intended degradation. Decide if MQM has caught the intended degradation.
>
> Degradation:
> degradation_type: {degradation_type}
> edit_description: {edit_description}
> visual_evidence_note: {visual_evidence_note}
>
> MQM Output:
> mqm_errors: {mqm_errors}
>
> Choose verdict and return concise reason:
> - same: MQM catches essentially the same issue.
> - related: MQM points to a related issue but not the intended issue strongly enough.
> - different: MQM misses the intended issue.

## B Dataset Statistics

Dataset details constructed and used in this study are shown in Table 8.

| Item | Value |
|---|---|
| *Base Dataset* | |
| Target Manga Work | *Give My Regards to Black Jack* Vol. 1 |
| Page Images (JA) | 196 |
| Page Images (EN) | 196 |
| Pages with Established Segment Alignment | 180 |
| Total Segment Count (180 pages) | 974 |
| Mean Segments per Page | 5.4 |
| *Experiment 1 (Degraded Translation Detection Benchmark)* | |
| Degraded Translation Instances | 75 |
| Base Unique Pages | 54 |
| *Instance Breakdown by Category* | |
| `speaker_or_addressee` | 16 |
| `referent_or_object` | 27 |
| `tone_emotion_or_style` | 26 |
| `action_or_state` | 6 |

Table 8: Dataset statistics.

## C Data Availability

The following materials are publicly available in the Hugging Face dataset repository at https://huggingface.co/datasets/joddy/gmr2bj_manga_mt_ja_en:

- Page IDs, page numbers, speech bubble segments, and Japanese-English parallel segment alignment tables for 180 pages.
- 75 degraded translation instances contradicting manga image content used in Experiment 1 (degraded target text, degradation type, intent, target segment, visual cue metadata).

**Data Copyright and Licensing.** All images in this study originate from data for *Give My Regards to Black Jack* officially distributed for download by Sato Manga Works Ltd., rather than from scans of physical books. Published terms of use allow copying, public transmission, adaptation, and secondary use under specified conditions. Figures and released datasets explicitly state "Give My Regards to Black Jack / SHUHO SATO." Because this permission is specific to this work, it cannot be directly applied to other manga titles. Usage will be reported to Sato Manga Works Ltd. within one month of publication. After verifying license compliance, the page images are released as part of the dataset. Official distribution page: https://densho810.com/free/.

## D Experiment 1 Paired Cluster Test

In Experiment 1, the same 75 degraded translation instances were evaluated by both TOJ (no image) and IAJ-minimal (with page image). Because these 75 instances originate from 54 base pages, we aggregated differences by source page to avoid counting instances from the same page as independent data points. We computed cluster sign-flip tests and cluster bootstrap 95% confidence intervals across these 54 page-level differences.

Because the 5 runs represent re-executions over identical inputs, they are not pooled as 375 independent observations. Rather than repeating mean and run-to-run range values from main text Table 2, test results per run are reported in Table 9.

For reference, exact McNemar test $p$-values based on instance-level paired disagreement are also listed. Because McNemar's test does not account for intra-page correlation, cluster sign-flip tests on base pages serve as our primary inference method.

## E Experiment 1: Additional Representative Examples

Figure 3 presents 2 additional representative degraded translations contradicting manga image content: changing to forceful speech contradicting character state (`bj_vol1_114`) and changing to hesitant speech contradicting resolute determination (`bj_vol1_116`).

## F Annotator Information

**Execution Summary** Six annotators evaluated the same set of 40 pages and completed post-task feedback. The 6 annotators were researchers belonging to the same laboratory as the primary author (non-collaborators). Compensation was paid equivalent to an hourly rate of 2,000 JPY. Completing 40 pages required approximately 1.5 to 2 hours per annotator.

**Human Verification Task Items** Rigid criteria were not enforced, allowing each annotator to judge independently. A screenshot of the annotation UI is shown in Figure 4. Using identical UIs, annotators entered the following items per page:

- **Main Judgment**: Select which judge's output felt superior overall.
  - `prefer_TOJ`: TOJ flags were superior.
  - `prefer_IAJ`: IAJ flags were superior.

| Run | TOJ (%) | IAJ-min. (%) | Diff (pp) | TOJ-only | IAJ-min.-only | McNemar $p$ | Cluster $p$ | Cluster 95% CI |
|---|---|---|---|---|---|---|---|---|
| 1 | 58.7% | 81.3% | +22.7 | 2 | 19 | 0.000221 | 0.000740 | [+11.0, +36.1] |
| 2 | 58.7% | 80.0% | +21.3 | 2 | 18 | 0.000403 | 0.001700 | [+8.3, +35.1] |
| 3 | 56.0% | 81.3% | +25.3 | 1 | 20 | $< 0.0001$ | $< 0.0001$ | [+13.3, +38.6] |
| 4 | 57.3% | 82.7% | +25.3 | 1 | 20 | $< 0.0001$ | $< 0.0001$ | [+13.9, +37.8] |
| 5 | 58.7% | 82.7% | +24.0 | 1 | 19 | $< 0.0001$ | 0.000390 | [+11.5, +37.7] |

Table 9: Significance test results for TOJ vs. IAJ-minimal in Experiment 1. Differences per run are percentage-point differences (IAJ-minimal − TOJ). "TOJ-only detected" indicates instances detected only by TOJ; "IAJ-min.-only detected" indicates instances detected only by IAJ-minimal, aggregated across 75 paired degraded translation instances. McNemar $p$ provides exact instance-level paired reference values. Cluster $p$ represents sign-flip test $p$-values over 54 page-level clusters, and Cluster 95% confidence interval (CI) reflects bootstrap confidence intervals resampling source pages.

bj_vol1_114 (JA)

bj_vol1_114 (EN)

**Degraded segment**
type: `tone_emotion_or_style`
JP "助けてくれよ先生……先生……"
EN (original) "Help me, Doctor... Doctor..."
EN (degraded) "Help me, Doctor! Doctor!"

**Degradation intent**
"Converted the desperate, trailing-off internal thoughts (indicated by ellipses and fuzzy bubble borders) into assertive, forceful shouts by replacing ellipses with exclamation marks and using direct, clear phrasing."

**IAJ error explanation**
"The translation uses exclamation marks, conveying a forceful, shouting tone.
However, the source uses ellipses ('……') and the visual context shows an intubated, dying patient, suggesting a weak, desperate plea or internal monologue.
Additionally, 'I AM NOT READY TO DIE' is a more composed phrasing than the raw 'I don't want to die yet' (オレはまだ死にたくねえ), losing the directness and the nuance of 'yet' (まだ)."

bj_vol1_116 (JA)

bj_vol1_116 (EN)

**Degraded segment**
type: `tone_emotion_or_style`
JP "僕は医者だ ……!! "
EN (original) "I am! I'm a Doctor!"
EN (degraded) "I... I'm a doctor...!!"

**Degradation intent**
"Changed the tone from a fierce, defiant declaration of identity to a hesitant, fearful-sounding stutter."

**IAJ error explanation**
"The repetition of 'I' followed by 'I'm' creates a stuttering effect that suggests hesitation or uncertainty.
This contradicts the character's extremely determined and resolute facial expression.
The Japanese text uses a space for a dramatic pause between the subject and predicate, which is better rendered without repeating the pronoun to maintain the intensity of the declaration."

Figure 3: Representative examples (`bj_vol1_114`, `bj_vol1_116`) of degraded translations contradicting manga image content in Experiment 1. Format matches Figure 2 (JA/EN page images + degraded segment + degradation intent + IAJ-full error explanation). The EN page images are shown for illustration only and were not provided to IAJ. *Give My Regards to Black Jack / SHUHO SATO*

  - `tie`: Difference was small or ranking was difficult. Must answer `tie_reason`.

- **Confidence**: Select confidence level in main judgment.
  - `high`: High confidence in main judgment.
  - `medium`: Medium confidence in main judgment.
  - `low`: Low confidence; judgment felt unstable.

- **Page-Level Output Validity**: Rate the overall validity of the complete TOJ and IAJ flag sets for the page independently on a 4-point scale.
  - `valid`: The complete flag set is valid overall.
  - `partially_valid`: The flag set is directionally valid but needs correction.
  - `invalid`: The complete flag set is invalid.
  - `unclear`: Cannot judge due to insufficient information.

- **Image Effect**: `image_effect_on_evaluation` (multiple-choice). Select how viewing images affected IAJ flags compared to TOJ.
  - `enabled_valid_detection`: Discovered valid flag via image.
  - `prevented_overflagging`: Prevented overflagging via image.
  - `strengthened_rationale`: Strengthened flag rationale via image.
  - `visual_misrecognition_or_overinterpretation`: Visual misrecognition or overinterpretation.
  - `missed_textual_issue`: Missed text issue due to viewing image.
  - `no_observable_effect`: No observable image effect (mutually exclusive).
  - `unclear`: Cannot judge image effect (mutually exclusive).

- **Image Information Usefulness**: `expected_image_helpfulness` (single-choice). Rate how useful manga images were for evaluating translation quality on this page.
  - `essential`: Difficult to judge proper wording/meaning/speaker/tone without image.
  - `helpful`: Text alone suffices, but image aids translation choices.
  - `not_needed`: Text alone is sufficient.
  - `unclear`: Cannot judge image usefulness.

  This item represents potential image usefulness as perceived by evaluators.

- **Tie Reason**: Single-choice reason when selecting `tie`.
  - `both_valid`: Both TOJ and IAJ flags are valid.
  - `both_partially_valid`: Both flags are partially valid.
  - `both_invalid`: Both flags are invalid.
  - `difference_too_small`: Output difference is too small to rank.
  - `rubric_dependent`: Judgment depends on which evaluation criterion is prioritized.
  - `other`: Other reason (requires text comment).

**Post-Task Feedback Items** After completing 40 pages, annotators answered post-task feedback items on 5-point Likert scales (1 = strongly disagree, 5 = strongly agree):

- **5-Point Likert Items**:
  - `overall_difficulty`: Comparing TOJ and IAJ flags to judge which was better was difficult.
  - `rubric_sufficiency`: Procedure explanations and item descriptions were sufficient to judge consistently.
  - `priority_clarity`: Priority rules were clear when source fidelity, naturalness, and visual fit conflicted.
  - `preference_label_clarity`: Criteria for selecting `prefer_TOJ`, `prefer_IAJ`, and `tie` were clear.
  - `example_helpfulness`: Concrete label examples or boundary cases would have aided decision-making.

- **Hardest Annotation Field** (`hardest_annotation_field`, single-choice):

  - `overall_preference`: Main judgment.
  - `preference_confidence`: Judgment confidence.
  - `TOJ_validity`: TOJ page-level output validity rating.
  - `IAJ_validity`: IAJ page-level output validity rating.
  - `tie_reason`: Reason for selecting tie.
  - `image_effect_on_evaluation`: Image effect on IAJ flags.
  - `expected_image_helpfulness`: Image usefulness for translation evaluation.
  - `none`: No item was particularly difficult.

- **Reasons for Difficulty** (`difficulty_reasons`, multiple-choice):
  - `small_difference`: Output difference between TOJ and IAJ was small.
  - `both_valid`: Both flags were valid.
  - `both_problematic`: Both flags had flaws.
  - `fidelity_vs_naturalness`: Conflict between source fidelity and target naturalness.
  - `text_vs_visual_fit`: Difficulty evaluating text vs. visual fit.
  - `severity_threshold`: Severity thresholds were difficult to calibrate.
  - `insufficient_context`: Context was insufficient for judgment.
  - `complex_judge_outputs`: Judge output content was complex.
  - `unclear_label_boundaries`: Label boundaries were unclear.
  - `image_quality`: Image quality hindered judgment.
  - `ui_issue`: UI display or operation issues.
  - `other`: Other reasons.

- **Most Prioritized Criterion** (`prioritized_criterion`, single-choice):
  - `source_fidelity`: Source fidelity.
  - `translation_naturalness`: English translation naturalness.
  - `visual_consistency`: Consistency with manga image.
  - `error_severity`: Flagged error severity.
  - `overall_balance`: Overall balance across criteria.
  - `case_by_case`: Evaluated on a case-by-case basis.
  - `unclear`: Could not set consistent criteria.

- **Desired Guidance Types** (`requested_guidance`, multiple-choice):
  - `label_examples`: Concrete examples for each label.
  - `boundary_examples`: Examples of boundary cases.
  - `tie_examples`: Concrete examples of tie cases.
  - `priority_rules`: Priority rules when criteria conflict.
  - `severity_rules`: Guidelines for severity assessment.
  - `image_effect_examples`: Concrete examples of image effects.
  - `full_walkthrough`: End-to-end task walkthrough.
  - `more_context`: Additional context.
  - `none`: No additional guidance needed.

- **Free Comments** (`free_comment`, optional): Free-text input for hesitation details, UI feedback, or requested explanations.

## G Automatic Matching and Score Aggregation

To detail the automatic output differences reported in §5, we aggregated TOJ / IAJ-full flag counts on official translations across 180 pages (main text Table 4).

**Common Flag Matching Procedure** Common flags in this paper are established by **rule-based automatic matching rather than human annotation**. Specifically, candidate TOJ/IAJ error pairs within the same `segment_index` are created, taking the maximum of explanation token Jaccard similarity and `SequenceMatcher` string similarity as the base score. We add $+0.15$ for matching `error_category` and $+0.05$ for matching `severity`, capping the score at 1.0. For the `SequenceMatcher` component, explanations are

Figure 4: Annotation UI screenshot. Left panel: JA/EN page images and comparison of source and translation segments. Middle panel: TOJ/IAJ flags. Right panel: annotation fields including main judgment (`prefer_IAJ`/`prefer_TOJ`/`tie`), confidence, page-level output validity, image effect, image usefulness, and comments. Images expand on click.

normalized with NFKC normalization, lowercasing, and removal of non-word characters; therefore, exact matches after this normalization already have a base similarity of 1.0. Candidates are sorted by score descending, executing 1-to-1 greedy matching while excluding previously matched errors. Pairs with `score < 0.45` are rejected without an exact-match exception. Exact normalized explanations still require 1-to-1 pairing within the same segment and do not guarantee human semantic identity. Accepted pairs are stored as `same_issue` in `common_errors`. Unmatched flags are output as `text_only_errors` or `vision_only_errors`. Restricting matching candidates to identical segments and combining string similarity with `error_category` and `severity` allows this matching to serve as a practical classification separating common and unique flags. However, common classification does not guarantee strict semantic identity or human ground truth, and inter-annotator agreement (IAA) for common matching was not separately calculated. Accordingly, TOJ-only / IAJ-only / common aggregations in §5 should be interpreted as diagnostic statistics comparing judge output trends rather than human gold labels.

### G.1 Model-Reported Scores and Auxiliary Score Deficits

The `quality_score` in this study is an auxiliary model-reported score directly output by judges alongside error lists, rather than a standard MQM quality score calculated from fixed severity weights. Prompts instructed judges to start from 100, penalize `major` more than `minor` or `neutral`, and avoid double-counting, but did not fix numerical penalty amounts per severity or aggregate formulas. Therefore, this score should not be interpreted as a raw MQM penalty sum or a metric mechanically recomputed from error counts.

For comparison, we define the auxiliary score deficit from model-reported scores as $D_p^{\text{judge}} = 100 - S_p$ per page. Mean score deficits reported in Table 4 and derived from the mean scores in Table 11 represent $D_p^{\text{judge}}$ averaged across 180 pages.

### G.2 Fixed-Weight Scoring Based on MQM Severity and Normalized Penalties

In addition to `quality_score`, we conducted an auxiliary analysis aggregating reported severity labels with fixed weights. Letting $n_{p,\sigma}$ be the count of flags with severity $\sigma$ on page $p$, we assign weights of 0, 1, and 5 to neutral, minor, and major severities, respectively, defining raw MQM penalty as:

$$D_p^{\text{MQM}} = 0n_{p,\text{neutral}} + 1n_{p,\text{minor}} + 5n_{p,\text{major}} \quad (1)$$

To account for text length variation across pages, we normalize penalty by official target word count $W_p$:

$$E_p^{\text{word}} = 100\frac{D_p^{\text{MQM}}}{W_p} \quad (2)$$

representing penalty points per 100 target words. The primary aggregation is computed as a dataset micro-average across all 180 pages:

$$E_{\text{micro}}^{\text{word}} = 100\frac{\sum_p D_p^{\text{MQM}}}{\sum_p W_p} \quad (3)$$

where lower values indicate smaller penalties.

Across all 3 models (Gemini, GPT-5.4-mini, Qwen3-VL), IAJ-full yielded lower normalized penalty-point values than TOJ. The difference from TOJ to IAJ-full (IAJ-full − TOJ) was $-1.23$, $-1.05$, and $-3.93$ penalty points per 100 target words, respectively. Page counts where IAJ-full penalty was lower, TOJ penalty was lower, or tied were 62/21/97 for Gemini, 70/50/60 for GPT-5.4-mini, and 92/42/46 for Qwen3-VL. Sensitivity checks across 4 different denominator choices (per 100 target words, per 10 segments, per 100 source characters, and per 100 target words excluding short target pages) consistently preserved directional gains across all 3 models. However, this does not directly validate individual flag accuracy or human correlation superiority.

### G.3 Correlation Between Severity-Weighted Auxiliary Penalties and `quality_score`

To examine the alignment between auxiliary penalties and `quality_score`, we calculated page-level correlations between `quality_score` and sign-flipped normalized MQM penalties ($-E_p^{\text{word}}$). Results are shown in Table 10.

Pooled across all conditions, Pearson $r = 0.492$ and Spearman $\rho = 0.817$, showing general ranking alignment between model-reported `quality_score` and severity-weighted auxiliary penalties. However, Pearson correlations varied by model and condition ($0.348$–$0.752$), indicating they cannot be treated as identical scale metrics. Removing text volume effects via normalization also weakened Pearson correlation relative to raw penalty sums.

| Model | Condition | Pearson $r$ | Spearman $\rho$ |
|---|---|---|---|
| `gemini-3-flash-preview` (Main) | TOJ | 0.402 | 0.762 |
| `gemini-3-flash-preview` (Main) | IAJ-full | 0.348 | 0.717 |
| `gpt-5.4-mini` (Auxiliary) | TOJ | 0.557 | 0.873 |
| `gpt-5.4-mini` (Auxiliary) | IAJ-full | 0.752 | 0.881 |
| `qwen3-vl-32b-instruct` (Auxiliary) | TOJ | 0.467 | 0.803 |
| `qwen3-vl-32b-instruct` (Auxiliary) | IAJ-full | 0.391 | 0.693 |
| 3 Models, 2 Conditions (Pooled) | All Conditions | 0.492 | 0.817 |

Table 10: Page-level correlation between `quality_score` and sign-flipped normalized MQM penalty ($-E_p^{\text{word}}$). Each model and condition has $n = 180$; pooled values have $n = 1080$.

Comparing improvement magnitudes from TOJ to IAJ-full between $\Delta S_p = S_{p,\text{IAJ}} - S_{p,\text{TOJ}}$ and $G_p = E_{p,\text{TOJ}}^{\text{word}} - E_{p,\text{IAJ}}^{\text{word}}$, Pearson/Spearman correlations were $0.779/0.783$ for `gemini-3-flash-preview`, $0.586/0.731$ for `gpt-5.4-mini`, and $0.726/0.820$ for `qwen3-vl-32b-instruct` (pooled 540 pairs: $0.664/0.773$). Thus, both metrics demonstrate moderate-to-strong alignment in improvement direction, though this correlation reflects convergent metric behavior rather than human ground-truth alignment.

## H Experiment 2 Model-Reported Score Results

In Experiment 2, we conducted automatic MQM evaluation with the primary model, `gpt-5.4-mini`, and `qwen3-vl-32b-instruct` on 180 official translation pages. Table 11 compares reported page scores (`quality_score`). Across all three models, IAJ-full yielded higher mean model-reported scores and lower auxiliary score deficits than TOJ. The number of pages where IAJ-full scored higher than TOJ also exceeded the reverse. However, this is an auxiliary diagnostic showing judge output distribution shifts on official translations, not proof of page-level output validity or universal superiority.

Error volume aggregations for auxiliary models in the format of main text Table 4 are shown in Table 12. In `gpt-5.4-mini`, IAJ-full produced fewer total error flags than TOJ, and `qwen3-vl-32b-instruct` similarly yielded fewer total and major flags. However, in Qwen, minor flags for IAJ-full exceeded TOJ, showing severity-level shifts vary by architecture.

## I Detailed TOJ Coverage in IAJ-full

**TOJ Flag Coverage by IAJ-full** Regarding coverage mentioned in §5, mathematical definition, target set, micro-average, and page-level distributions are detailed in Table 13. For each page $p$, let $\text{common}_p$ and $\text{TOJ-only}_p$ denote the numbers of retained and non-retained TOJ flags, respectively. Page-level coverage is defined as:

$$c_p = \frac{\text{common}_p}{\text{TOJ-only}_p + \text{common}_p}. \tag{4}$$

The dataset-level micro-average is defined as:

$$c_{\text{micro}} = \frac{\sum_p \text{common}_p}{\sum_p (\text{TOJ-only}_p + \text{common}_p)}. \tag{5}$$

We additionally report the page-level macro-average and median of $c_p$. Aggregated over 160 pages with at least 1 TOJ error flag (excluding 20 pages with 0 TOJ flags), nearly 30% (45 pages; 28.1%) exhibited 0% coverage (IAJ retained zero TOJ flags). This indicates that evaluation perspectives between TOJ and IAJ diverge significantly on select pages.

| Model | IAJ Higher | TOJ Higher | Tied | Mean IAJ | Mean TOJ | Mean Diff |
|---|---|---|---|---|---|---|
| `gemini-3-flash-preview` | 81 (45.0%) | 32 (17.8%) | 67 (37.2%) | 91.9 | 89.8 | +2.2 |
| `gpt-5.4-mini` | 90 (50.0%) | 43 (23.9%) | 47 (26.1%) | 87.9 | 86.4 | +1.5 |
| `qwen3-vl-32b-instruct` | 102 (56.7%) | 24 (13.3%) | 54 (30.0%) | 85.5 | 80.1 | +5.4 |

Table 11: Experiment 2 score summary across the primary and auxiliary models. For 180 official translation pages, the table shows page counts where the IAJ-full model-reported score exceeded TOJ, vice versa, ties, and mean model-reported scores (`quality_score`). Mean difference reflects average unrounded score difference (IAJ − TOJ).

| Metric | gpt TOJ | gpt IAJ-full | qwen TOJ | qwen IAJ-full |
|---|---|---|---|---|
| *All 180 Pages* | | | | |
| Total error flags | 463 | 444 | 568 | 547 |
| Mean / page | 2.57 | 2.47 | 3.16 | 3.04 |
| Major error flags | 136 | 123 | 212 | 146 |
| Mean major / page | 0.76 | 0.68 | 1.18 | 0.81 |
| Minor error flags | 301 | 285 | 348 | 375 |
| Mean minor / page | 1.67 | 1.58 | 1.93 | 2.08 |
| Neutral error flags | 26 | 36 | 8 | 26 |
| Mean neutral / page | 0.14 | 0.20 | 0.04 | 0.14 |
| *Page-Level Error Distribution* | | | | |
| 0-error pages | 24 (13.3%) | 36 (20.0%) | 11 (6.1%) | 4 (2.2%) |
| 1+ error pages | 156 (86.7%) | 144 (80.0%) | 169 (93.9%) | 176 (97.8%) |
| 0-major pages | 84 (46.7%) | 92 (51.1%) | 52 (28.9%) | 85 (47.2%) |
| 0-error in both judges | 24 (13.3%) | | 3 (1.7%) | |

Table 12: Error volume reported by auxiliary models on 180 official translation pages. Total error flags include `major`, `minor`, and `neutral`. gpt represents `gpt-5.4-mini`; qwen represents `qwen3-vl-32b-instruct`.

| Metric / Page Group | Value / Pages |
|---|---|
| Micro-Average Coverage (166 / 318 flags) | 52.2% |
| Page-Level Macro-Average Coverage (n=160) | 53.1% |
| Page-Level Median Coverage | 50.0% |
| 100% Coverage (Fully Retained) Pages | 54 pages (33.8%) |
| Partial Coverage ($0 < c_p < 1$) Pages | 61 pages (38.1%) |
| 0% Coverage (Fully Suppressed) Pages | 45 pages (28.1%) |

# From Error Detection to Credit Assignment: Do xCOMET Error Spans Provide Useful Policy Credit for Chinese–Malay Translation?

**Zi Chen Koo**
Department of Computer Science and Technology
Tsinghua University, Beijing 100084, China
zichenkoo@gmail.com

## Abstract

Sequence-level rewards assign the same group-relative advantage to every generated token, even when only a short translation span is erroneous. We ask whether xCOMET error spans provide useful token-level policy credit for Group Relative Policy Optimization (GRPO) in Chinese–Malay translation. Signed Lexical-Residual GRPO (SLR) adds a bounded, zero-mean local residual to the sequence advantage. Across three matched seeds, SLR improves reward-aligned COMET and MetricX-24, a learned metric not used in training, while chrF++ and BLEU differences remain unresolved. A blinded 300-item evaluation by the bilingual author does not resolve an adequacy or fluency preference and finds a higher omission rate under SLR (9.33% to 16.67%). A repeated span audit finds high sentence-level error detection but weak target-word localization; fewer than half of consistently marked error words receive negative residual credit. In this setting, error detection, localization, and policy-credit actionability are distinct: explainable metric spans change optimization behavior without automatically providing human-aligned token supervision.

## 1 Introduction

Machine translation (MT) rewards are usually assigned after a complete translation is generated. In outcome-supervised GRPO, each response receives one advantage relative to other responses sampled for the same source, and the same value is applied to every response token (Shao et al., 2024). This is efficient, but it does not say *which* token made one translation better than another. A locally wrong term can therefore be reinforced when it occurs in the best member of a weak rollout group, while correct tokens can be penalized in an otherwise below-average translation.

Explainable MT metrics expose a candidate local signal. xCOMET predicts both a sentence score and character-level error spans with severities (Guerreiro et al., 2024). Recent work maps these spans to generation tokens and directly optimizes severity rewards with REINFORCE or PPO (Ramos et al., 2026); large-scale WMT systems have also combined global MetricX feedback with token-level AutoMQM feedback (Finkelstein et al., 2025). These results establish fine-grained MT optimization. Its success still depends on whether detector boundaries identify policy actions that repair the translation.

We study this question for Chinese–Malay, an underrepresented pair with an additional target-control challenge. Malaysian Standard Malay and Indonesian share much of their lexicon and grammar, yet are distinct task targets. Generative models can answer Malay prompts in Indonesian (Nomoto, 2023), while broad-coverage language identifiers also struggle with closely related languages (Kargaran et al., 2023). Semantic adequacy and target variety must therefore be measured separately.

Our research question is: *when an explainable metric marks a translation span as erroneous, does converting that span into signed group-relative token credit improve the target construct measured by automatic and human evaluation?* Signed Lexical-Residual GRPO (SLR) adds a centered, severity-sensitive residual to the sequence advantage. The residual sums to zero within a response, is globally capped, and is disabled when spans are absent, too broad, or unmappable. This isolates signed local credit against a matched sequence-GRPO baseline.

Across three matched seeds, SLR improves MetricX-24 and COMET, while chrF++ and BLEU differences are unresolved, and it lowers the SoftLID-adjusted score. A blinded 300-item Chinese-to-Malay evaluation shows no resolved adequacy or fluency preference and a higher omission rate under SLR. In a separate 100-candidate

*Proceedings of the Eleventh Conference on Machine Translation*, pages 368–379
October 28-29, 2026 ©2026 Association for Computational Linguistics

unbiased span audit, xCOMET detects most sentences marked erroneous in both annotation passes but localizes their target words poorly. These results expose a gap between error detection, boundary localization, and policy-credit actionability.

This paper makes three contributions:

1. We formulate a bounded signed residual that can reverse local credit while preserving each response's mean GRPO advantage.

2. We conduct a matched three-seed evaluation on two test suites and separate reward components, MetricX, and target-language outcomes with source-clustered uncertainty.

3. We combine a 300-item blinded quality evaluation with a repeated bilingual span audit, showing that high sentence-level recall coexists with weak target-word localization and incomplete negative credit on error words marked consistently across passes.

## 2 Related Work

**Sequence-level and group-relative MT optimization.** Direct optimization of sentence-level MT metrics predates LLM reinforcement learning. Minimum-risk training estimates expected loss over sampled translations and admits non-differentiable sequence metrics (Shen et al., 2016). A subsequent REINFORCE study found that sampling strategy and the mixture of likelihood and RL objectives materially affected NMT performance, while reward shaping and a learned baseline yielded little additional gain in that setting (Wu et al., 2018).

GRPO replaces the learned value model with a baseline estimated from responses sampled for the same prompt (Shao et al., 2024). Recent MT applications generally retain a scalar sequence reward: Garcia Gilabert et al. (2025) combine terminology adherence with reference-free quality estimation; SSR-Zero uses a policy-generated quality score (Yang et al., 2026); and Su et al. (2026) combine semantic similarity with target-language consistency for Tibetan–Chinese expansion. PE-GRL instead localizes optimization through online post-editing (Shen et al., 2026). This literature establishes both sequence-level MT optimization and GRPO for MT, but does not test signed policy credit derived from post-hoc metric spans.

Outside MT, Outcome-Grounded Advantage Reshaping reallocates GRPO advantage with token outcome-sensitivity weights and renormalizes them to preserve total advantage mass (Li et al., 2026). Its nonnegative weights suppress or amplify tokens without reversing the sign of the sequence advantage. SLR instead tests signed corrections derived from external error spans.

**Fine-grained MT reward.** Ramos et al. (2026) align xCOMET character spans to generation tokens by overlap, assign the worst overlapping severity, and optimize the resulting local quality values with token-level REINFORCE and PPO. Their experiments cover English–German and English–French and report neural-metric and human gains, although lexical metrics can decrease in some settings. Feng et al. (2025) use approximate Monte Carlo tree search to construct token-level translation preferences and train process reward models; integrating those models into RL is left for future work. Finkelstein et al. (2025) add token-level Gemma-AutoMQM-QE advantages to a sequence-level MetricX advantage in a large proprietary multilingual system. Existing work therefore covers both direct xCOMET-severity optimization and additive global–local MT credit. We test whether a bounded, zero-mean xCOMET residual is actionable when added to group-relative sequence advantages in Chinese–Malay.

**Error detection versus localization.** xCOMET jointly predicts a sentence score and token-level error labels that are merged into character spans (Guerreiro et al., 2024). Its original span evaluation covers WMT language pairs including Chinese–English, but not Malay. A recent expert-span study reports substantial disagreement between human boundaries and automatic detectors: xCOMET-XXL attains approximately 0.26 character-level span F1 under that study's protocol (Thellmann et al., 2026). Its protocol and span unit differ from ours; both studies motivate separating sentence detection, boundary localization, and policy-credit actionability.

**Malay and Indonesian variety control.** Malay (`zsm`) and Indonesian (`ind`) are closely related standard varieties. Nomoto (2023) finds that a generative model often responds to Malay prompts in Indonesian even when it can identify the prompt language, locating the failure partly in generation rather than binary language identification. GlotLID covers many low-resource languages, but

its authors identify closely related languages and macrolanguage/variety granularity as general LID challenges (Kargaran et al., 2023). A recent comparison of OpenLID and GlotLID further shows that strong aggregate multilingual scores can hide confusion among closely related languages and that higher-precision ensembles reduce coverage (Fedorova et al., 2026). We use GlotLID as an operational control and report its decisions separately from translation quality.

## 3 Signed Lexical-Residual GRPO

### 3.1 Sequence baseline

For a source $x$, the policy samples a group of $G = 8$ translations $\{y_i\}_{i=1}^{G}$. The translation reward is

$$R_{\mathrm{MT},i} = 0.5C_i + 0.3F_i + 0.2B_i, \tag{1}$$

where $C_i$ is the sentence-level xCOMET-XL score and $F_i$ and $B_i$ are sentence-level chrF++ and BLEU, respectively. A graded language penalty $P_{\mathrm{lid}}$ and script penalty $P_{\mathrm{script}}$ produce

$$r_i = \mathrm{clip}\left(R_{\mathrm{MT},i} - P_{\mathrm{lid},i} - P_{\mathrm{script},i}, -1, 1\right). \tag{2}$$

Within each rollout group, we compute

$$A_i = \frac{r_i - \overline{r}}{\mathrm{sd}(r) + 10^{-6}}. \tag{3}$$

Here sd is the framework's within-group sample standard deviation. Let $\mathcal{T}_i$ denote the set of active policy-token positions in response $i$, and let $T_i = |\mathcal{T}_i|$. The matched sequence-GRPO baseline (B4) assigns $A_{i,t}^{B4} = A_i$ for every $t \in \mathcal{T}_i$.

### 3.2 Why nonnegative span weighting is insufficient

A nonnegative weighting rule $A_{i,t} = A_i w_{i,t}$ can redistribute update magnitude, but $\mathrm{sign}(A_{i,t}) = \mathrm{sign}(A_i)$ whenever $w_{i,t} > 0$. Consequently, a known local error cannot be penalized when its response has $A_i > 0$. Conversely, correct words in a response with $A_i < 0$ cannot be protected by a sign-locked weight. SLR introduces a signed residual specifically to test whether relaxing this constraint is useful.

### 3.3 Lexical quality residual

We segment a Malay response by whitespace and punctuation and a Chinese response with Jieba. After excluding punctuation and units that overlap no active policy token, let $\mathcal{L}_i$ denote the retained lexical units and let $L_i = |\mathcal{L}_i|$. Every retained unit $\ell$ starts with quality $q_{i,\ell} = 8$. If an xCOMET span overlaps the unit, we assign the worst overlapping severity using

$$q(\mathrm{correct}, \mathrm{minor}, \mathrm{major}, \mathrm{critical}) = (8, 4, 2, 1), \tag{4}$$

following the severity mapping of Ramos et al. (2026). We define the mean over retained units as $\overline{q}_i = L_i^{-1} \sum_{\ell \in \mathcal{L}_i} q_{i,\ell}$ and use the fixed severity range:

$$u_{i,\ell} = \frac{q_{i,\ell} - \overline{q}_i}{7}. \tag{5}$$

Unlike per-response RMS normalization, this retains the difference between minor, major, and critical errors in the common case where a response contains only one error severity.

For each $\ell \in \mathcal{L}_i$, let $\mathcal{T}_{i,\ell} \subseteq \mathcal{T}_i$ be its overlapping active policy tokens and let $K_{i,\ell} = |\mathcal{T}_{i,\ell}|$. The raw token residual is

$$g_{i,t}^{\mathrm{raw}} = \sum_{\substack{\ell \in \mathcal{L}_i: \\ t \in \mathcal{T}_{i,\ell}}} \frac{T_i}{L_i} \frac{u_{i,\ell}}{K_{i,\ell}}, \qquad t \in \mathcal{T}_i, \tag{6}$$

with $g_{i,t}^{\mathrm{raw}} = 0$ outside $\mathcal{T}_i$. Dividing by $K_{i,\ell}$ makes each lexical unit's total contribution invariant to subword fragmentation. Let $M_i = \max_{t \in \mathcal{T}_i} |g_{i,t}^{\mathrm{raw}}|$. One response-level scale,

$$\kappa_i = \begin{cases} 1, & M_i \le 2, \\ 2/M_i, & M_i > 2, \end{cases} \qquad g_{i,t} = \kappa_i g_{i,t}^{\mathrm{raw}}, \tag{7}$$

caps $|g_{i,t}| \le 2$ without changing severity ordering or the zero-sum property. The SLR token advantage is

$$A_{i,t}^{SLR} = A_i + \lambda g_{i,t}, \qquad \lambda = 0.25. \tag{8}$$

Therefore $|\lambda g_{i,t}| \le 0.5$ and

$$\sum_{t \in \mathcal{T}_i} g_{i,t} = 0, \qquad \frac{1}{T_i} \sum_{t \in \mathcal{T}_i} A_{i,t}^{SLR} = A_i. \tag{9}$$

At $\lambda = 0$, SLR is exactly B4. For $\lambda > 0$, zero mean preserves the response-average advantage, while the token-level policy gradient changes according to the localized residual.

### 3.4 Alignment and reliability gates

The live mapper reconstructs the exact generated byte stream from policy token IDs and maps character spans through UTF-8 byte overlap. This handles Chinese characters split across multiple

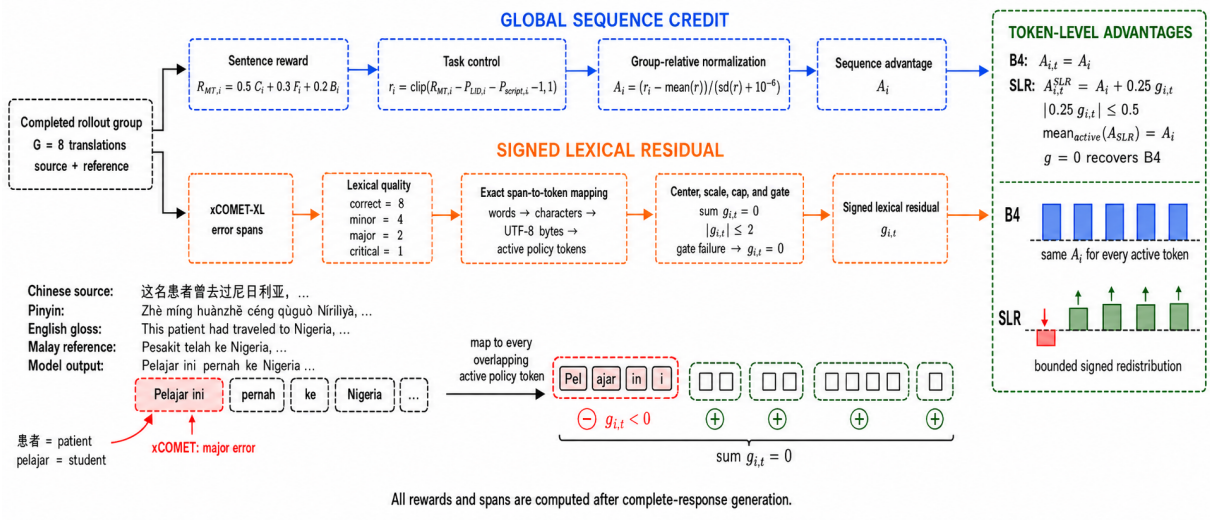

Figure 1: Training and credit assignment after complete-response generation. The upper branch produces sequence advantage $A_i$; the lower maps xCOMET spans to bounded, zero-mean residual $g_{i,t}$. B4 broadcasts $A_i$, whereas SLR adds $0.25 g_{i,t}$. In the frozen Chinese–Malay example, xCOMET marks "Pelajar ini" ("this student") as a major mistranslation of "this patient," and the mapper assigns its residual to every overlapping active token. Token pieces and bar heights are schematic; the right panel shows a possible sign reversal, but a negative residual need not make $A^{SLR}_{i,t}$ negative.

byte-level BPE tokens and non-canonical token sequences without re-tokenizing the displayed response. If a model emits an invalid UTF-8 sequence, the sample is counted and receives $g = 0$; any other response/token mismatch raises an error.

We also set $g = 0$ when there are no spans, no span overlaps an active lexical unit, all mapped units have the same quality, more than 60% of eligible words are marked erroneous, or the wrong-script penalty exceeds 0.30. Thus the intervention is local only when the detector output is both non-trivial and placeable on policy tokens.

# 4 Experimental Setup

## 4.1 Training data

The RL corpus contains 4,691 Chinese–Malay translation instances: 2,349 target Malay and 2,342 target Chinese. Malay sentences were collected from publicly accessible news, government, and general web pages. Source filtering removed malformed and machine-translated web text. Selected sentences were translated into Chinese with multiple LLMs, including few-shot GLM-4.7, and the resulting pairs were cleaned for completeness and bidirectional use.

Against the final corpus, neither evaluation suite contains an exact normalized sentence match. Shared 8-grams occur in 4/1,012 FLORES+ pairs and 6/1,997 NTREX pairs, all on the Chinese side.

## 4.2 Evaluation data

We use the public FLORES-200/FLORES+ `devtest` split for Malaysian Standard Malay (`zsm_Latn`) and Simplified Chinese (`zho_Hans`), containing 1,012 parallel items (Goyal et al., 2022; NLLB Team, 2024). FLORES-200 is released under CC BY-SA 4.0.

NTREX-128 contributes 1,997 official Malay (`msa`) and Chinese (`zho-CN`) news pairs (Federmann et al., 2022). NTREX references were translated independently from English; using them reciprocally for Chinese–Malay evaluation introduces translationese and occasional reference errors.

Both suites informed reward development. They evaluate the matched B4/SLR comparison under the same fixed reward but are not fully held out from the overall reward-design process.

For both suites, we translate every item in both directions with Chinese and Malay instruction prompts. This yields four conditions per item: 4,048 FLORES+ rows and 7,988 NTREX rows per model and seed.

## 4.3 Model and optimization

Both conditions initialize from the public `zai-org/GLM-4-9B-0414` checkpoint at revision `645b848`, released under the MIT license (Team GLM, 2024).

Each run uses four A100 GPUs with tensor parallelism 2. We train for 420 rollout steps, sampling 12 prompts and eight responses per prompt (96 responses per step). The maximum prompt and response lengths are 4,096 and 768 tokens, with sampling temperature 1.0. Adam uses learning rate $2 \times 10^{-6}$, cosine decay to $2 \times 10^{-7}$, eight warmup steps, weight decay 0.01, KL coefficient 0.001, and clipping bounds 0.20/0.28. Checkpoint 419 is the zero-indexed final iteration of this schedule, corresponding to approximately one pass through the training corpus. We run matched seeds 42, 43, and 44. The optimization difference is $A_{i,t} = A_i$ for B4 and Equation 8 for SLR.

### 4.4 Rewards and metrics

Training combines the sentence-level xCOMET-XL score (Rei et al., 2020; Guerreiro et al., 2024), sentence chrF++ with word order 2, and sentence BLEU, combined as Equation 1. BLEU and chrF++ use SacreBLEU 2.6.0 (Papineni et al., 2002; Popović, 2017; Post, 2018).

GlotLID-v3 predicts `ind_Latn` for 126/1,012 FLORES+ Malay references (12.5%) and 432/1,997 NTREX Malay references (21.6%), or 558/3,009 (18.54%) pooled. This disagreement on known-Malay references motivates a graded language penalty instead of hard rejection (Kargaran et al., 2023; Nomoto, 2023). For Malay targets, $P_{\text{lid}} = 0$ for `zsm_Latn`/`zsm_Arab` and $P_{\text{lid}} = 0.50 + 0.30c$ otherwise, including `ind_Latn`, where $c$ is GlotLID confidence. If $\rho_{\text{ws}}$ is the proportion of nonpunctuation characters in disallowed script ranges, then $P_{\text{script}} = \min(1, 3\rho_{\text{ws}})$. For Chinese targets, $P_{\text{lid}} = 0$ and $P_{\text{script}}$ is 0, 0.3, or 0.8 for Han ratios $h \geq 0.45$, $0.20 \leq h < 0.45$, or $h < 0.20$, respectively.

We report every reward component, the SoftLID-adjusted score, and a separate hard-evaluation validity flag: GlotLID must return an accepted Malay or Sinitic target label. We also score all checkpoint-419 outputs with the reference-based MetricX-24 Hybrid XXL v2p6 model; lower scores are better on its 0–25 scale (Juraska et al., 2024). MetricX is not used during training.

### 4.5 Human evaluation

The primary evaluation contains 300 unique Chinese-to-Malay sources at checkpoint 419, balanced over the two datasets, three seeds, and two prompt languages. Each item presents the Chinese source and two system outputs. System identity, the Malay reference, metric and reward values, LID decisions, and automatic error spans are hidden. Output order is randomized and balanced 150/150.

The author, who is bilingual in Chinese and Malay, recorded pairwise adequacy and fluency preference (A/B/tie), a separate variety label for each output (Malaysian Standard Malay, Indonesian, mixed, other, or uncertain), and whether each output contains an omission or major error. The protocol separates error category from severity and treats omission as an accuracy error, following MQM-style analysis without implementing full MQM (Freitag et al., 2021).

The author separately audited span localization on 150 paired Chinese-to-Malay outputs: 100 randomly sampled candidates form the primary set and 50 disagreement-enriched candidates are diagnostic. The same author-evaluator marked target error spans and source omissions in two separate passes from blank templates. Each pass displayed the Chinese source, Malay reference, and one candidate output, while system identity, metric and reward values, LID decisions, and xCOMET spans remained hidden. The second pass did not expose the first-pass labels. The repeated passes quantify intra-annotator repeatability, and the primary span reference is the intersection of target words marked in both passes.

### 4.6 Statistical analysis

We pair B4 and SLR outputs for every seed, dataset, direction, source, and prompt language. The primary cluster is a unique source–direction pair; seeds and prompt variants remain repeated observations within a cluster. System means first average within source. Confidence intervals use 20,000 paired bootstrap resamples of the 6,018 unique sources (36,108 output pairs). Common-valid results condition on both systems passing LID and are diagnostic because validity is affected by the policy.

Human preference effects are the proportion preferring SLR minus the proportion preferring B4, with ties retained. Error effects are paired differences in event rates. We use 50,000 paired item-bootstrap resamples and two-sided exact sign tests. Span-localization intervals use 10,000 source-clustered bootstrap resamples over the 100 unbiased candidates.

## 5 Automatic Results

### 5.1 The optimized neural signal improves

SLR increases the raw MT reward by $0.0021$ (95% source-clustered CI $[0.0013, 0.0030]$; Table 1). COMET accounts for nearly all of the gain: $+0.0046$ overall and $+0.0080$ for Chinese-to-Malay. Overall chrF++ and BLEU intervals cross zero, while Malay-to-Chinese chrF++ decreases by $0.0015$. Because COMET supplies half of the reward and xCOMET supplies the local spans, its increase measures alignment with the optimized signal.

### 5.2 MetricX favors SLR, primarily on NTREX

MetricX-24 favors SLR by $-0.082$ points overall on its 0–25 scale, where lower is better (Table 2). The per-seed differences are $-0.089$, $-0.096$, and $-0.061$ for seeds 42–44. The gain is larger for Chinese-to-Malay ($-0.118$) than Malay-to-Chinese ($-0.046$).

The effect is concentrated on NTREX. Its largest slice is NTREX Chinese-to-Malay ($-0.138$; 95% CI $[-0.201, -0.078]$). The corresponding FLORES+ direction-specific estimates, $-0.029$ for Malay-to-Chinese and $-0.078$ for Chinese-to-Malay, both have intervals crossing zero. MetricX thus favors SLR on this aggregate comparison, while its direction-level FLORES+ estimates remain unresolved.

### 5.3 Language control offsets the semantic gain

The SoftLID-adjusted score decreases by $0.0038$ overall. Target-language validity falls from 93.16% to 92.32%, driven by Chinese-to-Malay ($86.78\%$ to $84.95\%$); Malay-to-Chinese validity rises by 0.16 points. The human variety labels in Section 6 do not show a corresponding increase in Indonesian/mixed output, so detector validity and human variety are reported as distinct outcomes.

### 5.4 Common-valid outputs retain the metric pattern

Among rows where both systems pass the language detector, MetricX still favors SLR ($-0.079$; 95% CI $[-0.110, -0.048]$) and COMET increases by $0.0044$ (Table 3); chrF++ and BLEU remain unresolved. The learned-metric gains therefore persist beyond the additional LID failures. This subset is diagnostic because validity is affected by the policy.

### 5.5 Local credit is active but rarely changes sign

Across 120,960 training responses, 77.54% receive a nonzero local residual. The broad-span gate removes 12.96%, no detected span removes 6.82%, and invalid UTF-8 removes 0.10%. The cap is reached on 1.76% of all samples; $|\lambda g| \leq 0.5$ and the maximum absolute zero-sum error is $4.3 \times 10^{-14}$. A word-level sign-change event occurs in 11.90% of samples. Most active residuals therefore adjust magnitude without reversing a token's sequence-level credit.

## 6 Human Evaluation and Span Actionability

### 6.1 Translation quality

Adequacy yields 121 SLR preferences, 134 B4 preferences, and 45 ties; the $-4.33$ point interval crosses zero. Fluency is likewise unresolved (128/147/25; $-6.33$ points). The author's bilingual judgments therefore do not confirm the learned-metric gain as an adequacy or fluency improvement.

Omission differs clearly. The author marked omissions in 9.33% of B4 outputs and 16.67% of SLR outputs, a $+7.33$ point increase with 95% CI $[+2.33, +12.33]$. Major-error and Indonesian/mixed-variety differences remain unresolved. In particular, human variety labels do not support treating every GlotLID rejection as Indonesian drift.

### 6.2 Learned metrics and human preferences

On the 300-item sample, the mean MetricX difference is $+0.125$ after orienting positive values toward SLR, with a confidence interval crossing zero. MetricX and COMET agree with the non-tied human adequacy winner on 67.7% and 70.1% of eligible items (Table 6). The aggregate disagreement comes partly from effect magnitude: on human-SLR wins, mean MetricX and COMET improvements are $+1.330$ and $+0.0781$; on human-B4 wins, they are $-1.048$ and $-0.0266$. Continuous metric averages can therefore favor SLR even when B4 receives more pairwise votes.

Omission reveals a construct mismatch beyond this arithmetic. Among 42 items where only SLR is marked omissive, adequacy favors B4/SLR/tie on 27/11/4, yet mean MetricX and COMET still

| Scope | Metric (↑) | B4 | SLR | SLR−B4 [95% CI] |
|---|---|---|---|---|
| Overall | SoftLID score | 0.4668 | 0.4631 | -0.0038 [-0.0063, -0.0012] |

| zh→ms | chrF++ | 0.4243 | 0.4249 | +0.0006 [-0.0007, +0.0018] |
| zh→ms | BLEU | 0.1185 | 0.1189 | +0.0005 [-0.0007, +0.0017] |
| zh→ms | Target-language valid (%) | 86.78 | 84.95 | -1.84 [-2.49, -1.19] |

Table 1: Checkpoint-419 automatic evaluation over three matched seeds. Means are source-weighted; 95% intervals resample unique sources while keeping seeds and prompt-language variants within cluster. All metrics are higher-better. The SoftLID score includes the language and script penalties; $R_{\mathrm{MT}}$ does not. Validity differences are percentage points.

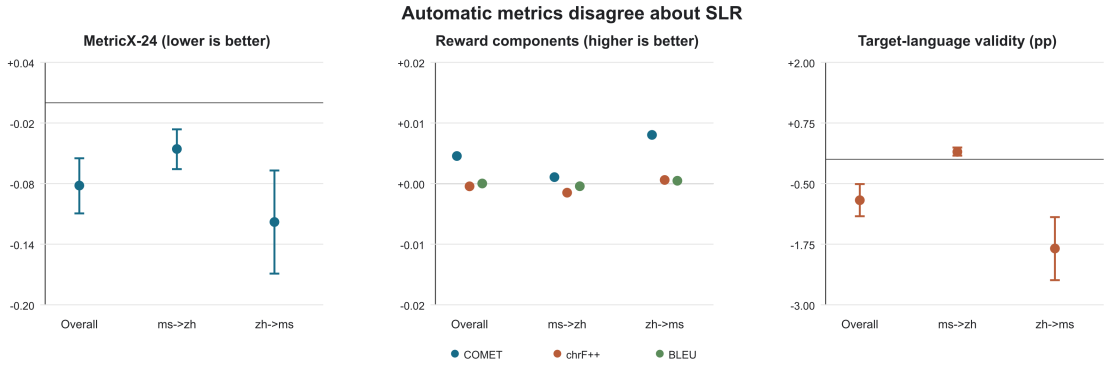

Figure 2: Checkpoint-419 effects. MetricX-24 and COMET favor SLR, lexical metrics remain near zero, and Chinese-to-Malay target-language validity decreases. Error bars show 95% unique-source bootstrap intervals where available.

| Scope | B4 | SLR | SLR−B4 [95% CI] |
|---|---|---|---|
| Overall | 3.992 | 3.910 | -0.082 [-0.110, -0.055] |
| ms→zh | 3.508 | 3.462 | -0.046 [-0.066, -0.026] |
| zh→ms | 4.476 | 4.358 | -0.118 [-0.169, -0.067] |
| FLORES+ | 3.362 | 3.309 | -0.053 [-0.102, -0.006] |
| NTREX-128 | 4.311 | 4.215 | -0.096 [-0.130, -0.063] |

Table 2: Reference-based MetricX-24 scores at checkpoint 419 (↓). Negative differences favor SLR. Intervals use unique-source clusters spanning seeds and prompt variants.

favor SLR (+0.268 and +0.0046). chrF++ and BLEU favor B4 (−0.0245 and −0.0158). MetricX and COMET differences have near-zero rank correlation with the paired omission label (+0.053 and −0.061). Within these cases SLR is 1.62 words shorter on average, although its overall length differs from B4 by only +0.12 words. On this subset, favorable learned-metric changes coexist with worse human coverage and do not encode the omission penalty expressed by the author-evaluator.

COMET supplies half of the training reward and xCOMET supplies the spans. MetricX is not used in training, but its item-level difference correlates with COMET at $r = 0.750$, and their winner signs agree on 71.8% of common-valid nonties. Their agreement provides convergent learned-semantic evidence.

Table 3: Checkpoint-419 common-valid-language diagnostic over three matched seeds. Rows are retained only when both systems pass the target-language detector. Means are source-weighted; intervals resample unique sources while keeping seed and prompt variants within cluster. Because validity is a post-treatment outcome, these estimates are diagnostic rather than primary.

| SLR outcome | Samples | Rate |
|---|---|---|
| Active local residual | 93,794 | 77.54% |
| No spans | 8,244 | 6.82% |
| No mapped span | 0 | 0.00% |
| Uniform lexical quality | 1,383 | 1.14% |
| Broad-span gate | 15,674 | 12.96% |
| Wrong-script gate | 1,748 | 1.45% |
| Invalid-UTF8 gate | 117 | 0.10% |

Table 4: Training-time SLR activation and reliability gates, pooled over all three seeds. Gated samples use the unmodified sequence-level advantage.

| Measure | B4 | SLR | Δ [95% CI] |
|---|---|---|---|
| Adequacy preference | 44.67 | 40.33 | -4.33 [-14.67, +6.00] |
| Fluency preference | 49.00 | 42.67 | -6.33 [-17.00, +4.67] |
| Omission rate | 9.33 | 16.67 | +7.33 [+2.33, +12.33] |
| Major-error rate | 53.67 | 56.00 | +2.33 [-6.67, +11.33] |
| Indonesian/mixed rate | 11.67 | 9.67 | -2.00 [-5.67, +1.67] |

Table 5: Blinded evaluation by the bilingual author on 300 Chinese-to-Malay sources. All entries are percentages; Δ is SLR minus B4 in percentage points. Preference rates retain 45 adequacy and 25 fluency ties. Intervals use 50,000 paired item-bootstrap resamples.

### 6.3 Error detection, localization, and residual orientation

Across the author's two blinded passes, intra-annotator repeatability for sentence-error presence is 91% for the unbiased candidates (Cohen's $\kappa = 0.591$), omission repeatability is 93% ($\kappa = 0.760$), and target-word macro F1 is 0.700. This repeatability provides a stability context for the detector comparison.

xCOMET identifies most sentences marked erroneous in both passes: any-span precision is 0.824 and recall is 0.904. Localization is much weaker. Macro target-word F1 is 0.259 (95% source-clustered CI $[0.200, 0.322]$), and strict character IoU is 0.177. After applying the same lexical gates used during training, the mean fraction of target words marked erroneous in both passes that receive a negative residual is 0.450 (95% CI $[0.335, 0.572]$; micro count 100/228). The residual direction agrees with the repeated-pass reference on fewer than half of the marked error words.

Localization quality does not differ by system: macro F1 is 0.270 for B4 and 0.249 for SLR, a paired difference of $-0.020$ with 95% CI $[-0.107, 0.071]$. Omissions expose a separate structural gap. An omitted source phrase has no generated target token, so the current target-span mapper cannot assign direct insertion credit to it.

## 7 Discussion

**SLR optimizes a learned semantic signal.** The residual is numerically stable and moves both reward-aligned COMET and MetricX, a learned metric not used in training. The blinded evaluation by the bilingual author does not resolve an adequacy or fluency preference and identifies a higher omission rate; chrF++ and BLEU add no resolved lexical evidence. The MetricX improvement is strongest on reciprocal NTREX and is unresolved within each FLORES+ direction. Together, these results characterize SLR as metric-specific policy change rather than an overall improvement in Chinese–Malay translation.

| Metric | $n$ | Mean SLR improvement [95% CI] | Adequacy winner agreement (%) | $\rho$ with omission difference |
|---|---|---|---|---|
| MetricX-24 | 300 | +0.1251 [-0.2278, +0.4720] | 67.7 | +0.053 |
| COMET | 244 | +0.0195 [+0.0040, +0.0349] | 70.1 | -0.061 |
| chrF++ | 300 | +0.0059 [-0.0122, +0.0239] | 55.6 | -0.230 |
| BLEU | 300 | +0.0064 [-0.0016, +0.0148] | 53.6 | -0.139 |

Table 6: Automatic metrics on the 300-item human-evaluation sample. Positive values favor SLR; MetricX is reoriented as B4 minus SLR because lower is better. COMET includes only the 244 pairs for which both systems pass the language gate. Winner agreement excludes human and metric ties. Correlations are descriptive Spearman coefficients.

| Measure | Estimate | 95% CI |
|---|---|---|
| Any-span precision / recall | 0.824 / 0.904 | – |
| Macro word precision / recall | 0.208 / 0.509 | – |
| Macro word F1 | 0.259 | [0.200, 0.322] |
| Error words with negative residual | 0.450 | [0.335, 0.572] |

Table 7: xCOMET localization and gated word-residual orientation on the 100 unbiased Chinese-to-Malay candidates. The reference is the target-word intersection of two blinded passes by the same bilingual author. Intervals use 10,000 source-clustered bootstrap resamples. The residual row is a word-level orientation diagnostic, not an observed final-advantage sign flip.

Language control is a second measurement axis. GlotLID validity decreases for Chinese-to-Malay, while the human labels do not show more Indonesian/mixed output. GlotLID's 18.54% Indonesian-prediction rate on known-Malay references shows why classifier validity and human variety must remain separate outcomes.

**Detection is not actionable credit.** The span audit identifies an actionability gap in the training signal. xCOMET usually detects that an erroneous sentence contains an error, but its word boundaries align poorly with the two-pass annotation. Reliability gates remove the broadest and least informative cases, yet the remaining residual places negative credit on only 45% of error words marked consistently across the two passes. A computable local residual is therefore not necessarily a correctly directed policy update. The gap between activation and credit reversal is also visible in the training diagnostics: 77.5% residual activation produces a word-level sign change in only 11.9% of responses.

Omission is harder still. Target-side spans can redistribute credit only over generated content. They cannot identify a missing phrase or specify where the policy should insert it. Source-coverage states, EOS credit, and explicit insertion or edit actions are candidate representations for this error class.

**Relation to successful fine-grained MT optimization.** Ramos et al. (2026) optimize local severity values directly with token-level REINFORCE/PPO on English–German and English–French. Finkelstein et al. (2025) combine MetricX with a Gemma-based AutoMQM evaluator at multilingual scale. These methods differ in evaluator, language pair, and optimization geometry. Their gains establish that local MT feedback can work; our results show that the evaluator-to-policy mapping is a separate empirical requirement. Fine-grained MT-RL should validate span localization, effective credit activation, and whether the representation covers the required correction, while reporting reward components, language control, and human error outcomes in addition to aggregate reward.

## 8 Conclusion

We tested whether xCOMET error spans provide useful signed policy credit for Chinese–Malay GRPO. SLR improves COMET and MetricX-24 across three matched seeds, while chrF++ and BLEU differences are unresolved; it lowers the SoftLID-adjusted score and increases human-marked omission. The author's 300-item blinded bilingual evaluation does not resolve an adequacy or fluency preference.

The repeated span audit exposes a credit-alignment gap. xCOMET reaches 0.904 sentence-level error recall but only 0.259 macro target-word F1, and the gated residual assigns negative credit to 45.0% of target words marked erroneous in both passes. Error detection, localization, and policy-credit actionability are therefore distinct properties. Before their spans are used as token-level rewards, explainable metrics should be evaluated for detection, localization, and policy actionability, including whether the credit representation can ex-

press the required correction.

## Limitations

The training comparison covers one 9B model, one language pair, one residual strength, and xCOMET-XL as the local evaluator. NTREX is English-sourced; reciprocal Chinese–Malay evaluation therefore contains translationese and occasional reference errors. COMET is part of the reward, MetricX is another learned metric, and GlotLID is imperfect for Malay–Indonesian separation.

The single author, who is bilingual in Chinese and Malay, completed the quality evaluation and both span-audit passes. System identity and experimental signals were withheld, and A/B order in the quality evaluation was randomized and balanced. The results may nevertheless reflect evaluator-specific judgments, and no independent second evaluator was available; the span-pass statistics measure intra-annotator repeatability rather than inter-annotator validation. The span audit measures word-level residual orientation rather than replaying final policy-token advantages. SLR also cannot assign direct insertion credit to content omitted from the generated response.

## Ethics Statement

The target construct is Malaysian Standard Malay, not a claim that Indonesian is linguistically inferior. Malay and Indonesian are closely related standard varieties associated with different speech communities and national contexts (Nomoto, 2023). Variety drift is a task mismatch only because the requested and referenced target is Malaysian Standard Malay.

The author, who is bilingual in Chinese and Malay, voluntarily completed the 300-item evaluation and both span-audit passes under the blinding protocols described in the experimental setup. No external participant was recruited. The internal training corpus, including its raw web text and cleaned parallel pairs, is not redistributed.

## Acknowledgments

The author thanks Bojie Wang for guidance in setting up the experimental environment, advice on tokenization, and for proposing the initial token-level GRPO direction explored in this project. The author also thanks Menyang Sun for identifying and assembling the evaluation datasets and benchmarks, and for collecting the Malay-language web data used to construct the training corpus. The author is grateful to Tsinghua University's Student Research Training (SRT) program for the opportunity and support that enabled this project, and thanks the program's mentors for helpful discussions and guidance throughout.

**Generative-AI assistance.** The author used OpenAI's ChatGPT and Codex, as well as Anthropic's Claude Code, for code development and debugging, literature search, analysis support, figure preparation, and manuscript drafting and revision. All scientific claims, interpretations, and reported results were verified by the author.

## A Implementation Checks

For every active sample, the implementation enforces

$$\left|\sum_{t\in\mathcal{T}_i} g_{i,t}\right| < 10^{-8}, \tag{10}$$

$$\max_t |g_{i,t}| \le 2, \tag{11}$$

$$g_{i,t} = 0 \text{ for masked tokens}, \tag{12}$$

$$A_{i,t}^{SLR}|_{\lambda=0} = A_i. \tag{13}$$

Across the three runs, the largest zero-sum residual is $4.3 \times 10^{-14}$. Every generated token ID has one byte-level map entry. Invalid UTF-8 is the only mapping exception assigned $g = 0$; all other response, backend, and token-count mismatches raise an error.

## B Additional MetricX Analysis

The three seed-level MetricX differences are $-0.0894$, $-0.0956$, and $-0.0608$. A Student-$t$ interval over the three seed means is $[-0.1281, -0.0358]$; a hierarchical sensitivity bootstrap that resamples both seeds and sources gives $[-0.1209, -0.0414]$. The primary estimate remains the unique-source clustered interval in Table 2.

COMET and MetricX contain 2,469 and 2,436 exact paired ties. Excluding pairs tied under either metric, their preference direction agrees on 20,105/29,542 pairs (68.1%).

## C Data and Annotation Checks

The final 4,691-row training corpus contains no exact normalized sentence match with either evaluation suite. Four FLORES+ and six NTREX unique pairs share at least one 8-gram with training data; all matches occur on the Chinese side.

For the author's two blinded span-audit passes, intra-annotator sentence-error agreement is 0.91 ($\kappa = 0.591$), omission agreement is 0.93 ($\kappa = 0.760$), target-word macro F1 is 0.700, and target-character IoU is 0.623. The primary reference uses the intersection of target words marked in both passes. The diagnostic 50-candidate stratum is excluded from all primary span estimates.

# Translationese as a Rational Response to Translation Task Difficulty

**Maria Kunilovskaya**
University of Technology Nuremberg*
maria.kunilovskaya@utn.de

## Abstract

Translated texts exhibit systematic differences from comparable texts originally written in the target language. Explaining this phenomenon, commonly known as *translationese*, remains an open challenge. Translationese has been attributed to production tendencies (e.g. interference, simplification), socio-cultural variables, and language-pair effects, yet a unified explanatory account is lacking. We investigate the hypothesis that translationese is a response to the cognitive load inherent in the translation task. We test whether observable translationese can be predicted from quantifiable measures of translation task difficulty. Translationese is measured as a segment-level probability of being a translation produced by an automatic classifier (*translatedness score*). Translation task difficulty includes source-text and cross-lingual transfer components. They are captured by information-theoretic metrics based on LLM surprisal and by established syntactic and semantic alternatives. We use a bidirectional English-German corpus comprising written and spoken subcorpora. Results indicate that translationese can only be explained in part by translation task difficulty, especially in the English-to-German direction. For most experiments, cross-lingual transfer difficulty contributes more than source-text complexity. Information-theoretic indicators match or outperform traditional features in written mode, but offer no advantage in spoken mode. Source-text syntactic complexity and translation-solution entropy emerged as the strongest predictors of translationese across language pairs and modes.

## 1 Introduction

Previous work in translation studies yielded abundant evidence that any cross-linguistic mediation exhibits systematic statistical deviations from the patterns observed in comparable non-translated, originally-authored texts in the target language. This property of translations is usually referred to as *translationese* (Gellerstam, 1986). Evidence from corpus-based and computational studies confirms that translationese is pervasive, reinforcing its view as an intrinsic feature of cross-linguistic mediation, which produces a translational variant of the target language, often described as a "third code" (Frawley, 1984; Baker, 1993).

Crucially, this phenomenon appears to be largely independent of translation quality. In fact, one could argue that texts entirely devoid of translationese may border on transcreation, adaptation, or similar forms of mediated communication that allow the source message to be substantially modified in response to the needs of the target audience or a different communicative purpose. Such modifications may involve, for example, simplifying the message, rendering only its gist, omitting or adding information, or otherwise repurposing the source content. Such outputs, while possibly effective for their intended purpose, diverge from the conventional goal of translation – namely, to render the source content faithfully using the most appropriate means of the target language. This goal is most straightforward when the source and target texts serve the same communicative purpose and their intended audiences are broadly comparable in the socio-demographic characteristics relevant to the communication. When either the audience or the communicative purpose changes, adaptation of the message itself may become necessary.

At the same time, both the strength and the linguistic manifestation of translationese vary substantially. They are conditioned by multiple factors, most prominently translation direction (i.e. source–target pairing) (Evert and Neumann, 2017; Kunilovskaya et al., 2021), register (Redelinghuys, 2016; Kunilovskaya and Corpas Pas-

*This work was carried out while the author was affiliated with the Department of Language Science and Technology, Saarland University.

*Proceedings of the Eleventh Conference on Machine Translation*, pages 380–397
October 28-29, 2026 ©2026 Association for Computational Linguistics

tor, 2021), translator expertise (De Sutter et al., 2017; Bizzoni and Lapshinova-Koltunski, 2021), and mode (written vs. spoken). Extensive research has also documented recurrent translationese patterns including simplification (Corpas Pastor et al., 2008), shining-through (Teich, 2003), explicitation (Blum-Kulka, 1986; Baker, 1993), and over-normalisation (Hansen-Schirra, 2011).

Despite this wealth of descriptive findings, the field still lacks a principled account that integrates these factors within a unified explanatory framework. We therefore ask whether translationese can be understood as a consequence of cognitive constraints inherent in the translation task, and whether an information-theoretic perspective can provide such a framework.

Building on prior applications of information theory (IT) to language (Shannon, 1948; Levy, 2008), we adopt the view that linguistic encoding is shaped by cognitive constraints: speakers select forms that balance communicative goals against processing effort (Gibson, 1998; Jaeger, 2010). We extend this perspective to translation, conceptualising it as a task in which production choices are similarly governed by cognitive pressures. Supporting evidence comes from Lim et al. (2024), who show that IT-based difficulty indicators, comparable to those used here, correlate with behavioural measures of translation processing, including production duration and eye-tracking metrics, in an experimental setting. Motivated by this work, we ask whether such indicators can also account for systematic properties of translated texts. Theoretically, more complex source texts should yield more deviant translations, particularly in simultaneous interpreting. Translationese can thus be seen as a rational trade-off between accuracy and fluency, aimed at managing cognitive load under the assumption that producing translationese-marked text may require less effort. This perspective unifies a range of recurrent deviations (explanatory wordiness, simplification, overly literal renderings, or reduced lexical variety) as cognitively rational strategies rather than lapses in translation quality.

Given the differences between monolingual and cross-lingual language processing, any explanation of translated language must consider the source language input and the cognitive demands of cross-linguistic transfer. Early corpus-based research on translationese, especially following Baker (1993), focused primarily on target-language output, often without directly incorporating the corresponding source text into the analysis. Subsequent work has increasingly considered the source, although its influence and the cognitive cost of mapping between languages have often been examined indirectly, for example, by comparing translations from multiple source languages into a single target language (e.g. Evert and Neumann, 2017; Nikolaev et al., 2020; Hu and Kuebler, 2021). In this work, we directly connect the presence of translationese in high-quality professional translations and simultaneous interpreting to the difficulty of the translation task, estimated from aligned source–target segments.[1] We investigate two questions: (1) to what extent translationese can be explained by task difficulty, and (2) how much IT measures of difficulty contribute relative to established structural features. In doing so, we address a gap in previous studies, which rarely analyse translationese in relation to the aligned source material, and test the hypothesis that translationese can be understood as a cognitive response to variation in translation difficulty.

The remainder of the paper is organised as follows. Section 2 presents the methodology, including the *translatedness score*, a measure of translationese, and representations of *translation task difficulty*. Section 3 describes the experimental setup, covering data, feature handling, and modelling approach. Section 4 reports the results and discusses their implications, and Section 5 offers concluding remarks.

## 2 Methodology

Investigating the link between translation task difficulty and translationese involves two challenges: to quantify translationese and to identify relevant translation task parameters. The next two sections address these in turn.[2]

### 2.1 Translatedness Score

Previous work demonstrated that humans, including translation experts, struggle with distinguishing translated and original documents (Baroni and Bernardini, 2006; Wein, 2023), let alone quantifying translationese in a document. To address this limitation, we introduce the *translatedness score* – a measure that captures the extent to which a

[1] "Segment" refers to an aligned unit in the parallel corpus, which may consist of one or more sentences.

[2] To ensure reproducibility, the code and data is released at `https://github.com/SFB1102/b7-rational-mediation`.

text exhibits properties of mediated language. This score is defined as the *probability of being a translation*, predicted by a binary classifier trained to distinguish the text types: translations (targets, tgt) vs. comparable originals (org) in the target language.

A central design requirement is construct validity: the classifier must meaningfully capture translatedness. This entails choosing both an appropriate feature set and an appropriate level of analysis (segment vs. document level). Translationese indicators should be structural (e.g. morphosyntactic patterns, abstract lexical cues) rather than surface features to avoid exploiting domain- or topic-related signals. Character n-grams (Popescu, 2011) or neural embeddings (Borah et al., 2023) were shown to capture the properties of texts that are not directly related to translation-specific linguistic patterns.

Translationese emerges more clearly over larger spans of text. Previous studies employing hand-engineered features (most notably, part-of-speech n-grams) have used chunks ranging from 80 to 2000 words in size (Volansky et al., 2015; Rabinovich and Wintner, 2015). For instance, for translated English and German parliamentary speeches, Kunilovskaya et al. (2024) obtained 80.0% and 88.8% accuracy on full speeches of approximately 700 tokens using a broad set of delexicalised structural features. The best result achieved in Pylypenko et al. (2021) on handcrafted features (PoS-trigrams) is 76.6% and 73.1% for the same target languages.

Although segment-level translationese classification is challenging due to a weaker signal, it presents a practical compromise. First, our translation difficulty indicators are mostly defined at the segment level, and aggregating them to larger text spans risks smoothing over differences between segments. Second, assigning a document-level translatedness score to each segment is suboptimal: it increases the number of observations but violates the assumption of independence, as all segments from the same document inherit the same score regardless of their individual properties. Finally, our focus lies in quantifying the extent of translatedness, rather than maximising classification accuracy. Preliminary experiments confirmed these concerns: both document- and segment-level regression experiments using probability-based scores from document-level classifiers produced noisy results. Based on these considerations, we opted for segment-level classification using the feature set from Kunilovskaya et al. (2024) with minor modifications. Their feature set covers 58 linguistically-motivated phenomena, including grammatical forms, morphological word classes, clause types, syntactic dependencies, word order patterns, discourse elements, and textual measures.

Generally, the feature extraction is straightforward and involves counting the occurrences of Universal Dependencies (UD) tags of the same name. For example, the value for *nn* feature is obtained by counting tokens marked with the PoS tag *NOUN*, and finite and past-tense verb forms *fin, pastv* are counted as the number of tokens marked with the morphological features *VerbForm=Fin* and *Tense=Past*. The features *amod, aux, ccomp, nmod, nsubj* and *obj* are counts of the respective dependency relation tags. Translationese predictors that require additional extraction rules or filtering and emerged as useful in our experiments are described in Table 5 (Appendix A).

Some known translationese predictors are also informative as indicators of translation task complexity. To ensure the validity of the experimental setup, three typical translationese features – lexical density, number of clauses, and mean dependency distance – are deliberately reserved as predictors for subsequent regression experiments. Pairwise collinearity between translationese predictors (measured on targets) and structural source difficulty indicators does not exceed Spearman $\rho = 0.7$. The initial pool of 55 potential translationese indicators was reduced to 37 after filtering out 18 low-variance features (see Section 3.3). For a comprehensive description and a full rationale behind the feature set, we refer the reader to the original study (Kunilovskaya et al., 2024).

### 2.2 Translation Task Difficulty

Translation task difficulty is conceived as comprising two components: source text comprehension effort and source-target transfer effort. Each component is represented by features that can be categorised as IT or structural (grammatical and lexical), depending on their nature.

We begin with the IT features, which provide a principled way to quantify the processing cost associated with encoding and transfer effort. The IT indicators operationalise difficulty by capturing the predictability of linguistic units in context: more predictable items are easier to process and may be reduced or omitted (Delogu et al., 2017;

| Category | Feature | Description |
|---|---|---|
| **IT** | src_gpt_AvS | Average surprisal of UD tokens in a source segment, derived from dedicated GPT-2 models (English, German). |
| **Grammar** | src_tree_depth | Maximum dependency tree depth (longest path from root to any leaf), capturing hierarchical syntactic complexity. |
| | src_branching | Average branching factor (number of dependents per head), capturing horizontal syntactic complexity. |
| | src_mdd | Mean dependency distance: linear-to-hierarchical integration effort, reflecting comprehension difficulty (Jing and Liu, 2015). |
| | src_n_clauses | Number of finite and non-finite clauses per segment, approximated via clausal dependencies *csubj, advcl, acl, xcomp, ccomp*. |
| **Lexis** | src_lex_dens | Ratio of unique content words (PoS-disambiguated) to total tokens. |
| | src_wlen | Average word length in characters, excluding punctuation. |
| | src_mwe | Number of multiword expressions (*flat*, *fixed*, *compound*), excluding numerals and proper names. |
| | src_numerals | Number of numerals, including single-word and multiword expressions. |
| | src_propn | Number of proper names, including single-word and multiword expressions. |

Table 1: Source-side features used to model source text comprehension difficulty, grouped by feature type.

Rutherford et al., 2017), whereas less predictable (more surprising) items incur higher cognitive effort, correlating with longer reading times (Jaeger, 2010; Hao et al., 2020) and neurophysiological responses (Huber et al., 2024; Michaelov et al., 2024). These effects are formalised in surprisal theory (Hale, 2001; Levy, 2008), rooted in Shannon's notion of information (Shannon, 1948). Within this framework, the central measure of information is *surprisal*, defined as the negative log probability of a word given its context (Equation 1).

$$S(w) = -log_2(P(w|context)) \quad (1)$$

Recent work derives these probabilities from large language models (LLMs), primarily of the GPT-2-small family, whose estimates correlate best with experimental measures of processing difficulty (Oh and Schuler, 2023; Shain et al., 2024).

This study uses *average segment surprisal (AvS)*, computed by averaging word-level surprisals across all Stanza-defined words in a segment. AvS derived from monolingual GPT-2 models of the source languages (English or German) represents source comprehension difficulty and reflects the predictability of source text words within the source language. AvS derived from translation-direction-specific neural machine translation (NMT) models represents transfer difficulty and captures the uncertainty associated with source-to-target mapping. AvS was used in translation studies to correlate the information content of source and target segments (Kunilovskaya et al., 2023), in clinical linguistics to capture both lexical and structural components of sentence information (Rezaii et al., 2023) and in text readability research (Lowder et al., 2018).

Complementing NMT-based surprisal, *entropy of translation solutions* captures uncertainty over translation choices and thus reflects transfer complexity. It quantifies the number and distribution of alternative target-language realisations available for a given source item, estimated from large parallel corpora. This measure has been used as an indicator of translation difficulty in several studies (Carl et al., 2016; Teich et al., 2020; Kunilovskaya et al., 2025). Unlike syntagmatic surprisal, which captures predictability within a sequence, translation entropy is paradigmatic: it captures uncertainty among alternative target-language realisations of the same source item. The entropy of translation solutions is defined in Equation 2.

$$H(T \mid S) = -\sum_{t \in T} P(t \mid S) \log_2 P(t \mid S) \quad (2)$$

Here, $H(T \mid S)$ denotes the entropy of the set of translations $T$ for a source item $S$. The summation iterates over all possible translation variants $t \in T$, and $P(t \mid S)$ is the probability of observing translation $t$ given the source $S$. Higher entropy indicates a larger set of similarly probable translation options, implying greater cognitive demand for that source item during source–target transfer.

In addition to IT measures, we model translation difficulty using established structural indicators of source-text complexity. Our feature selection draws on two related strands of previous research.

First, source-side complexity features used in the *QuEST++* quality estimation framework (Specia et al., 2018) include type–token ratio (TTR), syntactic tree depth and width, number of clauses, and related measures. Second, research on cognitive load in interpreting points to lexical density, formulaicity (frequency of multiword expressions), subordination, and numerical expressions as potential sources of processing difficulty (Plevoets and Defrancq, 2020; Kajzer-Wietrzny et al., 2024). We additionally include mean dependency distance, which has been associated with cognitive load in interpreting (Liang et al., 2017) and has also proved a strong indicator of translationese (Fan and Jiang, 2019). Together, these measures form a set of ten features intended to capture source-text comprehension difficulty (the *source* subset), presented in Table 1.

Importantly, the translationese classifiers and regression models rely on non-overlapping feature sets, derived from the target and source texts, respectively. This separation is critical: if the same features were used in both steps, the translatedness score from classifiers (used as the response variable in regression) could inadvertently reflect text difficulty via a shining-through effect, thus compromising the integrity of the experimental design.

Cross-lingual transfer difficulty in this study was represented by four features (*transfer* subset): average target segment surprisal, mean word alignment score, entropy of translation solutions per segment and teacher-forced pseudo-BLEU. They are described in Table 2. All of transfer features are LLM-based and/or IT-inspired.

The basic feature set (comprising source-text difficulty and transfer difficulty indicators) was extended with eight modified variants. The modifications included (i) AvS versions averaged over content words only (*src_gpt_AvS_content, mt_AvS_content, mean_align_content, tot_entropy_content*), (ii) AvS versions averaged over LLM subwords instead of UD-defined surface tokens (*src_gpt_AvS_subw*, *mt_AvS_subw*) and (iii) versions computed over syntactic subtrees rather than individual words, namely subtree-based alignment (cosine similarity between aligned trees; *mean_cosine*) and entropy over trees (*tot_entropy_trees*). Subtrees were extracted using UD tags (id and head_id), limiting the depths of possible subtrees to 1. Taken together, the 22 indicators capture complementary dimensions of translation task difficulty that may shape translation decisions. The alphabetical list appears in Table 9 (Appendix B).

The general expectation is that greater difficulty increases cognitive load, under which translators prioritise content preservation over target-language naturalness, resulting in higher translatedness of the output. Accordingly, we expect a positive association with translatedness for features signalling structural and lexical complexity of the source (*src_gpt_AvS, src_branching, src_lex_dens, src_mdd, src_wlen, src_n_clauses, src_tree_depth*), translation ambiguity (*tot_entropy*) and cross-lingual predictability as reflected in MT surprisal (*mt_AvS*). Features associated with processing ease or the availability of stereotypical, structurally isomorphic solutions – such as formulaicity (*src_mwe*), alignment strength (*mean_align*), and higher MT performance (*bleu*) – are expected to correlate negatively with translatedness. Two additional indicators, numerals (*src_numerals*) and proper names (*src_propn*), are included as potentially relevant predictors, although their effect direction is less clear.

The experiments used LLM-based features from base and fine-tuned models. Fine-tuning was performed on 120k non-overlapping segments from the *EPIC–EuroParl–UdS* corpus. According to the corpus curators (Kunilovskaya and Pollkläsener, 2026), fine-tuning was thorough and robust, ensuring reliable surprisal estimates. Despite this, downstream regression gains from the fine-tuned models were limited and inconsistent across settings (see Figure 7, Appendix B); therefore, all results reported in this study use the base models.

## 3 Experimental Setup

### 3.1 Data

The data come from *EPIC-EuroParl-UdS*[4], a bidirectional English–German corpus containing written translations and simultaneous interpretations of European Parliament debates (Kunilovskaya and Pollkläsener, 2026). Both components originate from official European Parliament records. The written data are based on the officially published proceedings and their translations, while the spoken data consist of manual transcriptions of official video recordings of parliamentary debates and their simultaneous interpretations.

[4]The data used in this study are publicly available as provided by the original authors: `https://zenodo.org/records/19010272`.

| Feature | Description |
|---|---|
| mt_AvS | Average target segment surprisal: mean surprisal of UD tokens in a target segment derived from NMT models, conditioned on the full source segment and preceding target context. Higher values indicate less predictable source-target mappings and increased transfer difficulty, hypothesised to trigger translationese. |
| mean_align | Mean word alignment score: computed using contextualised token representations from *bert-base-multilingual-cased*. Subword alignment is based on dot-product attention (layer 8) with bidirectional softmax filtering ($10^{-2}$), following *AWESoME* (Dou and Neubig, 2021). Segment-level averages over aligned word pairs; higher scores indicate stronger alignment and lower transfer difficulty. |
| tot_entropy | Entropy of translation solutions per segment: captures uncertainty in translating source lemmas. Entropy is computed on lemmas (not surface tokens) to account for morphological variation. Translation solution sets use word alignments from both training and test splits of *EPIC–EuroParl–UdS*. Missing values for unaligned words and singletons are replaced with the subcorpus median plus two standard deviations. Higher entropy signals less consistent translation patterns and greater cross-lingual transfer difficulty. |
| bleu | Teacher-forced pseudo-BLEU[3]: segment-level BLEU between reference targets and token-wise *argmax* predictions under gold prefixes, computed with *sacrebleu*. Higher scores indicate more predictable target realisations and lower transfer difficulty. |

Table 2: Transfer features used to model cross-lingual transfer difficulty.

The corpus is aligned at document and segment levels and balanced across translation directions and modes. It contains UD annotation and word-level surprisal indices from GPT-2[5], and OPUS NMT de-en and en-de models (Tiedemann and Thottingal, 2020).

Table 3 summarises the quantitative parameters of the eight text categories by mode (written vs. spoken), language pair (deen, ende), and text type (original/source vs. target).

| mode | lpair | type | words | segs | docs |
|---|---|---|---|---|---|
| spoken | deen | src, org | 62,900 | 3,060 | 165 |
| | | tgt | 60,408 | 2,896 | |
| | ende | src, org | 69,801 | 3,260 | 137 |
| | | tgt | 60,590 | 3,092 | |
| written | deen | src, org | 77,225 | 3,211 | 170 |
| | | tgt | 85,380 | 3,216 | |
| | ende | src, org | 76,061 | 3,063 | 170 |
| | | tgt | 76,588 | 3,063 | |

Table 3: Quantitative parameters of the textual data by mode, language pair (lpair) and text type.

Average segment length ranges from 25.5 to 27.8 words for written data and 19.5 to 21.4 words for spoken data, with standard deviations of approximately 15 and 13 words, respectively. Segments shorter than 4 tokens were filtered out.

### 3.2 Feature Preprocessing

Classification and regression features went through the same data preprocessing pipeline. Following (Evert and Neumann, 2017), morphological and lexical raw counts and per-word/subtree alignment scores are normalised by segment word count; syntactic and continuous features (`mdd`, `mhd`, `lex_dens`, `ttr`) are averaged across sentences. To enhance comparability and reduce the influence of outliers, highly right-skewed features were transformed using $log(1 + x)$ function, which compresses long tails and makes distributions more symmetric. Skewness was measured using Fisher's moment coefficient (adjusted for sample size), with a threshold of 1.0 used to identify features requiring transformation.

### 3.3 Machine Learning Models

Translationese classifiers and subsequent regressions were run in the same experimental setup. The machine learning (ML) models were trained separately for each language (de = German, en = English) and mode under a 10-fold cross-validation setup. We used a linear *Support Vector Machine* (SVM) with default *scikit-learn* parameters (kernel='linear', C=1.0). To prevent data leakage, segment-level experiments employed *GroupKFold*, ensuring that all segments from the same document were assigned to the same split, either training or test. Classifiers' performance was evaluated using macro-F1 (precision and recall are well-balanced in all experiments). For regression, we report Spearman correlation coefficient ($\rho$) between predicted scores and true translatedness score, the measure of regression fit ($R^2$) and Mean Absolute Error (MAE).

[5]English (Radford et al., 2019), German (Schweter, 2020)

Many of the count-based features are susceptible to *low variance*, particularly at the segment level, making them noisy and uninformative for ML algorithms. Consequently, we filtered out the 18 lowest-variance features shared across all mode-language datasets. This global decision reduced models' complexity and fixed the input dimensionality at 37 features across classifiers, facilitating direct comparison of their performance. None of the difficulty features had low variance.

Additionally, separately for each mode and target language, we eliminated *collinear features* (Pearson's $r > 0.85$), retaining the feature with the higher univariate F1 score to preserve non-redundant signal. All features were independently scaled to zero mean and unit standard deviation.

Feature selection was performed using cross-validated *Recursive Feature Elimination* (RFECV) from *scikit-learn* (folds=10), which selects features iteratively within each fold. A minimum of two features was enforced. The reported performance after feature selection should be interpreted as conservative, as RFECV favours stable individual predictors and does not capture potential joint effects among weaker features.

To interpret feature contributions in the final classification and regression models, we employed *SHapley Additive exPlanations* (SHAP) (Lundberg and Lee, 2017), a unified framework based on Shapley values from cooperative game theory, which quantifies the average marginal contribution of each feature to the model's predictions across all possible feature coalitions.

## 4 Results

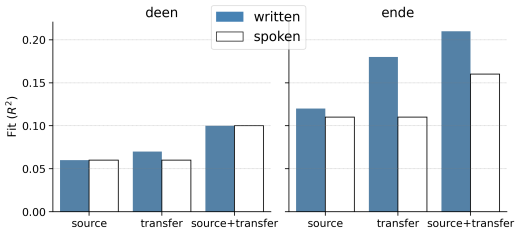
### 4.1 Translationese Classification

Table 4 reports macro-F1 scores averaged across folds for the four segment-level classification tasks (with standard deviations), alongside document-level results for comparison.

The performance of the segment-level classifiers is relatively low, with F1 scores around 60%, only 10 percentage points above the random baseline for a balanced binary task. The lower performance compared to document-level classification (F1 scores between 74% and 84%) is expected, given the weaker translationese signal in shorter text spans. The signal is further reduced by excluding lexical density and two syntactic complexity indicators from the translationese feature set.

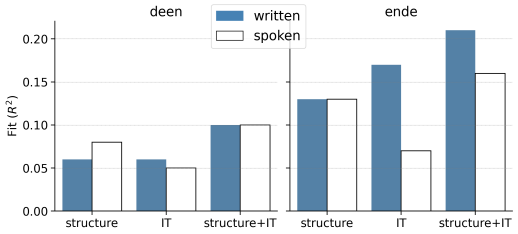
Nevertheless, our goal is not to maximise classification accuracy, but to capture graded variation in translatedness using theoretically motivated structural features. We argue that the classifier's probability for the translated class provides such a gradient: even when a translation is classified as original, a lower translatedness score can meaningfully indicate a weaker translationese signal. For comparison, we additionally tested embedding-based classifiers (DeBERTa and DistilBERT variants), which achieve over 96% document-level accuracy. While expected, such high performance is not necessarily advantageous for our purposes: embedding-based models may exploit signals not directly related to translationese (Borah et al., 2023), and highly confident predictions reduce the variation in translatedness scores that constitutes our response variable. Our structural classifiers instead capture a weaker but interpretable signal under conditions explicitly designed to avoid information leakage. In our experiments, the resulting probabilities are approximately normally distributed, with a subtle shift to the right of the 0.5 threshold, reflecting more salient or uniform patterns in mediated language (Figure 6, Appendix B). These patterns are consistent with previous findings of higher predictability of simultaneous interpreting transcripts and greater detectability of mediated German compared to English (Evert and Neumann, 2017).

We analyse deviation patterns using feature importances. Feature-level patterns are more reliable at the document level, as segment-level signals are weakened and distorted; this is visible in Figure 3, where SHAP profiles reveal different feature strength and groupings across representations. The results further suggest that translationese is captured primarily by feature combina-



| mode | support | lang | F1±SD | selected |
|---|---|---|---|---|
| segment-level | | | | |
| written | 6,274 | de | 60.85±2.61 | 13 |
| | 6,279 | en | 55.74±2.94 | 33 |
| spoken | 6,152 | de | 60.44±1.62 | 34 |
| | 6,156 | en | 59.50±3.49 | 12 |
| document-level | | | | |
| written | 340 | de | 82.27±6.34 | 21 |
| | | en | 74.29±5.89 | 18 |
| spoken | 302 | de | 84.02±5.91 | 27 |
| | | en | 76.30±6.91 | 26 |

Table 4: Performance of segment- and document-level SVM classifiers. *Selected* reflects the final feature subset after collinearity removal and RFECV (out of 37).



tions rather than strongly deviant individual cues. Only a few features show notable univariate performance, especially in written data (Table 6, Appendix A). As shown in Figure 5, features without statistically significant class differences can still contribute to predictions; for example, lower frequencies of personal pronouns (*ppron*) favour the target class in spoken English (subplot d), despite the non-significant difference in Table 6.

### 4.2 Regression Results and Discussion

This section tests whether translation task difficulty predicts translatedness score from the classifiers and compares the explanatory power of two difficulty components (source comprehension vs. cross-lingual transfer) and two types of indicators (IT vs. structural).

(a) Source-based and transfer-specific predictors.

(b) Structural and information-theoretic predictors.

Figure 1: Variance in translatedness explained by linear regression models across language pairs and mediation modes. The two panels compare difficulty components and indicator types on the x-axis.

For ease of interpretation, $R^2$ values are visualised in Figure 1, while the full tabular results are provided in Appendix B (Tables 7 and 8). The regression results show that translation task difficulty explains a modest but consistent share of the variance in translatedness scores, with clear differences by direction and mode. Overall, the models account for between 6% and 21% of the variance. The explanatory power is highest for English→German direction, particularly in the written mode, where the combined model reaches $R^2 = 0.21$. In contrast, the models explain considerably less variance for German→English, where the best-performing models in both written and spoken modes reach only $R^2 = 0.10$, with smaller differences between the modes.

Across all settings, the combined *source+transfer* models consistently outperform models based on a single difficulty type, indicating that comprehension-related and transfer-related factors capture complementary aspects of translation task difficulty. Transfer features tend to be more predictive of translationese than source complexity in written mode, but this edge disappears in interpreting, where the difficulty components are on par in both translation directions (Figure 1a).

With regard to the type of difficulty indicators (Figure 1b, Table 8), the two feature types (IT vs. structural) perform comparably in German→English written translation ($R^2 = 0.06$). For English→German translation, IT features clearly outperform structural alternatives ($R^2 = 0.17$ vs. 0.13). In spoken mode, however, structural features yield substantially stronger results in both translation directions.

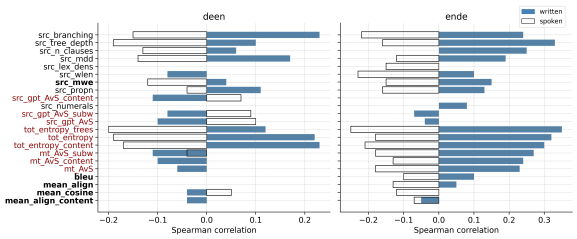


Figure 2: Univariate analysis: Spearman correlation between translation difficulty indicators and translatedness score. Source text difficulty indicators (src_) appear first. Features expected to correlate negatively with translatedness are shown in bold, and IT features are in red on the y-axis. The bars for non-significant $\rho$ values are removed.

An unexpected finding emerged in the analysis of the directionality of individual feature contributions. Figure 2 shows Spearman correlations between translation-difficulty features and translatedness for written (blue bars) and spoken (empty bars) data in both translation directions, revealing marked cross-modal asymmetries. For several features, written and spoken data show opposite tendencies: notably, *src_branching* and *src_tree_depth* correlate positively with translatedness in written tasks but negatively in spoken tasks across both language pairs. One possible explanation is that written translation allows greater preser-

vation of source structure, so increasing source complexity may produce stronger source-language interference and hence more translationese. Under the time constraints of simultaneous interpreting, however, greater source complexity makes close structural reproduction increasingly difficult. Incremental processing may instead promote simplification and reformulation in target-language-preferred forms, resulting, paradoxically, in less translationese as source complexity increases.

This interpretation, however, requires some qualification with respect to translation direction. In German-to-English interpreting, structural source features remain more influential than information-theoretic features (see the taller transparent "spoken" bar in Figure 1b), suggesting that the structural properties of spoken German may still impose substantial processing demands. Indeed, although spoken source texts are structurally simpler than written ones in both languages, the difference is systematically smaller for German; German source texts also show greater complexity than English on mean dependency distance and word length (`src_mdd` and `src_wlen` in Table 9, compare `written_deen|mean` with `written_ende|mean` and `spoken_deen|mean` with `spoke_ende|mean`). Source structure may therefore remain more consequential when interpreting from German, whose spoken input retains more written-like structural complexity. Whether this reflects the style of German parliamentary speech or broader cross-linguistic structural differences remains an open question.

These findings are further supported by the SHAP importance rankings and granular statistical analysis provided in Figures 8 and 10 Appendix B.

The heatmap in Figure 8 shows that IT indicators of transfer difficulty, notably *mt_AvS* and *translation solution entropy*, are the strongest predictors of translationese, particularly in the English→German direction. In contrast, the lighter colour intensity for the German→English direction indicates a weaker association between translation task difficulty and translationese, consistent with the generally lower intensity of translationese in this direction.

## 5 Conclusion

This study examined translationese as a linguistic marker of cognitive processes involved in human translation and interpreting. By linking measures of translation task difficulty to the degree of translatedness in the target text, we explored whether systematic deviations in mediated language can be explained by the complexity of the translation task.

The results show that translation difficulty accounts for a measurable but limited share of variation in translationese. Regression analyses explain up to 21% of the variance in translatedness scores, with the relationship strongest in written translation and particularly in the English→German direction. Cross-lingual transfer indicators generally provide stronger explanatory signals than source-comprehension measures, suggesting that transfer difficulty contributes to translationese but cannot provide a comprehensive account of it.

The relationship also differs across mediation modes. Increasing source complexity tends to correlate with more translationese in written output but, for several structural features, with less translationese in interpreting, possibly reflecting greater simplification and target-oriented reformulation under time constraints. This pattern is direction-dependent, with source structure remaining comparatively influential in German→English interpreting. These exploratory findings point to different responses to translation difficulty across modes and languages.

Importantly, information-theoretic measures do not consistently outperform traditional structural indicators and have particularly limited explanatory power for spoken data. Thus, under the present operationalisation, surprisal- and entropy-based metrics appear too coarse to support a unified information-theoretic account of translationese. Instead, our results delimit its empirical scope: cognitive difficulty contributes to translationese, but its explanatory power depends on modality, translation direction, and its operationalisation.

More broadly, by relating gradient translatedness to difficulty estimated from aligned source–target data, this study provides a direct empirical test of cognitive explanations of translationese and quantifies their explanatory limits. The results motivate more targeted models that distinguish sources of difficulty and the strategies translators and interpreters use to manage them.

## Limitations

Several limitations should be considered when interpreting the results. First, the outcomes depend on the chosen feature set. Linguistic feature extrac-

tion is inherently fragile and sensitive to preprocessing decisions, annotation errors, and normalisation choices. Many frequency-based features are also sensitive to sample length, which may affect their stability across segment and document representations.

Second, latent structural dependencies between source and target features may introduce a degree of indirect information leakage, potentially confounding the observed effects of source comprehension on translationese.

Third, the analysis does not explicitly model individual speaker effects. Especially in spoken data, stylistic variation between speakers may influence feature distributions and interact with mediation-related patterns. Future work should therefore account for speaker identity and other individual-level variables.

Fourth, the results are derived from a specific corpus and set of language pairs. While the observed patterns are consistent within this dataset, their generalisability to other domains, genres, or language combinations remains to be tested. Although the analysis suggests systematic differences between written and spoken mediation, these patterns may also reflect differences in topics, communicative conditions and document length across spoken and written subcorpora, although they come from the same global source.

Finally, this study does not attempt a detailed linguistic analysis of the individual predictors and their interactions. Although the modelling results reveal systematic patterns in the feature space, a closer examination of how specific linguistic cues contribute to these patterns would provide additional explanatory depth. Conducting such analysis is left for future work.

We do not foresee direct negative societal impacts from this study. Nevertheless, metrics of translation difficulty or predictability could be misapplied in evaluative settings (e.g., assessing translators or systems) if treated as definitive indicators rather than exploratory analytical tools.

## Acknowledgments

We are deeply grateful to Christina Pollkläsener for her enduring support and many insightful discussions throughout this project, as well as for her careful review and proofreading of the final manuscript. We also thank the anonymous reviewers for their thoughtful and constructive feedback, which helped us substantially improve the paper.

This work was funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation), Project-ID 232722074, as part of the Collaborative Research Center SFB 1102.

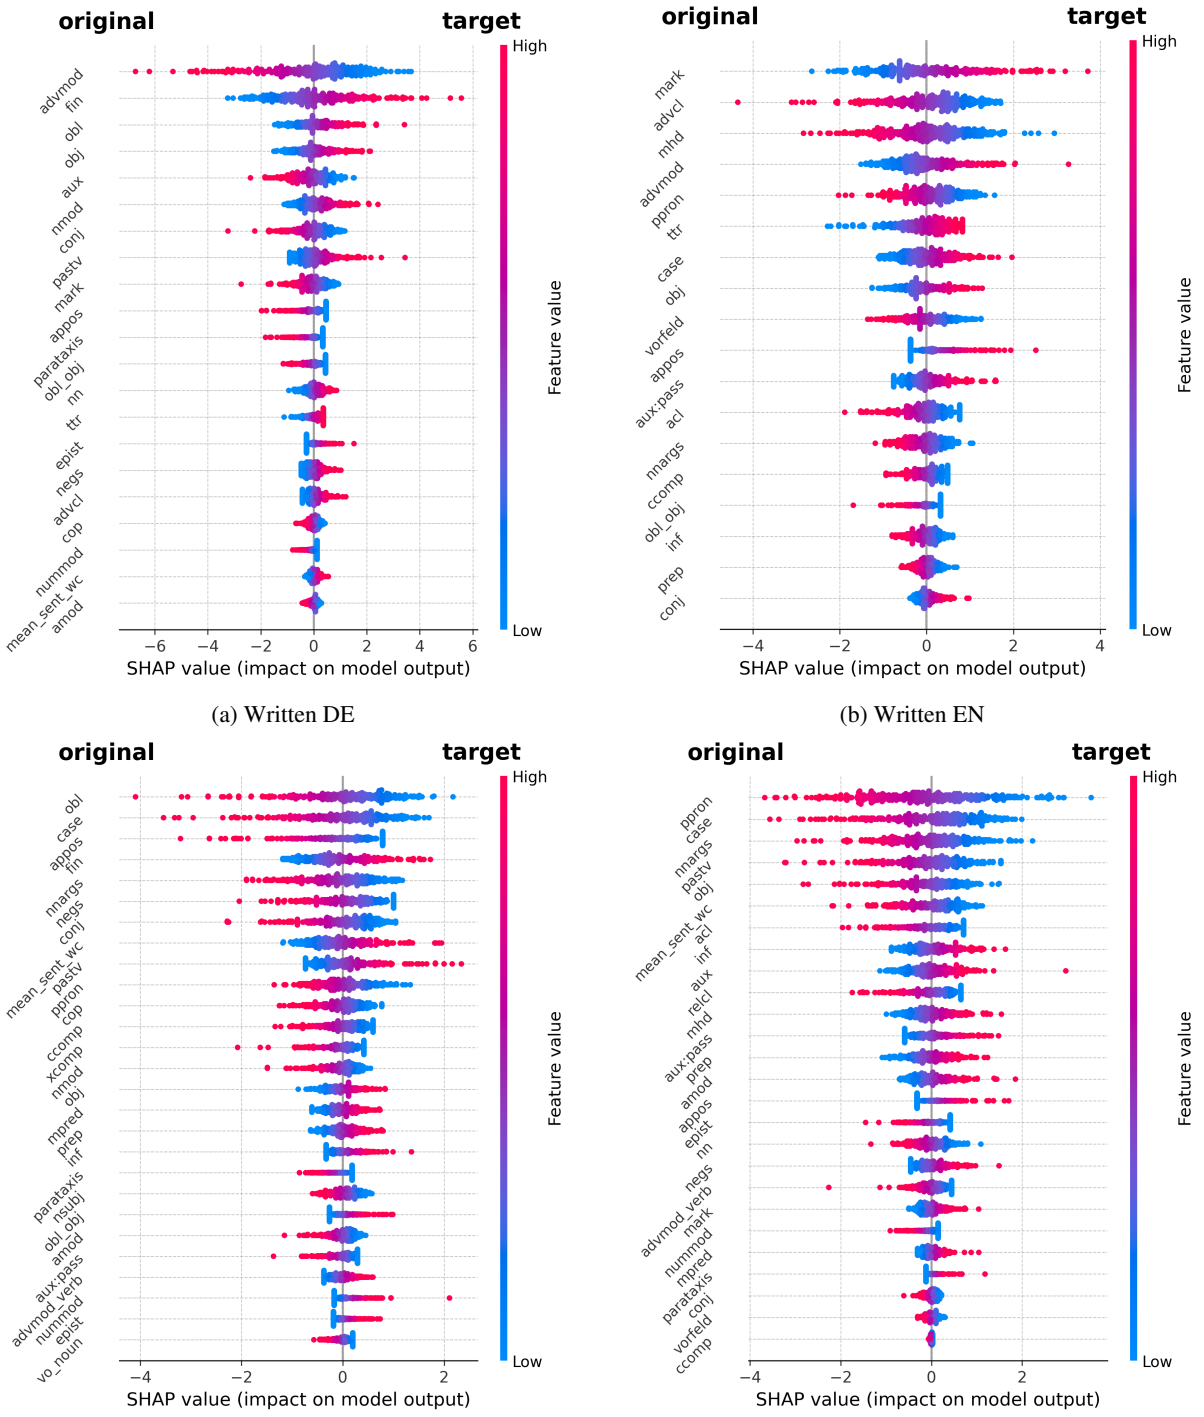
# A Appendix. Additional Details on Segment-Level Translationese

This appendix provides details on features and their performance, beginning with a description of some complex predictors. We then look into feature impact through SHAP-based importance rankings and class-prediction contributions, and directional frequency comparisons, complemented with univariate discriminative performance and statistical analysis of differences.

| Feature | Description |
|---|---|
| advmod | Adverbial modifiers per sentence, excluding negatives. Count of *advmod* dependency relations for tokens where morphological features do not contain *=Neg*. |
| mean_sent_wc | Mean sentence length. Count of UD tokens per sentence. |
| mhd | Mean hierarchical distance. Average length of paths from the root to all nodes along the dependency edges (Jing and Liu, 2015). |
| nnargs | Ratio of nouns, inc. proper names, as core verb arguments to the total of arguments. Count of tokens tagged as *NOUN* or *PROPN* to tokens tagged *nsubj*, *obj*, or *iobj*. |
| relcl | Relative clauses. Count of relative clauses in declarative sentences based on language-specific cues. For English, count of pronouns such as *which, that, whose, whom, what, who* tagged as pronouns with head relation *acl:relcl*. For German, count of pronouns like *der, welch, was, wer*, or pronouns containing *wo* with feature *PronType=Int,Rel* occurring near commas (up to 3 tokens away). |
| epist | Discourse markers of epistemic stance. Count of total occurrences of items from pre-defined language-specific lists (64 items for English, 74 for German, e.g., *at least, perhaps, angeblich, kein Zweifel*). |
| mpred | Modal predicates, including modal adjectives in predicative function (e.g., *likely, obvious, supposed, klar, unbedingt, möglich*). For English, count of modal auxiliaries (PoS tag *MD*) excluding *will* and *shall*, including non-*AUX have* followed by nearby infinitive verbs, ignoring causatives, plus modal adjectives with *AUX* dependents. For German, count of core modal verbs (*dürfen, können, mögen, müssen, sollen, wollen*) and modal adjectives in predicative function. |
| ppron | Personal pronouns. Count of personal pronouns in a segment, filtered by language-specific pronoun lists and morphological features: *PRON* with *Person=* feature, excluding possessive pronouns (*Poss=Yes*). |

Table 5: Examples of useful translationese predictors requiring less-trivial extraction rules and/or filtering.



(a) Segment-level features.

(b) Document-level features.

Figure 3: Segment vs. document feature importances: Average absolute SHAP values for translationese predictors by mode and target language on a shared scale. Darker shades indicate higher feature importance; blank cells indicate that a feature was not selected for the given task. Features are grouped by selection overlap: the top block shows predictors selected by all four classifiers, followed by predictors shared by mode (written, spoken) and by target language (German, English). Segment-level analysis dilutes feature importance and obscures patterns that are clearer at the document level. The grouping sizes further suggest that mode yields more consistent deviation patterns than translation direction.

Table 6: Document-level frequency comparison between targets and originals and macro F1 scores for single-feature classifiers. '–' indicates either no statistically significant difference ($p > 0.05$) between classes or cases where a single-feature classifier produced no predictions for one class in at least one fold, rendering the metric undefined. Arrows (↗, ↘) denote significantly higher or lower average feature frequency in target texts. Three features exhibiting statistically significant class differences for all directions and modes are highlighted. Univariate performances with F1 scores $> 65$ are in bold. Features are sorted alphabetically.

## Abstract

Text style transfer (TST) is naturally a supervised task — rewrite a sentence in a target style while preserving its meaning — yet the parallel corpora that supervision requires exist for only a handful of style domains. A common workaround is to *normalize* an input into a style-agnostic intermediate and then *stylize* it into the target style, but the normalizer is typically a lightweight, task-specific paraphraser applied only at test time, feeding a correspondingly small stylizer. We observe that a style-stripping normalizer already exists at scale: neural MT systems trained on hundreds of millions of general-domain sentence pairs preserve content while regressing toward generic phrasing, so roundtrip translation through a pivot language strips stylistic signal without any task-specific training. This turns normalization from an inference-time patch into a data-generation tool. Roundtrip-translating a monolingual in-style corpus yields a pseudo-parallel corpus on which we LoRA-finetune an instruction-tuned LLM as the stylizer (RT-SFT); applying the same normalizer to test queries keeps that stylizer in-distribution. We show that across four style domains, RT-SFT outperforms state-of-the-art methods, such as few-shot in-context learning, by considerable margins. We also report on effective retrieval augmentation methods for expert style domains with strict terminology and naming conventions.

## 1 Introduction

Text Style Transfer (TST) is the task of rephrasing text by modifying stylistic attributes while preserving its core, attribute-independent semantics and intent (Shen et al., 2017; Toshevska and Gievska, 2024). These attributes encompass formality, attitude, verbosity, preferred terminology, and other characteristics inherent to the text. A central obstacle in TST is the scarcity of annotated parallel corpora, which prevents the use of fully supervised training or finetuning (Pan et al., 2024) in most style domains.

One established approach to this problem is *normalize-then-stylize*: a normalizer maps an input to a style-agnostic form, either a latent encoding or text, and a stylizer regenerates that form in the target style. STRAP (Krishna et al., 2020), for instance, normalizes by paraphrasing the input to strip its style before decoding with a style-specific generator. The advantage of this framing is that the normalizer defines a single shared domain through which every input passes, whatever style it arrives in, so the stylizer never has to accommodate unpredictable source styles.

Robustness to diverse, unpredictable input styles therefore depends on the training data for the normalizer. Most current normalizers are trained on curated *paraphrase corpora* such as ParaFusion (Jayawardena and Yapa, 2024). Such corpora are reported to offer limited lexical and syntactic diversity (Hu et al., 2019; Krishna et al., 2020; Jayawardena and Yapa, 2024), and paraphrasers trained on them degrade on stylistic features unseen during training. A second line of work prompts an instruction-tuned LLM to paraphrase without any parameter update (Roy et al., 2023; Sun et al., 2025). We argue that this is less principled: the stylizer unavoidably carries the stylistic features and biases of the prompted LLM.

We propose roundtrip translation as the normalizer: a sentence is translated into a pivot language and then back into the original language, a technique previously used to assess MT robustness and generation quality (Somers, 2005; Moon et al., 2020). This requires neither paraphrase supervision nor a prompted LLM (Figure 1). We first train two Marian NMT models (Junczys-Dowmunt et al., 2018) on general-domain parallel corpora (Kocmi et al., 2025), and compose them into an English–pivot–English roundtrip pipeline. Applying this pipeline to a non-parallel corpus in the

*Proceedings of the Eleventh Conference on Machine Translation*, pages 398–411
October 28-29, 2026 ©2026 Association for Computational Linguistics

target style produces an RT-normalized counterpart for each sentence, and the two sides form a pseudo-parallel corpus that restores a supervised TST setting in a domain with no bitext. We then finetune an instruction-tuned LLM on this corpus as the stylizer (an RT-SFT-LLM), with retrieval augmentation applied to both the finetuning and the inference prompts (§3.3). At test time we pass the query through the same roundtrip pipeline before generation, so that the stylizer receives the RT-normalized input it was trained on (§3.1). We show in §4.3 that this alignment raises style accuracy in all four domains.

We evaluate our method (§4) on four style domains with distinctive stylistic features (§4.1.1), against two established baselines: few-shot In-Context Learning (ICL) (Reif et al., 2022; Suzgun et al., 2022) and Automatic Post-Editing (APE) (Simard et al., 2007; Moon et al., 2022). Following prior work, we measure transfer quality with BERT-based style classifiers trained on held-out data and content preservation with BLEU (Subramanian et al., 2018; Wan et al., 2023; Aycock and Bawden, 2024).

Our **main contributions** are:

- **Pseudo-parallel dataset construction** (§3.1). We use roundtrip translation through general-domain MT as a style normalizer, synthesizing the parallel corpus that supervised finetuning requires in domains that lack bitext.
- **Retrieval augmentation for finetuning and inference** (§3.3). We apply retrieval augmentation to the **finetuning** prompts as well as the inference prompts, and show that its benefits extend beyond prompting by aligning the retriever with the generator.
- **Systematic evaluation of RT-SFT-LLMs** (§4). We benchmark RT-SFT-LLMs across four style domains using four LLMs as base model, three prompt templates, and several retrieval and inference configurations, against established baselines.

## 2 Related Work

**Unsupervised and semi-supervised TST** Because corpora that align the same content across styles are scarce, most work performs style transfer from non-parallel data. Early neural approaches disentangle content from style in a latent space

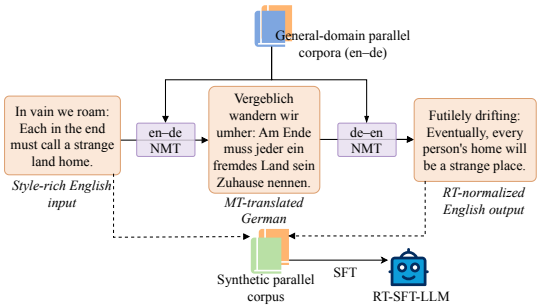

Figure 1: Our proposed workflow for finetuning large language models (LLMs) for text style transfer (TST) using only non-parallel data in the target domain. A bilingual general-domain parallel dataset is used to train a pair of neural machine translation (NMT) models capable of translating between English and a pivot language. We then obtain RT-normalized texts of the original in-domain texts by roundtrip translating the in-domain set with the NMT models. This enables supervised finetuning of LLMs for TST, where we finetune LLMs for RT-normalized-domain to target-domain transfer using the synthetic parallel corpus.

and recombine the content with a target-style representation (Shen et al., 2017; Nangi et al., 2021; Voigt et al., 2018), typically using adversarial objectives and auxiliary losses that preserve content through the transfer (Tian et al., 2018; Nouri, 2022). Semi-supervised methods further reduce the reliance on task-specific data by exploiting generic pretrained resources and reward models (Lai et al., 2021). More recent work abandons explicit disentanglement, instead synthesizing pseudo-parallel data with LLMs and refining generation with reinforcement learning: Pan et al. (2024) couple LLM prompting with attention masking, while intensity-controllable methods first supervise-finetune a base transfer model and then apply reinforcement learning with hierarchical rewards to modulate stylistic strength (Gu et al., 2026). Our method also assumes only non-parallel, target-style data, but recovers a supervised training signal through normalization (§3).

**Normalize-then-stylize** A strategy for non-parallel TST is to first map the input to a style-agnostic intermediate—to *normalize* it—and then generate in the target style—to *stylize* it. The normalizer has taken many forms: a learned diverse paraphraser (Krishna et al., 2020), roundtrip or back-translation through a pivot language whose output is assumed to retain content but not style (Prabhumoye et al., 2018; Rabinovich et al., 2017;

Zhang et al., 2018; He et al., 2020), denoising and latent-variable encoders (Subramanian et al., 2018; Riley et al., 2021), abstract-meaning-representation graphs (Jangra et al., 2022), and, most recently, diffusion paraphrasers (Horvitz et al., 2024a). In these methods the normalizer is typically applied *at inference time* and paired with a comparatively small stylizer: STRAP (Krishna et al., 2020) paraphrases the input at test time to strip its style and then decodes with a style-specific GPT-2; Horvitz et al. (2024b) reconstruct text from a neutralized paraphrase conditioned on an authorship embedding; conversational methods reduce an utterance to a style-free form and rewrite it (Roy et al., 2023); and synthesize-then-decode prompting amplifies the target style only at decoding (Sun et al., 2025). We adopt this paradigm but realize it with two components trained at scale—a general-domain neural machine translation (NMT) model as the normalizer (through roundtrip translation) and an instruction-tuned LLM, finetuned to map normalized text to the target style, as the stylizer—together with retrieval augmentation at both training and inference (§3). This trained, LLM-scale realization is precisely what prior, largely inference-time methods lack.

**Prompt engineering and in-context learning** A parallel line of work performs TST with LLMs purely through prompting, without updating any parameters. Reif et al. (2022) frame transfer as instruction-guided rewriting with augmented zero-shot prompts; other methods rerank sampled candidates by style strength and fluency (Suzgun et al., 2022), supply retrieved in-domain exemplars as few-shot "shots" (Liu et al., 2024a; Chen, 2024; Bhandarkar et al., 2024; Aycock and Bawden, 2024), or optimize the prompt template and its retrieved context (Zhang et al., 2024; Wan et al., 2023; Tao et al., 2024). The most recent methods steer generation through register analysis (Yang and Carpuat, 2025), structure long-document transfer (Wu and Deng, 2025), and probe how far prompting alone can go (Toshevska and Gievska, 2025; Mukherjee et al., 2024). Such approaches require no training, but they are inherently prompt-bound: they cannot adapt model parameters to a target domain, which limits terminology control and long-range stylistic consistency. We instead finetune the stylizer (§3).

**Supervised TST and parameter-efficient finetuning** When aligned data are available, style transfer can be cast as supervised sequence-to-sequence learning, as in Jhamtani et al. (2017)'s copy-augmented model for Shakespearean English. The bottleneck is data: parallel style corpora exist for only a handful of domains—modern-to-Shakespearean English (Xu et al., 2012), formality (Rao and Tetreault, 2018; Briakou et al., 2021), biblical prose (Carlson et al., 2018), expert-versus-layman medical text (Cao et al., 2020), and, more recently, parallel detoxification corpora (Dementieva et al., 2025; Protasov et al., 2025)—and new benchmarks continue to target these same well-resourced settings (Xie et al., 2025; Jangra et al., 2025). Parameter-efficient finetuning of LLMs for TST has begun to appear (Liu et al., 2024b; Mukherjee et al., 2024) but remains confined to domains with existing parallel data. We remove this constraint: by normalizing a monolingual target-style corpus, we synthesize the parallel data that supervised finetuning requires and extend it to domains with no bitext (§3).

Figure 2: Example sentences illustrating semantically equivalent content in various styles. Outputs of our roundtrip translation pipeline are considered RT-normalized.

## 3 Methods

### 3.1 Roundtrip Translation

Unlike most state-of-the-art methods that instantiate the *normalize-then-stylize* paradigm (Krishna et al., 2020), we train both components at scale. The normalizer is a pair of neural machine translation (NMT) models, trained with Marian (Junczys-Dowmunt et al., 2018) on a large general-domain

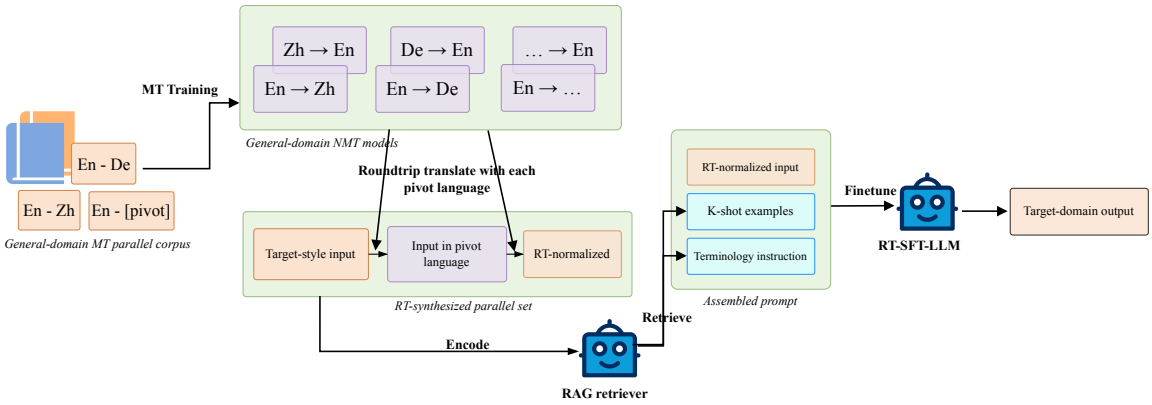

Figure 3: **Our proposed workflow.** We train MT systems using general domain parallel data for Chinese-English and German-English two-way translations, and roundtrip-translate target style text to obtain RT-normalized counterparts. We roundtrip translate every record with both pivot languages and mix the synthetic corpus. The synthetic parallel corpus is then used for finetuning a stylizer LLM, with retrieved information injected in the prompt.

corpus between English and a pivot language; composed into a roundtrip translation pipeline, it strips pronounced stylistic features while preserving content, yielding *RT-normalized* text; Figure 2 shows RT-normalized outputs alongside the same content rendered in each target style. Applying it to a monolingual in-style corpus pairs every sentence with its RT-normalized counterpart, producing the pseudo-parallel corpus on which we parameter-efficiently finetune an instruction-tuned LLM as the stylizer (an *RT-SFT-LLM*; Figure 1). At test time the two run in sequence, the normalizer followed by the stylizer (Figure 3).

This sequencing resolves a distribution mismatch: during finetuning the stylizer sees only RT-normalized inputs, whereas an arbitrary query at test time may carry pronounced, unseen style. Passing the query through the same roundtrip pipeline first mirrors the training-time construction exactly, and is the analogue of STRAP's inference-time paraphrasing (Krishna et al., 2020), realized here by an NMT normalizer. We compare RT-first inference against feeding the raw query directly in §4.3, and find that it improves target-style conformity, especially for stylistically diverse or out-of-domain inputs.

### 3.2 RT-SFT with Parameter Efficient LoRA Finetuning

LoRA (Low-Rank Adaptation of Large Language Models) is an efficient approach that reduces computational and memory costs by using low-rank approximation techniques (Hu et al., 2021). The LoRA approach involves freezing the pre-trained model's weight matrices and introducing trainable low-rank decomposition matrices into the model's layers. This approach allows us to finetune the 7B and 8B LLMs with 2 NVIDIA A100 GPUs, each with 80GB of memory. Hyperparameters and configurations we used are given in Appendix B.

### 3.3 RAG Retrievers for RT-SFT-LLMs

Lewis et al. (2020) proposed the Retrieval Augmented Generation (RAG) framework in which a retriever-generator model is trained end-to-end to enhance coherence between the pre-trained retriever and generator subsystems. In a similar spirit, our RAG system injects retrieved information into both finetuning and inference-time prompts for RT-SFT-LLM, unlike previous RAG-based TST methods where RAG is primarily considered a prompting technique (Liu et al., 2024a; Wan et al., 2023; Aycock and Bawden, 2024; Zhang et al., 2024). In §4.2, we present the performance of our system with increasing levels of retrieval augmentation compared against our method without RAG (RT-SFT 0-shot) and state-of-the-art inference-time RAG without training (5-shot In-Context Learning). We show that RAG introduced at training time produces considerable improvements compared to both RT-SFT without RAG and inference-time RAG.

#### 3.3.1 Relevant Example Retrieval Augmentation

The first type of retrieval augmentation we report on obtains sentence pairs as instructions for how we would like the query to be transferred. Results demonstrate that examples relevant to the query are

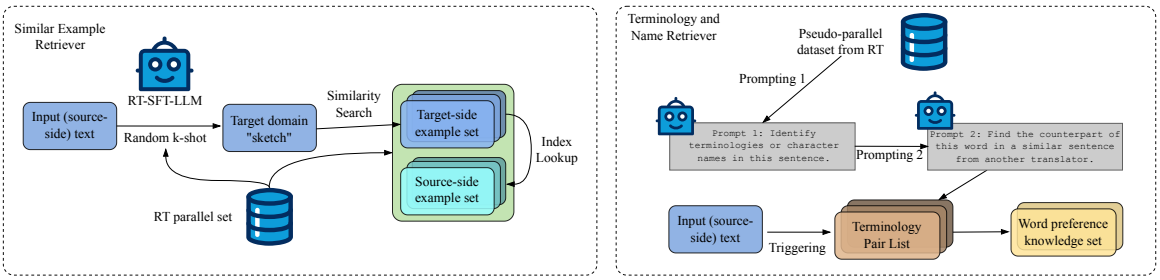

Figure 4: **Retrieval augmentation workflow. Left (a):** Relevant example retriever. We encode **the target-side texts** of the parallel synthetic datasets for nearest-neighbor search. For each query, we first do k-shot inference with the RT-SFT-LLM to obtain an "in-domain" sketch, which is used as search query in the target-side dataset to obtain the k most relevant pairs. **Right (b)** Terminology and name retriever: For each instance in the synthetic parallel datasets, the first LLM call extracts relevant words from the source side, then the second call matches them with their counterparts in the target side, yielding a terminology pair list for each domain.

more instructive and bring stronger performance improvements (§4.2).

We vectorize the pseudo-parallel corpus and use Faiss (Douze et al., 2024) (Figure 4) to retrieve nearest neighbors, following the original RAG schema (Lewis et al., 2020). Interestingly, we found that searching with the target side (in-domain) retrieves better instances than searching with the source (out-of-domain) side, giving slightly better results. We thus use retrieved examples with relevant target sides for example prompt injection. Specifically, we exclude the current instance itself during retrieval to avoid leakage.

For inference-time RAG where the target side text is unavailable and is what we want to predict, we take a "sketch-first" approach following Wang et al. (2022)'s two-round retrieval schema (Figure 4). We first perform few-shot inference with **randomly selected** examples to generate a draft "sketch" output that resembles the in-domain transferred generation, though of limited quality due to the random shots. We then use this draft as the query to retrieve the most relevant examples from the Faiss vector bank for a refined second-round inference. In §4.3, we show that relevant example augmentation at inference time through this approach yields better performance than randomly selected examples and inference without any examples (Table 3).

#### 3.3.2 Terminology and Name List Retrieval

Diction and word preference are important aspects of text style domains. The same concept or object can be referred to by different terminologies in different domains. In literary translation domains, there is a similar issue of **naming consistency**, where machine-translated works may use semantic translations and direct translations in different contexts to refer to the same characters, causing confusion (Matusov, 2019).

We improve our RT-SFT-LLM's terminology correctness and long-context consistency by retrieving a **terminology and name list** from our pseudo-parallel corpus (Figure 4). For each record in the pseudo-parallel corpus, we first prompt an LLM with the source side of the paired sentences and ask it to identify any domain-specific terms or names in it. Then, we do a second round of prompting with the target side of the sentence pairs alongside the retrieved domain-specific terms, and ask the LLM to find their counterparts. Through this pipeline, we construct a list of source domain to target domain preferred terminology pairs. If any of the source-side words are present in the query, we add a one-sentence instruction in the inference prompt that provides terminology and name transfer guidance. The prompts we used are in Appendix A.

### 3.4 Evaluation: BLEU and Style Classification Accuracy Score

We primarily evaluate two aspects of our models, namely style-transfer quality and content preservation. For each style domain we train a BERT-based (Devlin et al., 2018) style classifier on held-out in-domain data, following Liu et al. (2024b,a); Mukherjee et al. (2024). The classifier scores a given text between 0 and 1, where we treat 1 as "in-domain" and 0 as "out-of-domain". We apply the trained classifier to the output of our RT-SFT-LLMs to yield a style-classification accuracy that measures how well the output matches the target style. BLEU is computed between the generation and the reference in-domain text, measuring how

well the transferred output preserves the intended content.

# 4 Experiments

## 4.1 Experiment Setup

### 4.1.1 Datasets, Synthetic Data Generation, and Baselines

| Dataset | Training | Dev | Test |
|---|---|---|---|
| WMT26-eng-zho | 241,429,382 | 3,000 | – |
| WMT26-deu-eng | 1,128,176,715 | 3,000 | – |
| MSD | 130,199 | 150 | 675 |
| Shakespeare | 24,852 | 1,313 | 1,293 |
| GYAFC | 103,562 | 1,000 | 2,748 |
| ParaDetox | 19,466 | 150 | 150 |

Table 1: **Datasets.** Underlined counts are parallel (aligned) sentence pairs; plain counts are monolingual sentences. The WMT26 General Machine Translation corpora (Kocmi et al., 2025) are used to train the roundtrip-translation normalizers; we use only the parallel portion of the released splits and manually hold out 3,000 sentence pairs per language pair as dev set. The four style datasets are used as training data for our RT-SFT method. Note that although 3 of the 4 style domains provide parallel training data, we only use the in-domain side of them during training, as our system only requires in-domain non-parallel training data. We use the provided, human-annotated parallel sentences only for the dev and test sets.

**Machine-translation data** We build the roundtrip translation normalizer from two general-domain parallel corpora released for the WMT26 General Machine Translation shared task (Kocmi et al., 2025), covering English–Chinese and German–English. We use only the parallel portion of the released splits to train the Marian NMT models (Junczys-Dowmunt et al., 2018), holding out 3,000 sentence pairs per language pair as a development set; detailed configurations are given in Appendix B. Every in-style sentence is roundtrip translated through both the Chinese and the German pivot, and the two resulting RT-normalized–to–target pairs are pooled into a single synthetic corpus for finetuning. Corpus sizes are reported in Table 1.

**Style-transfer datasets.** We evaluate on four publicly available benchmarks, each targeting a specific style and providing a human-aligned parallel test set. The domains are: expert medical text (**MSD**; Cao et al., 2020), Shakespearean English (**Shakespeare**; Xu et al., 2012), formal text (**GYAFC**; Rao and Tetreault, 2018), and detoxified text (**ParaDetox**; Logacheva et al., 2022). Split sizes are listed in Table 1, where underlined counts denote parallel data and plain counts denote monolingual data.

**Baselines:** First, we set up an **In-Context Learning (ICL)** baseline method by prompting the LLMs with the same prompt from our own method, with the addition of few-shot examples retrieved based on similarity and the absence of finetuning. The second baseline we adopt is **Automatic Post-Editing (APE)**: we train an additional MT model for each domain on the output (RT-normalized) versus text input (target style), so that it performs English-to-English "translations" that bring RT-normalized texts to in-domain. This is a widely-used practice that accompanies Machine Translation systems (Simard et al., 2007; Moon et al., 2022), where the additional APE module learns to correct systematic errors in the MT system through NMT training. Our variant is monolingual (source-free), post-editing the roundtrip output directly to match the target text, which is the input to the roundtrip translation pipeline.

### 4.1.2 TST Prompt Templates

We experimented with three potential prompt templates for TST finetuning. Prompt details and experiments on prompts are in Appendix A. After testing and careful evaluation, we decided to use the following prompt template for our method:

> **Rewrite the given sentence into the style of [style name].**
> Here are [n] examples:
> Input: [example input i]. Output: [example output i].
> .....
> Note that you may want to rewrite "[input term]" to "[output term]" for contextual consistency.
> Now go ahead: Input: [query input]. The [style name] output:

## 4.2 Overall Performance Comparison

This subsection compares roundtrip-translation supervised finetuning (**RT-SFT**) against three reference points across the four style domains (Table 2). We use Llama-3.1-8B-Instruct as the base model and are finetuned on the synthetic corpus of §4.1.1, which pools roundtrip translations through both pivots (Chinese and German); an experiment on various LLMs as the base model is reported in §4.4. **COPY** offers a calibration where we measure the

| Method | MSD | | Shakespeare | | GYAFC | | ParaDetox | |
|---|---|---|---|---|---|---|---|---|
| | Acc. | BLEU-ref | Acc. | BLEU-ref | Acc. | BLEU-ref | Acc. | BLEU-ref |
| COPY | 0.107 | 14.01 | 0.009 | 15.35 | 0.149 | 16.54 | 0.012 | 20.03 |
| 5-shot In-Context Learning (2022) | 0.396 | 9.58 | 0.771 | 12.79 | 0.521 | 19.34 | 0.792 | **21.35** |
| Automatic Post-Editing (2022) | 0.672 | 12.21 | 0.693 | 11.90 | 0.435 | 17.74 | 0.720 | 17.35 |
| RT-SFT 0-shot | 0.706 | 11.32 | 0.841 | 11.47 | 0.591 | 21.33 | 0.820 | 18.40 |
| RT-SFT random-3-shot | 0.715 | 13.35 | 0.809 | 13.21 | 0.620 | 22.41 | 0.893 | 18.11 |
| RT-SFT random-5-shot | 0.732 | 13.61 | 0.794 | 13.42 | 0.611 | 22.22 | 0.891 | 18.09 |
| RT-SFT relevant-3-shot | **0.797** | 13.59 | 0.841 | 14.65 | 0.642 | **24.79** | **0.935** | 17.91 |
| RT-SFT relevant-5-shot | 0.782 | 13.53 | 0.839 | 14.77 | **0.644** | 4.32 | 0.931 | 19.35 |
| + terminology and name retrieval | 0.763 | **13.79** | **0.842** | **17.35** | 0.612 | 24.17 | 0.912 | 19.91 |

Table 2: **Main results.** TST performance of RT-SFT against baselines across the four style domains (base model: Llama-3.1-8B-Instruct; synthetic corpus pooled from German and Chinese roundtrip pivots). *random* and *relevant* indicate whether the $k$ in-context example pairs are sampled at random or retrieved for relevance; + *terminology and name retrieval* adds domain-specific term guidance when triggered (§3.3.2). Best result per column in bold, excluding COPY: returning the input unchanged attains very high BLEU at near-zero style accuracy, a known artefact of BLEU-based TST evaluation (Pang, 2019). RT-SFT improves style accuracy over both baselines in all four domains and in every configuration tested, and relevant-example retrieval improves accuracy over random examples in all eight paired comparisons.

BLEU and accuracy of the input itself against the target text. Among RT-SFT variants, **$k$-shot (random)** supplies $k$ randomly drawn RT-normalized-to-target pairs and **$k$-shot (relevant)** the $k$ most relevant pairs, retrieved by cosine-distance search at finetuning time and by the procedure of §3.3.1; the final variant adds **terminology and name retrieval** (§3.3.2). Results are single runs, and we do not interpret accuracy differences below 0.02.

Style accuracy is measured by a BERT classifier trained per domain (§3.4), so the COPY row calibrates it: it reports how often an untransferred input is already labelled in-domain. The near-zero values on Shakespeare (0.009) and ParaDetox (0.012) show that these boundaries are almost linearly separable, whereas MSD (0.107) and GYAFC (0.149) are harder to classify, and their scores must be read against a higher floor and a correspondingly lower ceiling (0.797 and 0.644, against 0.842 and 0.935). Against this calibration, RT-SFT improves accuracy over both baselines in all four domains and in every configuration tested—24 of 24 cells. Neither half of the method suffices alone: zero-shot RT-SFT, which uses no retrieval at all, beats ICL by +0.310, +0.070, +0.070 and +0.028, and beats APE by +0.034, +0.148, +0.156 and +0.100. Retrieval augmentation therefore adds to these gains rather than producing them. APE leads ICL only on MSD (0.672 vs. 0.396), the domain with the most specialized lexicon.

BLEU must be read jointly with accuracy, since the two trade off systematically in TST: it is widely reported by prior work that untransferred input routinely outscores most systems (Pang, 2019; Mukherjee et al., 2023). Our COPY row reproduces this—considerably high BLEU across all four domains, and the highest BLEU on MSD (14.01) at only 0.107 accuracy—and explains the single column in which a baseline leads: 5-shot ICL takes the top ParaDetox BLEU (21.35) at a comparatively low style accuracy (0.792, against 0.912–0.935 for the relevant-shot RT-SFT variants); consistent with the style–content trade-off, it underedits toward the input. A BLEU drop relative to COPY is thus expected wherever source and reference already overlap heavily. Where they genuinely diverge the trade-off does not bind: on GYAFC and Shakespeare the best RT-SFT variant leads on both metrics, improving BLEU by +5.45 and +4.56 over the stronger baseline.

Retrieval improves both metrics, but unevenly. Relevant examples beat random ones on accuracy in all eight paired comparisons (mean +0.043) and on BLEU in six of eight (mean +1.06), with gains concentrated where a length- and vocabulary-matched exemplar is available: +2.38 on GYAFC and +1.44 on Shakespeare at $k$=3, against +0.24 on MSD. The number of shots has no consistent effect, 3-shot winning five of eight cells by margins well below the relevant-vs-random gap. Terminology and name retrieval behaves as the lexical intervention it is: added to relevant-5-shot it raises BLEU in three of four domains—most on Shakespeare (+2.58, the largest single gain in the table),

| Inference methods | MSD | | Shakespeare | | GYAFC | | ParaDetox | |
|---|---|---|---|---|---|---|---|---|
| | Acc. | BLEU-ref | Acc. | BLEU-ref | Acc. | BLEU-ref | Acc. | BLEU-ref |
| COPY | 0.107 | 14.01 | 0.009 | 15.35 | 0.149 | 16.54 | 0.012 | 20.03 |
| 5-shot In-Context Learning (2022) | 0.396 | 9.58 | 0.771 | 12.79 | 0.521 | 19.34 | 0.792 | **21.35** |
| Automatic Post-Editing (2022) | 0.672 | 12.21 | 0.693 | 11.90 | 0.435 | 17.74 | 0.720 | 17.35 |
| 0-shot inference | 0.730 | 13.31 | 0.791 | 17.21 | 0.595 | 23.96 | 0.909 | 17.07 |
| random 5-shot inference | 0.759 | 11.53 | 0.841 | 17.01 | 0.575 | 21.17 | 0.893 | 18.63 |
| relevant 5-shot inference without RT normalization | 0.671 | **14.55** | 0.731 | **18.69** | 0.556 | **26.62** | 0.902 | 20.21 |
| relevant 5-shot inference | **0.763** | 13.79 | **0.842** | 17.35 | **0.612** | 24.17 | **0.912** | 19.91 |

Table 3: TST performance under different inference procedures. All groups use one Llama-3.1-8B-Instruct RT-SFT-LLM, finetuned with 5-shot relevant examples and terminology retrieval (§4.2); baseline rows are repeated from Table 2 for reference. All RT-SFT rows apply RT-first inference except *without RT normalization*, which feeds the raw query. Best result per column in bold, excluding COPY. RT-first inference raises style accuracy and lowers BLEU in all four domains; relevant-example retrieval raises BLEU in all four while leaving accuracy largely unchanged.

where the style is carried by a fixed vocabulary and by character names—but on GYAFC, where formality is realized syntactically, it lowers both metrics. Averaged over the four domains it trades 0.017 accuracy for 0.82 BLEU. We therefore recommend it for domains with a stable terminology or naming convention, and relevant-example retrieval alone elsewhere.

### 4.3 Inference-time methods

We next perform ablation studies on the inference procedure (Table 3). All groups use the same Llama-3.1-8B-Instruct RT-SFT-LLM, finetuned with 5-shot relevant examples and terminology retrieval (§4.2), and differ only in what is done at test time: **0-shot** prompts with the task description alone, while **random** and **relevant 5-shot** append examples sampled at random or retrieved by the procedure of §3.3.1. The **without RT normalization** row feeds the raw query directly into the finetuned stylizer LLM without being normalized by the RT pipeline, and provides the controlled contrast isolating RT-first inference.

RT-first inference yields a strictly monotone trade: style accuracy rises in all four domains ($+0.092$, $+0.111$, $+0.056$, $+0.010$) and BLEU falls in all four ($-0.76$, $-1.34$, $-2.45$, $-0.30$). Aligning the query with the finetuning distribution thus costs some semantic drift through the pivot. The gain is largest on MSD and Shakespeare, whose source registers are the most strongly marked, and negligible on ParaDetox, where source and target differ by a small lexical edit and little style remains for the normalizer to strip.

At inference time, relevant examples act on content rather than style: against random 5-shot they raise BLEU in all four domains (mean $+1.72$) but leave accuracy unchanged in three of four, reversing the pattern of Table 2, where finetuning-time relevance was primarily an accuracy lever. Random examples are actively harmful—0-shot inference exceeds random 5-shot on BLEU in three of four domains. That 0-shot inference here also exceeds the 0-shot-*finetuned* model of Table 2 on BLEU in three domains, neither prompt containing any example, indicates that the benefit of retrieval-augmented finetuning is retained in the weights.

### 4.4 Experiments on Pretrained LLMs

To demonstrate the generalizability of RT-SFT, we repeated the experiment with three other pretrained LLMs under the best configuration of §4.2—relevant 5-shot examples with terminology and name retrieval (Table 4). Style accuracy is again given by the per-domain BERT classifier of §3.4, and COPY provides the untransferred floor.

Every model clears that floor in all sixteen cells, by margins of 0.403 to 0.900, so the synthetic corpus supplies a usable training signal irrespective of the base LLM. Llama-3.1-8B-Instruct is strongest on both metrics—leading style accuracy in all four domains and BLEU in three, with Gorilla-openfunctions-v2 ahead by 0.02 on ParaDetox—and we therefore adopt it for §4.2 and §4.3. Gorilla and Mistral-7B are indistinguishable from each other on both metrics (average BLEU 17.32 vs. 17.22, accuracy 0.710 vs. 0.700). Scale is not the binding constraint: opt-2.7b, roughly a third the size of the others, trails Llama by only 0.095 in average accuracy and still exceeds the 5-shot ICL baseline of Table 2 in three of four domains. As in §4.2, all four models fall below the input itself

| Pretrained LLMs | MSD | | Shakespeare | | GYAFC | | ParaDetox | |
|---|---|---|---|---|---|---|---|---|
| | Acc. | BLEU-ref | Acc. | BLEU-ref | Acc. | BLEU-ref | Acc. | BLEU-ref |
| COPY | 0.107 | 14.01 | 0.009 | 15.35 | 0.149 | 16.54 | 0.012 | 20.03 |
| meta-llama/Llama-3.1-8B-Instruct | **0.763** | **13.79** | **0.842** | **17.35** | **0.612** | **24.17** | **0.912** | 19.91 |
| gorilla-llm/gorilla-openfunctions-v2 | 0.661 | 11.07 | 0.733 | 17.11 | 0.573 | 21.15 | 0.874 | **19.93** |
| mistralai/Mistral-7B | 0.692 | 12.21 | 0.749 | 15.97 | 0.552 | 22.23 | 0.806 | 18.45 |
| facebook/opt-2.7b | 0.631 | 11.39 | 0.701 | 13.33 | 0.606 | 21.27 | 0.811 | 17.21 |

Table 4: TST finetuning performance across base LLMs (relevant 5-shot finetuning with terminology and name retrieval; synthetic corpus pooled from German and Chinese roundtrip pivots). The Llama-3.1-8B-Instruct row is the best configuration of Table 2, repeated here for comparison. COPY returns the input unchanged and gives the untransferred floor for each domain's style classifier. Best result per column in bold, excluding COPY. All four base models exceed that floor in every domain; Llama-3.1-8B-Instruct leads on style accuracy in all four and on BLEU in three.

(COPY) on MSD and ParaDetox BLEU, where source and reference already overlap heavily.

## 5 Conclusion

We presented a method for Text Style Transfer that addresses the scarcity of parallel corpora by using roundtrip translation as a style normalizer to generate parallel training data. Because general-domain NMT preserves content while regressing toward generic phrasing, roundtrip-translating a monolingual in-style corpus yields the pseudo-parallel data that supervised finetuning requires, turning normalization from an inference-time patch into a data-generation tool. LoRA-finetuning an instruction-tuned LLM on this corpus improves style-classification accuracy over both In-Context Learning and Automatic Post-Editing in all four domains and in every configuration tested, and does so without either half of the method being sufficient alone: zero-shot RT-SFT, which uses no retrieval, already beats ICL—the same model and prompt without the synthetic corpus—and APE, the same corpus without the LLM stylizer. BLEU behaves as expected under the style–content trade-off (Mukherjee et al., 2023; Pang, 2019), and RT-SFT leads on both metrics in the two domains where source and reference genuinely diverge.

Retrieval augmentation applied at training time, rather than only in the prompt, improves style accuracy in all eight paired comparisons against randomly sampled examples, and its benefit is retained in the weights: a retrieval-augmented model prompted with no examples outperforms one finetuned without retrieval and likewise prompted with none. Terminology and name retrieval trades a small amount of accuracy for content preservation, and helps most where the target style is carried by a fixed vocabulary.

Roundtrip-translating the query at inference time to match the finetuning distribution raises style accuracy in all four domains and lowers BLEU in all four, a trade whose size tracks how strongly marked the source register is. Quantifying that trade-off under stylistically diverse and genuinely out-of-domain queries is the natural next step, along with varying the pivot language and extending a single RT-SFT-LLM to multi-style and non-binary transfer.

## Limitations

The main limitations of our work are as follows:

- **Semantic drift and error propagation.** Our method relies on machine translation models to generate parallel finetuning datasets. As a result, its performance depends on the quality of the underlying NMT systems and their training data. We observed that when these models introduce errors or cause semantic drift during roundtrip translation, such inaccuracies become embedded in the synthetic parallel corpus used for finetuning. We applied post-processing steps to mitigate such effects, and further efforts could also be made to test various NMT methods or architectures to find the most suitable configuration for the TST task. These improvements and post-editing works, however, are beyond the scope of this study.

- **Alternatives for the Current Roundtrip Translation Pipeline**. In this work, we primarily used Marian to train the NMT models and did not explore alternative methods or

workflows for performing roundtrip translation. An intriguing potential alternative is to employ large language models to perform machine translation, either by ICL or finetuning, which might yield better results compared to the current Marian-based approach. However, we did not test these alternative approaches in the current study owing to constraints on time and space.

- **Limits to domains with available corpus**. Due to data availability constraints, our experiments are conducted on four style domains, which may not fully capture the range of stylistic variations encountered in real-world scenarios. This limitation could introduce biases into our analysis and potentially restrict the generalizability of our methods. We selected benchmarks that are as diverse and distinctive as possible—spanning Shakespearean English, formality, expert–layman medical communication, and toxicity—in an effort to enhance the overall robustness and applicability of our method. We strive to enhance the generalizability of our experiments and demonstrate the effectiveness of our method in different domains and conditions.

**Candidate prompt templates for LLM style transfer finetuning**.

# A Prompt Templates

### TST finetuning prompts:

We experimented with three potential prompt templates for RT-SFT (Table 5). These prompts organize the query input sentence and several example sentence pairs into a prompt, with proper task descriptions and guidance for the generation. Templates (I) and (II) explicitly state the rewriting task, but have different orders of the example and query content. Template (III) is a classic Machine Translation prompt template with demonstrated effectiveness for Machine Translation with LLM. By changing language name to style domain name, we adapt it to guide LLM for text style transfer task.

In this experiment (Table 6), we conducted relevant 5-shot finetuning with terminology retrieval on Llama-3.1-8B-Instruct with the different templates, while leaving other conditions unchanged. Template (I) has the overall highest style accuracy score in the two tested domains. We thus used Template (I) throughout.

### Terminology retrieval prompts:

We retrieved domain-specific term and name pair lists for each domain to enhance TST performances, by calling the LLM twice for each instance in the synthetic parallel corpus. The prompts we used are shown in Table 7.

| Template | MSD | | Shakespeare | |
|---|---|---|---|---|
| | Acc. | BLEU-ref | Acc. | BLEU-ref |
| COPY | 0.107 | **14.01** | 0.009 | 15.35 |
| APE (2022) | 0.672 | 12.21 | 0.693 | 11.90 |
| Template I | **0.763** | 13.79 | **0.842** | 17.35 |
| Template II | 0.614 | 12.91 | 0.773 | 16.69 |
| Template III | 0.721 | 13.63 | 0.751 | **18.01** |

Table 6: BLEU and acc. score across the MSD and Shakespeare domains for three potential templates. Template (I) has consistently higher style accuracy score, indicating robust ability in transferring to target style. Both Template (I) and (III) have stably high BLEU score.

Table 7: Prompts for terminology RAG

| Prompt type | Prompt Text |
|---|---|
| First round | Identify terminologies or character names in the sentence and return in comma separated format, without any additional explanation. Sentence: [source-side sentence]. Terminologies and names: |
| Second round | Find the counterpart of the word [source-side retrieved word] in the following sentence and return a single word, without any additional explanation. Sentence: [target-side sentence]: |

**Prompts for terminology RAG**. The first prompt retrieves a list of terminologies and names from the source side sentence of each parallel instance, and for each of these retrieved words, the second prompt retrieves its counterpart in the corresponding target side sentence.

# B Hyperparameters and experiment configurations

### LoRA finetuning hyperparameters:

We set the learning rate to 2e-4, rank for the low-rank approximation is set to 512, the scaling factor is set to 256, and we use float16 data type. A dropout rate of 0.05 is applied. We save and evaluate the model every 2000 steps.

### Marian Configurations:

We used Marian for the Neural Machine Translation model pairs in the roundtrip translation system. In our system we used the Transformer architecture with R2L Reranking, with learning rate 0.0001, 49500 BPE operations, and step size 20000.

### Decoding configuration:

All generation from the RT-SFT-LLMs uses greedy decoding with beam size 1 and temperature 0. Generation is run with vllm in float16. The sketch-first

retrieval pass of §3.3.1 is decoded with the same configuration, so the first-round sketch, and hence the neighbour set it retrieves for the second round, is fixed for a given query and checkpoint.

# Multilingual Reasoning Cascades Need More Context

## Abstract

Translation cascades for reasoning translate the query from another language to English, reason in English, and translate the answer back to the original language. This is a competitive approach to multilingual reasoning, but structurally lossy, since each stage discards information later stages may need, including cues for cultural grounding, register, and disambiguation. We examine the benefits of a simple and training-free intervention: a *context-aware* translation cascade, which additionally provides the original question, the English-translated question, and the reasoning trace to the final cascade stage for target-language generation. We evaluate gains across ten multilingual benchmarks including various task types, three backbone models, and 285 high-, mid-, and low-resource languages, and demonstrate strong gains for open-ended generation across models and resource regimes. We show that the original language question carries most of the beneficial context. Our study emphasizes the need to better design information flow in multilingual reasoning cascades for mitigating error propagation, and provides a simple and actionable default strategy: preserve the original user question until the end of the pipeline.[1]

## 1 Introduction

Large language models reason more effectively in English than in most other languages (Shi et al., 2023). Translation cascades exploit this for multilingual reasoning by translating the target-language input into English (MT1), reasoning in English, then translating the answer back (MT2). This approach matches or outperforms end-to-end multilingual generation on a range of tasks (Liu et al., 2025; Intrator et al., 2024). However, cascaded systems notoriously suffer from error propagation (Zhu et al., 2019). We target a structural weakness: while MT2 only has access to the final English answer but not the original language and English question, accurate and grounded translation of the final English answer may require informational cues present only in the original question, depending on the syntax of the target language, cultural context, or simply to recover from errors in intermediate stages.

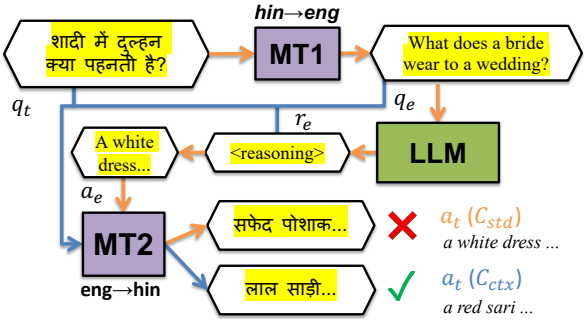

Figure 1: Standard cascade ($C_{std}$, orange) vs. context-aware cascade ($C_{ctx}$, orange+blue). In $C_{std}$, MT2 translates only the English answer $a_e$. In $C_{ctx}$, the final stage additionally receives the original target-language question $q_t$, the English question $q_e$, and the English reasoning trace $r_e$, and acts as a second reasoning stage for error recovery and translation

Contextual information could be critical in tasks requiring cultural context and grounding, given certain answer formats (Veselovsky et al., 2026), or for certain target languages that have poor translation support (Liu et al., 2019). However, in some settings, additional context can be damaging, e.g., distracting or confusing (Yang et al., 2025). In this work, we thus explore: *when does extra context benefit the multilingual reasoning cascade?*

We introduce a minimal and targeted intervention: a *context-aware MT cascade* ($C_{ctx}$). This differs from the *standard cascade* ($C_{std}$) in that $C_{ctx}$ additionally feeds into MT2 the original input and intermediate outputs, as depicted in Figure 1. Although we retain the conventional label MT2, the context-aware final stage performs more than iso-

*Equal contribution.

| Source | Cascade state | Outputs ($a_t$) | Why context helps |
|---|---|---|---|
| **Reasoning Error** | $q_t$: Qual o ingrediente principal da chanfana?<br>$q_e$: What is the main ingredient of chanfana?<br>$r_e$: "Chanfana is a traditional dish from Extremadura in Spain..."<br>$a_e$: The main ingredient is lamb. | $C_{std}$: O ingrediente principal da chanfana é o cordeiro (lamb).<br>$C_{ctx}$: O ingrediente principal da chanfana é o cabrito (goat). | English reasoning misidentifies the dish as Spanish. Seeing the Portuguese question lets $C_{ctx}$ recover the intended Portuguese dish. |
| **MT2 Error** | $q_t$: Apabila orang Melayu berbuka puasa di bulan Ramadan, makanan pertama yang dimakan biasanya ialah<br>$q_e$: When Malays break their fast during Ramadan, the first food they usually eat is<br>$r_e$: "... start their iftar with dates and water ..."<br>$a_e$: Dates | $C_{std}$: Tarikh (calendar date)<br>$C_{ctx}$: Kurma (date fruit) | The word "dates" is ambiguous. Without context, MT2 chooses the calendar sense; with the Malay question and reasoning, it chooses the food sense. |
| **MT1 Error** | $q_t$: 街边有个小摊在做糖人。糖人师傅用勺子舀起熬好的糖稀，在石板上快速勾勒。糖人与泥塑相比，更容易被碰碎的是<br>$q_e$: Which is more likely to be broken, candy figurines or clay figurines?<br>$r_e$: "... clay figurines are more likely to be broken ..."<br>$a_e$: Candy figurines are less likely to be broken. | $C_{std}$: 街头小贩制作的糖果塑像比陶土塑像更容易保持完整。(less likely)<br>$C_{ctx}$: 糖人比泥塑更容易被碰碎。(more likely) | The English translation abstracts the culture-specific item (food made of sugar) into generic "candy figurines." Seeing the original Chinese lets $C_{ctx}$ recover this information and reason correctly. |

Table 1: Standard cascade ($C_{std}$) vs. context-aware cascade ($C_{ctx}$) as described in Figure 1. Errors are shown in red; correct outputs are shown in green. $C_{ctx}$ resolves target-language ambiguity and recovers from upstream translation or reasoning errors using the retained context.

lated translation: it generates the target-language answer while using upstream context for disambiguation and, when necessary, error recovery.

We analyze the usefulness of a context-aware cascade given the task type (open-ended QA, MCQ-style QA, and Math), and resourcedness of the target language. We find that the context-aware cascade shows strong gains for open-ended generation with cultural reasoning as opposed to classification style or exact-answer tasks, allowing small open-source models to considerably bridge the gap with strong proprietary models in these settings. The benefit extends to languages of varying resourcedness. Finally, our ablation study shows that the original user question is the most beneficial context to propagate. Our study provides a simple recommendation for translation cascades with reasoning: in settings requiring grounding and nuance, preserve the user's question until the end of the pipeline.

## 2 Method

Let $q_t$ be the original question in language $t$. A standard cascade system (1) translates $q_t$ to English to get $q_e$ (`MT1`); (2) reasons in English, producing reasoning trace $r_e$; (3) answers in English with $a_e$; and (4) translates the answer to the original language to produce $a_t$ (`MT2`). Our methodology provides a controlled setup to compare the **standard cascade** ($C_{std}$) and the **context-aware cascade** ($C_{ctx}$), which differ only in the information available in the prompt context of the `MT2` module, as shown in Figure 1. Specifically, in $C_{std}$, `MT2` receives only $a_e$, whereas in $C_{ctx}$, `MT2` additionally receives $q_t$, $q_e$, and $r_e$. For multiple-choice and math tasks, where $a_e$ is already language-neutral, $C_{std}$ requires no additional MT2 realization step; $C_{ctx}$ nevertheless applies the context-aware final stage to permit error recovery.

Note that as a consequence, the two systems differ in the role played by the final stage. In $C_{std}$, `MT2` performs answer translation from $a_e$ alone. In $C_{ctx}$, it functions as a second reasoning step: translation remains the primary goal when the upstream answer is correct, while the model may revise the answer when the provided context reveals an upstream translation or reasoning error.

## 3 Experiments

**Models.** We use three backbone models: Llama-3.1-8B-Instruct (Llama Team, AI @ Meta, 2024), Mistral-7B-Instruct-v0.3 (Jiang et al., 2023), and GPT-4o-mini (OpenAI, 2024). All components use greedy decoding ($T$=0). See Appendix A for prompts. We use the same model checkpoint for every role (`MT1`, reasoner, `MT2`), avoiding confounds from mixed-model pipelines.

**Datasets.** We evaluate on ten multilingual benchmarks grouped by output regime:

- **Open-ended QA:** We use `Aya Evaluation Suite` (human-annotated subset) (Singh et al., 2024), `BLEnD` (Myung et al., 2024), `MKQA` (Longpre et al., 2021), and `Global-PIQA-OE`[2] (Chang et al., 2025) to evalu-

[2]While `Global-PIQA` is typically an MCQ dataset, we elicit open-ended responses for questions without providing

| Dataset | $C_{ctx} - C_{std}$ Llama | Mistral | GPT |
|---|---|---|---|
| *Open-ended QA (chrF)* | | | |
| Aya | **+4.70** | +2.28* | +0.87* |
| BLEnD | +2.67 | +0.77 | 0.00* |

Table 3: Language-level win rates (%) for the context-aware cascade ($C_{ctx}$) over the standard cascade ($C_{std}$). Results that are *not* statistically significant with a BH-corrected (Benjamini and Hochberg, 1995) binomial sign test, $p > 0.05$ are marked with *.

ate open-ended generation requiring cultural, commonsense, and factual grounding.

- **Multiple-choice QA:** We evaluate on `Global-MMLU` (Singh et al., 2025), `Global-PIQA`, `MCSQA` (Sakai et al., 2024), and `Belebele` (Bandarkar et al., 2024) as MCQ-style tasks for cultural, factual, and commonsense knowledge and reading comprehension.
- **Math and exact-answer reasoning:** We use `MGSM` (Shi et al., 2023) and `MMath` (Luo et al., 2025) to evaluate exact-answer reasoning.

**Languages and resource levels.** We evaluate on all languages supported by each dataset, totaling 285 languages across all benchmarks, consisting of 94 high-resource languages, 77 mid-resource languages, and 114 low-resource languages.[3] We provide dataset language coverage in Appendix B.

**Evaluation.** For multiple-choice tasks we report **accuracy** after extracting the predicted option with a deterministic parser. For open-ended tasks we report **chrF** (Popović, 2015) against the gold reference after Unicode NFKC normalization and lowercasing. We also evaluate open-ended answer quality on a sampled subset of outputs using GPT-5.4-mini as an LLM judge to verify that differences in chrF are consistent with differences in answer quality. For math tasks we report **exact-match accuracy** on the final numerical answer after stripping units and normalizing decimal separators.

## 4 Results and Discussion

### 4.1 When Does Context Help?

Table 2 summarizes results for all datasets and models, averaged over languages.[4] In general, we see broad improvement: $C_{ctx}$ significantly outperforms $C_{std}$ on 18 of 30 model×dataset settings and is neutral (no significant difference) on 10. We also look at **language wins** for each setting in Table 3, i.e. the fraction of languages per dataset for which $C_{ctx}$ wins over $C_{std}$ (ties excluded from the denominator), and find that $C_{ctx}$ benefits more than half of the languages for Llama and Mistral. We provide absolute scores and per-language breakdowns in Appendix D.

**Tasks with context-sensitive responses benefit from context-aware cascade.** $C_{ctx}$ outperforms $C_{std}$ consistently on tasks requiring cultural grounding, including on open-ended benchmarks like `Aya`

options, and refer to this as "`Global-PIQA-OE`".

[3]These are categorized into resource tiers following Singh et al. (2025) based on the amount of available web data.

[4]We also evaluate the end-to-end approach E2E, where the model solves the task natively in the target language, shown in Appendix D. We find that a cascaded approach wins in most model-dataset settings, confirming previous studies about the relevance of cascaded systems (Liu et al., 2025).

| | Llama-3.1-8B-Instruct | | Mistral-7B-Instruct-v0.3 | |
|---|---|---|---|---|
| **Dataset** | $C_{ctx}$ | gap closed | $C_{ctx}$ | gap closed |
| Aya | 14.26 | **92%** | 11.99 | 46% |
| Global-PIQA-OE | 14.31 | 38% | 14.58 | 32% |
| BLEnD | 12.14 | 34% | 9.05 | 9% |
| MKQA | 14.62 | 10% | 12.09 | 5% |

Table 4: Fraction of the open-model-to-GPT-4o-mini gap closed by the context-aware cascade, on the four open-ended benchmarks. *Gap closed* is $(C_{ctx} - C_{std})/(\text{GPT-4o-mini}_{std} - C_{std})$, the share of the standard-cascade gap from the open model to GPT-4o-mini that the context-aware cascade recovers. On Aya, the most culturally grounded benchmark, Llama with $C_{ctx}$ nearly closes the gap to the larger proprietary model. GPT-4o-mini standard-cascade reference scores: Aya 14.65, BLEnD 17.26, Global-PIQA-OE 18.15, MKQA 26.25 (chrF).

`Evaluation Suite` (e.g., with `Aya` Arabic going from 8.67 → 13.63 chrF), as well as MCQ tasks like `Global-PIQA`. This is intuitive: $C_{ctx}$ is helpful when the target-language answer is likely to require information that may be lost in the English language reasoning, such as language- and culture-specific grounding information. On the other hand, for short, self-contained responses, as in Math, $C_{ctx}$ may match $C_{std}$ or even degrade performance. Including more context may mislead the final answer, and therefore is not trivially beneficial, motivating application only in relevant scenarios.

**Answer quality evaluation supports chrF results.** We use GPT-5.4-mini as an LLM judge on sampled open-ended outputs to test whether chrF improvements reflect genuine improvements in answer quality. Evaluation takes into consideration factuality, relevance, and cultural grounding. We sample 100 open-ended examples—25 from each dataset—with each example evaluated for all three backbone models, yielding 300 pairwise judgments. The sample spans 70 dataset-specific language or locale groups (6 in Aya, 14 in BLEnD, and 25 each in Global-PIQA-OE and MKQA), providing broad multilingual coverage despite its limited size. As shown in Table 5, GPT-5.4-mini prefers $C_{ctx}$ in 36.3% of comparisons, compared with 16.3% for $C_{std}$, while 47.3% are judged as ties. Among non-tied comparisons, $C_{ctx}$ accounts for 69.0% of wins and has more wins than losses in 11 of 12 model–dataset settings. These results provide complementary evidence that the gains observed with chrF reflect improvements in answer quality rather than only greater surface-form overlap. We provide details on evaluation and human validation of the judge in Appendix E.

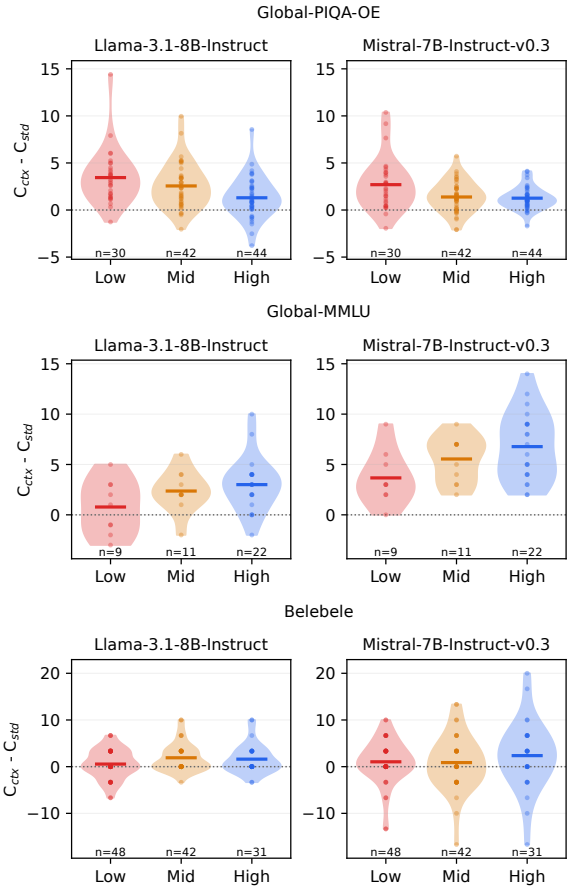

Figure 2: Gains of the context-aware cascade ($C_{ctx}$) over the standard cascade ($C_{std}$) across resource levels on `Global-PIQA-OE`, `Global-MMLU`, and `Belebele` for Llama-3.1-8B-Instruct and Mistral-7B-Instruct-v0.3.

**Benefits are consistent across language resourcedness.** Figure 2 shows gains made by $C_{ctx}$ over $C_{std}$ for each tier of resourcedness for Llama and Mistral over all languages in `Global-PIQA-OE`, `Global-MMLU`, and `Belebele`. We see that $C_{ctx}$ benefits languages in all tiers, indicating that a considerable part of the gains come from lossiness inherent to the structure of the standard cascade.

### 4.2 Weaker backbone models benefit more from context

We find that $C_{ctx}$ benefits smaller models such as Llama and Mistral broadly, but gives fewer benefits for GPT-4o-mini, while still helping for several datasets and languages. In fact, the gap-closing results in Table 4 show that improvements from the context-aware final stage can recover a substantial portion of the performance gap between the open models and GPT-4o-mini. The recovered share is

| Dataset | Llama-3.1-8B-Instruct | Mistral-7B-Instruct-v0.3 | GPT-4o-mini | All models |
|---|---|---|---|---|
| Aya | 48 / 36 / 16 | 36 / 36 / 28 | 32 / 52 / 16 | 38.7 / 41.3 / 20.0 |
| BLEnD | 36 / 52 / 12 | 32 / 60 / 8 | 28 / 68 / 4 | 32.0 / 60.0 / 8.0 |
| Global-PIQA-OE | 44 / 36 / 20 | 24 / 52 / 24 | 48 / 32 / 20 | 38.7 / 40.0 / 21.3 |
| MKQA | 52 / 32 / 16 | 28 / 56 / 16 | 28 / 56 / 16 | 36.0 / 48.0 / 16.0 |
| **Overall** | 45 / 39 / 16 | 30 / 51 / 19 | 34 / 52 / 14 | 36.3 / 47.3 / 16.3 |

Table 5: Cells report $C_{ctx}$ win / tie / $C_{std}$ win percentages in a pairwise semantic evaluation of sampled open-ended outputs using GPT-5.4-mini as an LLM judge. Shade intensity is scaled to the magnitude of the non-tied preference between $C_{ctx}$ and $C_{std}$. Each model–dataset cell contains 25 judgments.

| Model | OK | STRUCT. | ENTITY | EVENT | CULTURAL | HALLUC. |
|---|---|---|---|---|---|---|
| GPT-4o-mini | 65.05 | 20.78 | 0.87 | 7.52 | 1.12 | 4.66 |
| Llama-3.1-8B-Instruct | 40.00 | 23.33 | 2.94 | 16.72 | 1.84 | 15.16 |
| Mistral-7B-Instruct-v0.3 | 26.70 | 16.14 | 4.56 | 19.09 | 2.19 | 31.32 |

Table 6: Distribution over all datasets of GPT-5.4-mini translation-judged error labels (%). STRUCT. denotes structural/formatting error, ENTITY denotes referent/entity substitution, EVENT denotes event/constraint distortion, CULTURAL denotes cultural/local-term mistranslation, and HALLUC. denotes hallucination/over-answering. The most prominent errors across all models are structural/formatting errors, event/constraint distortions, and hallucination/over-answering.

largest on `Aya`, where $C_{ctx}$ closes 92% of the gap for Llama. This may be because $C_{ctx}$ serves as an error recovery mechanism for reasoning or translation flaws in the pipeline. Weaker models may make "unforced" translation or reasoning errors which additional context may mitigate, whereas stronger models are already capable of avoiding such errors. For example, as shown in the Math block in Table 2, Llama still benefits from $C_{ctx}$ on tasks that require minimal language context: $C_{ctx}$ improves over $C_{std}$ by +9.37 points on MGSM and +2.70 points on MMath. This suggests that translation flaws in the pipeline can introduce errors in math tasks and $C_{ctx}$ helps mitigate these errors. The extent of recovery varies considerably across datasets, suggesting that $C_{ctx}$ can address pipeline errors like translation but cannot fully compensate for broader reasoning capability gaps between models.

**Weaker backbone models produce less faithful translations.** We verify this for `MT1` translation via an analysis of translation errors made by the `MT1` modules of our compared systems. Specifically, for each $(q_t, q_e)$ pair, we use GPT-5.4-mini as a judge to determine whether the English text preserves the meaning of the original input. We then develop a translation error taxonomy from a manual inspection of model translations, focusing on recurring failure modes that could change the meaning of the downstream task. More details on how the error taxonomy was developed and human-judge agreement can be found in Appendix F.

- STRUCTURAL/FORMATTING ERROR covers errors such as leaked templates, untranslated source-script text, missing question bodies, repeated options, placeholders, or meta-text.
- REFERENT/ENTITY SUBSTITUTION covers cases where a central person, place, object, or other noun phrase is replaced by an incorrect one.
- EVENT/CONSTRAINT DISTORTION covers cases where the same core referents remain but the action, relation, negation, condition, comparison, or quantity changes.
- CULTURAL/LOCAL-TERM MISTRANSLATION covers cases where a culture-specific term such as a food, festival, institution, clothing item, household item, or local artifact is translated literally or mapped to the wrong referent.
- HALLUCINATION/OVER-ANSWERING covers cases where the model invents content not present in the source, replaces the source with an unrelated question or statement, or answers/explains the task instead of translating it.
- OK indicates that the translation is faithful.

Table 6 reports the resulting label distribution for GPT-4o-mini, Llama-3.1-8B-Instruct, and Mistral-

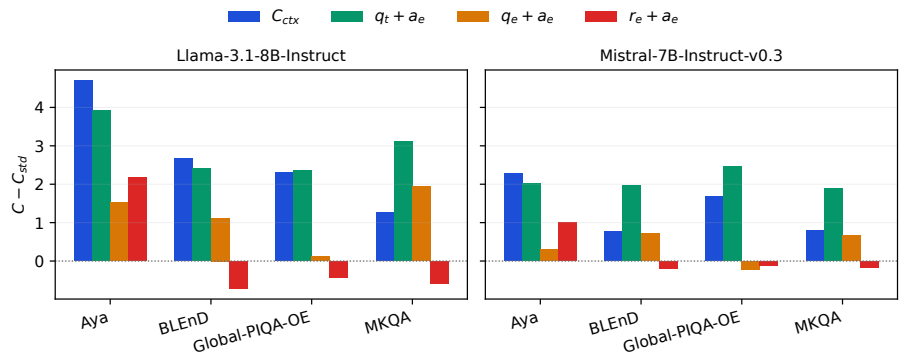

Figure 3: Improvements over $C_{std}$ on open-ended datasets for Llama-3.1-8B-Instruct and Mistral-7B-Instruct-v0.3. Bars show the change in chrF when MT2 is given full context ($C_{ctx}$) or ablated context variants: $q_t + a_e$, $q_e + a_e$, and $r_e + a_e$.

7B-Instruct-v0.3. We find that GPT-4o-mini produces higher-quality translations than the other two models (65% faithful translations versus 40% and 27%), with a considerable proportion of errors related to hallucination across all models. The high rate of translation errors from the weaker backbone models indicates that they have more scope for error recovery from context than stronger models. Thus, for weaker models, better cascade choices serve as a cheap strategy for boosting performance.

### 4.3 Which Context Should Be Retained?

We perform an ablation by individually providing (a) the original question $q_t$, (b) the English question $q_e$, and (c) the reasoning trace $r_e$, alongside the English answer $a_e$, in order to understand which component provides the most benefit. Figure 3 indicates that providing only the original question $q_t$ and English answer $a_e$ is competitive on open-ended tasks: it outperforms $C_{ctx}$ on three of four open-ended datasets with Mistral-7B-Instruct-v0.3 and two of four with Llama-3.1-8B-Instruct. Providing the reasoning trace $r_e$ alongside the English answer $a_e$, on the other hand, yields little improvement and can even degrade performance. Detailed per-dataset ablation results are provided in Appendix G.

## 5 Takeaways

We present two actionable takeaways from our study: (1) Treat the information flow of the cascade as a design factor rather than as fixed preprocessing. (2) Treat the output-side translation stage as a translation-oriented reasoning module rather than isolated translation, and preserve the user's original input until that stage.

## 6 Related Work

Translation cascades match or exceed end-to-end multilingual generation on many tasks (Liu et al., 2025; Bentivogli et al., 2021; Intrator et al., 2024) such as multilingual question answering (Clark et al., 2020), cross-lingual transfer (Ebing and Glavaš, 2024), and mathematical reasoning (Shi et al., 2023), but suffer from error propagation across stages (Zhu et al., 2019; Asai et al., 2021). In end-to-end models, studies show that reasoning failures on non-English inputs arise partly because models cannot bridge between the target language and the English-dominant reasoning language (Kang et al., 2026; Bafna et al., 2025). Liu et al. (2025) show that cascades underperform on culturally-grounded inputs where translating into English discards culture-specific framing. Relatedly, Lee et al. (2026) improve culture-aware multilingual moral reasoning through culture-specific theoretical grounding and native-language reasoning; in contrast, our method preserves cultural information already present in the input throughout the cascade. Prior work also suggests that preserving cross-lingual semantic information can help: translation-following demonstrations improve cross-lingual alignment (Ranaldi et al., 2024), while selective input span translation can improve translation cascades (Paul et al., 2025). These findings motivate structural improvements to the cascade architecture.

## 7 Conclusion

This paper shows that default translate-reason-translate cascades for multilingual reasoning suffer from loss of cultural and language-specific cues and weak translation performance for low-resource

languages. We refashion the final translation step into a translation-oriented reasoning stage and show resulting benefits. Our studies show the value of information flow analysis for cascaded approaches, and we recommend our training-free approach for robustness in multilingual reasoning cascades.

## Limitations

Our study explores a training-free modification to the information flow of the standard cascade. While automatic metrics and our sampled semantic evaluation confirm benefits of the context-aware cascade, our human evaluation is limited to validating the LLM judge on a small subset; we leave larger-scale human evaluation and more detailed qualitative analyses to future work.

We test three models, including two smaller open-source models and one strong proprietary model, and show that our approach largely benefits smaller models in our studied settings. This suggests that cascade design choices matter less for models with stronger native multilingual capabilities, similarly to how cascaded systems themselves grow less relevant in settings where native multilinguality is strong (Bentivogli et al., 2021). We leave it to future work to explore the needs of stronger models.

Finally, we evaluate the cascade as deployed (single pass reasoning with greedy decoding): exploring further decoding strategies is orthogonal to this work. We believe that better information flow design of cascades is a fundamental improvement that would benefit from further exploration discussed above.

## Ethics Statement

Our work is about improving translation cascade design with large language models. We foresee no negative ethical implications of our work beyond general concerns with research in LLMs. We used AI for coding assistance and typo and grammatical error correction.

# A Prompts

We provide prompts for each system ($C_{ctx}$, $C_{std}$, and E2E) and task-type (open-ended QA, multiple-choice QA, and math). For open-ended tasks, $C_{std}$ MT2 receives only the English answer. For multiple-choice and math tasks, whose outputs are already language-neutral option labels or numerical values, $C_{std}$ requires no additional target-language realization step. In $C_{ctx}$, the prompt additionally supplies the original target-language question, the English question, and the English reasoning trace, and explicitly instructs the model to answer in the cultural context of the target language.

## A.1 Open-ended

Figures 4–8 show the prompts used for E2E, `MT1`, English reasoning, and the $C_{std}$ and $C_{ctx}$ `MT2` stages on open-ended tasks.

```
You are an advanced reasoning assistant. You will be provided with a question in {language}.
Your task is to analyze the query step-by-step and provide a direct answer in {language}.

Instructions:
1. Reasoning Process: Before answering, break down the problem logically. Analyze the
constraints, perform necessary calculations, or outline your arguments. Enclose this entire
thought process within <think> tags.
2. Final Output: Provide only the final, concise result in {language} within <answer> tags.

Required Format:
<think> [Detailed step-by-step logic and analysis in {language} goes here] </think>
<answer> [Final answer in {language} goes here] </answer>

Input: {question}
Output:
```

Figure 4: E2E prompt for Open-ended QA.

```
Translate the following question to English: {question}

Required Format:
<translation> [English translation of the question goes here] </translation>

Output:
```

Figure 5: `MT1` prompt for Open-ended QA.

```
You are an advanced reasoning assistant. You will be provided with a question. Your task is
to analyze the query step-by-step and provide a direct answer in English.

Instructions:
1. Reasoning Process: Before answering, break down the problem logically. Analyze the
constraints, perform necessary calculations, or outline your arguments. Enclose this entire
thought process within <think> tags.
2. Final Output: Provide only the final, concise result in English within <answer> tags.

Required Format:
<think> [Detailed step-by-step logic and analysis in English goes here] </think>
<answer> [Final answer in English goes here] </answer>

Input: {question}
Output:
```

Figure 6: LLM prompt for Open-ended QA.

```
You are an advanced translation assistant. You will be provided with a sentence in English.
You need to translate the sentence to {language}.

Required Format:
<answer> [Final answer in {language} goes here] </answer>

Input: {english sentence}
Output:
```

Figure 7: MT2 $C_{std}$ prompt for Open-ended QA.

```
You are an advanced reasoning assistant. You will be provided with a question, the English
question, the English thinking process and answer. You need to answer the question in the
{language}. You need to answer the question in cultural context of the {language}.

Required Format:
<answer> [Final answer in {language} goes here] </answer>

Input:{question}
English Question: {english question}
English Thinking Process: {english thinking process}
English Answer: {english answer}
Output:
```

Figure 8: MT2 $C_{ctx}$ prompt for Open-ended QA.

### A.2 Multiple-choice

Figures 9–12 show the prompts used for E2E, MT1, English reasoning, and the $C_{ctx}$ MT2 stage on multiple-choice tasks. Because the standard-cascade output is already an option label, $C_{std}$ requires no additional target-language realization (MT2) step. We provide the available options (e.g., A, B, C, D) when specifying the answer format; this varies over datasets since datasets may have different numbers of options.

```
You are an advanced reasoning assistant. You will be provided with a multiple-choice question
in {language}. Your task is to analyze each option step-by-step and select the correct answer
in {language}.

Instructions:
1. Reasoning Process: Before answering, break down the problem logically. Evaluate each
option and explain why it is correct or incorrect. Enclose this entire thought process within
<think> tags.
2. Final Output: Provide only the letter of the correct option ({possible answer choice
letters}) within <answer> tags.

Required Format:
<think> [Detailed step-by-step logic and analysis of each option in {language} goes here]
</think>
<answer> [{possible answer choice letters}] </answer>

Input: {question}
{options text}
Output:
```

Figure 9: E2E prompt for Multiple-choice.

```
Translate the following multiple-choice question and all its options to English.

Required Format:
<question_translation> [English translation of the question goes here]
</question_translation>
{options translation format}
```

```
Input: {question}
{options text}
Output:
```

Figure 10: MT1 prompt for Multiple-choice.

```
You are an advanced reasoning assistant. You will be provided with a multiple-choice question.
Your task is to analyze each option step-by-step and select the correct answer in English.

Instructions:
1. Reasoning Process: Before answering, break down the problem logically. Evaluate each
option and explain why it is correct or incorrect. Enclose this entire thought process within
<think> tags.
2. Final Output: Provide only the letter of the correct option ({possible answer choice
letters}) within <answer> tags.

Required Format:
<think> [Detailed step-by-step logic and analysis of each option in English goes here]
</think>
<answer> [{possible answer choice letters}] </answer>

Input: {question}
{options text}
Output:
```

Figure 11: LLM prompt for Multiple-choice.

```
You are an advanced reasoning assistant. You will be provided with a multiple-choice
question, the English question, the English thinking process and answer. You need to select
the correct option for the question. You need to answer the question in the cultural context
of the {language}.

Required Format:
<answer> [{possible answer choice letters}] </answer>

Input: {question}
{options text}
English Question: {english question}
English Thinking Process: {english thinking process}
English Answer: {english answer}
Output:
```

Figure 12: MT2 $C_{ctx}$ prompt for Multiple-choice.

### A.3 Math

Figures 13–16 show the prompts used for E2E, MT1, English reasoning, and the $C_{ctx}$ MT2 stage on math tasks. Since the standard-cascade output is already a numerical value, $C_{std}$ requires no additional target-language realization step. Unlike the open-ended setting, the $C_{ctx}$ prompt does not request cultural grounding. It receives the original problem, its English translation, and the English solution, and produces the final answer in the required format. This setting therefore evaluates whether the retained context can support error recovery even when the output is an exact answer rather than culturally situated text.

```
You are an advanced mathematics reasoning assistant. You will be provided with a math problem
in {language}. Your task is to solve it step-by-step and present the final answer.

Instructions:
1. Reasoning Process: Solve the problem step-by-step in {language}, showing all calculations
and logical deductions. Enclose this entire process within <think> tags.
2. Final Answer: Place only the final answer inside \\boxed{{}} immediately after the closing
</think> tag.
```

```
Required Format:
<think> [Detailed step-by-step solution in {language} goes here] </think> \\boxed{{[Final
answer]}}

Input: {question}
Output:
```

Figure 13: E2E prompt for Math.

```
Translate the following question to English: {question}

Required Format:
<translation> [English translation of the question goes here] </translation>

Output:
```

Figure 14: MT1 prompt for Math.

```
You are an advanced mathematics reasoning assistant. You will be provided with a math problem.
Your task is to solve it step-by-step and present the final answer.

Instructions:
1. Reasoning Process: Solve the problem step-by-step in English, showing all calculations and
logical deductions. Enclose this entire process within <think> tags.
2. Final Answer: Place only the final answer inside \\boxed{{}} immediately after the closing
</think> tag.

Required Format:
<think> [Detailed step-by-step solution in English goes here] </think> \\boxed{{[Final
answer]}}

Input: {question}
Output:
```

Figure 15: LLM prompt for Math.

```
You are an advanced mathematics reasoning assistant. You will be provided with a math problem
in {language}, along with its English translation and full English solution. Present the
final answer in {language}.

Required Format:
<answer> \\boxed{{[Final answer]}} </answer>

Input: {question}
English Question: {english question}
English Thinking Process: {english thinking process}
English Answer: {english answer}
Output:
```

Figure 16: MT2 $C_{ctx}$ prompt for Math.

### A.4 Translation quality

Figure 17 shows the prompt used for our translation quality analysis in Appendix F. It contains descriptions and examples of our error taxonomy.

```
You are a translation quality auditor. You will be given a source-language text and a
candidate translation into English. The input comes in two forms: some items are a question
only; others bundle the answer options into the same sentence as the question. In both cases,
compare the candidate translation against the source and decide whether it contains an error.
Error categories:
```

1. Structural / formatting error
The output is not a clean translation --- it leaks annotation templates, repeats identical translations for distinct options, drops the question body, uses placeholders, outputs meta text, or leaves untranslated source-script text inside the English output.
Source = ``正确翻译（ Cho tam giác ABCABC ABC nội tiếp trên đường tròn $\omega\omega$ $\omega$. ... Tính giá trị $m+nm+n$ m+n. ）: ''
Correct: only the Vietnamese question, translated (no template wrapper).
Error: the stored translation keeps the Chinese annotation template 正 确 翻 译 （…）: wrapped around the text instead of containing only the translated question.
2. Referent / entity substitution
The overall topic changes because a key referent is swapped for a different one. This includes person, team, place, organization, object, instrument, food item, artifact, or other central noun phrase.
Source = ``ラムズはいつスーパーボウルでプレーしましたか''
Correct: ``When did the Rams play in the Super Bowl?''
Error: ``When was the Super Bowl that the Lions played in?'' --- the team Rams is replaced by Lions.
Source = ``He put the flute in a hot room.''
Correct: ``He put the flute in a hot room.''
Error: ``He put the clock in a hot room.'' --- the main object changes from flute to clock.
3. Event / constraint distortion
The same core referents remain, but who-did-what, the key action/relation, negation, condition, comparison, or quantity is changed or dropped.
Source = ``Akeredolu fofin de awọn ọlọkada l'Ondo.''
Correct: ``Akeredolu has given new motorcycles to the riders in Ondo.''
Error: ``Akeredolu appoints new Ondo commissioners'' --- the action ``giving motorcycles'' becomes ``appointing commissioners.''
Source = ``Who was the bridge sold to?''
Correct: ``Who was the bridge sold to?''
Error: ``Who sold the bridge?'' --- the same bridge remains, but the relation changes.
4. Cultural / local-term mistranslation
A culture-specific food, idiom, institution, festival, clothing item, household item, or local artifact is translated literally or mapped to the wrong referent.
Source = ``Um misto quente é um sanduíche feito com pão.''
Correct: `A ``misto quente'' is a sandwich made with bread.'
Error: ``A hot mix is a sandwich made with bread'' --- the Brazilian food term ``misto quente'' (ham-and-cheese toastie) is literally rendered as ``hot mix.''
5. Hallucination / over-answering
The model invents content not in the source, replaces the source with an unrelated question or statement, or solves/explains the task instead of translating it.
Source (a math problem) = ``A group of 7 friends split a bill of $84 equally. How much does each pay?''
Correct: preserves the question.
Error: ``Each person pays $12.'' --- the model answered the problem instead of translating it, producing a number absent from the source.
Source = ``What snack is popular at a local fair?''
Correct: ``What snack is popular at a local fair?''
Error: ``What is the current role of the national parliament?'' --- this invents a different, unrelated question.
Decision order (when more than one category could apply, assign the FIRST that matches):
1 -> The output is not a clean translation: it leaks code / templates / annotations / placeholders, drops the question body, repeats or merges options, outputs meta text like ``unknown question'', OR leaves part of the text untranslated in the source script.
5 -> Otherwise, the model invents content absent from the source, replaces the source with an unrelated question or statement, or answers / solves / explains the task instead of translating it.
2 -> Otherwise, a key referent is swapped for a DIFFERENT one (person / team / place / org / object / instrument / item / topic). A mere spelling / transliteration variant of the SAME referent (e.g. ``Ishikawa'' -> ``Ishekawa'') is NOT category 2 --- that is OK.
4 -> Otherwise, a culture-specific term (food / idiom / institution / festival / clothing / artifact) is mapped to the wrong referent.
3 -> Otherwise, the same core referents remain but an action / relation / quantity / condition / comparison / negation is changed or dropped. Use 3 ONLY as the residual meaning error --- never as a catch-all for messy output (that is 1), unrelated invented content (that is 5), or referent swaps (that are 2).
OK -> none of the above; the translation is faithful.
Mark OK when the meaning is preserved even if the English wording changes. Do NOT mark an error just because:

```
- the translation is a paraphrase rather than literal - a search-query fragment stays a
fragment - a bare name is copied as a bare name - singular/plural, article choice, or
phrasing differences do not change meaning - a close wording variant like ``type'' vs
``kind'' preserves the same meaning
The source may be a full sentence, a question fragment, a title, a search query, or just a
name. Judge meaning fidelity, not grammatical style.
Output format:
Return a single JSON object and nothing else (no preamble, no markdown fences):
json{ ``error type'': ``'' }
Rules:
1. question: the source-language text, copied verbatim. 2. translation: the candidate English
translation, copied verbatim. 3. error type: one of 1, 2, 3, 4, 5, or OK if the translation
is faithful. 4. For items with bundled options, a single dropped or merged option still
counts as category 1. 5. A correct answer value does not make the translation correct; judge
by meaning only. 6. Before deciding, explicitly check these high-risk, easy-to-miss changes
and treat any of them as category 3: - Negation flips: a ``not / no / never'' (or its source-
language equivalent) present on one side but missing on the other (e.g. ``which is NOT a
demand'' -> ``which is a demand''). - Quantity / condition changes: numbers, percentages,
quantifiers (``all / some / at least / only / most''), or time / conditional phrases
(``before / after / if / except'') that differ between source and translation. - Relation
changes: same referents but changed role structure (e.g. ``sold to'' vs ``sold by'', ``caused
by'' vs ``caused''). A fluent, well-formed English sentence can still be wrong this way ---
do NOT mark OK just because the translation reads naturally.
Now evaluate the following item:
question: {question} translation: {translation}
```

Figure 17: Prompt used for analyzing translation errors.

### A.5 Answer quality

Figure 18 shows the prompt used for our pairwise semantic evaluation in Appendix E. It instructs the judge to compare blinded candidate answers based on semantic answer quality and to treat purely stylistic or paraphrastic differences as ties.

```
You are a multilingual semantic answer-quality evaluator. Compare two candidate answers to
the same question. Candidate order is randomized and carries no meaning.

Judge semantic answer quality, prioritizing:
- factual correctness;
- whether the answer addresses the intended question;
- preservation of culturally and linguistically relevant meaning;
- whether either answer introduces a factual error, mistranslation, or inappropriate
interpretation.

Reference answers are evidence, but may be incomplete: a semantically correct alternative
formulation can still be valid. Differences that are only stylistic, grammatical, or
paraphrastic should normally be a tie. Do not prefer an answer merely because it is longer,
more detailed, or has greater surface overlap with a reference. Use TIE when neither answer
has a meaningful semantic advantage.

Return a short reason grounded in the question, reference, and candidates. Do not speculate
about which system produced either candidate.

Question (original target language):
{question}

Reference answer(s), where available:
- {reference_answer_1}
- {reference_answer_2}

Candidate A:
{candidate_a}

Candidate B:
{candidate_b}

Choose A, B, or TIE according to the semantic evaluation criteria.
```

Figure 18: Prompt used for pairwise answer quality evaluation.

## B Languages

Table 7 lists the languages evaluated per dataset with their resource tier assignment. Resource tiers follow Singh et al. (2025): high-resource languages have substantial web presence and strong multilingual model coverage; low-resource languages have limited digital resources.

| Dataset | Total | High | Mid | Low |
|---|---|---|---|---|
| *Open-ended QA* | | | | |
| Aya* | 6 | 4 | 1 | 1 |
| BLEnD* | 14 | 9 | 1 | 4 |
| Global-PIQA-OE* | 116 | 44 | 42 | 30 |
| MKQA | 25 | 19 | 6 | 0 |
| *Multiple-choice QA* | | | | |
| Global-MMLU* | 42 | 22 | 11 | 9 |
| Belebele | 121 | 31 | 42 | 48 |
| Global-PIQA* | 116 | 44 | 42 | 30 |
| MCSQA | 8 | 8 | 0 | 0 |
| *Math* | | | | |
| MGSM | 11 | 7 | 4 | 0 |
| MMath | 10 | 9 | 1 | 0 |

Table 7: Resource-level breakdown by dataset. * denotes culturally grounded datasets.

**Aya Evaluation Suite (human-annotated subset)** (6 languages): Telugu, Yoruba, Arabic, Turkish, Portuguese, Chinese.
**BLEnD** (14 languages): Chinese (Simplified), Spanish (Spain), Spanish (Mexico), Indonesian, Korean (South Korea), Korean (North Korea), Greek, Persian, Arabic (Algeria), Azerbaijani, Javanese, Assamese, Hausa, Amharic.
**MCSQA** (8 languages): Chinese, Dutch, English, French, German, Japanese, Portuguese, Russian.
**MGSM** (11 languages): Chinese, English, French, German, Japanese, Russian, Spanish, Bengali, Swahili, Telugu, Thai.
**MMath** (10 languages): Chinese, English, French, Japanese, Spanish, Arabic, Korean, Portuguese, Thai, Vietnamese.
**MKQA** (25 languages): Arabic, Chinese (Hong Kong, Simplified, Taiwan), Danish, Finnish, French, German, Hebrew, Hungarian, Italian, Japanese, Khmer, Korean, Malay, Norwegian, Dutch, Polish, Portuguese, Russian, Spanish, Swedish, Thai, Turkish, Vietnamese.
Full language lists for Global-MMLU (42), Belebele (121), and Global-PIQA/Global-PIQA-OE (116) are available in the per-language results tables in §D.

## C Experimental details

**Hardware and API costs.** All experiments were run on NVIDIA A100 (80GB) and NVIDIA L40S GPUs. For each model (Llama-3.1-8B-Instruct, Mistral-7B-Instruct-v0.3) and each method (E2E, $C_{std}$, $C_{ctx}$), inference across all datasets took approximately 74 hours. We used the OpenAI API for querying GPT-4o-mini and GPT-5.4-mini. Our experiments cost about 100 USD in total.

**Generation parameters.** For all model components (MT1, reasoner, and MT2), we use the following decoding configuration:

- `max_new_tokens`: 4096
- `batch_size`: 16

These settings are held constant across all backbone models (Llama-3.1-8B-Instruct, Mistral-7B-Instruct-v0.3, and GPT-4o-mini), datasets, and cascade configurations ($C_{std}$, $C_{ctx}$, E2E) to ensure comparability.

## D Detailed results

See our absolute score averages over languages per dataset and model in Table 8, and per-language breakdown per model below.

| | Llama-3.1-8B-Instruct | | | Mistral-7B-Instruct-v0.3 | | | GPT-4o-mini | | |
|---|---|---|---|---|---|---|---|---|---|
| **Dataset** | $C_{std}$ | E2E | $C_{ctx}$ | $C_{std}$ | E2E | $C_{ctx}$ | $C_{std}$ | E2E | $C_{ctx}$ |

## E Answer quality

**Sampling and judging.** Examples are selected independently of chrF scores and cascade performance using deterministic sampling. Within each dataset, language or locale groups and examples within each group are shuffled, followed by round-robin selection across groups to encourage language coverage. The same sampled examples are used across all three backbone models.
We use GPT-5.4-mini as the semantic judge. For each comparison, the judge receives the original target-language question, available reference answer(s), and the two candidate outputs, with model and cascade identities omitted. Candidate order is deterministically randomized and approximately balanced within each model–dataset combination. The judge selects the first candidate, the second candidate, or a tie based on factual correctness, relevance to the intended question, preservation of culturally and linguistically relevant meaning, and factual or translation errors. Purely stylistic or paraphrastic differences are treated as ties. Each judgment also includes a brief justification. Prompt is shown in Figure 18.

**Human validation.** Two human annotators independently evaluate 48 randomly sampled comparisons using the same blinded inputs, labels, and evaluation criteria as the LLM judge. The validation subset is selected independently of the LLM judge's prediction.
Pairwise agreement between the two human annotators is 0.65 Cohen's $\kappa$. Agreement between GPT-5.4-mini and the two human annotators is 0.75 and 0.54 Cohen's $\kappa$, respectively. Three-way agreement among the two human annotators and GPT-5.4-mini is 0.65 Fleiss' $\kappa$. These agreement levels indicate reasonably consistent judgments overall, while also reflecting some annotator variation, and support using the LLM judge for aggregate answer quality evaluation.

## F Translation quality

**Taxonomy development.** We develop the translation error taxonomy through manual inspection of MT1 outputs across datasets and backbone models, focusing on recurring failures that alter information relevant to the downstream task. We group these failures according to the aspect of the source meaning that is changed, yielding the five error categories described in Section 4: structural/formatting error, referent/entity substitution, event/constraint distortion, cultural/local-term mistranslation, and hallucination/over-answering, in addition to the OK label for faithful translations. The resulting definitions and representative examples are incorporated into the judge prompt shown in Figure 17.

**Human validation.** To validate the judge model, two human annotators independently labeled approximately $0.25\%$ of the translated data (across all datasets and models) using the same label definitions. The agreement scores are computed only on this human-audited subset. Pairwise agreement between the two human annotators was $0.72$ Cohen's $\kappa$. Agreement between the judge and the two human annotators was $0.68$ and $0.77$ Cohen's $\kappa$, respectively. The three-way agreement among the two human annotators and the judge was $0.72$ Fleiss' $\kappa$. These agreement scores suggest that the judge's labels are reliable enough for aggregate analysis. After this validation step, we apply the judge to the full translated data.

## H Significance testing

We now assess whether the context-aware cascade ($C_{ctx}$) consistently improves over the standard cascade ($C_{std}$) at the language level. For each model and dataset, we treat languages as the analysis units and perform two paired tests. First, for the earlier win-rate analysis (Table 3), we apply an exact binomial sign test after discarding tied languages, testing whether $C_{ctx}$ or $C_{std}$ beats the other more often than expected under a $50/50$ null. Second, for the magnitude analysis (Table 2), we apply a two-sided Wilcoxon signed rank test (Wilcoxon, 1945) to the per-language differences $C_{ctx} - C_{std}$, testing whether the distribution of language-level gains is shifted above or below $0$.

Because we evaluate multiple datasets per model, we report Benjamini-Hochberg (BH) corrected $p$-values (Benjamini and Hochberg, 1995), with correction applied separately within each model across

Table 41: BH-corrected $p$-values for the Wilcoxon signed-rank test (two-sided) over language-level differences $C_{ctx} - C_{std}$. Green indicates a significant result in the direction $C_{ctx} > C_{std}$, red indicates a significant result in the direction $C_{std} > C_{ctx}$, and uncolored cells are not significant. BH correction is applied separately within each model across the ten datasets, and we use $p \leq 0.05$.

the ten benchmarks. These tests treat languages as approximately independent analysis units, which we acknowledge is a simplifying assumption given genealogical and areal correlations.

Table 41 and Table 42 show that the statistical evidence for improvements from $C_{ctx}$ depends strongly on model strength. For Llama-3.1-8B-Instruct, the effect is highly consistent: 9 of 10 datasets remain positively significant after the BH correction under the Wilcoxon signed-rank test and 8 of 10 under the binomial sign test. Mistral-7B-Instruct-v0.3 is less consistent overall, but still shows broad evidence of improvement: 6 of 10 datasets were positively significant under both tests. By contrast, GPT-4o-mini passes far fewer tests: only 3 of 10 datasets were positively significant under both tests. These patterns are consistent with the discussion in § 4 about stronger improvements from context for weaker models.

## Abstract

Translations generated by Large Language Models (LLMs) often exhibit unnatural stylistic traces distinct from human-written translations, which we refer to as LLM translationese. We propose *MELT*, a training-free post-editing framework for mitigating LLM translationese across five target languages (Korean, Chinese, Japanese, German, and French) without weight updates. MELT defines translationese patterns based on faithfulness, voice, register, naturalness, and surface form, and combines a three-stage verification gate with selective multi-agent debate to preserve meaning and mitigate self-bias. Experiments on FLORES-200 show that verification contributes most to quality improvement and that MELT achieves the lowest calibration error with respect to Oracle preference across the five languages. Our analysis further shows that LLM translationese exhibits language-specific realizations while sharing a common mechanism of English-structure mimicry.

## 1 Introduction

Large Language Models (LLMs) have been widely adopted across natural language processing (NLP) tasks, including machine translation, summarization, and multilingual text generation (Brown et al., 2020; Minaee et al., 2025; Zhu et al., 2025; Qin et al., 2025; Zhao et al., 2026). LLM-generated translations often exhibit unnatural yet fluent stylistic artifacts distinct from human translations, which we refer to as LLM translationese. Despite their fluency, LLM-generated texts often exhibit subtle but measurable stylistic artifacts that distinguish them from naturally authored human text (Li et al., 2025; McGovern et al., 2025). We refer to this unnatural yet fluent style as *translationese* (Toral, 2019; Gellerstam, 1986; Baker, 1993; Volansky et al., 2015; Vanmassenhove et al., 2019). The existence and detectability of translationese have been quantified along multiple axes: including SFT-induced translationese, multilingual lexical and structural naturalness (Guo et al., 2025), PPL-curvature based detection (Mitchell et al., 2023; Hans et al., 2024), and lexical and morphosyntactic fingerprints that persist across models in the same family (McGovern et al., 2025).

| *(a) French: grammatical anglicism* | |
|---|---|
| **Source (En)** | Travellers are strongly advised to be aware of any risk of severe weather affecting their area… |
| **LLM (Fr)** | Les voyageurs sont fortement conseillés de se renseigner sur tout risque de conditions météorologiques sévères affectant leur région… |
| **MELT (Fr)** | Il est recommandé aux voyageurs de se tenir informés des risques de conditions météorologiques sévères dans leur région… |
| *(b) Korean: lexical calque* | |
| **Source (En)** | Several million vials of encephalitis vaccine have also been promised by the government… |
| **LLM (Ko)** | 정부는 내년을 대비하기 위해 여러 백만 개의 뇌염 백신 병을 약속했습니다… |
| **MELT (Ko)** | 정부는 내년을 대비해 수백만 개의 뇌염 백신을 약속했습니다… |

Table 1: *LLM translationese examples.* Each row pair: a single LLM call produces text whose surface looks fluent but whose construction (red) is a direct calque of English grammar / lexicon that the target language does not natively use. MELT edits are shown in blue and result in a more human-like sentence.

Table 1 presents examples of LLM translationese. French (Fr) example, *Les voyageurs sont fortement conseillés ...* appears fluent but closely mirrors the English passive construction "Travellers are strongly advised ...". This use of *conseiller* with the advised entity as the grammatical subject is non-idiomatic in French, revealing

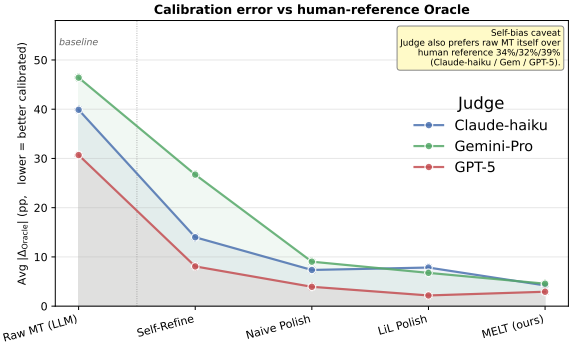

Figure 1: Calibration error of LLM-as-judge evaluation. Average $|\Delta_O|$ scores acorss five languages for each method and judge (lower = closer to human reference). Self-Refine (Madaan et al., 2023), LiL Polish (Li et al., 2025); Naive Polish is a single-prompt baseline.

an English-structured calque. Similarly, the Korean (Ko) phrase "여러 백만 개의 뇌염 백신 병", literally "several million encephalitis vaccine bottles," sounds unnatural in Korean because it mechanically maps "vials" to "병" ("bottles") and "several million" to the non-idiomatic phrase "여러 백만." Together, these examples demonstrate that surface-level fluency does not necessarily indicate target-native naturalness. Figure 1 reports the calibration of translated outputs using LLM against the oracle reference, showing that translationese introduces substantial variation in judge calibration.

Prior studies on mitigating translationese can be divided into two categories: translationese, which refers to unnatural expressions caused by source-language interference, and post-training distortion, which refers to stylistic artifacts induced by post-training processes such as RLHF or instruction tuning. For translationese, Li et al. (2025) analyze literal translation patterns in English-Chinese LLM translation and propose an SFT-based polishing model to reduce them. Guo et al. (2025) quantify English-centric lexical and syntactic transfer in multilingual LLM outputs for Chinese and French, and mitigate this effect with DPO. These studies show that LLMs can transfer English-centric expression patterns into non-English target languages, weakening native patterns of expression in the target language. For post-training distortion, Mitchell et al. (2023) and Hans et al. (2024) detect text generated by LLMs using PPL-curvature and zero-shot likelihood comparison. McGovern et al. (2025) analyze lexical and morphosyntactic fingerprints that persist across models in the same family, showing that each model family can exhibit distinguishable stylistic patterns.

However, several important gaps remain in prior studies. Existing studies have largely centered on high-resource languages, leaving typologically distant languages, such as Korean and Japanese, comparatively underexplored. In addition, most mitigation approaches rely on training-time adaptation, such as SFT or DPO, which requires additional model training and limits practical deployability. More broadly, the field lacks a unified framework for examining cross-lingual manifestations of translationese under a shared taxonomy and consistent evaluation protocol.

To address these challenges, we propose *MELT* (**M**ultilingual **E**diting for **LL**M-ese with **T**raining-free post-editing), and apply it consistently to five target languages, such as Korean, Chinese, Japanese, German, and French, with English as the source language. Figure 2 illustrates the overall architecture of MELT. To examine whether this design is effective for mitigating LLM translationese, we begin by asking the following questions: 1) How does LLM translationese manifest across different target languages? 2) Can inference-time post-editing mitigate translationese while preserving the meaning of the source text? 3) Does an LLM judge reward translationese removal as naturalness, or does it misinterpret it through self-bias?

We detect translationese patterns across five categories: faithfulness, voice, register, naturalness, and surface forms. MELT then performs conditional editing on the detected spans exhibiting translationese patterns, followed by verification of semantic preservation and naturalness through surface-level checks, bidirectional NLI, and LLM-judge-based gating. For categories with a potential risk of self-bias, MELT further applies selective debate between a universal judge and a native judge. If any gate fails, the edited output is safely rolled back to the original translation. This *detect-edit-verify* process applies the same framework to five languages in parallel without updating model weights, enabling cross-lingual comparison, inference-time mitigation, and evaluation reliability analysis within a single pipeline.

Our contributions are summarized as follows:

- We define and analyze a multilingual taxonomy of LLM translationese across five languages using five categories.
- We propose MELT, a plug-and-play post-editing framework, and show that training-

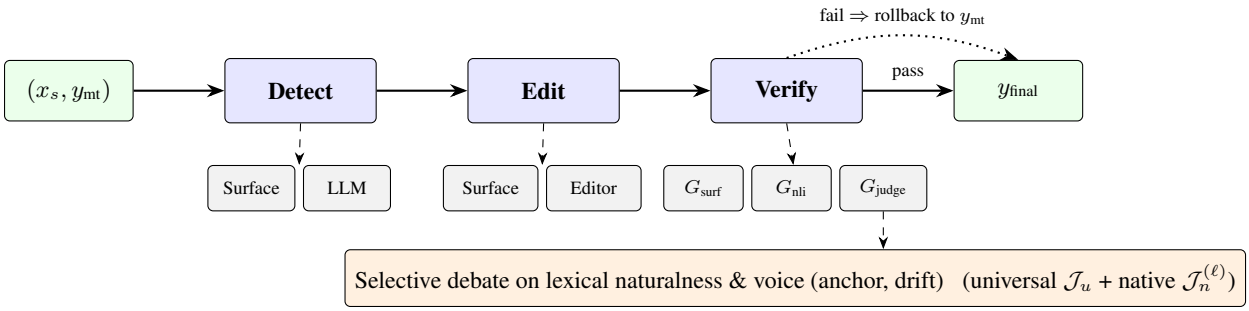

Figure 2: MELT architecture. Given an input pair $(x_s, y_{\text{mt}})$, the final output $y_{\text{final}}$ is produced through detection, editing, verification, and selective debate restricted to self-bias-prone categories.

free editing can mitigate translationese while preserving meaning.

- MELT achieves the best calibration with human reference (Oracle) in terms of prefer-edit rate across five target languages, and better preserves stylometric distribution in recovery scenarios.

## 2 The MELT Model

We propose *MELT*, a translationese post-editing model that operates at inference time without updating model weights. MELT (i) *detects* translationese accumulated in the initial LLM translation, (ii) performs span-conditioned *editing* based on the translationese taxonomy (Section D), and (iii) *verifies* meaning preservation and naturalness through multi-stage verification gates. For categories with a high risk of self-bias, MELT selectively invokes a multi-agent debate between a universal judge and a native judge to obtain judgments that are robust to self-bias.

### 2.1 Preliminary

Given an input pair $(x_s, y_{\text{mt}})$, the final output $y_{\text{final}}$ is produced through our framework. We denote the English source sentence as $x_s$, the initial LLM translation in target language $\ell$ (Korean (Ko), Chinese (Zh), Japanese (Ja), German (De), or French (Fr)) as $y_{\text{mt}}$, and the final output of MELT as $y_{\text{final}}$, defined as follows:

$$\text{MELT} : (x_s, y_{\text{mt}}) \mapsto y_{\text{final}} \tag{1}$$

Translationese manifests in five patterns, namely faithfulness, voice, register, naturalness, and surface form. The meaning of each sentence must be preserved via bidirectional NLI entailment, and naturalness must be improved over the baseline $y_{\text{mt}}$. Any candidate that fails to satisfy either constraint is rolled back, and $y_{\text{mt}}$ is returned as the output.

### 2.2 Detecting Translationese Patterns

Translationese can be divided into deterministic signals from surface form (Wang et al., 2023), such as comma overuse and em-dash frequency, and indeterministic signals from semantic and discourse categories, such as English-style introductory phrases and meta-commentary. The MELT detector performs two detection paths in parallel and integrates the results. A contiguous segment suspected of translationese within the initial translation $y_{\text{mt}}$ is defined as a span $s = (b,\ e,\ c)$. $b$ and $e$ denote character offsets in $y_{\text{mt}}$ ($0 \le b < e \le |y_{\text{mt}}|$), $c$ denotes one of the categories in the translationese taxonomy. The detector produces a set of such spans, which serve as conditioning signals specifying *where and by which category criterion to edit* in the editing stage, and spans belonging to categories with a high risk of self-bias are subject to judgment by the debate gate.

The deterministic detector $\Phi_{\text{surf}}$ measures deviations of lexical markers relative to native corpus statistics, such as comma $z$-score and em-dash frequency, and extracts positions exceeding a threshold as a span set $\mathcal{S}_{\text{surf}}$ for the surface form and quantitative naturalness categories. Here, the $z$-score is the standardized value of marker frequency against the native corpus ($z = (r - \mu_{\mathcal{N}})/\sigma_{\mathcal{N}}$, where $r$ is the marker frequency of the input and $\mathcal{N}$ denotes the native corpus), and a value of $z > \tau_z$ (default 2.0) is flagged as over-use, following common practices in stylometric authorship analysis (Patchala and Bhatnagar, 2018). The prompt-conditioned LLM detector $\Phi_{\text{llm}}$ receives the translationese taxonomy definition as a system prompt and outputs a span set $\mathcal{S}_{\text{llm}}$ for the faithfulness, voice, register, and naturalness categories. The two results are deduplicated using an Intersection over Union (IoU) threshold of $\tau_{\text{IoU}}$=0.5, while spans with different categories

are retained to enable multi-category diagnosis:

$$\mathcal{S} = \mathcal{S}_{\text{surf}} \cup \{\, s \in \mathcal{S}_{\text{llm}} : \text{Keep}(s) \}. \quad (2)$$

Where $\text{Keep}(s)$ denotes the case in which the IoU with any span in $\mathcal{S}_{\text{surf}}$ is below $\tau_{\text{IoU}}$ or the category differs.

### 2.3 Span-Conditioned Editing

Based on the detected spans, MELT performs editing in two stages. First, a surface fixer T is applied to remove surface noise through meaning-preserving deterministic transformations, including Unicode NFC normalization, leading and trailing whitespace removal, and half-width and full-width unification for Zh, and the output is defined as $y' = T(y_{\text{mt}})$. Surface form corrections with potential for meaning change, such as comma and em-dash, are handled in the subsequent stage. The LLM editor then performs span-conditioned generation by injecting the category labels of the detected spans into the prompt:

$$y_e = \mathcal{E}(x_s,\, y',\, \mathcal{S}). \quad (3)$$

The prompt is composed of native instructions in the target language $\ell$ to mitigate prompt-level bias from English-based reasoning, and is provided together with the list of detected spans per category, such as "[naturalness] rewrite English-style passive constructions into active voice".

### 2.4 Verifying Edits

Directly applying the output of the LLM editor may introduce meaning distortion or hallucination. To prevent this, MELT reflects the edited result only when the candidate $y_e$ satisfies all three complementary verification gates. First, the deterministic gate $G_{\text{surf}}$ checks that the change in the metric set $\mathcal{M}$, including comma $z$-score, em-dash frequency, length variance, and epistemic-marker drift, does not deteriorate beyond the allowed range:

$$G_{\text{surf}}(y_e) = \mathbf{1}\big[\, \forall m \in \mathcal{M},\; m(y_e) - m(y_{\text{mt}}) \geq -\tau_{\text{deg}} \,\big]. \quad (4)$$

where $\tau_{\text{deg}}$=0.5 is a threshold set to alleviate excessive rejection observed on a pilot subset. To verify meaning preservation, bidirectional NLI entailment (Maynez et al., 2020) is applied. Forward $p_f$ and backward $p_b$ entailment probabilities are estimated using mDeBERTa-XNLI, and the gate is passed only when the entailment scores in both directions meet or exceed the threshold:

$$G_{\text{nli}}(y_e) = \mathbf{1}\big[\, \min(p_f, p_b) \geq \tau_{\text{nli}}^{(\ell)} \,\big]. \quad (5)$$

Bidirectional verification simultaneously detects omission (where only $p_f$ is high) and hallucination (where only $p_b$ is high), and the threshold is calibrated per language. Finally, the LLM-based universal judge $\mathcal{J}_u$ evaluates factual preservation of the edited output $y_e$:

$$G_{\text{judge}}(y_e) = \mathcal{J}_u\big(x_s, y_{\text{mt}}, y_e\big) \in \{0, 1\}. \quad (6)$$

This stage additionally evaluates factual consistency, register consistency, and discourse naturalness that are difficult to capture through deterministic metrics and NLI-based verification alone.

The edited result is reflected only when all three verification gates return True; otherwise, the original translation $y_{\text{mt}}$ is retained. Here, $\mathcal{G} = \{G_{\text{surf}}, G_{\text{nli}}, G_{\text{judge}}\}$ is as follows:

$$y_{\text{final}}^{(\text{verify})} = \begin{cases} y_e & \text{if } \prod_{g \in \mathcal{G}} g(y_e) = 1, \\ y_{\text{mt}} & \text{otherwise.} \end{cases} \quad (7)$$

### 2.5 Debate on Self-bias-prone Categories

Relying solely on a universal judge is vulnerable to the self-bias problem, in which an LLM tends to regard its own pretraining distribution as *natural expression* (Xu et al., 2024; Chen et al., 2025). This problem does not manifest uniformly across all categories. While surface form errors and faithfulness categories can be complemented by surface metrics and NLI-based verification, categories related to lexical naturalness and voice rely heavily on native-level linguistic intuition, making stable judgment difficult with a universal judge alone. Accordingly, MELT applies an additional debate gate exclusively to categories with a high risk of self-bias. *Voice anchor* refers to stylistic characteristics that should be preserved to maintain the speaker's characteristic voice, such as distinctive lexical choices or sentence patterns, whereas *voice drift* refers to changes that move the output away from these characteristics toward more generic or model-like expression.

$$\mathcal{D}_{\text{sel}} = \{\, \text{lexical naturalness},\; \text{voice anchor},\; \text{voice drift} \,\}. \quad (8)$$

This limits additional inference costs by performing debate only for the categories that require it.

The debate consists of two stages. First, the universal judge $\mathcal{J}_u$ and the native judge $\mathcal{J}_n^{(\ell)}$ each

produce a verdict and a confidence score for the same input. If the verdicts of the two judges agree and the difference in confidence is small, the judgment is finalized. If the two verdicts conflict, a cross-examination stage is performed, in which each judge re-evaluates by referring to the verdict and reasoning of the other judge. Through this process, the universal judge and the native judge mutually compensate for each other's blind spots.

For each category $d \in \mathcal{D}_{\text{sel}}$, the confidences of the two judges are combined using a native priority weight $w_n^{(d)} \in [0, 1]$. The debate gate is passed when the weighted sum of confidences favoring the edit $\hat{c}_d$ meets or exceeds the threshold:

$$G_{\text{debate}}^{(d)}(y_e) = \mathbf{1}\left[\, \hat{c}_d \geq \tau_{\text{debate}} \,\right]. \tag{9}$$

Since lexical naturalness depends on native lexical preference, and voice anchor and voice drift are centered on author-specific register consistency, the weight of the native judge is set relatively higher for these categories.

### 2.6 Final Verification and Decision

The final output of MELT is determined by applying the verification gates (Section 2.4) and the selective debate gates (Section 2.5):

$$y_{\text{final}} = \begin{cases} y_e & \text{if all gates pass,} \\ y_{\text{mt}} & \text{otherwise.} \end{cases} \tag{10}$$

The edited result $y_e$ is reflected only when all verification gates ($G_{\text{surf}}, G_{\text{nli}}, G_{\text{judge}}$) and selective debate gates ($G_{\text{debate}}^{(d)}$, $d \in \mathcal{D}_{\text{sel}}$) return 1; otherwise, the original translation $y_{\text{mt}}$ is retained. Through this process, MELT operates in four stages of detect, edit, verify, and debate without additional model training or weight updates, preventing edited results that fail verification from being reflected in the final output.

## 3 Experiments

### 3.1 Setup

**Datasets** For the multilingual experiments, we use translation tasks based on FLORES-200 (NLLB Team et al., 2022), covering five language pairs with English as the source language and Korean (Ko), Chinese (Zh), Japanese (Ja), German (De), and French (Fr) as target languages. For the monolingual experiments, we evaluate texts generated by back-translating texts written by authors in each language through English using an LLM. See Appendix B for details.
