The sentences are parsed using the Stanford parser,<sup>6</sup> and the values of the features are obtained from the parse trees, using the sizes (in nodes or words) of the siblings and ancestor sub-trees for each analyzed noun. In the sample parse trees on the right side of Figure 2, the first NP ancestor is marked with a red rectangle, and the values of the features are computed

We can distinguish three subsets of features. The first subset includes lexical and positional features: the original noun, automatic baseline translations of both occurrences from the baseline MT system, and the distance between the sentences that contain the two nouns. The second subset includes features that capture the size of the siblings in the parse trees of each of the two nouns. The third subset includes the size of sub-tree for the latest noun phrase ancestor for each analyzed noun, and also the depth distances to the next noun phrase ancestor.

### 4.3 Semantic Features

The semantic features, to be used independently or in combination with the syntactic ones, are divided into two groups: discourse vs. local context features, which differ by the amount of context they take into account. On the one hand, local context features represent the immediate context of each of the nouns in the pair and their translations, i.e. three words to their left and three words to their right in both source and MT output, always within the same sentence.

On the other hand, discourse features capture those cases where the inconsistent translations of a noun might be due to a disambiguation problem of the source noun, and semantic similarity can be leveraged to decide which of the two translations best matches the context. To compute the

discourse features, we use the word2vec word vector representations generated from a large corpus (Mikolov et al., 2013), which have been successfully used in the recent past to compute similarity between words (Schnabel et al., 2015). Specifically, we employ the model trained on the English Google News corpus<sup>7</sup> with about 100 billion words.

For each pair of inconsistent translations ( $T_1$ ,  $T_2$ ) of a source noun  $N$ , we compute the cosine similarities  $c_1$  and  $c_2$  between the vector representation of each translation and the mean vector of their contexts. These mean vectors, noted  $\vec{v}_1$  and  $\vec{v}_2$ , are computed by averaging all vectors of the words in the respective contexts of  $T_1$  and  $T_2$ . Here, the contexts consist of 20 words to the left and 20 words to the right of each  $T_i$ , possibly crossing sentence boundaries. The cosine similarities  $c_1$  and  $c_2$  are thus:

$$c_1 = \cos(\vec{T}_1, \vec{v}_1) = \frac{\vec{T}_1 \cdot \vec{v}_1}{\|\vec{T}_1\| \|\vec{v}_1\|} \quad (1)$$

$$c_2 = \cos(\vec{T}_2, \vec{v}_2) = \frac{\vec{T}_2 \cdot \vec{v}_2}{\|\vec{T}_2\| \|\vec{v}_2\|} \quad (2)$$

The two values  $c_1$  and  $c_2$  are used as features, allowing classifiers to learn that, in principle, higher values indicate a better translation in the sense of its semantic similarity with the context.

In the Example 1 from Figure 1, the German word *Politik* is translated into the English words *policy* and then *politics*. The semantic similarity between the word *politics* and its context ( $c_2$ ) is lower than the similarity between *policy* and its context ( $c_1$ ), which we consider to be an indication that the first occurrence, namely *policy*, has better chances to be the correct translation – which is actually the case in this example.

### 4.4 Integration with the MT System

The classifier outputs a post-editing decision for each pair of repeated nouns: replace  $T_1$  with  $T_2$ , replace  $T_2$  with  $T_1$ , or do nothing. This decision can be directly executed, or it can be combined in a more nuanced fashion with the MT system. Therefore, to modify translations using this decision, we propose and test three approaches for using in in an MT system:

**Post-editing:** directly edit the translations  $T_1$  or  $T_2$  depending on the classifier’s decision.

Class (1, 2, 0)	1

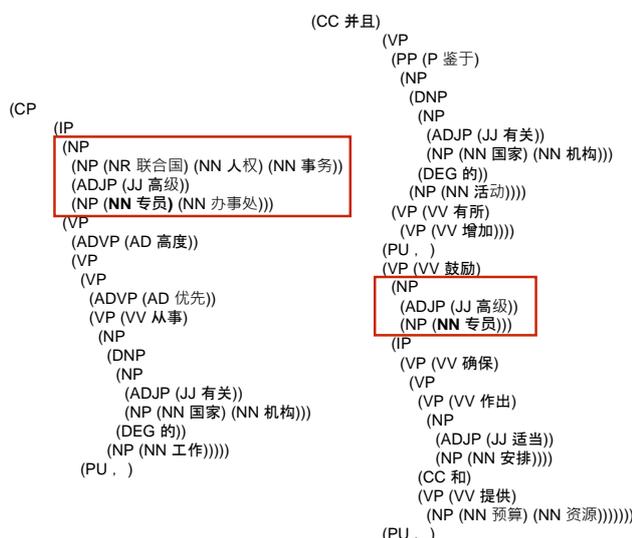

Figure 2: Definition of syntactic features (left) and illustration of their values on a Chinese text (top). The red boxes in the parse trees (right) show the first NP ancestors of the examined nouns.

**Re-ranking:** search among the translation hypotheses provided by the SMT system (in practice, the first 10,000 ones) for those where  $T_1$  and  $T_2$  are translated as predicted by the classifier, and select the highest ranking one as the new translation. If none is found, the baseline 1-best hypothesis is kept.

**Re-ranking + Post-editing:** after applying re-ranking, if no hypothesis conforms to the prediction of the classifier, instead of keeping the baseline translation we post-edit it as in the first approach.

## 5 Results and Analysis

We first present the results of the classification task, i.e. the prediction of the correct translation variant (1<sup>st</sup> / 2<sup>nd</sup> / None), for Chinese-English and German-English translation respectively in Tables 2 and 3, with 10-fold cross-validation on the training sets. Then, we present the scores on the test sets for both the classification task and its

Methods are sorted by average accuracy over the three feature sets. The best scores are in bold.

## 5.1 Best Scores of Classification and MT

The classification accuracy is above 80% when applying 10-fold cross-validation, for both language pairs, and reaches 74–78% on the test sets. As the classes are quite balanced, a random baseline would reach around 33% only. Kappa values reach 0.75 on the dev sets and 0.60–0.67 on the test sets. The performances of the classifiers appear thus to be well above chance, and the comparable performances achieved on the unseen test sets indicate that over-fitting is unlikely.

The ordering of methods by performance is remarkably stable: Decision Trees (J48) and SVMs get the lowest scores, followed by Random Forests, and then by the MaxEnt classifier. The ordering {J48, SVM} < RF < MaxEnt is observed over both language pairs, over the three types of features, and the four datasets, with 1-2 exceptions only. Overall, the best configuration of our method found on the training sets is, for both languages, the MaxEnt classifier with all features.

There is a visible rank correlation between the increase in classification accuracy and the increase in BLEU score, for all languages, features, classifiers, and combination methods with MT. The best configurations found on the training sets bring the following BLEU improvements: for ZH/EN, from 11.07 to 11.36, and for DE/EN, from 17.10 to 17.67. In fact, syntactic features turn out to reach an even higher value on the test set, at 17.75. To interpret these improvements, they should be compared to the oracle BLEU scores obtained by using a “perfect” classifier, which are 11.64 for ZH/EN and 17.99 for DE/EN. Our method thus bridges 51% of the BLEU gap between baseline and oracle on ZH/EN and 64% on DE/EN – a significant improvement.

The BLEU scores of the three different methods for using classification for MT (Tables 4 and 5) clearly show that the combined method outperforms both post-editing and re-ranking alone, for all languages and features. Post-editing, the easiest one to implement, has little consideration for the words surrounding the nouns, while re-ranking works on MT hypotheses and thus ensures that a better global translation is found that is also consistent. However, in some cases, no hypothesis conforms to the consistency decision, and in this case post-editing the best hypothesis appears to be beneficial.

## 5.2 Feature Analysis: Syntax vs. Semantics

On the training sets, syntactic features always outperform the semantic ones when using the Max-

ZH/EN		DE/EN	
Translation of the 2 <sup>nd</sup> occurrence	0.165	Translation of the 1 <sup>st</sup> occurrence	0.162

Table 6: Top ten syntactic features ranked by information gain for each language pair.

Ent classifier, and their joint use outperforms their separate uses. For the other classifiers (not the best ones on the training sets), on ZH/EN, adding semantic features to syntactic ones decreases the performance. Indeed, semantic features (specifically the discourse ones) are intended to disambiguate nouns based on contexts, but here, manual inspection of the data showed that these are similar for  $T_1$  and  $T_2$ , which makes prediction difficult.

Semantic features appear to be more useful in German compared to Chinese. We hypothesize that this is because translation ambiguities of Chinese nouns, i.e. cases when the same noun can be translated into English with two very different words, are less frequent and less semantically divergent than in German. In other words, semantic features are less useful in Chinese because cases of strong polysemy or homonymy seem to be less frequent than in German. Such a characteristic is suggested for English vs. Chinese by Huang (1995), and we believe it extends to German.

These facts might also explain the results obtained when using all features, for German and Chinese. As in Chinese semantic features are less helpful, given also the limited amount of data, combining them with syntactic ones actually decreases the performance of the syntactic ones used independently. In contrast, semantic features are more helpful on German dataset, and also improve results when we considered along with the syntactic ones together.

Table 6 shows the top ten syntactic features for ZH/EN and for DE/EN, ranked by information gain computed using Weka. These features include both lexical information and properties of the parse tree. The analysis shows that lexical features are significantly more important than purely syntactic ones, for both languages. However, the syntactic ones are not negligible.

cosSim.	Inst.	Local Context		Discourse		Both	
		Acc.	$\kappa$	Acc.	$\kappa$	Acc.	$\kappa$
0.0–0.1	141	63.8	0.27	73.8	0.47	66.0	0.31
0.1–0.2	341	70.1	0.40	75.4	0.51	71.0	0.42
0.2–0.3	350	73.1	0.43	68.0	0.35	72.3	0.41
0.3–0.4	350	72.6	0.45	66.0	0.32	68.6	0.37

Table 7: Effects of semantic similarity (cosSim) on classification (10-fold c.-v.). The scores with discourse features increase as similarity between  $T_1$  and  $T_2$  decreases.

Table 7 shows an analysis of the effect of the semantic features on different training sets in terms of accuracy and kappa scores. These training sets are built according to the cosine similarity between  $T_1$  and  $T_2$ , as follows: for each training instance (pair of nouns), we compute the cosine similarity between the vector representation of  $T_1$  and  $T_2$ ; then, we group instances by intervals and carry out 10-fold c.-v. classification experiments for each subset. The lower the range values, the more dissimilar the translation pairs  $T_1$  and  $T_2$ , and the better the scores of discourse features. Specifically, when the translations are dissimilar, the classifier makes better predictions with the discourse features, i.e. considering a larger context. However, the more similar the words are, the better the local context features, i.e. the surrounding words.

### 5.3 Extension to Triples of Repeated Nouns

Finally, we consider briefly the case of nouns that appear more than twice. Using our dataset, we identified them as noun pairs that share the same word, i.e. triples of repeated nouns, to which we limit our investigation. There are 129 ZH/EN triples and 138 DE/EN ones.

We defined the following method to determine the translation of such nouns when their baseline translations are different across the two pairs. If  $T_1$ ,  $T_2$  and  $T_3$  are the translation candidates, we

aim to find the consistent translation  $T_c$  as follows. If two of the  $T_i$  are identical, we use this value as  $T_c$ , but if they all differ, then we compare the syntactic features of the three source occurrences, and select the one with the highest number of features with highest values, and use its value as  $T_c$ . Going back to our classifier, if the decision for a particular instance pair is not ‘none’, then we replace the translations of the instance pairs with  $T_c$ .

We tested the method with the three feature types and the four classifiers, i.e. 12 cases per language. On ZH/EN, a small increase of BLEU is observed in 5 cases (0.01), a decrease in two cases (0.02), and no variation in 5 cases. On DE/EN, half of the cases show a small improvement (up to 0.03) and the rest stay the same. The method appears to work better on DE/EN, possibly because the initial accuracy on pairs is lower, but improvements are overall very small. The main conclusion from experimenting with triples, and considering also longer lexical chains of consistent nouns, is that the pairwise method should be replaced by a different type of consistency predictor, which remains to be found.

## 6 Conclusion and Perspectives

We presented a method for flexibly enforcing consistent translations of repeated nouns, by using a machine learning approach with syntactic and semantic features to decide when it should be enforced. We experimented with Chinese-English and German-English data. To build our datasets, we detected source-side nouns which appeared twice within a fixed distance and were translated differently by MT. Syntactic features were defined based on the complexity of the parse trees containing the nouns, thus capturing which of the two occurrences of a noun is more syntactically bound, while semantic features focused on the similarity between each translated noun and its context. The trained classifiers have shown that they can predict consistent translations above chance, and that, when combined to MT, bridge 50–60% of the gap between the baseline and an oracle classifier.

In future work, we will consider whether neural MT is prone to similar consistency problems, and whether they can be addressed by a similar method. The answer is likely positive, because both PBSMT and NMT assume that consistency simply results from correct individual translations, whereas human translators often take consistency

into account for lexical choice. Moreover, a better consideration of legitimate lexical variation, e.g. using multiple references or human evaluators, should improve the assessment of consistency enforcement strategies.

## Abstract

While previous research on readability has typically focused on document-level measures, recent work in areas such as natural language generation has pointed out the need of sentence-level readability measures. Much of psycholinguistics has focused for many years on processing measures that provide difficulty estimates on a word-by-word basis. However, these psycholinguistic measures have not yet been tested on sentence readability ranking tasks. In this paper, we use four psycholinguistic measures: idea density, surprisal, integration cost, and embedding depth to test whether these features are predictive of readability levels. We find that psycholinguistic features significantly improve performance by up to 3 percentage points over a standard document-level readability metric baseline.

## 1 Introduction

Previous work on readability has classified or ranked texts based on document-level measures such as word length, sentence length, number of different phrasal categories & parse tree depth (Petersen, 2007), and discourse coherence (Graesser et al., 2004), inter alia. However, not all applications that need readability ratings deal with long documents. For many applications in text simplification, computer-aided language learning (CALL) systems, authorship tools, translation, and information retrieval, sentence-level readability metrics are direly needed.

For instance, an automatic text simplification system must begin by asking which portions of a text need to be simplified. To this end, a measure that can assign ratings on a sentence-by-sentence

level can help target simplification only to those sentences which need it most, and such measures also serve to confirm that the resulting ‘simplified’ sentence is in fact simpler than the original sentence.

Similarly, CALL and other pedagogical systems will benefit if it is possible to predict which portions of a text will be harder for students. Authorship tools can offer more specific editorial advice when they know why individual sentences can cause difficulties for readers. Translation tools can aim to preserve not just meaning but also the approximate difficulty of the sentences they are translating or use a sentence-level difficulty metric to target output that is easier to understand. Furthermore, information retrieval systems also benefit when they can return not merely relevant texts, but also texts appropriate to the reading level of the user. Recently there has been an increased interest in sentential models of text difficulty in the automatic text simplification and summarization communities in particular (Vajjala and Meurers, 2014; Macdonald and Siddharthan, 2016).

One area that has produced a lot of research on sentence level processing difficulty is psycholinguistics. Over the past three decades, a number of theories of *human* sentence processing (i.e. reading) have been proposed and validated in a large variety of experimental studies. The most important sentence processing theories have furthermore been implemented based on broad-coverage tools, so that estimates for arbitrary sentences can be generated automatically. For example, eye-tracking studies of reading times on a large corpus of newspaper text have found that measures such as *integration cost* and *surprisal* provide partial explanations for subjects’ reading behavior (Demberg and Keller, 2008).

This paper leverages these implemented measures based on psycholinguistic theories of sen-

tence processing in order to test whether they can help to more accurately score individual sentences with respect to their difficulty. In the process, we evaluate the contributions of the individual features to our models, testing their utility in examining fine-grained distinctions in sentence difficulty. Section 2 reviews the literature on readability in general before we shift to psycholinguistic theories of sentence processing in Section 4. In Section 5 we discuss our methods, including the corpora used, how features were extracted, and the set up for our averaged perceptron models. Section 6 presents our findings which we connect to related work on sentence-level readability models in 3. Finally we offer our conclusions and suggestions for future work in Section 7.

## 2 Readability

Chall's (1958) comprehensive review of readability research in the first half of the 20<sup>th</sup> century divides the early work in readability into "survey and experimental studies" and "quantitative associational studies". Studies of the former category took place during the 1930s and 1940s and included surveys of expert and reader opinion as well as experimental studies which manipulated texts according to one variable at a time in order to determine the effects of those variables on readers. The results of these studies suggest that, once you have managed to control for reader interest in the content of a text, the most important factor with respect to its readability is its 'style', e.g. its "scope of vocabulary and...kinds of sentences" (Gray and Leary, 1935, as quoted in (Chall, 1958)).

Our study belongs to the second class, relating the features of a text to its ordering relative to some other texts. The earliest work in this direction was by L. A. Sherman, who proposed a quantitative analysis of text difficulty based on the number of clauses per sentence, among other features (Sherman, 1893). Where Sherman's pedagogical focus was on literature, Lively & Pressey (1923) focused on vocabulary as a bottleneck in science education. Work in this vein led to the development of a number of readability formulae in the mid-20<sup>th</sup> century<sup>1</sup>, including the familiar Flesch-Kincaid Grade-Level score (Kincaid et al., 1975).

<sup>1</sup>For a comprehensive review of the literature up to 1958, we recommend (Chall, 1958). For a more recent review of the literature, we recommend Chapter 2 of (Vajjala, 2015). For an introduction to some of the major studies from the 20th century, we recommend the self-published (Dubay, 2007).

These formulae typically use a linear combination of average word length and average sentence length, though some also incorporate a vocabulary-diversity term. The simple, two-feature versions of these models are still widely used, and inspired our BASELINE model.

More recently, Petersen (2007) sought to apply familiar natural language processing techniques to the problem of identifying text difficulty for non-native readers. In particular, she used a number of parse-based features which captured, for example, the average number of noun and verb phrases per sentence and the height of the parse tree. Petersen trained SVM classifiers to classify texts as belonging to one of four primary school grade levels based on the Weekly Reader educational newspaper<sup>2</sup>. These document-level models achieved  $F$ -scores in the range of 0.5 to 0.7, compared to the  $F$ -scores between 0.25 and 0.45 achieved by the Flesch-Kincaid Reading Ease score for the same texts.

Recent work has also looked at features related to discourse and working memory constraints. Feng et al. (2009) worked on a model of readability for adults with intellectual disabilities. Considering working memory constraints, they extracted features related to the number of entities mentioned in a document and the 'lexical chains' (Galley and McKeown, 2003) that connected them. They found that their features resulted in a better correlation (Pearson's  $r = -0.352$ ) compared to both Flesch-Kincaid score ( $r = -0.270$ ) and a number of 'basic' linguistic features based on those used by Petersen & Ostendorf (2009) ( $r = -0.283$ ).<sup>3</sup>

Coh-Metrix (Graesser et al., 2004) also includes a number of measures related to discourse coherence, for example. Such features are not suited to the problem of determining the difficulty of sentences in isolation, but they have also been shown to better predict readability for second-language learners compared to 'traditional' readability measures like those described above (Crossley et al., 2011).

<sup>2</sup><http://www.weeklyreader.com>

<sup>3</sup>Correlations here are negative because Feng et al. correlated predicted reading levels with the performance of adults with intellectual disabilities on comprehension tests. The adults with disabilities are expected to perform worse on the comprehension test as the grade level of the text increases.

### 3 Measuring Sentence Complexity

**Classification** Few studies to date have addressed sentence-level readability for English. Napoles & Dredze (2010) built their own corpus with documents from English and Simple English Wikipedia to train both document- and sentence-level classifiers. Using bag-of-words features, unigram and bigram part-of-speech features, type-token ratio, the proportion of words appearing on a list of easier words, and parse features similar to Petersen's, their binary classifier achieved an accuracy of 80.8% on this task. The structure of this task, however, is not suited to text simplification applications, because the sentences are not controlled for meaning. Classifying a sentence in isolation as more likely to be from Simple Wikipedia or English Wikipedia is not as useful as a model trained to differentiate sentences carrying the same meaning. This work is not directly comparable to that of Vajjala & Meurers (2012; 2014) or subsequent work on ranking sentences by their complexity due to the differences in choice of corpora and task structure.

In the medical domain, Kauchak et al. (2014) also looked at sentence-level classification, identifying sentences as being either simple or difficult. Their features included word length, sentences length, part-of-speech counts, average unigram frequencies and standard deviation, and the proportion of words not on a list of the five thousand most frequent words as well as three domain-specific features based on an ontology of medical terminology.

**Ranking** Vajjala & Meurers (Vajjala and Meurers, 2014; Vajjala, 2015) were the first to look at *ranking* sentences rather than classifying them, having observed that the distributions of predicted reading levels across the two subcorpora of the Parallel Wikipedia corpus (Zhu et al., 2010, PWKP) were different. While the Simple English portion of the corpus was clearly skewed toward the lower grade levels, it appears that the English portion of the corpus was evenly distributed across all grade levels, making binary-classification difficult.

This led Vajjala & Meurers to develop a ranking model using the predicted reading levels from a multiclass classifier trained on whole documents. For each sentence pair, they assumed that the English Wikipedia sentence should be classified at a higher level than the Simple English

Wikipedia sentence. Using a hard cut-off (i.e.  $rank(sent_{english}) > rank(sent_{simple})$ ), their model achieved about 59% accuracy, although this improved to 70% by relaxing the inequality constraint to include equality. Based on the finding that 30% of sentence pairs from the PWKP corpus are incorrectly ranked despite lying within one reading level of each other, we hypothesize that finer-grained distinctions may be necessary to tease apart the differences in related pairs of sentences.

**Offline Psycholinguistic Features** While Vajjala & Meurers (2012; 2014) do use some psycholinguistically-motivated features, their features are primarily lexical in nature and therefore complementary to ours, which depend on the sentence processing context. They drew psycholinguistic features from the MRC psycholinguistic database (Wilson, 1988), including word familiarity, concreteness, imageability, meaningfulness, and age of acquisition. These features were coupled with a second age of acquisition database and values related to the average number of senses per word.

**Towards online considerations** More recently, Ambati et al. (2016) used an incremental parser to extend Vajjala & Meurers work. Since human processing is incremental, they reasoned, features from an incremental parser might be more informative than features extracted from a non-incremental parser. To this end, they used the incremental derivations from a combinatorial grammar (CCG) parser. Ambati et al. ran several models on the English and Simple English Wikipedia data set (Hwang et al., 2015, ESEW): one using only the syntactic features from (Vajjala and Meurers, 2014); another (INCCCG) using only features from the incremental parser; and INCCCG+, incorporating morpho-syntactic and psycholinguistic features from (Vajjala and Meurers, 2014). At the sentence level, they include sentence length, number of CCG constituents in the final parse, and the depth of the CCG derivation. They also use count features for the number of times each CCG derivation rule is applied (e.g. forward application, type-raising). Finally, they include counts of different CCG syntactic categories as well as the average 'complexity' of the syntactic categories. While the parser they use is inspired by human behavior, in that it is an incremental parser, these features do not re-

late to any specific linguistic theory of sentence processing.

The work presented here is most comparable to that of Vajjala & Meurers and Ambati et al., as we all address the problem of ranking sentences according to their linguistic complexity. Our study is the only one of the three to examine features based on theories of online sentence processing. Ambati et al. (2016) provide accuracy information for their own features as well as Vajjala & Meurers' (2014) features on the English and Simple English Wikipedia corpus (ESEW) which we use, but used a 60-20-20 training-dev-test split where we used 10-fold cross-validation, making the results not directly comparable.

#### 4 Theories of Online Sentence Processing

For our purposes, we focus on readability as reading ease and on linguistic constraints in particular, rather than constraints of medium (relating to e.g. legibility), reader interest, or comprehensibility. Without directly modeling comprehensibility, we assume that making material easier to read will also make it easier to comprehend. Here we focus on four psycholinguistic theories of human sentence processing: idea density, surprisal, integration cost, and embedding depth.

Kintsch (1972) defined **propositional idea density** as the ratio of propositions or ideas to words in the sentences.<sup>4</sup> Keenan & Kintsch conducted two different experiments in order to examine free reading behavior as well as subjects' performance in speeded reading conditions. They found that "the number of propositions [in a text] had a large effect upon reading times, [but] it could only account for 21% of their variance" when subjects were allowed to read freely. Subjects' overall recall was worse for more dense texts in the speeded reading condition. In addition to effects of idea density, they found that propositions which were presented as surface-form modifiers (as opposed to, e.g., main verbs) were "very poorly recalled" and that propositions playing a subordinate role relative to another proposition were also less-well recalled. Finally, propositions involving a proper name were generally recalled better than similar propositions involving, e.g., a common noun.

While Kintsch & Keenan (1973) looked at the

<sup>4</sup> This notion of idea density is closely related to Perfetti's (1969) notion of *lexical density* insofar as both are related to the number of so-called *content words* in the text.

influence of propositional idea density on reading times and recall for both individual sentences as well as short paragraphs, work since the 1970s has been limited to the level of multiple sentences and used primarily as an indicator of cognitive deficits (Ferguson et al., 2014; Bryant et al., 2013; Farias et al., 2012; Riley et al., 2005). This paper returns to the examination of idea density's applicability for individual sentences.

Surprisal, on the other hand, has been widely examined in theories of language comprehension at a variety of levels, including the word- and sentence-levels. **Surprisal** is another word for Shannon (1948) information, operationalized in linguistics as the probability of the current word conditioned on the preceding sequence of words:

$$\text{surprisal}(w_n) = -\log(P(w_n|w_1 \dots w_{n-1})) \quad (1)$$

where  $w_i$  is the  $i^{\text{th}}$  word in the sentence and  $P(w_1 \dots w_i)$  denotes the probability of the sequence of  $i$  words  $w_1 \dots w_i$ .

One reason psycholinguists consider surprisal as a factor in sentence processing difficulty is that it makes sense in a model of language users as rational learners. Levy (2008) argues the rational reader's attention must be spread across all possible analyses for the sentence being observed. Based on prior experience, the reader expects some analyses to be more probable than others and therefore allocates more resources to those analyses. In this analysis, surprisal is derived as a measure of the cost paid when the reader misallocates resources: when a new word invalidates a highly probable analysis, the reader has effectively 'wasted' whatever resources were allocated to that analysis. The notion of surprisal is also used in theories of language production, see the Uniform Information Density hypothesis (Jaeger, 2006; Levy and Jaeger, 2007; Jaeger, 2010, UID).

While surprisal focuses on predictability effects in sentence processing, Gibson's (1998; 2000) **Dependency Locality Theory** (DLT) focuses on the memory cost of recalling referents and integrating new ones into a mental representation. DLT proposes that the the distance between syntactic heads and dependents, measured by the number of intervening discourse referents, approximates the difficulty that the listener or reader will have integrating the two units. This model maintains that the act of creating a new discourse referent and holding it in memory makes it more difficult to recall

a previous discourse referent and connect that discourse referent to the current one.<sup>5</sup>

In addition to *integration cost*, DLT proposes a *storage cost* associated with the number of open dependencies that must be maintained in memory. The notion of connected components in van Schijndel et al.'s (2012; 2013) incremental parsing model picks up this idea. Related models were also suggested earlier by Yngve (1960) and Miller's (1956a; 1956b) whose work was based on results showing that human working memory is limited to  $7 \pm 2$  items. Yngve's mechanistic, incremental model of language production considered the evaluation of phrase structure grammars (PSGs) in a system with finite memory, exploring the structure speakers must keep track of during production and how grammars might be structured to avoid overtaxing working memory.

Van Schijndel et al. develop this idea further in the context of a hierarchical sequence model of parsing. In this incremental model of parsing, at each stage the reader has an *active* state (e.g. S for sentence) and an *awaited* state (e.g. VP for verb phrase).<sup>6</sup> At each new word, the parser must decide between continuing to analyze the current connected component or hypothesizing the start of a new one.<sup>7</sup>

These measures provide an idealized representation of the number of different states a human parser must keep track of at any point in time. We refer to this number of states as the **embedding depth** of a sentence at a particular word, and the ModelBlocks parser of van Schijndel et al. (2012) calculates this number of states averaged over the beam of currently plausible parses. Also of interest is the *embedding difference*, which is the embedding depth at the present word relative to the previous word, elaborated upon in the following example.

Consider the state described above (i.e. that of being in the active state S and awaiting state VP) might be reached after a reader has observed a noun phrase, resulting in the state S/VP. This

means that the word sequence observed so far will be consistent with a sentence if the reader now observes a verb phrase. If, however, the next word in the input is inconsistent with the start of a verb phrase (e.g. the relative clause marker *that*), then this parse will be ruled out and another must be considered. At this point the parser must hypothesize the beginning of a new connected component, i.e. a new syntactic substructure that must be completed before continuing to parse the top-level of the sentence. Therefore, the parser must now keep track of two states: (1) the fact that we are still looking for a VP to complete the overall sentence; and (2) the fact that we now have a relative clause to parse before we can complete the current NP. In this example, we are at embedding depth 1 or 0 up until we encounter the word *that*, which increases the embedding depth by 1, resulting in a nonzero embedding difference score.

#### 4.1 Experimental Evidence

We have already explained the experimental findings of Kintsch & Keenan (1973) with respect to idea density, but what behavioral evidence is there to suggest that the remaining theories are valid?

Demberg & Keller (2008) examined the relationship between both surprisal and integration cost and eye-tracking times in the Dundee corpus (Kennedy and Pynte, 2005). Demberg & Keller found that increased surprisal significantly correlated with reading times. Although they found that integration cost did not significantly contribute to predicting eye-tracking reading times in general, its contribution was significant when restricted to nouns and verbs. They also found that surprisal and integration cost were uncorrelated, suggesting that they should be considered complementary factors in a model of reading times. Another eye-tracking study divided surprisal into lexical and syntactic components, finding that lexical surprisal was a significant factor but not syntactic surprisal (Roark et al., 2009).

Wu et al. (2010) examined surprisal, entropy reduction, and embedding depth in a study of psycholinguistic complexity metrics. Their study of the reading times of 23 native English speakers reading four narratives indicated that embedding difference was a significant predictor of reading times for closed class words. Moreover, this contribution was independent of the contribution of surprisal, indicating that the two measures are

<sup>5</sup> Gildea & Temperley (2010) measure dependencies in terms of word span, such that adjacent words have a dependency length of one. This approach produces similar difficulty estimates nouns and verbs, with the caveat that distances are systematically increased, and is defined for all words in a sentence.

<sup>6</sup> In Combinatory Categorical Grammar notation, this state is denoted S/VP.

<sup>7</sup> These connected components are the parsing analogues to the constituents awaiting expansion in Yngve's analysis.

capturing different components of the variance in reading times. Since integration cost was a significant predictor of reading times for nouns and verbs (i.e. not closed class words) and embedding depth was a significant predictor of reading times for closed class words, integration cost and embedding depth should also be complementary to each other.

## 5 Methods

### 5.1 Corpora

We used two corpora in this work. The **English and Simple English Wikipedia** corpus of Hwang et al. (2015, ESEW) is a new corpus of more than 150k sentence pairs designed to address the flaws of the Parallel Wikipedia Corpus of Zhu et al. (2010, PWKP), which was previously dominant in work on text simplification, by using a more sophisticated method of aligning pairs of English and Simple English sentences. We used the section labeled as having ‘good’ alignments for our work and assumed that, in every sentence pair, the Simple English sentence should be ranked as easier than the English sentence ( $rank=1 < rank=2$  in Table 1). This provides a large corpus with noisy labels, as there are likely to be instances where the English and Simple English sentences are not substantially different or the English sentence is the easier one.<sup>8</sup>

For a more controlled corpus, we use Vajjala’s (2015) **One Stop English** (OSE) corpus. This corpus consists of 1577 sentence triples, drawn from news stories edited to three difficulty levels: elementary, intermediate, and advanced. Vajjala used  $TF * IDF$  and cosine similarity scores to align sentences from stories drawn from `onestopenglish.com`. While One Stop English does not publish an explanation of their methods for creating these texts, they are at least created by human editors for pedagogical purposes, so the labels should be more consistent and reliable than those associated with the ESEW corpus.

The three levels of *OSE* make it possible to compare system performance on sentence pairs which are close to one another in difficulty (e.g. ‘advanced’ versus ‘intermediate’ sentences) with

<sup>8</sup>Indeed, 37,095 of the 154,805 sentence pairs have the same sentence for both English and Simple English Wikipedia and were therefore excluded from our experiments.

performance on pairs which are further apart, as with ‘advanced’ sentences paired with their ‘elementary’ counterparts. In this paper we will refer to the pairs of advanced and elementary sentences as  $OSE_{far}$ , the remaining pairs as  $OSE_{near}$ , and the full OSE dataset as  $OSE_{all}$ . An example triple of sentences from the corpus is given in Table 2.

### 5.2 Feature Extraction and Feature Sets

We used two parsers to extract 22 features from the corpora. The `ModelBlocks` parser provided features based on surprisal and embedding depth while the Stanford parser<sup>9</sup> provided the dependency parses used to calculate integration cost and idea density features. Both parsers are trained and perform near the state of the art on the standard sections of the Wall Street Journal section of the Penn Treebank.

From `ModelBlocks`’ complexity feature extraction mode, we took the lexical and syntactic surprisal features. We used the average lexical surprisal and average syntactic surprisal as idealized measures of the channel capacity required to read a sentence. While this underestimates the channel capacity required to process a sentence, it is at least internally consistent, insofar as a sentence with higher average surprisal overall is likely to require a higher channel capacity as well. We also used the maximum of each form of surprisal as a measure of the maximum demand on cognitive resources. These features comprise the `SURPRISAL` model.

We also calculated average and maximum values for the embedding depth and embedding difference output from `ModelBlocks`. The average provides an estimate of the typical memory load throughout a sentence, while the (absolute) embedding difference is a measure of how many times a reader needs to push or pop a connected component to or from their memory store. These features comprise the `EMBEDDING` model.

To extract the remaining features, we first ran the Stanford dependency parser on both corpora. The program `icy-parses` uses part-of-speech tags and head-dependent relations to determine the total, average, and maximum integration cost across a sentence. Here average integration cost functions as another kind of memory load estimate while the maximum value models the most-

Table 2: Example sentences from One Stop English, at levels advanced (3), intermediate (2), and elementary (1). The pair 3–1 is in  $OSE_{far}$ , the pairs 3–2 and 2–1 are in  $OSE_{near}$ , and all three pairs are in  $OSE_{all}$ .

difficult-to-integrate point in the sentence. These features comprise the INTEGRATIONCOST model.

Finally, we use a modified version of the `IDD3` library from Andre Cunha (Cunha et al., 2015) to extract idea density decomposed across three types of propositional idea: predications, modifications, and connections.<sup>10</sup> Here we use only averaged features, as the crucial measure is the idea *density* rather than the raw number of ideas being expressed. These features comprise the IDEADENSITY model.

As a point of comparison for these models, we created a `BASELINE` which used only sentence length and the average word length as features.

We also created models based on features grouped by the parser used to extract them: `SURPRISAL+EMBED` for the `ModelBlocks` parser and `IDEA+INTEGRATION` for the Stanford parser. While `ModelBlocks` achieves competitive accuracies, it is much slower than other state-of-the-art parsers available today. Therefore we wanted to provide a point of comparison regarding the relative utility of these parsers: grouping features by parser allows us to assess the trade-off between model accuracy and the time necessary for feature extraction.

Finally, we considered combinations of the parser-grouped features with the baseline (`BASE+SURPRISAL+EMBED` and `BASE+IDEA+INTEGRATION`) and a

<sup>10</sup>Code available at: <https://github.com/dmhowcroft/idd3>.

`FULLMODEL` using the baseline features and all of the psycholinguistic features.

**Replication** The scripts required for replication are available at <https://github.com/dmhowcroft/eacl2017-replication>. This includes pointers to the corpora, pre-processing scripts and settings for the parsers, as well as scripts for feature extraction and running the averaged perceptron model.

### 5.3 Ranking as Classification

In order to rank sentences, we need some way of generating a complexity score for each sentence. Using a perceptron model allows us to train a simple linear scoring model by converting the ranking task into a classification task.

Suppose we have two sentences  $s_1$  and  $s_2$  with feature vectors  $\mathbf{s}_1$  and  $\mathbf{s}_2$  such that  $s_1$  is more complex than  $s_2$ . Then we want to train a perceptron model such that

$$\text{score}(s_1) > \text{score}(s_2) \quad (2)$$

$$\mathbf{W} \cdot \mathbf{s}_1 > \mathbf{W} \cdot \mathbf{s}_2 \quad (3)$$

$$\mathbf{W} \cdot (\mathbf{s}_1 - \mathbf{s}_2) > 0 \quad (4)$$

We refer to the vector  $\mathbf{s}_1 - \mathbf{s}_2$  as a vector of *difference features*. In order to train the model, we take all pairs of sentences present in a given corpus and create a difference vector as above. In half of the cases, we flip the sign of the difference vector, creating a binary classification task with balanced classes. The learning problem is now to

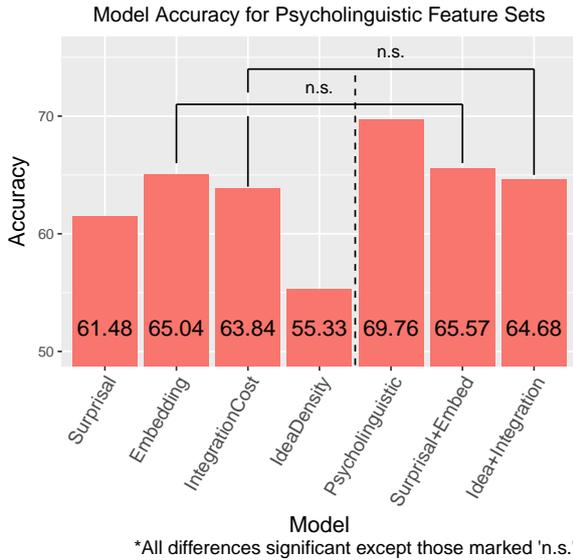

Figure 1: Results on the ESEW corpus for each set of psycholinguistic features individually (first 4 columns) and altogether (5th column), with the feature sets based on the `ModelBlocks` and Stanford parsers in the last two columns.

classify each difference vector based on whether the first term in the difference was the ‘easier’ or the ‘harder’ sentence

Note that the benefit to this approach is that the resulting weight vector  $\mathbf{W}$  learned via the classification task can be used directly to score individual sentences as well, with the expectation that higher scores will correspond to more difficult sentences.

We use an averaged perceptron model (Collins, 2002) implemented in Python as our classifier.

## 6 Analysis & Results

The feature sets for individual psycholinguistic theories only achieve accuracies between 55% and 65% (see the first 4 columns of Fig. 1). Combining all of these features into the `PSYCHOLINGUISTIC` model improves performance to nearly 70% (column 5). Looking at the feature sets grouped by parser (columns 6 and 7), we see that the combination of surprisal and embedding depth (from the `ModelBlocks` parser) significantly outperforms the combination of integration cost and idea density (from the Stanford Parser). However, the strength of the features derived from `ModelBlocks` seems to be primarily driven by the `EMBEDDING` features, while the strength of the dependency-parse-derived features appears to stem from `INTEGRATIONCOST`.

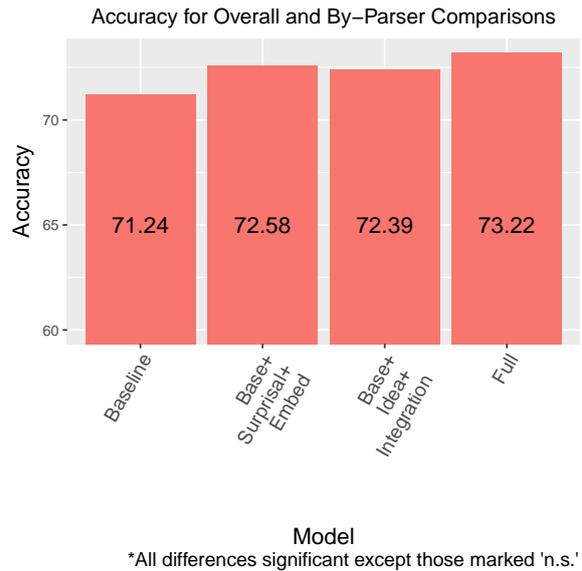

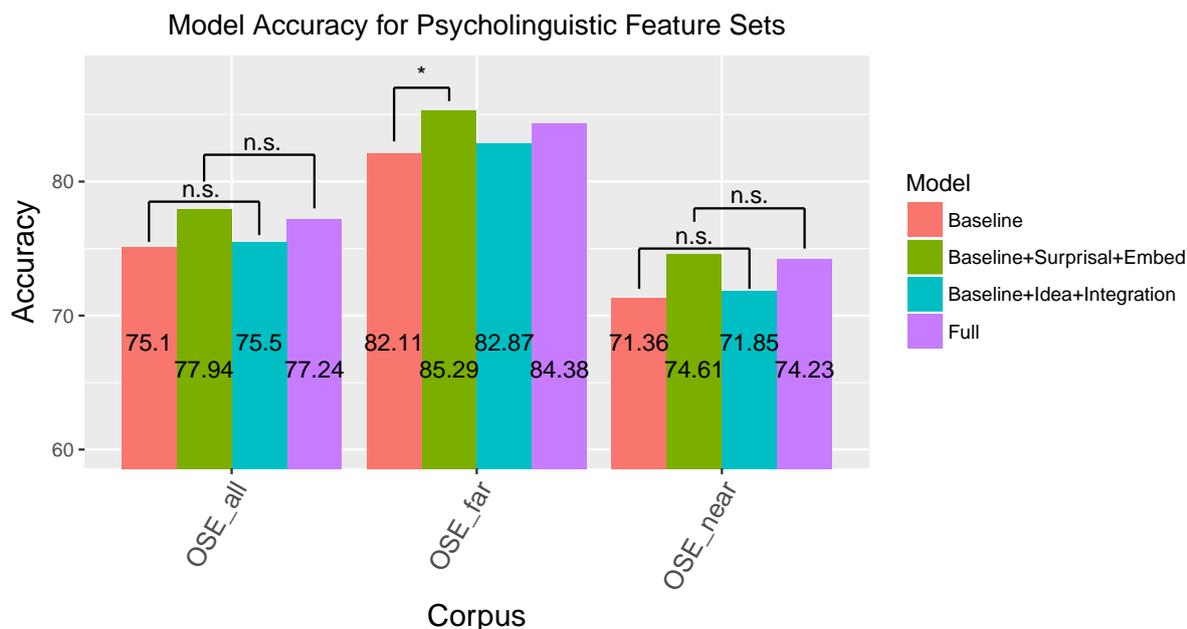

Figure 2: Results for the baseline model, our two parser-grouped feature sets, and the full model on the ESEW corpus.

Moving to Figure 2, we see that our `BASELINE` features achieved an accuracy of 71.24%, despite using only average word length and sentence length. This is 1.48 percentage points higher than the 69.76% accuracy of the `PSYCHOLINGUISTIC` model, which includes surprisal, embedding depth, integration cost, and idea density. However, the `FULL` model (column 4) outperforms the `BASELINE` by a statistically significant<sup>11</sup> 1.98 percentage points ( $p \ll 0.01$ ). This confirms our primary hypothesis: psycholinguistic features based on online sentence processing can improve models of sentence complexity beyond a simple baseline.

To address the secondary hypothesis, we turn to the `OSE` data in Figure 3. The best model for this corpus uses the baseline features combined with embedding depth and surprisal features extracted from `ModelBlocks`. In both  $OSE_{far}$  and  $OSE_{near}$  we gain about 3 points over the baseline when adding these features (3.18 and 3.25 points, respectively), which is similar to the gains for the `FULL` model over the baseline. The fact that the increase in performance between the `BASELINE` model and the best performing model does not differ between the  $OSE_{near}$  and the  $OSE_{far}$  datasets suggests a lack of support for our secondary hypothesis that these features are espe-

<sup>11</sup> Using McNemar’s (1947) test throughout, as is standard for paired samples like ours, with Bonferroni correction where appropriate.

\*All differences significant except those marked 'n.s.'

Figure 3: Results for the baseline model, our two parser-grouped feature sets, and the full model on the OSE corpus, with additional breakdown by level proximity.

cially helpful for distinguishing items of similar difficulty levels.

These results warrant a full comparison to the work of Ambati et al. (2016), despite the differences in our evaluation sets. Ambati et al. found that their features based on incremental CCG derivations achieved an accuracy of 72.12%, while the offline psycholinguistic features of Vajjala & Meurers came in at 74.58%, 1.36 percentage points better than our 73.22%. Finally, a model combining all of Vajjala & Meurers features with the incremental CCG features achieved a performance of 78.87%. Since the features examined in our study are complementary to those proposed by these two previous studies, a model combining all of these features should further improve in accuracy.

## 7 Conclusion

We examined features for the ranking of sentences by their complexity, training linear models on two corpora using features derived from psycholinguistic theories of online sentence processing: idea density, surprisal, integration cost, and embedding depth.

Surprisal coupled with embedding depth and our baseline features (average word length & sentence length) performed as well as the full model

across all subsets of the OSE corpus. Integration cost and idea density were less effective, suggesting that the gain in speed from running a faster dependency parser may not be worth it. Instead, it is necessary to use the slower `ModelBlocks` parser to extract the more useful features.

Overall, our strongest model combined the baseline features and the online psycholinguistic features. Because these features are complementary to features which have been explored in other work (Vajjala and Meurers, 2014; Ambati et al., 2016), the next step in future work is to combine all of these features and conduct a more comparison between the features proposed here and those examined in earlier work. In the meantime, we have demonstrated that features derived from psycholinguistic theories of sentence processing can be used to improve models for ranking sentences by readability.

## Abstract

The cataloging of product listings through taxonomy categorization is a fundamental problem for any e-commerce marketplace, with applications ranging from personalized search recommendations to query understanding. However, manual and rule based approaches to categorization are not scalable. In this paper, we compare several classifiers for categorizing listings in both English and Japanese product catalogs. We show empirically that a combination of words from product titles, *navigational breadcrumbs*, and *list prices*, when available, improves results significantly. We outline a novel method using correspondence topic models and a lightweight manual process to reduce noise from mis-labeled data in the training set. We contrast linear models, gradient boosted trees (GBTs) and convolutional neural networks (CNNs), and show that GBTs and CNNs yield the highest gains in error reduction. Finally, we show GBTs applied in a language-agnostic way on a large-scale Japanese e-commerce dataset have improved taxonomy categorization performance over current state-of-the-art based on deep belief network models.

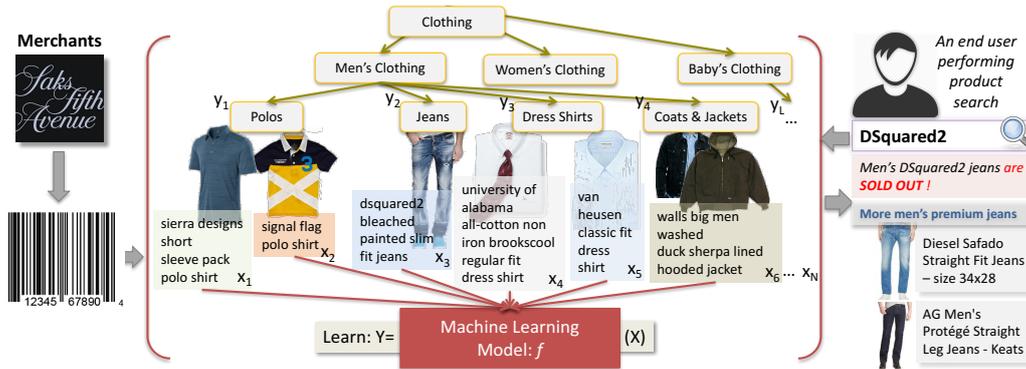

## 1 Introduction

Web-scale e-commerce catalogs are typically exposed to potential buyers using a taxonomy categorization approach where each product is categorized by a label from the taxonomy tree. Most e-commerce search engines use taxonomy labels to optimize query results and match relevant listings to users' preferences (Ganti et al., 2010). To illustrate the general concept, consider Fig. 1. A merchant pushes new men's clothing listings to

an online catalog infrastructure, which then organizes the listings into a taxonomy tree. When a user searches for a denim brand, "*DSquared2*", the search engine first has to understand that the user is searching for items in the "*Jeans*" category. Then, if the specific items cannot be found in the inventory, other relevant items in the "*Jeans*" category are returned in the search results to encourage the user to browse further. However, achieving good product categorization for e-commerce market-places is challenging.

Commercial product taxonomies are organized in tree structures three to ten levels deep, with thousands of leaf nodes (Sun et al., 2014; Shen et al., 2012b; Pyo et al., 2016; McAuley et al., 2015). Unavoidable human errors creep in while uploading data using such large taxonomies, contributing to mis-labeled listing noise in the data set. Even EBay, where merchants have a unified taxonomy, reported a 15% error rate in categorization (Shen et al., 2012b). Furthermore, most e-commerce companies receive millions of new listings per month from hundreds of merchants composed of wildly different formats, descriptions, prices and meta-data for the *same products*. For instance, the two listings, "*University of Alabama all-cotton non iron dress shirt*" and "*U of Alabama 100% cotton no-iron regular fit shirt*" by two merchants refer to the same product.

E-commerce systems trade-off between classifying a listing directly into one of thousands of leaf node categories (Sun et al., 2014; ?) and splitting the taxonomy at predefined depths (Shen et al., 2011; ?) with smaller subtree models. In the latter case, there is another trade-off between the number of hierarchical subtrees and the propagation of error in the prediction cascade. Similar to (Shen et al., 2012b; Cevahir and Murakami, 2016), we classify product listings in two or three steps, depending on the taxonomy size. First, we predict the top-level category and then clas-

**Figure 1:** E-commerce platform using taxonomy categorization to understand query intent, match merchant listings to potential buyers as well as to prevent buyers from navigating away on search misses.

sify the listings using another one or two levels of subtree models selected by the previous predictions. For our large-scale taxonomy categorization experiments on product listings, we use two in-house datasets,<sup>1</sup> a publicly available Amazon product dataset (McAuley et al., 2015), and a publicly available Japanese product dataset.<sup>2</sup>

Our paper makes several contributions: 1) We perform large-scale comparisons with several robust classification methods and show that Gradient Boosted Trees (GBTs) (Friedman, 2000; ?) and Convolutional Neural Networks (CNNs) (LeCun and Bengio, 1995; ?) perform substantially better than state-of-the-art linear models (Section 5). We further provide analysis of their performance with regards to imbalance in our datasets. 2) We demonstrate that using both *listing price* and *navigational breadcrumbs* – the branches that merchants assign to the listings in web pages for navigational purposes – boost categorization performance (Section 5.3). 3) We effectively apply correspondence topic models to detect and remove mis-labeled instances in training data with minimal human intervention (Section 5.4). 4) We empirically demonstrate the effectiveness of GBTs on a large-scale Japanese product dataset over a recently published state-of-the-art method (Cevahir and Murakami, 2016), and in turn the otherwise language-agnostic capabilities of our system given a language-dependent word tokenization method.

## 2 Related Work

The nature of our problem is similar to those reported in (Bekkerman and Gavish, 2011; Shen et al., 2011; Shen et al., 2012b; Yu et al., 2013b; Sun et al., 2014; Kozareva, 2015; ?), but with

<sup>1</sup>The in-house datasets are from Rakuten USA, managed by Rakuten Ichiba, Japan’s largest e-commerce company.

<sup>2</sup>This dataset is from Rakuten Ichiba and is released under Rakuten Data Release program.

more pronounced data quality issues. However, the existing methods for noisy product classification have only been applied to English. Their efficacy for *moraic* and *agglutinative* languages such as Japanese remains unknown.

The work in Sun et al. (2014) emphasizes the use of simple classifiers in combination with large-scale manual efforts to reduce noise and imperfections from categorization outputs. While human intervention is important, we show how unsupervised topic models can substantially reduce such expensive efforts for product listings crawled in the wild. Further, unlike Sun et al. (2014), we adopt stronger baseline systems based on regularized linear models (Hastie et al., 2003; Zhang, 2004; Zou and Hastie, 2005).

A recent work from Pyo et al. (2016) emphasizes the use of recurrent neural networks for taxonomy categorization purposes. Although, they mention that RNNs render unlabeled pre-training of word vectors (Mikolov et al., 2013) unnecessary, in contrast, we show that training word embeddings on the whole set of three product title corpora improves performance for CNN models and opens up the possibility of leveraging other product corpora when available.

Shen et al. (2012b) advocate the use of algorithmic splitting of the taxonomy using graph theoretic latent group discovery to mitigate data imbalance problems at the leaf nodes. They use a combination of k-NN classifiers at the coarser level and SVMs (Cortes and Vapnik, 1995) classifiers at the leaf levels. Their SVMs solve much easier *k*-way multi-class categorization problems where  $k \in \{3, 4, 5\}$  with much less data imbalance. We, however, have found that SVMs do not work well in scenarios where *k* is large and the data is imbalanced. Due to our high-dimensional feature spaces, we avoided k-NN classifiers that can cause

prohibitively long prediction times under arbitrary feature transformations (Manning et al., 2008; Cevahir and Murakami, 2016).

The use of a bi-level classification using k-NN and hierarchical clustering is incorporated in Cevahir and Murakami (2016)’s work, where they use nearest neighbor methods in addition to Deep Belief Networks (DBN) and Deep Auto Encoders (DAE) over both titles and descriptions of the Japanese product listing dataset. We show in Section 5.6, that using a tri-level cascade of GBT classifiers over titles, we significantly outperform the k-NN+DBN classifier on average.

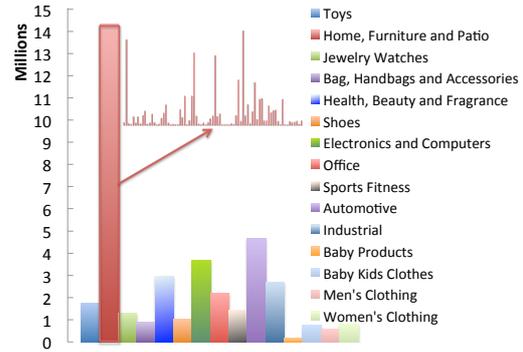

### 3 Dataset Characteristics

We use two in-house datasets, named BU1 and BU2, one publicly available Amazon dataset (AMZ) (McAuley et al., 2015), and a Japanese product listing dataset named RAI (Cevahir and Murakami, 2016) (short for Rakuten Ichiba) for the experiments in this paper.

BU1 is categorized using human annotation efforts and rule-based automated systems. This leads to a high precision training set at the expense of coverage. On the other hand, for BU2, noisy taxonomy labels from external data vendors have been automatically mapped to an in-house taxonomy without any human error correction, resulting in a larger dataset at the cost of precision. BU2 also suffers from inconsistencies in regards to incomplete or malformed product titles and metadata arising out of errors in the web crawlers that vendors use to aggregate new listings. However, for BU2, the noise is distributed identically in the training and test sets, thus evaluation of the classifiers is not impeded by it.

The Japanese RAI dataset consists of 172,480,000 records split across 26,223 leaf nodes. The distribution of product listings in the leaf nodes is based on the popularity of certain product categories and is thus highly imbalanced. For instance, the top level “Sports & Outdoor” category has 2,565 leaf nodes, while the “Travel / Tours / Tickets” category has only 38. The RAI dataset has 35 categories at depth one (level-one categories) and 400 categories at depth two of the full taxonomy tree. The total depth of the tree varies from three to five levels.

The severity of data imbalance for BU2 is shown in Figure 2. The top-level “Home, Furniture and Patio” subtree that accounts for almost half of the BU2 dataset. Table 1 shows dataset

**Figure 2:** Top-level category distribution of 40 million deduplicated listings from an earlier Dec 2015 snapshot of BU2. Each category subtree is also imbalanced, as seen in exploded view of the “Home, Furniture, and Patio” category.

characteristics for the four different kinds of product datasets we use in our analyses. It lists the number of branches for the top-level taxonomy subtrees, the total number of branches ending at leaf nodes for which there are a non-zero number of listings and two important summary statistics that helps quantify the nature of imbalance. We first calculate the Pearson correlation coefficient (PCC) between the number of listings and branches in each of the top-level subtrees for each of the four datasets.

A perfectly balanced tree will have a PCC of 1.0. BU1 shows the most *benign* kind of imbalance with a PCC of 0.643. This confirms that the number of branches in the subtrees correlate well with the volume of listings. Both AMZ and RAI datasets show the highest branching factors in their taxonomies. For the AMZ dataset, it could be

Datasets	Subtrees	Branches	Listings	PCC	KL
BU1	16	1,146	12.1M	0.643	0.872
BU2	15	571	60M	0.209	0.715
AMZ	25	18,188	7.46M	0.269	1.654
RAI	35	26,223	172.5M	0.474	7.887

**Table 1:** Dataset properties on: total number of top-level category subtrees, branches and listings

due to the fact that the crawled taxonomy is different from Amazon’s internal catalog. The Rakuten Ichiba taxonomy has been incrementally adjusted to grow in size over several years by creating new branches to support newer and popular products. We observe that for RAI, AMZ and BU2 in particular, the number of branches in the subtrees do not correlate well with the volume of listings. This indicates a much higher level of imbalance.

We also compute the average Kullback-Leibler

(KL) divergence,  $KL(p(\mathbf{x})|q(\mathbf{x}))$ , (Cover and Thomas, 1991) between the empirical distribution over listings in branches for each subtree rooted in the nodes at depth one,  $p(\mathbf{x})$ , compared to a uniform distribution,  $q(\mathbf{x})$ . Here, the KL divergence acts as a measure of imbalance of the listing distribution and is indicative of the categorization performance that one may obtain on a dataset; high KL divergence leads to poorer categorization and vice-versa (see Section 5).

#### 4 Gradient Boosted Trees and Convolutional Neural Networks

GBTs (Friedman, 2000) optimize a loss functional:  $\mathcal{L} = E_y[L(y, F(\mathbf{x})|\mathbf{X})]$  where  $F(\mathbf{x})$  can be a mathematically difficult to characterize function, such as a decision tree  $f(\mathbf{x})$  over  $\mathbf{X}$ . The optimal value of the function is expressed as  $F^*(\mathbf{x}) = \sum_{m=0}^M f_m(\mathbf{x}, \mathbf{a}, \mathbf{w})$ , where  $f_0(\mathbf{x}, \mathbf{a}, \mathbf{w})$  is the initial guess and  $\{f_m(\mathbf{x}, \mathbf{a}, \mathbf{w})\}_{m=1}^M$  are *additive boosts* on  $\mathbf{x}$  defined by the optimization method. The parameter  $\mathbf{a}_m$  of  $f_m(\mathbf{x}, \mathbf{a}, \mathbf{w})$  denotes split points of predictor variables and  $\mathbf{w}_m$  denotes the boosting weights on the leaf nodes of the decision trees corresponding to the partitioned training set  $\mathbf{X}_j$  for region  $j$ . To compute  $F^*(\mathbf{x})$ , we need to calculate, for each boosting round  $m$ ,

$$\{\mathbf{a}_m, \mathbf{w}_m\} = \arg \min_{\mathbf{a}, \mathbf{w}} \sum_{i=1}^N L(y_i, F_m(\mathbf{x}_i)) \quad (1)$$

with  $F_m(\mathbf{x}) = F_{m-1}(\mathbf{x}) + f_m(\mathbf{x}, \mathbf{a}_m, \mathbf{w}_m)$ . This expression is indicative of a gradient descent step:

$$F_m(\mathbf{x}) = F_{m-1}(\mathbf{x}) + \rho_m (-g_m(\mathbf{x}_i)) \quad (2)$$

where  $\rho_m$  is the step length and  $\left[\frac{\partial L(y, F(\mathbf{x}))}{\partial F(\mathbf{x})}\right]_{F(\mathbf{x}_i)=F_{m-1}(\mathbf{x}_i)} = g_m(\mathbf{x}_i)$  being the search direction. To solve  $\mathbf{a}_m$  and  $\mathbf{w}_m$ , we make the basis functions  $f_m(\mathbf{x}_i; \mathbf{a}, \mathbf{w})$  correlate most to  $-g_m(\mathbf{x}_i)$ , where the gradients are defined over the *training data* distribution. In particular, using Taylor series expansion, we can get closed form solutions for  $\mathbf{a}_m$  and  $\mathbf{w}_m$  – see Chen and Guestrin (2016) for details. It can be shown that  $\mathbf{a}_m = \arg \min_{\mathbf{a}} \sum_{i=1}^N (-g_m(\mathbf{x}_i) - \rho_m f_m(\mathbf{x}_i, \mathbf{a}, \mathbf{w}_m))^2$  and  $\rho_m = \arg \min_{\rho} \sum_{i=1}^N L(y_i, F_{m-1}(\mathbf{x}_i) + \rho f_m(\mathbf{x}_i; \mathbf{a}_m, \mathbf{w}_m))$  which yields,

$$F_m(\mathbf{x}) = F_{m-1}(\mathbf{x}) + \rho_m f_m(\mathbf{x}, \mathbf{a}_m, \mathbf{w}_m) \quad (3)$$

Each boosting round  $m$  updates the weights  $w_{m,j}$  on the leaves and helps create a new tree

in the next iteration. The optimal selection of decision tree parameters is based on optimizing the  $f_m(\mathbf{x}, \mathbf{a}, \mathbf{w})$  using a logistic loss. For GBTs, each decision tree is resistant to imbalance and outliers (Hastie et al., 2003), and  $F(\mathbf{x})$  can approximate arbitrarily complex decision boundaries.

The convolutional neural network we use is based on the CNN architecture described in LeCun and Bengio (1995; Kim (2014) using the TensorFlow framework (Abadi and others, 2015). As in Kim (2014), we enhance the performance of “vanilla” CNNs (Fig. 3 **right**) using word embedding vectors (Mikolov et al., 2013) trained on the product titles from all datasets, without taxonomy labels. Context windows of width  $n$ , corresponding to  $n$ -grams and embedded in a 300 dimensional word embedding space, are convolved with  $L$  filters followed by rectified non-linear unit activation and a max-pooling operation over the set of all windows  $W$ . This operation results in a  $L \times 1$  vector, which is then connected to a softmax output layer of dimension  $K \times 1$ , where  $K$  is the number of classes. Section A lists more details on parameters.

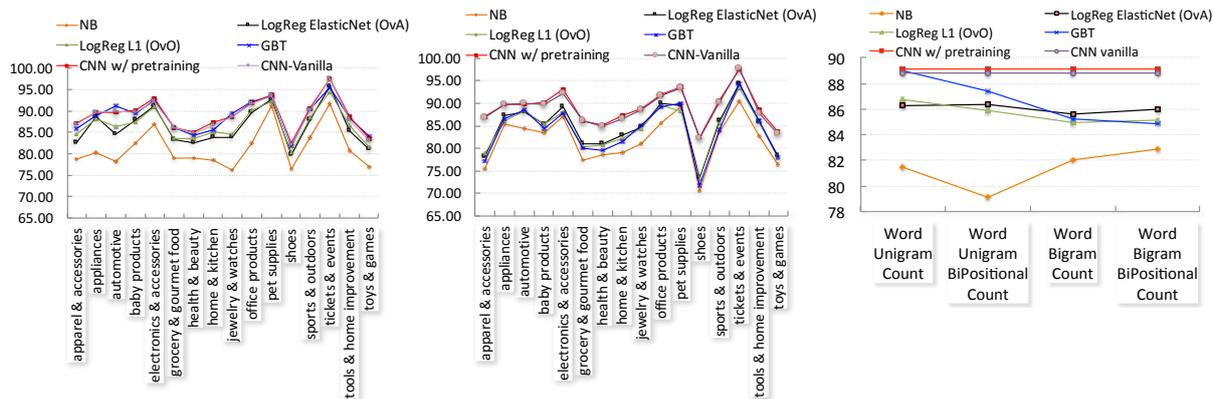

The CNN model tries to allocate as few filters to the context windows while balancing the constraints on the back-propagation of error residuals with regards to cross-entropy loss  $\mathcal{L} = -\sum_{k=1}^K q_k \log p_k$ , where  $p_k$  is the probability of a product title  $\mathbf{x}$  belonging to class  $k$  predicted by our model, and  $q \in \{0, 1\}^K$  is a one-hot vector that represents the true label of title  $\mathbf{x}$ . This results in a higher predictive power for the CNNs, while still matching complex decision boundaries in a smoother fashion than GBTs. We note here that for all models, the predicted probabilities are *not* calibrated (Zadrozny and Elkan, 2002).

## 5 Experimental Setup and Results

We use Naïve Bayes (NB) (Ng and Jordan, 2001) similar to the approach described in Shen et al. (2012a) and Sun et al. (2014), and Logistic Regression (LogReg) classifiers with  $L_1$  (Fan et al., 2008) and Elastic Net regularization, as robust baselines. Parameter setups for the various models and algorithms are mentioned in Section A.

### 5.1 Data Preprocessing

**Product listing datasets in English** – BU1 is exclusively comprised of product titles, hence, our features are primarily extracted from these titles. For AMZ and BU2, we additionally extract the list

**Figure 3:** Classifier performance on BU1 test set. The CNN classifier has only one configuration and thus shows constant curves in all plots. **Left** figure shows prediction on 10% test set using word unigram count features; **middle** figure shows prediction on 10% test set using word bigram bi-positional count features; and the **right** figure shows mean micro-precision over different feature setups except CNNs. In all figures, “OvO” means “One vs. One” and “OvA” means “One vs All”.

price whenever available. For BU2, we also use the leaf node of any available *navigational breadcrumbs*. In order to decrease training and categorization run times, we employ a number of vocabulary filtering methods. Further, English stopwords and rare tokens that appear in 10 listings or less are then filtered out. This reduces vocabulary sizes by up to 50%, without a significant reduction in categorization performance. For CNNs, we replace numbers by the nominal form [NUM] and remove rare tokens. We also remove punctuations and then lowercase the resulting text. Parts of speech (POS) tagging using a generic tagger from Manning et al. (2014) trained on English text produced very noisy features, as is expected for out-of-domain tagging. Consequently, we do not use POS features due to the absence of a suitable training set for listings unlike that in Putthividhya and Hu (2011). For GBTs, we also experiment with title word expansion using nearest neighbors from Word2Vec model (Mikolov et al., 2013), for instance, to group words like “*t-shirts*”, “*tshirt*”, “*t-shirt*” in their respective equivalence classes, however, the overall results have not been better.

**Product listing datasets in Japanese** –CJK languages like Japanese lack white space between words. Hence, the first pre-processing step requires a specific Japanese tokenization tool to properly segment the words in the product titles.

For our experiments, we used the MeCab<sup>3</sup> tokenizer trained using features that are augmented with in-house product keyword dictionaries. Romaji words written using Latin characters are sep-

arated from Kanji and Kana words. All brackets are normalized to square brackets and punctuations from non-numeric tokens are removed. We also use canonical normalization to change the code points of the resulting Japanese text into an NFKC normalized<sup>4</sup> form, then remove anything outside of standard Japanese UTF-8 character ranges. Finally, the resulting text is lowercased.

Due to the size of the RAI dataset taxonomy tree, three groups of models are trained to classify new listings into one of 35 level-one categories, then one of 400 level-two categories, and, finally, the leaf node of the taxonomy tree. We have found this scheme to be working better for the RAI dataset than a bi-level scheme that we adopted for the other English datasets.

Applying GBTs on the Japanese dataset involved a bit more feature engineering. At the tokenized word-level, we use counts of word unigrams and word bi-grams. For character features, the product title is first normalized as discussed above. Consequently, character 2, 3, and 4-grams are extracted with their counts, where extractions include single spaces appearing at the end of word boundaries. Identification of the best set of feature combinations in this case has been performed during cross-validation.

## 5.2 Initial Experiments on BU1 dataset

Our initial experiments use unigram counts and three other features: word bigram counts, bi-positional unigram counts, and bi-positional bigram counts. Consider a title text “*120 gb hdd 5400rpm sata fdb 2 5 mobile*” from the “*Data*

<sup>3</sup><https://sourceforge.net/projects/mecab/>

<sup>4</sup><http://unicode.org/reports/tr15/>

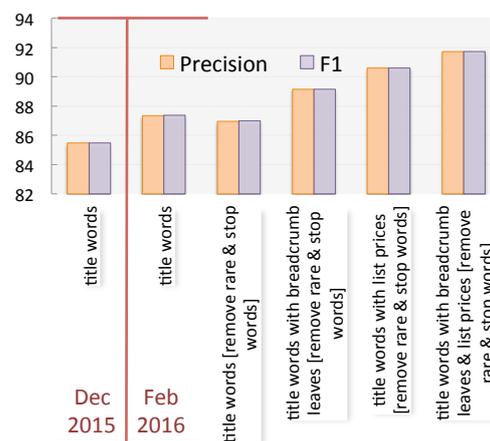

storage” leaf node of the *Electronics* taxonomy subtree and another title text “acer aspire v7 582pg 6421 touchscreen ultrabook 15 6 full hd intel i5 4200u 8gb ram 120 gb hdd ssd nvidia geforce gt 720m” from the “Laptops and notebooks” leaf node. In such cases, we observe that merchants tend to place terms pertaining to storage device specifics in the front of product titles for “Data storage” and similar terms towards the end of the titles for “Laptops”. As such, we split the title length in half and augment word uni/bigrams with a left/right-half position.

This makes sense from a Naïve Bayes point of view, since terms like “120\_gb”[Left\_Half], “gb\_hdd”[Left\_Half], “120\_gb”[Right\_Half] and “gb\_hdd”[Right\_Half] de-correlates the feature space better, which is suitable for the naïve assumption in NB classification. This also helps in slightly better explanation of the class posteriors. These assumptions for NB are validated in the three figures: Fig. 3 **left**, Fig. 3 **middle** and Fig. 3 **right**. Word unigram count features perform strongly for all classifiers except NB, whereas bi-positional word bigram features helped only NB significantly.

Additionally, the micro-precision and F1 scores for CNNs and GBTs are significantly higher compared to other algorithms on word unigrams using paired *t*-test with a *p*-value < 0.0001. The performances of GBTs and LogReg  $L_1$  classifiers deteriorate over the other feature sets as well. The bi-positional and bigram feature sets also do not produce any improvements for the AMZ dataset. Based on these initial results, we focus on word unigrams in all of our subsequent experiments.

### 5.3 Categorization Improvements with Navigational Breadcrumbs and List Prices on BU2 Dataset

BU2 is a challenging dataset in terms of class imbalance and noise and we sought to improve categorization performance using available meta-data. To start, we experiment with a smaller dataset consisting of  $\approx 500,000$  deduplicated listings under the “Women’s Clothing” taxonomy subtree, extracted from our Dec 2015 snapshot of 40 million records. Then we train and test against  $\approx 2.85$  million deduplicated “Women’s Clothing” listings from the Feb 2016 snapshot of BU2. In all experiments, 10% of the data is used as test set. The womens clothing category had been chosen due to the importance of the category from a business

**Figure 4:** Improvements in micro-precision and F1 for GBTs on BU2 dataset for “Women’s Clothing” subtree

standpoint, which provided early access to listings in this category. Further, data distributions remain the same in the two snapshots and the Feb 2016 snapshot consists of listings in addition to those for the Dec 2015 snapshot.

The first noteworthy fact in Fig. 4 is that the micro-precision and F1 of the GBTs substantially improve after increasing the size of the dataset. Further, stop words and rare words filtering decrease precision and F1 by less than 1%, despite halving the feature space. The addition of navigational leaf nodes and list prices prove advantageous, with both features independently boosting performance and raising micro-precision and F1 to over 90%. Despite finding similar gains in categorization performance for other top-level subtrees by using these meta features, we needed a system to filter mis-categorized listings from our training data as well.

### 5.4 Noise Analysis of BU2 Dataset using Correspondence LDA for Text

The BU2 dataset has the noisiest ground-truth labels, as incorrect labels have been assigned to product listings. However, since the manual verification of millions of listings is infeasible, using some proxy for ground truth is a viable alternative that has previously produced encouraging results (Shen et al., 2012b). We next describe how resorting to unsupervised topic models helped to detect and remove incorrect listings.

As shown in Fig. 8, categorization performance for the “Shoes” taxonomy subtree is over 25 points below the “Women’s Clothing” category. Such a large difference could be caused by incorrect assignments of listings to the correct cat-

**Figure 5:** Selection of most probable words under the latent “noise” topics over listings in “*Shoes*” subtree. Human annotators inspect whether such sets of words belong to a Shoes topic or not.

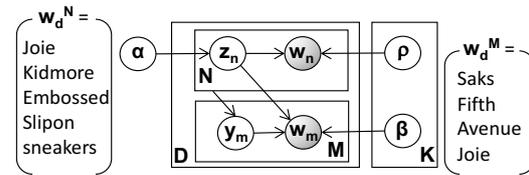

egories. However, unlike Sun et al. (2014), as there are over 3.4 million “*Shoes*” listings in the BU2 dataset, a manual analysis to detect noisy labels is infeasible. To address this problem, we compute  $p(\mathbf{x})$  over latent topics  $z_k$ , and automatically annotate the most probable words over each topic.

We choose our CorrMMLDA model (Das et al., 2011) to discover the latent topical structure of the listings in the “*Shoes*” category because of two reasons. Firstly, the model is a natural choice for our scenario since it is intuitive to assume that store and brand names are distributions over words in titles. This is illustrated in the graphical model in Fig. 7, where the store “*Saks Fifth Avenue*” and the brand “*Joie*” are represented as words  $w_{d,m}$  in the  $M$  plate of listing  $d$  and are distributions over the words in the product title “*Joie kidmore Embossed slipon sneakers*” represented as words  $w_{d,n}$  in the  $N$  plate of the same listing  $d$ . The title words are in turn distributions over the latent topics  $z_d$  for listing  $d \in \{1..D\}$ .

Secondly, the CorrMMLDA model has been shown to exhibit lower held-out perplexities indicative of improved topic quality. The reason behind the lower perplexity stems from the following observations: Using the notation in Das et al. (2011), we denote the free parameters of the variational distributions over words in brand and store names, say  $\lambda_{d,m,n}$ , as multinomials over words in the titles and those over words in the title, say  $\phi_{d,n,k}$ , as multinomials over latent topics  $z_d$ . It is easy to see that the posterior over the topic  $z_{d,k}$  for each  $w_{d,m}$  of brand and store names, is dependent on  $\lambda$  and  $\phi$  through  $\sum_{n=1}^{N_d} \lambda_{d,m,n} \times \phi_{d,n,k}$ . This means that if a certain topic  $z_d = j$  generates all words in the title, i.e.,  $\phi_{d,n,j} > 0$ , then

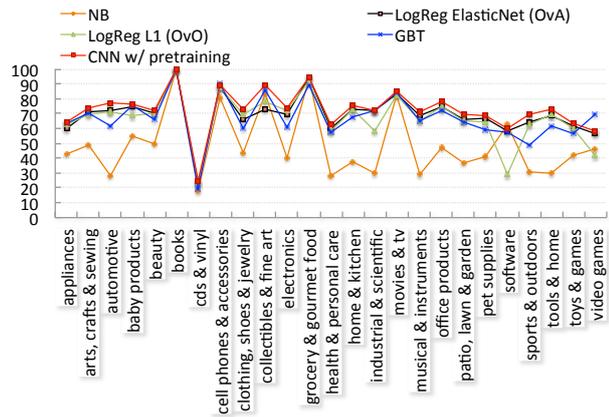

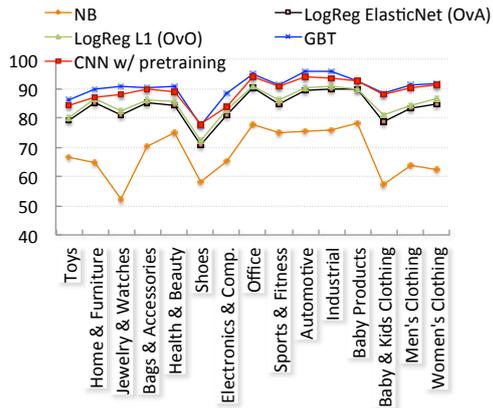

**Figure 7:** Correspondence MMLDA model.

only that topic also generates the brand and store names thereby increasing likelihood of fit and reducing perplexity. The other topics  $z_d \neq j$  do not contribute towards explaining the topical structure of the listing  $d$ .

**Figure 8:** Micro-precision and F1 across fifteen top-level categories on 10% (4 million listings) of Dec 2015 BU2 snapshot.

We train the CorrMMLDA model with  $K=100$  latent topics. A sample of nine latent topics and their most probable words shown in Fig. 5 demonstrates that topics outside of the “*Shoes*” domain can be manually identified, while reducing human annotation efforts from 3.4 million records to one hundred. We choose  $K = 100$  since it is roughly twice the number of branches for the Shoes subtree. This choice provides modeling flexibility while respecting the number of ground

**Figure 9:** Micro-precision on 10% of BU2 across categories (see Sect. 5.4)

**Figure 10:** Micro-precision on 10% of AMZ across categories

Dataset	NB	LogReg ElasticNet	LogReg L1	GBT	CNN w pretraining	Mean KL	$\log(N/B)$
BU1	81.45	86.30	86.75	89.03*	89.12*	0.872	9.27
BU2	68.21	84.29	85.01	90.63*	88.67	0.715	11.54
AMZ	49.01	69.39	66.65	67.17	72.66*	1.654	6.02

**Table 2:** Mean micro-precision on 10% test set from BU1, BU2 and AMZ English datasets

truth classes.

We next run a list of the most probable six words, the average length of a “*Shoes*” listing’s title, from each latent topic through our GBT classifier trained on the full, noisy data, *but without considering any metadata*, due to bag-of-words nature of the topic descriptions. As shown in the bottom two rows in Fig. 6, categories mismatching their topics are manually labeled as ambiguous. As a final validation, we uniformly sampled a hundred listings from each ambiguous topic detected by the model. Manual inspections revealed numerous listings from merchants not selling shoes are wrongly cataloged in the “*Shoes*” subtree due to vendor’s error. To this end, we remove listings corresponding to such “*out-of-category*” merchants from all top-level categories.

Thus, by manually inspecting  $K \times 6$  most probable words from the  $K=100$  topics and  $J \times 100$  listings, where  $J \ll K$ , instead of 3.4 million, a few annotators accomplished in hours what would have taken hundreds of annotators several months according to the estimates in Sun et al. (2014).

## 5.5 Results on BU2 and AMZ Datasets

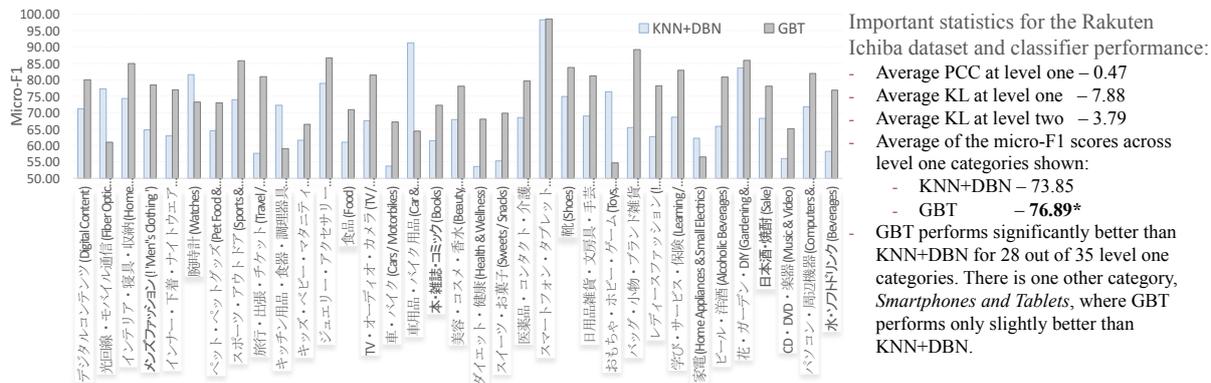

In section 5.2, we have shown the efficacy of word unigram features on the BU1 dataset. Figure 8 shows that LogReg with  $L_1$  regularization (Yu et al., 2013b; Yu et al., 2013a) initially achieves 83% mean micro-precision and F1 on the initial BU2 dataset. This falls short of our expectation of achieving an overall 90% precision (red line in

Fig. 8), but forms a robust baseline for our subsequent experiments with the AMZ and the cleaned BU2 datasets. We additionally use the list price and the navigational breadcrumb leaf nodes for the BU2 dataset and, when available, the list price for the AMZ dataset.

Overall, Naïve Bayes, being an overly simplified generative model, generalizes very poorly on all datasets (see Figs. 3, 9 and 10). A possible option to improve NB’s performance is to use sub-sampling techniques as described in Chawla et al. (2002); however, sub-sampling can have its own problems for when dealing with product datasets (Sun et al., 2014).

From Table 2, we observe that most classifiers tend to perform well when  $\log(N/B)$  is relatively high. The  $N$  in the previous ratio is the total number of listings and  $B$  is the total number of categories. Figures with a \* are statistically better than other non-starred ones in the same row except the last two columns. From Fig. 9 and Table 2, it is clear that GBTs are better on BU2.

We also experiment with CNNs augmented to use meta-data while respecting the convolutional constraints on title text, however, the performance improved only marginally. It is not immediately clear why all the classifiers suffer on the “*CDs and Vinyl*” category, which has more than 500 branches – see Fig. 10. The AMZ dataset also suffers from novel cases of data imbalance. For instance, most of the listings in “*Books*” and “*Gro-*

**Figure 11:** Comparison of GBTs versus the method from Cevahir and Murakami (2016) on a 10% test set from the Rakuten Ichiba Japanese product listing dataset.

cery” are in one branch, with most other branches containing less than 10 listings. In summary, from both Figs. 9 and 10, we observe that GBTs and CNNs with pre-training perform best even in extreme data imbalance. It is possible that GBTs need finer parameter tuning per top-level subtree for datasets resembling AMZ.

## 5.6 Results on Rakuten Ichiba Dataset

In this section, we report our findings on the efficacy of GBTs vis-a-vis another hybrid nearest neighbor and deep learning based method from Cevahir and Murakami (2016). Our decision to employ a tri-level classifier cascade, instead of the bi-level one used for the other datasets, stems from our observations of the KL divergence values (see Section 3 and Table 1) at the first and second level depths of the RAI taxonomy tree. Moving from the first level down to the second decreases the KL divergence by more than 50%. We thus expect GBTs to perform better due to this reduced imbalance. We also cross-validated this assumption on some popular categories, such as “Clothing”.

From Fig. 11 and the statistics noted therein, we observe that, on average, GBTs outperform the KNN+DBN model from Cevahir and Murakami (2016) by 3 percentage points across all top level categories, which is statistically significant under a paired  $t$ -test with  $p < 0.0001$ . As with previous experiments, only a common best parameter configuration has been set for GBTs, without resorting to time consuming cross-validation across all categories. For the 29 categories on which GBTs do better, the mean of the absolute percentage improvement is 11.78, with a standard deviation of 5.07. Also, it has been observed that GBTs **significantly** outperform KNN+DBN in 28 of those categories.

The comparison in Fig. 11 is more holistic. Un-

like the top level categorization scores obtained in Figs. 3, 9 and 10, the scores in Fig. 11 have been obtained by categorizing each test example through the entire cascade of hierarchical models for two classifiers. Even with this setting, the performance of GBTs is significantly better.

## 6 Conclusion

Large-scale taxonomy categorization with noisy and imbalanced data is a challenging task. We demonstrate deep learning and gradient tree boosting models with operational robustness in real industrial settings for e-commerce catalogs with several millions of items. We summarize **our contributions** as follows: 1) We conclude that GBTs and CNNs can be used as new state-of-the-art baselines for product taxonomy categorization problems, **regardless of the language used**; 2) We quantify the nature of imbalance for different product datasets in terms of distributional divergence and correlate that to prediction performance; 3) We also show evidence to suggest that words from product titles, together with leaf nodes from navigational breadcrumbs and list prices, when available, can boost categorization performance significantly on all the product datasets. Finally, 4) we showcase a novel use of topic models with minimal human intervention to clean large amounts of noise particularly when the source of noise cannot be controlled. This is unlike any experiment reported in previous publications on product categorization. Automatic topic labeling for a given category with a pre-trained classifier from another dataset can help create an initial taxonomy over listings for which none exist. A major benefit of this approach is that it reduces manual efforts on initial taxonomy creation.

## A Supplemental Materials: Model Parameters

In this paper, the baseline classifiers comprise of Naïve Bayes (NB) (Ng and Jordan, 2001) similar to the approach described in Shen et al. (2012a) and Sun et al. (2014), and Logistic Regression (LogReg) classifiers with  $L_1$  (Fan et al., 2008) and Elastic Net regularization. The objective functions of both GBTs and CNNs involve  $L_2$  regularizers over the set of parameters. Our development set for parameter tuning is generated by randomly selecting 10% of the listings under the “*apparel / clothing*” categories. The optimized parameters obtained from this scaled-down configuration is then extended to all other classifiers to reduce experimentation time.

For parameter tuning, we set a linear combination of 15%  $L_1$  regularization and 85%  $L_2$  regularization for Elastic Net. For GBTs (Chen and Guestrin, 2016) on both English and Japanese data, we limit each decision tree growth to a maximum depth of 500 and the number of boosting rounds is set to 50. Additionally, for leaf node weights, we use  $L_2$  regularization with a regularization constant of 0.5. For GBTs on English data, the initial learning rate is 0.2. For GBTs on Japanese data, the initial learning rate is assigned a value of 0.05 .

For CNNs, we use context window widths of sizes 1, 3, 4, 5 for four convolution filters, a batch size of 1024 and an embedding dimension of 300. The parameters for the embeddings are non-static. The convolutional filters are initialized with Xavier initialization (Glorot and Bengio, 2010). We use mini-batch stochastic gradient descent with Adam optimizer (Kingma and Ba, 2014) to perform parameter optimization.

LogReg classifiers and CNN need data to be normalized along each dimension, which is not needed for NB and GBT.

# Recognizing Insufficiently Supported Arguments in Argumentative Essays

## Abstract

In this paper, we propose a new task for assessing the quality of natural language arguments. The premises of a well-reasoned argument should provide enough evidence for accepting or rejecting its claim. Although this criterion, known as sufficiency, is widely adopted in argumentation theory, there are no empirical studies on its applicability to real arguments. In this work, we show that human annotators substantially agree on the sufficiency criterion and introduce a novel annotated corpus. Furthermore, we experiment with feature-rich SVMs and convolutional neural networks and achieve 84% accuracy for automatically identifying insufficiently supported arguments. The final corpus as well as the annotation guideline are freely available for encouraging future research on argument quality.<sup>1</sup>

## 1 Introduction

Argumentation is an omnipresent routine and an integral part of our daily verbal communication. It is a verbal activity that aims at increasing or decreasing the plausibility of a controversial standpoint (van Eemeren et al., 1996, p. 5). Well-reasoned arguments of high quality are not only important for making thoughtful decisions and persuading a particular audience but also play a major role for drawing widely accepted conclusions. Computational argumentation is a recent research field in natural language processing that focuses on the analysis of arguments in natural language texts. Novel advances have a broad applica-

tion potential in various areas like debating technologies (Levy et al., 2014; Rinott et al., 2015), policy making (Sardianos et al., 2015), information retrieval (Carstens and Toni, 2015), and legal decision support (Mochales-Palau and Moens, 2009). Recently, computational argumentation is receiving increasing interest in *intelligent writing assistance* (Song et al., 2014; Stab et al., 2014) since it enables *argumentative writing support* systems that provide tailored feedback about arguments in student essays.

Most of the existing approaches in computational argumentation consider argumentation as discourse structures and focus on the identification of arguments in natural language texts. For instance, existing approaches classify text units as argumentative or non-argumentative (Moens et al., 2007), recognize argument components such as *claims* or *premises* at the sentence-level (Mochales-Palau and Moens, 2009; Kwon et al., 2007; Eckle-Kohler et al., 2015) or clause-level (Levy et al., 2014; Sardianos et al., 2015), or identify argument structures by classifying pairs of argument components (Stab and Gurevych, 2014). However, these approaches are of limited use for argumentative writing support systems since they do not recognize the weak points of arguments.

Despite the comprehensive theoretical framework on argument quality in logic and argumentation theory (van Eemeren et al., 1996; Damer, 2009), there are only few computational approaches that focus on the assessment of arguments in natural language texts. These existing approaches either identify undisputed arguments in online communities (Cabrio and Villata, 2012), assess the persuasiveness of arguments (Wei et al., 2016), compare and rank arguments regarding their convincingness (Habernal and Gurevych, 2016b), or summarize the argumentation strength

<sup>1</sup><https://www.ukp.tu-darmstadt.de/data/argumentation-mining>

of an entire essay in a single holistic score (Persing and Ng, 2015). Our approach is based on the theoretical framework proposed by Johnson and Blair (2006). In particular, we focus on the *sufficiency criterion* that an argument fulfills if its premises provide enough evidence for accepting or rejecting the claim. The following example argument illustrates a violation of the sufficiency criterion:

**Example 1:** “*It is an undeniable fact that tourism harms the natural habitats of the destination countries. As Australia’s Great Barrier Reef has shown, the visitors cause immense destruction by breaking corals as souvenirs, throwing boat anchors or dropping fuel and other sorts of pollution.*”

The premise of this argument represents a particular example (second sentence) that supports a general claim in the first sentence. The argument is a generalization from one sample to the general case. However, a single sample is not enough to support the general case. Therefore, the argument does not comply with the sufficiency criterion.

**Example 2:** “*Cloning will be beneficial for people who are in need of organ transplants. Cloned organs will match perfectly to the blood group and tissue of patients since they can be raised from cloned stem cells of the patient. In addition, it shortens the healing process.*”

Example 2 illustrates a sufficiently supported argument. It is reasonable to accept that transplantation patients will benefit from cloning if it enables a better match and an accelerated healing process.

Our primary motivation is to create an argument analysis method for argumentative writing support systems that classifies an argument as *sufficient* if its premises provide enough evidence for accepting its claim (example 2) or as *insufficient* if its premises do not provide enough evidence (example 1). Therefore, our first research question is whether human annotators can reliably apply the sufficiency criterion to real arguments and if it is possible to create annotated data of high quality. The second research question addresses the automatic recognition of insufficiently supported arguments. We investigate if, and how accurately, insufficiently supported arguments can be identified by computational techniques.

The contribution of this paper is threefold: first, we investigate to what extent human annotators agree on the sufficiency criterion. We present the results of an annotation study with three annotators and show that our annotation guideline successfully guides annotators to substantial agreement. Second, we show that insufficiently supported arguments can be identified with high accuracy using convolutional neural networks (CNN). The experimental results show that a CNN significantly outperforms several challenging baselines and manually created features. Third, we introduce a novel corpus for studying the quality of arguments.

## 2 Related Work

Previous works in computational argumentation focused primarily on approaches for *argument mining*. These include, for example, methods for the identification of arguments in legal texts (Moens et al., 2007), news articles (Eckle-Kohler et al., 2015; Sardianos et al., 2015), or user-generated web discourse (Habernal and Gurevych, 2016a). Other approaches address the classification of argument components into claims and premises (Mochales-Palau and Moens, 2009), supporting and opposing claims (Kwon et al., 2007), or backings, rebuttals and refutations (Habernal and Gurevych, 2016a). Levy et al. (2014) recognize context-dependent claims and Rinott et al. (2015) retrieve several types of evidence from Wikipedia. Approaches for identifying the structure of arguments recognize argumentative relations between argument components using context-free grammars (Mochales-Palau and Moens, 2009), pair classification (Stab and Gurevych, 2014), or maximum spanning trees (Peldszus and Stede, 2015). However, none of these approaches consider the quality of arguments.

Similarly, most existing corpora in computational argumentation are only annotated with argument components (Habernal and Gurevych, 2016a; Aharoni et al., 2014; Mochales-Palau and Moens, 2009) or argument structures (Reed et al., 2008; Stab and Gurevych, 2014; Peldszus and Stede, 2015) and do not include annotations of argumentative quality issues. Other resources in the field contain arguments annotated with different properties such as emotions and sarcasm (Walker et al., 2012), the type of reasoning (Reed et al.,

2008) or the stance on a topic (Somasundaran and Wiebe, 2009). However, there is no corpus of arguments annotated with the sufficiency criterion.

Currently there are only few approaches that focus on the automatic assessment of argument quality. Cabrio and Villata (2012) employed textual entailment for identifying undisputed arguments in online discussions. They built a graph that represents attack and support relations between arguments and applied the abstract argumentation framework (Dung, 1995) for identifying accepted arguments. Although their approach is capable of finding undisputed arguments among a given set of arguments, it does not answer why a specific argument is of inferior quality than another argument. Thus, their approach is of limited use for guiding students since it does not pinpoint particular weaknesses of arguments.

Park and Cardie (2014) proposed an approach for classifying propositions as verifiable (experiential and non-experiential) or unverifiable. Their best approach based on a support vector machine achieves a macro F1 score of .690. Although the verifiability of propositions enables to determine appropriate types of support, it does not answer if an argument is sufficiently supported or not.

Persing and Ng (2015) introduced an approach for recognizing the argumentation strength of an essay. They found that pos n-grams, prompt adherence features, and predicted argument components perform best. However, their model determines a single holistic score that summarizes the argumentation quality of the entire essay. Consequently, it does not provide formative feedback that guides students to improve their arguments.

Recently, researchers proposed approaches for automatically assessing the persuasiveness of arguments. For instance, Wei et al. (2016) proposed an approach for ranking user comments taken from online fora and found that argumentation related features are effective for this task. Cano-Basave and He (2016) ranked speakers in political debates by using semantic frames which indicate persuasive argumentation features, and Habernal and Gurevych (2016b) compared the convincingness of argument pairs using feature-rich SVMs and bidirectional LSTMs. However, the persuasiveness score of an argument is only of limited use for argumentative writing support, since it summarizes various quality criteria and does not explain why an argument is weak.

### 3 Argument Quality: Theoretical Background

An argument consists of several *argument components*. It includes a claim and one or more premises. The *claim* (also called *conclusion*) is a controversial statement and the central component of an argument. The *premises* constitute the reasons for believing the claim to be true or false (Damer, 2009, p. 14). Assessing the quality of arguments is a complex task since arguments in natural language are hardly ever in a standardized form (Damer, 2009; Govier, 2010). Moreover, argument quality is a product of many different criteria (Johnson and Blair, 2006). The quality of an argument depends, for instance, on its lexical clarity and phrasing (representation), the level of trust that the audience has in the arguer (ethos), and the emotions and values appealed by the argument (pathos). The *logical quality* of arguments (logos) is, however, independent of all other merits, defects and external influence factors (Johnson and Blair, 2006, p. 50). Certainly, external factors or the presentation style can have a strong influence on the persuasive power of arguments. However, these factors can at most masquerade an illogical argument but not improve its logical quality. Therefore, the logical quality is most suitable for assessing the (intrinsic) quality of arguments and for providing feedback about written arguments respectively.

Traditionally, there are two different perspectives on the logical quality of arguments: (i) the formal logic perspective and (ii) the informal logic perspective. The objective of *formal logic approaches* is to distinguish deductively valid arguments from invalid arguments (van Eemeren et al., 1996, chapter 1.2), i.e. to recognize if the claim of an argument follows necessarily from its premises. However, formal logic approaches cannot be applied to everyday arguments since the vast majority of arguments do not follow deductive inference rules (Damer, 2009; van Eemeren et al., 1996).

*Informal logic* aims at developing theoretical frameworks for analyzing arguments in ordinary natural language (Groarke, 2015). These include, for example, *fallacy theories* which focus on determining particular argumentative mistakes that can be observed with a marked degree of frequency. Current theories list various forms of fallacious arguments. For instance, the framework proposed by Damer (2009) describes 61 different fallacy

types. However, fallacy theories are not appropriate for recognizing logically good arguments (van Eemeren et al., 1996, p. 178) since it is unknown if all fallacies are already known. To overcome this limitation, Johnson and Blair (2006) proposed three binary criteria, known as RAS-criteria, that a logically good argument needs to fulfill:

- *Relevance*: An argument fulfills the relevance criterion, if all of its premises count in favor of the truth (or falsity) of the claim.
- *Acceptability*: An argument fulfills the acceptability criterion if its premises represent undisputed common knowledge or facts.
- *Sufficiency*: An argument complies with the sufficiency criterion if its premises provide enough evidence for accepting or rejecting the claim.

The relevance criterion addresses the relation between each premise and the claim whereas the acceptability criterion focuses on the truthfulness of each individual premise. Both need to be evaluated independently for each premise of the argument. The sufficiency criterion addresses the premises of an argument together. It is fulfilled if the relevant premises of an argument are enough for justifying (or rejecting) the claim. The sufficiency criterion presupposes a non-empty set of relevant premises. However, an argument can violate the relevance criterion and comply with the sufficiency criterion at the same time. For instance, an argument can have several relevant premises that are sufficient for accepting the claim and additional premises that are not relevant to the claim. This also implies that a sufficient argument has a non-empty set of relevant premises but it is unknown if all premises of a sufficient argument are relevant to the claim.

In contrast to fallacy theories, the RAS-criteria enable to distinguish good from bad arguments with respect to logical quality since each argument that complies with all three criteria is a logically good one (Govier, 2010; Johnson and Blair, 2006). Moreover, the RAS-criteria attribute a particular defect to the relation between individual premises and the claim (relevance), the truthfulness of individual premises (acceptability), or the premises considered together (sufficiency). Therefore, they enable purposeful feedback for resolving particular defects of weak arguments and are well suited for argumentative writing support systems.

## 4 Corpus Creation

We conducted our annotation on a corpus of 402 argumentative essays that has been previously annotated with argumentation structures (Stab and Gurevych, 2016). By analyzing the annotated argumentation structures, we found that each body paragraph contains at least one argument and only 4.3% of all body paragraphs include several arguments, i.e. claims supported by premises. Therefore, we considered each body paragraph as an individual argument. This approximation has additional practical advantages for the identification of insufficiently supported arguments since it does not require the identification of argumentation structures in advance and prevents potential error propagation. Following this procedure, we extracted 1,029 arguments with an average length of 94.6 tokens and 4.5 sentences per argument.

### 4.1 Annotation Study

Three non-native annotators with excellent English proficiency independently annotated the arguments as sufficient or insufficient. We used 64 arguments from the corpus for elaborating the annotation guideline and 20 arguments for collaborative training sessions with the annotators. In these sessions, all three annotators collaboratively analyzed arguments for resolving disagreements and obtaining a common understanding of the annotation guideline. For the actual annotation task, we used the freely available brat rapid annotation tool (Stenetorp et al., 2012).

#### 4.1.1 Inter-Annotator Agreement

All three annotators independently annotated an evaluation set of 433 arguments. We evaluated the agreement between the annotators using several inter-annotator agreement measures implemented in DKPro Agreement (Meyer et al., 2014). We used observed agreement and the two chance-corrected measures Fleiss'  $\kappa$  (Fleiss, 1971) and Krippendorff's  $\alpha$  with nominal distance function (Krippendorff, 1980). The three annotators agreed on 91.07% of all 433 arguments (observed agreement). The chance-corrected agreement scores of  $\kappa = .7672$  and  $\alpha = .7673$  show substantial agreement between the annotators which allows “*tentative conclusions*” (Krippendorff, 1980). Therefore, we conclude that human annotators can reliably identify insufficiently supported arguments in argumentative essays.

### 4.1.2 Analysis of Disagreements

In order to identify the reasons for the disagreements, we manually investigated all arguments on which the annotators disagreed. We found that a high proportion of these arguments include modal verbs in their claims. The following example illustrates such an argument:

*“Watching television too often can have a negative effect on communication abilities. For instance, children often prefer watching cartoons or movies instead of meeting their classmates and thus they will not learn how to communicate properly.”*

Due to the modal verb “*can*” in the claim of this argument (first sentence), it is sufficient to provide one specific example as premise. However, annotators tend to overlook modal verbs and over-hastily annotate these arguments as insufficient.

The second most frequent cause of disagreements is due to the length of the arguments. In particular, one annotator annotated remarkably fewer arguments as insufficient. These arguments exhibit a comparatively large number of premises. This indicates that longer arguments are more likely to be perceived as sufficient than shorter arguments.

We also observed that several disagreements are due to hard cases. For instance, assessing the sufficiency of the following argument depends on the subjective interpretation of the undetermined quantification “*many*” in the claim:

*“Living in big cities provides many opportunities. First of all, it will be easier to find a job in a city. Also there are various bars and clubs where you can meet new people. Above all there are shopping malls and cinemas for spending your free time.”*

We also found that annotators do not agree on arguments including terms such as “*some*”, “*various*”, or “*large number*”. Thus, extending the annotation guideline with an explanation of how to handle modal verbs, the number of premises and undetermined qualifiers could further improve the agreement between the annotators in future annotation studies.

## 4.2 Creation of the Final Corpus

We merged the annotations of the three annotators on the evaluation set using majority voting. The remaining arguments have been annotated by the two annotators with the highest pairwise agreement on the evaluation set ( $\alpha = .815$ ). Disagreements on the remaining arguments have been manually resolved in discussions among the two annotators. Table 1 shows an overview of the corpus.

size	
tokens	97,370
sentences	4,593
arguments	1,029
class distribution	
sufficient	681 (66.2%)
insufficient	348 (33.8%)

Table 1: Size of the final corpus and class distribution of sufficiency annotations.

The class distribution is skewed towards sufficiently supported arguments. However, the proportion of 33.8% insufficiently supported arguments indicates that students frequently do not support their claims with sufficient evidence.

## 5 Experiments

We consider the identification of insufficiently supported arguments as a binary classification task and label each body paragraph as *sufficient* or *insufficient*. For preventing errors in model assessment due to a particular data splitting (Krstajic et al., 2014), we used a repeated 5-fold cross-validation setup and ensured that arguments from the same essay are not distributed over the train, test and development sets. We repeated the cross-validation 20 times which yields a total of 100 folds. As evaluation scores, we used accuracy and macro F1 score as well as the F1 score, precision and recall of the class “insufficient”. Whereas the precision indicates the performance of the model to identify arguments that are really in need of revision, recall shows how well the model recognizes all insufficiently supported arguments in an essay. All evaluation scores are reported as average including the standard deviation over the 100 folds. In order to determine the macro F1 score, we employ macro-averaging as proposed by Sokolova and Lapalme (2009, p. 430). For model selection and hyperparameter tuning, we randomly sampled 10% of the training set of each

fold as a development set. For significance testing, we employ Wilcoxon signed-rank test on macro F1 scores with a significance level of  $\alpha = .005$ .

We employ several models from the DKPro Framework (Eckart de Castilho and Gurevych, 2014) for preprocessing. We use the language tool segmenter<sup>2</sup> for tokenization and sentence splitting. We employ the Stanford parser (Klein and Manning, 2003) and named entity recognizer (Finkel et al., 2005) for constituency parsing and recognizing organizations, persons and locations. Note that only the model described in Section 5.2 requires all preprocessing steps. All other models use only the tokenization of the language tool segmenter.

### 5.1 Baselines

For our experiments, we use the following two baselines: First, we employ a majority baseline that classifies each argument as sufficient. Second, we use a support vector machine with polynomial kernel implemented in the Weka framework (Hall et al., 2009). We employ the 4,000 most frequent lowercased words as binary features and refer to this model as SVM-bow.

### 5.2 Manually Created Features (SVM)

Our first system is based on manually created features. As a learner, we use the same support vector machine as for SVM-bow. For feature extraction and experimentation, we use the DKPro TC text classification framework (Daxenberger et al., 2014). We tried various features which have been used previously for assessing the quality or the persuasiveness of arguments (cf. Section 2). For instance, we experimented with argument structures (Stab and Gurevych, 2014), transitional phrases (Persing and Ng, 2015), semantic roles (Das et al., 2014) and discourse relations (Lin et al., 2014). However, we found that only the following features are effective for recognizing insufficiently supported arguments:

**Lexical:** To capture lexical properties, we employ the 4,000 most frequent lowercased words as binary features analogous to SVM-bow.

**Length:** We use the number of tokens and the number of sentences as features since sufficiently supported arguments might exhibit more premises than insufficiently supported arguments (cf. Section 4.1.2).

**Syntax:** For capturing syntactic properties, we extract binary production rules from the constituent parse trees of each sentence of the argument as described by Stab and Gurevych (2014).

**Named Entities (ner):** We assume that arguments with insufficient support refer to particular entities in order to justify more general claims (cf. example 1 in Section 1). Thus, we add the number of named entities appearing in the argument and the average occurrence of named entities per sentence to our feature set. We consider organizations, persons and locations separately. Thus the named entity features comprise six features in total, i.e. three binary and three numeric features.

### 5.3 Convolutional Neural Network (CNN)

Our second model is a convolutional neural network with max-over time pooling (Collobert et al., 2011). We use the implementation provided by Kim (2014). The selection of this model is motivated by the excellent performance that the model achieves in many different classification tasks like sentiment classification of question classification. We found in our experiments that instead of using several convolutional layers with different window sizes, a single convolutional layer with a window size of 2 and 250 feature maps performs best. For representing each word of an argument, we use word embeddings trained on the google news data set by Mikolov et al. (2013). In order to adapt these vectors to the identification of insufficient arguments, we use non-static word vectors as proposed by Kim (2014). We train the network with stochastic gradient descent over shuffled mini-batches with the Adadelta update rule (Zeiler, 2012), a dropout rate of .5 and a mini-batch size of 50. For finding the best model, we apply early stopping on the development sets.

### 5.4 Results

Table 2 shows the results of the model assessment on the test sets. The SVM-bow model with unigram features achieves .755 macro F1 score and .785 accuracy. It significantly outperforms the majority baseline by .357 macro F1 score which indicates that lexical features are informative for identifying insufficiently supported arguments. The support vector machine with manually created features significantly outperforms both the majority baseline and SVM-bow. It achieves .798 accuracy and .770 macro F1 score and thus outperforms the SVM-bow model by .015 macro F1

<sup>2</sup><https://www.languagetool.org/>

	<i>Accuracy</i>	<i>Macro F1</i>	<i>F1 Insufficient</i>	<i>Precision</i>	<i>Recall</i>
Human Upper Bound*	.911±.022	.887±.026	.940±.015	.863±.058	.808±.109
Baseline Majority	.662±.033	.398±.012	0	0	0
Baseline SVM-bow †	.785±.029	.755±.034	.661±.051	.709±.067	.624±.067
SVM †‡	.798±.028	.770±.032	.681±.047	.731±.060	.641±.061
CNN †‡	<b>.843±.025</b>	<b>.827±.027</b>	<b>.770±.039</b>	<b>.762±.054</b>	<b>.784±.068</b>

Table 2: Results of model assessment on the test sets and comparison to human upper bound († significant improvement over baseline majority; ‡ significant improvement over Baseline SVM-bow; \*determined on a subset of 433 arguments).

score. We obtain the best performance by using the CNN model. It significantly outperforms all other models with respect to all evaluation scores and achieves .827 macro F1 score and an accuracy of .843. The results also show that the SVM model with manually created features achieves a considerably lower recall compared to precision. Thus, the model is less suitable for exhaustively finding all insufficiently supported arguments. In contrast, the CNN model is more balanced with respect to precision and recall and considerably outperforms the recall of the SVM model. Therefore, the CNN model outperforms the SVM model in finding insufficiently supported arguments in argumentative essay and performs better for recognizing arguments that are really in need of revision.

We determine the human upper bound by averaging the evaluation scores of all three annotator pairs on the 433 independently annotated arguments (cf. Section 4). Human annotators achieve an accuracy of .911. The CNN model yields only .068 less accuracy compared to the human upper bound and thus achieves 92.5% of human performance.

### 5.5 Feature Analysis

Although the CNN model outperforms the support vector machine with manual features, we analyzed the features for gaining a better understanding of insufficiently supported arguments and to investigate which linguistic properties are informative for recognizing arguments with insufficient support. Table 3 shows the macro F1 scores of the support vector machine using individual features and the results of feature ablation tests on the development sets.

The results show that lexical features are most effective for identifying insufficiently supported arguments. They achieve the best macro F1 score of .749 when used individually. Removing lexical features from the feature set also yields the highest

	<i>Macro F1</i>	<i>F1 Insuf.</i>	<i>F1 Suf.</i>
BS Majority	.396±.020	0	.793±.041
only lexical	.749±.048	.649±.070	.835±.040
only length	.397±.023	.002±.015	.792±.040
only syntax	.640±.063	.502±.101	.767±.047
only ner	.681±.059	.410±.114	.823±.039

all w/o length	.766±.049	.674±.068	.847±.040
all w/o syntax	.755±.049	.659±.070	.839±.040
all w/o ner	.760±.050	.666±.069	.843±.041
all features	.768±.049	.677±.068	.848±.040

Table 3: Results of the SVM using individual features and feature ablation tests on the dev sets.

decrease in macro F1 score compared to the other features. The second best features are named entities. Using only named entity features yields a macro F1 score of .681. Thus, we can confirm our assumption that named entities are informative features for assessing the sufficiency of arguments. Syntactic features are also effective for recognizing insufficiently supported arguments. They yield .640 macro F1 score when used individually. The results also show that the length of an argument is only marginally informative for assessing the sufficiency of arguments. Using the length features individually yields only a slight improvement of the macro F1 score over the majority baseline. However, removing the length from the entire feature set causes a slight decrease of .002 in the macro F1 score compared to the system which uses all features. We achieve the best results by combining all features.

For gaining further insights into the characteristics of insufficiently supported arguments, we ranked all unigrams using information gain. The top ten words are “example”, “my”, “was”, “instance”, “i”, “for”, “me”, “friend”, “he”, and “did”. This might be an indication that *examples* (signaled by the terms “example” and “instance”)

or *personal experiences* (signaled by terms such as “*me*”, “*my*”, “*friend*” or “*he*”) are not sufficient for developing strong arguments.

## 5.6 Error Analysis

In order to analyze the most frequent errors of the convolutional neural network, we manually investigated all arguments which are wrongly classified in each run of the repeated cross-validation experiment. In total, we found 41 sufficient arguments which are consistently misclassified as insufficient (false positives) and 28 insufficient arguments that are always misclassified as sufficient (false negatives).

Among the false positives, we observed that 35 arguments include examples as evidence which are signaled by terms like “*example*” or “*instance*”. Thus, the model tends to overemphasize the presence of particular lexical indicators. Most of these arguments either refer to an example in addition to other premises which are already sufficient to support the claim or include an example for specifying another premise. However, we also found several false negatives which include examples as evidence. Thus, the model does not solely rely on these lexical clues.

Among the 28 false negatives, we found 8 arguments that refer to multi-word named entities which are not captured by word embeddings. Another 5 false negatives support the claim by means of personal experience and 3 ones cite numbers, i.e. previous studies or empirical evidence.

## 6 Discussion

Although the convolutional neural network achieves promising results, the sufficiency criterion is only one of three criteria that a logically good argument needs to fulfill. Thus, our approach is not yet able to separate logically good from illogical arguments. In our experiments, we also analyzed arguments with respect to the relevance and acceptability criterion. In particular, we conducted several annotation studies with varying guidelines and two annotators on a set of 100 arguments. For annotating the relevance criterion, we presented the annotated structure of each argument to the annotators and asked them to assess the relevance of each premise for the claim individually. In order to evaluate the acceptability criterion, we asked the annotators to mark each premise as acceptable if it represents undisputed

common knowledge or a fact. However, we found that human annotators hardly agree on these criteria. We obtained low agreement scores of  $\kappa = .435$  for the relevance criterion and  $\kappa = .259$  for the acceptability criterion, which is not sufficient for creating a reliable corpus. In addition, we found that the violations of the relevance and acceptability criteria are less frequent than violations of the sufficiency criterion in argumentative essays. We observed that only 15% of the arguments include a premise that violates the relevance criterion and 14% of all premises violate the acceptability criterion. Although this imbalance explains the low agreement scores (Artstein and Poesio, 2008, p. 573), it also poses additional requirements for the size of the corpus and for computational models.

Although we didn’t obtain adequate agreement scores for the acceptability and relevance criteria, we implemented a system that identifies insufficiently supported arguments in argumentative essays with a reasonable accuracy. Given that sufficiency flaws are the most frequent quality defects in argumentative essays, our system represents an important milestone for realizing argumentative writing support systems.

## 7 Conclusion

We presented a novel approach for assessing the quality of natural language arguments. In particular, we focused on the sufficiency criterion that each logically good argument needs to fulfill. Previous approaches on argument quality are of limited use for argumentative writing support systems since they are not capable of recognizing particular weaknesses in argumentative texts. To overcome this limitation, we conducted an empirical study on the applicability of the sufficiency criterion to real arguments in argumentative essays. The inter-annotator agreement of  $\alpha = .7673$  shows that human annotators substantially agree in this annotation task and confirms that humans can reliably separate sufficiently supported arguments from insufficiently supported arguments. We introduced a novel corpus annotated with the sufficiency criterion for studying logical mistakes in argumentation. This corpus is freely available for ensuring the reproducibility of our results and to encourage future research on argument quality. Furthermore, we presented the results of our experiments for automatically rec-

ognizing if an argument is sufficiently supported or not. We found that convolutional neural networks significantly outperform challenging baselines and manually created features with a macro F1 score of .827 and an accuracy of .843. Moreover, we showed that insufficiently supported arguments frequently exhibit particular lexical indicators. In addition, the feature analysis revealed that named entities and syntactic features are good indicators for separating sufficiently supported arguments from insufficiently supported arguments.

For future work, we plan to continue with our experiments with the relevance and acceptability criteria. In addition, we plan to integrate our method in writing environments for evaluating its effectiveness for supporting authors.

## Acknowledgments

This work has been supported by the Volkswagen Foundation as part of the Lichtenberg-Professorship Program under grant No. I/82806 and by the German Federal Ministry of Education and Research (BMBF) as a part of the Software Campus project AWS under grant No. 01|S12054. We thank our annotators Can Diehl and Radhika Gaonkar for their valuable contributions and the anonymous reviewers for their helpful comments.

## Abstract

Descriptive document clustering aims to automatically discover groups of semantically related documents and to assign a meaningful label to characterise the content of each cluster. In this paper, we present a descriptive clustering approach that employs a distributed representation model, namely the paragraph vector model, to capture semantic similarities between documents and phrases. The proposed method uses a joint representation of phrases and documents (i.e., a co-embedding) to automatically select a descriptive phrase that best represents each document cluster. We evaluate our method by comparing its performance to an existing state-of-the-art descriptive clustering method that also uses co-embedding but relies on a bag-of-words representation. Results obtained on benchmark datasets demonstrate that the paragraph vector-based method obtains superior performance over the existing approach in both identifying clusters and assigning appropriate descriptive labels to them.

## 1 Introduction

Document clustering is a well-established technique whose goal is to automatically organise a collection of documents into a number of semantically coherent groups. Descriptive document clustering goes a step further, in that each identified document cluster is automatically assigned a human-readable label (either a word or phrase) that characterises the semantic content of the documents within the cluster. Descriptive clustering

methods have been shown to be useful in a variety of scenarios, including information retrieval (Bharambe and Kale, 2011), analysis of social networks (Zhao and Zhang, 2011), and large-scale exploration (Nassif and Hruschka, 2013) and visualisation of text collections (Kandel et al., 2012).

A number of previously proposed descriptive clustering techniques work by extending a standard document clustering approach. Documents are typically clustered based on a bag-of-words (BoW) representation (i.e., the occurrence counts of the words that appear in each document). Then, each cluster is labelled using the most commonly occurring word or phrase within the cluster (Weiss, 2006). In contrast to this approach, the recently proposed descriptive clustering approach (CEDL) (Mu et al., 2016) maps documents and candidate cluster labels into a common semantic vector space (i.e., co-embedding). The co-embedding space facilitates the straightforward assignment of descriptive labels to document clusters. The CEDL method has been shown to generate accurate cluster labels and achieved improved clustering performance when compared to standard descriptive clustering methods. Nonetheless, the co-embedding is based solely on a BoW representation of the documents and is thus limited in its ability to accurately represent the semantic similarity between documents.

In this paper, we investigate a specific case of descriptive clustering that selects a single multi-word phrase to characterise each cluster of documents (Li et al., 2008). Firstly, we assume descriptive phrases are to be selected from a candidate phrase set extracted from the corpus during preprocessing. The proposed method then follows the co-embedding descriptive clustering paradigm of the CEDL algorithm. However, in-

stead of using a BoW representation, we employ the paragraph vector (PV) (Le and Mikolov, 2014) model to learn a distributed vector representations of phrases and documents. These distributed representations move beyond unstructured BoW representations by considering the local contexts in which words and phrases appear within documents, which provides a more precise estimate of semantic similarity.

In particular, we present two extensions to the initial PV-based method that enable models that learn a common co-embedding space of documents and phrases. The first extension jointly learns co-embeddings of documents and phrases. The second extension constructs ‘pseudo-documents’ consisting of the lexical context surrounding each occurrence of a particular phrase. Each of these contexts are treated as separate document instance that are associated with a single embedded vector. In both cases, after clustering the document embedding vectors, each embedded phrase is a candidate cluster label. To select the most appropriate descriptive label amongst these candidates, we first rank the documents according to their proximity to each candidate label’s embedding vector and then select the phrase whose ranking maximises the average precision for a given cluster.

We compare the results obtained by our PV-based descriptive clustering method against two methods: spectral clustering (Shi and Malik, 2000), which only identifies clusters (but does not assign labels to them), and the previously introduced CEDL method (Mu et al., 2016), which carries out both clustering and labelling. Experimental results based on publicly available benchmark text collections demonstrate the effectiveness and superiority of our methods in both clustering performance and labelling quality.

## 2 Related Work

### 2.1 Descriptive Clustering

Descriptive clustering methods typically use an unsupervised approach to firstly group documents into flat or hierarchical clusters (Steinbach et al., 2000). Document clusters are then characterised using a set of informative and discriminative words (Zhu et al., 2006), phrases (Mu et al., 2016; Li et al., 2008) or sentences (Kim et al., 2015).

Early approaches to descriptive clustering

followed the description-comes-first (DCF) paradigm (Osiński et al., 2004; Weiss, 2006; Zhang, 2009). DCF-based methods work by firstly identifying a set of cluster labels, and subsequently forming document clusters by measuring the relevance of each document to a potential cluster label. DCF-based approaches have several shortcomings, which include poor clustering performance and low readability of cluster descriptors (Lee et al., 2008; Carpineto et al., 2009).

More recent developments in descriptive clustering have proposed alternative techniques, which approach the problems of improving clustering performance and descriptive label quality from various different angles. For instance, Scaiella et al. (2012) identifies Wikipedia concepts in documents and then computes relatedness between documents according to the linked structure of Wikipedia. Navigli and Crisafulli (2010) propose a method that takes into account synonymy and polysemy. Their method utilises the Google Web1T corpus to identify word senses based on word co-occurrences and computes the similarity between documents using the extracted sense information.

More recently, Mu et al. (2016) presented their co-embedding based descriptive clustering approach that learns a common co-embedding vector space of documents and candidate descriptive phrases. The co-embedded space simplifies the clustering and cluster labelling task into a more straightforward process of computing similarity between pairs of documents and between documents and candidate cluster labels.

### 2.2 Distributed Representation

Distributed representation techniques are becoming increasingly important in a number of supervised learning tasks, e.g., sentiment analysis (Dai et al., 2015), text classification (Dai et al., 2015; Ma et al., 2015) and named entity recognition (Turian et al., 2010). A number of models have been proposed to learn distributed word or phrase representations in order to predict word occurrences given a local context (Mnih and Hinton, 2009; Mikolov et al., 2013b; Mikolov et al., 2013a; Pennington et al., 2014). Subsequently, the PV model was proposed to learn representations of both words and documents (Le and Mikolov, 2014; Dai et al., 2015). The PV model has been

shown to be capable of learning a semantically richer representation of documents compared to unstructured BoW models. To our knowledge, our work constitutes the first attempt to use distributed representation models to co-embed documents and phrases for unsupervised descriptive clustering.

### 3 Proposed Descriptive Clustering Method

As outlined above, the descriptive clustering task (i.e., grouping documents according to semantic relatedness and characterising the cluster content using a representative descriptive phrase) relies heavily on learning a representation of documents and phrases that can accurately capture relevant semantic information. A particularly effective strategy for descriptive clustering is to jointly map documents and descriptive phrases together into a common embedding space (Mu et al., 2016). The clustering of documents and selection of descriptive phrases for each cluster is then carried out by calculating the cosine similarities between documents (to form clusters), and between documents and descriptive phrases (to determine descriptive labels) in the learned space. Instead of relying on the commonly used BoW model, we propose a novel descriptive clustering approach. Our method uses similarities computed from distributed joint embeddings of documents and phrases, which are learned by considering both the global context provided by the document and the local context of the descriptive phrases. We propose two different strategies to learn these embeddings, as described below.

#### 3.1 Joint Learning of Document and Phrase Embeddings

The first strategy jointly learns the distributed representations for documents and phrases by representing phrases, words, and documents as vectors that are used both to predict the occurrence of words in given documents (reflecting global document content information), and to predict the co-occurrences of words and phrases within a sliding window, to reflect the local context information.

We extend the PV model described in Dai et al. (2015) to simultaneously generate word, phrase and document embeddings. The objective function is to maximise the log probability of words and phrases conditioned on either their global or

local context:

$$\begin{aligned} & \sum_{t \in \mathcal{T}_P} \log p(p_t | d_t) + \frac{1}{|\mathcal{C}_t|} \sum_{c \in \mathcal{C}_t} \log p(p_t | c) \quad (1) \\ & + \sum_{s \in \mathcal{T}_W} \log p(w_s | d_s) + \frac{1}{|\mathcal{C}_s|} \sum_{c \in \mathcal{C}_s} \log p(w_s | c) \end{aligned}$$

where  $\mathcal{T}_P$  is the set of training phrase instances;  $p_t \in \mathcal{P}$  is the  $t$ -th phrase instance;  $d_t$  denotes the document corresponding to the  $t$ -th training instance;  $c$  denotes a member of the local context  $\mathcal{C}_t = [q_{t-L}, \dots, q_{t-1}, q_{t+1}, \dots, q_{t+L}]$ , which occurs within a window size of  $L$  of the training instance ( $|\mathcal{C}_t| = 2L$ ) and consists of both words and phrases  $q_t \in \mathcal{P} \cup \mathcal{W}$ ; likewise,  $\mathcal{T}_W$  is the set of training word instances;  $w_s \in \mathcal{W}$  is the  $s$ -th target word instance;  $d_s$  denotes the document corresponding to the  $s$ -th training instance; and  $\mathcal{C}_s$  is its local context with  $|\mathcal{C}_s| = 2L$ . To summarise, the probability terms  $p(p_t | d_t)$  and  $p(w_s | d_s)$  model the document content information from a global level, while  $p(p_t | c)$  and  $p(w_s | c)$  model the local context. There are  $2L + 1$  conditional probabilities estimated for each training instance.

The probability of a given lexical unit  $q_t \in \mathcal{P} \cup \mathcal{W}$  (either a word or a phrase) is modelled using the vector embeddings of the  $|\mathcal{P}| + |\mathcal{W}|$  words and phrases and the softmax function as follows:

$$p(q_t | d_t) = \frac{\exp(\mathbf{u}_{q_t}^\top \mathbf{z}_{d_t})}{\sum_{q \in \mathcal{P} \cup \mathcal{W}} \exp(\mathbf{u}_q^\top \mathbf{z}_{d_t})} \quad (2)$$

$$p(q_t | c) = \frac{\exp(\mathbf{u}_{q_t}^\top \mathbf{z}_c)}{\sum_{q \in \mathcal{P} \cup \mathcal{W}} \exp(\mathbf{u}_q^\top \mathbf{z}_c)} \quad (3)$$

where  $\mathbf{u}_{q_t}$  is a weight vector specific to the target word or phrase,  $\mathbf{z}_{d_t}$  is the embedding vector of the document corresponding to instance  $t$ , and  $\mathbf{z}_c$  is the embedding vector of a word or phrase in the context of  $q_t$ . Since the document, phrase and word vectors all use the same weight vector  $\mathbf{u}_{q_t}$  to predict the target phrase, they are necessarily in the same vector space.

#### 3.2 Phrase Embeddings via Local Context Pseudo-Documents

The previous model considers learning an embedding as a multi-objective problem by trying to predict phrases and words based on the global and local context. Besides indexing, Equation (1) treats words and descriptive phrases interchangeably. An alternative approach is to treat phrases

as ‘pseudo-documents’ by using the sets of words appearing in the local context of each phrase occurrence. Specifically, training instances for a phrase’s embedding vector are constructed by extracting the local context around each occurrence of a phrase in the document collection. Using the augmented training set, consisting of both the original documents and the additional pseudo-documents, we can then employ any existing PV model (Le and Mikolov, 2014; Dai et al., 2015) to learn the document-phrase co-embeddings.

However, due to the significant differences in the sizes and numbers of documents and pseudo-documents, there is a danger that the addition of the pseudo-documents can have a detrimental effect on the performance of the model. Thus, we adopt a two-stage training procedure. Firstly, an embedding model is trained using only the documents. Then, we fix the weights of the model and optimise the phrase embeddings by providing the pseudo-documents as the input to the model.

We have integrated the above-mentioned process with two PV approaches, namely the distributed memory model (PV-DM) Le and Mikolov (2014), and the extension of the distributed BoW model (PV-DBOW) in Dai et al. (2015).

In the PV-DM model, the probability that a target word will appear in a given lexical context is conditioned on the surrounding co-occurring words and also the document:

$$\sum_{t \in \mathcal{T}_W} \log p(w_t | \mathcal{C}_t, d_t), \quad (4)$$

where  $w_t$  is the target word for instance  $t$ ,  $\mathcal{T}_W$  is the set of training word instances,  $\mathcal{C}_t = [w_{t-L}, \dots, w_{t-1}, w_{t+1}, \dots, w_{t+L}]$  are context words that occur within a window size of  $L$  words around  $w_t$ , and  $d_t$  denotes the document corresponding to the  $t$ -th training instance. The probability is modelled using a softmax function.

For phrase  $p$ , the objective is to maximise the sum of the log probabilities  $\sum_{t \in \mathcal{T}_p} \log p(w_t | \mathcal{C}_t, p)$  where  $w_t \in \mathcal{T}_p$  are the word instances that appear in local context around the phrase, i.e.,  $\mathcal{T}_p$  is the set of word instances across all pseudo-documents, and  $\mathcal{C}_t$  is the set of words that occur around the  $t$ -th word instance which also occur within the pseudo-documents for the phrase. Explicitly, the optimal embedding vector for the phrase is determined by

solving the following optimisation problem:

$$\max_{\mathbf{z}_p} \sum_{t \in \mathcal{T}_p} \log \frac{\exp(\mathbf{u}_{w_t}^\top \mathbf{x}_t + \mathbf{v}_{w_t}^\top \mathbf{z}_p)}{\sum_w \exp(\mathbf{u}_w^\top \mathbf{x}_t + \mathbf{v}_w^\top \mathbf{z}_p)} \quad (5)$$

$$\mathbf{x}_t = [\mathbf{x}_{w_{t-L}}^\top, \dots, \mathbf{x}_{w_{t-1}}^\top, \mathbf{x}_{w_{t+1}}^\top, \dots, \mathbf{x}_{w_{t+L}}^\top]^\top$$

where  $\mathbf{x}_t$  is the concatenation of all word vectors in the context of word  $w$  and  $\{\mathbf{u}_w\}_w$  and  $\{\mathbf{v}_w\}_w$  for  $w$ . To find an approximate solution, the parameters of the embedding vector are randomly initialised and optimised using stochastic gradient descent; the gradient is calculated via backpropagation (Rumelhart et al., 1986).

The PV-DBOW model simplifies the PV-DM model by ignoring the local context of words in the log probability function. The probability that a target word will appear in a given lexical context is conditioned solely by the document. Dai et al. (2015) introduced a modified version of the PV-DBOW model that treats words and documents as interchangeable inputs to the neural network. This enables the model to jointly learn word and document embeddings in the same space; we denote the model as PV-DBOW-W. Essentially, the objective of the PV-DBOW-W model is a combination of both the skip-gram model (Mikolov et al., 2013b) that generates word embeddings and the PV-DBOW method which is used for learning document embeddings:

$$\sum_{t \in \mathcal{T}_W} \log p(w_t | d_t) + \frac{1}{|\mathcal{C}_t|} \sum_{c \in \mathcal{C}_t} \log p(w_t | c). \quad (6)$$

To optimise the embedding of a specific phrase, denoted  $p$ , the existing word embeddings remain fixed, and the objective function is simplified as  $\sum_{t \in \mathcal{T}_p} \log p(w_t | p)$  where  $w_t \in \mathcal{T}_p$  are word instances that appear in the local contexts around the phrase. The optimal embedding vector for this phrase is determined by solving the following optimisation problem:

$$\max_{\mathbf{z}_p} \sum_{t \in \mathcal{T}_p} \log \frac{\exp(\mathbf{u}_{w_t}^\top \mathbf{z}_p)}{\sum_w \exp(\mathbf{u}_w^\top \mathbf{z}_p)} \quad (7)$$

where the weight vectors  $\{\mathbf{u}_w\}_w$  are fixed. As in the previous model, the parameters of the embedding vector are randomly initialised and optimised using stochastic gradient descent.

### 3.3 Descriptive Phrase Selection

Given co-embeddings of documents and phrases, any clustering algorithm can be applied. We use k-means, with the cosine similarity-based distance metric, to cluster the documents. Given the set of documents within each identified cluster  $\mathcal{G}_1, \dots, \mathcal{G}_K$ , the document embedding vectors  $\{\mathbf{z}_d\}_{d=1}^N$  and the descriptive phrase embedding vectors  $\{\mathbf{z}_p\}_{p=1}^P$ , we then select a descriptive phrase that best represents the documents assigned to a cluster.

A baseline approach for descriptive phrase selection is to select the phrase whose embedding vector is nearest to the cluster centroid; however, proximity to the cluster centroid is not always a good indicator of cluster membership, as it ignores the location of documents belonging to other clusters. An ideal phrase vector should lie closer to documents within the cluster than documents outside of the cluster. Accordingly, we rank documents based on their proximity to a candidate phrase and calculate the average precision of this ranking (where documents belonging to the given cluster are the true positives).

For cluster  $\mathcal{G}$ , we define the cluster membership indicator for each document as:

$$y_d = \begin{cases} 1 & d \in \mathcal{G} \\ 0 & \text{otherwise} \end{cases} \quad (8)$$

For a given phrase  $p$ , let  $\pi_p(1)$  be the index of the nearest document to the phrase, and  $\pi_p(i)$  be the index of the  $i$ -th nearest neighbour. The precision after the  $k$ -nearest documents are retrieved is  $P_{\pi_p}(k) = \frac{1}{k} \sum_{i=1}^k y_{\pi_p(i)}$ . The phrase which maximises the average precision  $\bar{P}_p$  is selected as the cluster descriptor

$$p^* = \arg \max_p \left\{ \bar{P}_p = \frac{1}{|\mathcal{G}|} \sum_{k \in |\mathcal{G}|} P_{\pi_p}(k) \right\}, \quad (9)$$

where  $|\mathcal{G}|$  is the number of documents in the cluster.

## 4 Results

We evaluate the proposed PV-based descriptive clustering methods in terms of cluster quality and descriptive phrase selection. Additionally, we show a visualisation of the co-embedding space in the supplementary material.

### 4.1 Datasets

We use two well-known, publicly available datasets: ‘Reuters-21578 Text Categorization Test Collection’ from the Reuters newswire (Lewis, 1997), and the ‘20 Newsgroups’ email dataset<sup>1</sup>. We pre-process the 20 Newsgroups corpus to remove email header information while for both datasets we extract candidate phrases using Termine (Frantzi et al., 2000), an automatic term extraction tool.

For the Reuters corpus, we use the complete document collection for training the PV models. For evaluation, we use both the training and testing sets of the modApte split, and select the 10 categories with the largest number of documents. Moreover, we remove documents that belong to multiple categories, this process results in an evaluation set of 8,009 documents. For the 20 Newsgroups dataset, we use the complete set of 18,846 documents for training the PV models. We remove words and phrases that only appear in a single document and then remove any empty documents. This process results in an evaluation set of 18,813 documents with 20 categories, organised into 4 higher level parent categories. Table 1 summarises various characteristics of the employed datasets, including: a) number of documents, b) number of candidate phrases and c) category labels.

Table 1: Categories included in the evaluation subsets. ‘R10’ corresponds to the 10 largest categories after removing documents with multiple categories; the number of documents is in parentheses. All 20-Newsgroups categories have between 628 and 997 documents.

Reuters - 8,009 docs - 9,984 words - 11,732 phrases

### 4.2 Paragraph Vector Models

In this section, we provide implementation details for the three PV models (PV-DBOW-WP,

<sup>1</sup><http://qwone.com/~jason/20Newsgroups/>

PV-DBOW-W, and PV-DM), introduce a fourth model (PV-CAT) and explain the different settings that we use throughout the experiments. The PV-DBOW-WP model is used to jointly train phrase, word and document co-embeddings. For the PV-DBOW-W and PV-DM models, we use the two-stage training approach, in which the document embeddings and softmax weights are trained first, and then the phrase co-embeddings are trained using pseudo-documents. A window size of 10 words around the target phrase is used as the local context to create the pseudo-documents.

Each PV model has a number of parameters, including the dimension of the embedded spaces and the size of the context window. We set all embedding dimensions to 100. For the PV-DBOW-W and PV-DBOW-WP model, we use a context window of 10 words/phrases while for the PV-DM model a window size of 2 words (we tuned the size of the context window by applying the two PV models to a small development set of the Reuters corpus). This disparity in window size is not surprising since the PV-DM model considers the order of words within the local context and uses different parameters for the vectors at each location in the context window, Equation (5), whereas an increased window size does not add additional parameters to the PD-DBOW model.

We create an additional model, namely PV-CAT, by concatenating the vector representations induced by the PV-DBOW-W and the PV-DM models. This is performed after training the document and the phrase vectors. Intuitively, the concatenation of the PV-DBOW-W and PV-DM feature vectors can provide complimentary information given that the two models are trained using a different size of context window (i.e., 10 and 2 words, respectively).

Given that the size of the vocabulary is very large, computing the softmax function during stochastic gradient descent is computationally expensive. For faster training, different optimisation algorithms can be used to approximate the log probability function. We use a combination of negative sampling and hierarchical softmax via backpropagation (Mnih and Hinton, 2009; Mikolov et al., 2013b). Specifically, we use negative sampling and then further optimise the embeddings using hierarchical softmax. Although, these are different optimisation approaches, both methods can be applied in this ad-hoc manner.

Moreover, we follow the process described in Le and Mikolov (2014) to tune the learning rate. For this, we set the initial learning rate to 0.025 and decrease it linearly during 10 training epochs such that the learning rate is 0.001 during the last training epoch.

### 4.3 Baseline Methods

As our first baseline, we perform spectral clustering based on the affinity matrix produced according to the cosine similarity between the standard term-frequency inverse document (tf-idf) representation of the documents. We used the normalised cut (NC) spectral clustering algorithm proposed by Shi and Malik (2000).

We also compare our proposed method to the CEDL algorithm (Mu et al., 2016), which uses a measure of second-order similarity between phrases and documents, based on their co-occurrences at the document level, to obtain a spectral co-embedding. We use the same parameters suggested in the original publication, but carried out minor changes to the algorithm to allow the method to be scaled up to larger datasets. To compare clustering performance, we also run the CEDL algorithm without the phrase co-embeddings.

### 4.4 Evaluation of Cluster Quality

In this experiment, we evaluate the clustering performance of the methods by comparing automatically generated document clusters against the gold standard categories. For all methods, we use k-means clustering with cosine similarity as the distance metric. Following previous approaches (Xie and Xing, 2013), we set the number of clusters equal to the number of gold standard categories. As evaluation metrics, we use the macro-averaged F1 score<sup>2</sup>, and normalised mutual information<sup>3</sup>.

Table 2 compares the clustering performance achieved by four PV models (PV-DBOW-WP, PV-DBOW-W, PV-DM, and PV-CAT) against the performance of the baselines (i.e., the two versions of the CEDL algorithm and spectral clustering via normalised cut).

<sup>2</sup>For each category, the maximum F1 score across the clusters is used.

<sup>3</sup>Normalised mutual information  $\frac{MI(G,C)}{\max\{H(G),H(C)\}}$  is defined as the mutual information between the automatically generated clusters and gold standard categories  $MI(G,C)$  divided by the maximum of the entropy of the clusters  $H(G)$  or the categories  $H(C)$ .

Table 2: Clustering performance assessed by correspondence measures to gold standard categories. *NC*: spectral clustering via normalised cut, *CE1*: CEDL, *CE2*: CEDL without phrase co-embeddings, *PV1*: PV-DBOW-WP, *PV2*: PV-DBOW-W, *PV3*: PV-DM, *PV4*: PV-CAT.

<sup>†</sup> Average of 10 random subsets using 10% of each category’s documents.

The PV-DBOW-W and PV-CAT methods yield the best clustering performance on the Reuters dataset. Performance gains over the three baseline methods range between 6% – 12% (F1 score) and 8% – 9% (normalised mutual information). On the 20 Newsgroups dataset, the PV-DBOW-WP and PV-CAT models outperformed the baseline methods<sup>4</sup> by approximately 2% – 21% (F1 score) and 3% – 18% (normalised mutual information). Moreover, we note that the performance achieved by the PV-CAT model exceeds the best results reported in Xie and Xing (2013) (normalised mutual information of 0.6159 using a multi-grain clustering topic model).

Finally, we note that co-embedding is not designed as a mechanism for improving cluster quality. For CEDL, the co-embedding of phrases reduced the clustering performances in most datasets. This reduction in performance is equally observed for the paragraph vector models when applied to the Reuters dataset: the jointly trained co-embedding model (i.e., PV-DBOW-WP) achieved a lower performance than the two-stage approach PV-DBOW-W (F1 score of 0.56 and 0.66, respectively).

<sup>4</sup>Our implementation of the CEDL algorithm did not scale up to the entire dataset (‘all’), but average results on random subsets were consistent, as shown in the table.

## 4.5 Evaluation of Cluster Labelling

In this section, we evaluate the cluster labels (i.e., multi-word phrases) selected by the proposed PV-based descriptive clustering methods. As a baseline approach, we use the CEDL algorithm that produces a co-embedded space of documents and phrases<sup>5</sup>.

For each document cluster, we apply the phrase selection criterion, Equation (9), to identify the phrase that best describes the underlying cluster. Then for each gold standard category, the cluster having the highest proportion of documents belonging to the category is determined. This process means some clusters are assigned to multiple categories while other clusters are left unassigned. For each assigned cluster, we rank all documents according to their similarity to the automatically selected phrase (in the co-embedding space), where documents within the cluster have precedence over documents outside the cluster. We evaluate the quality of the cluster label by computing the average precision of this ranking in recalling the gold standard category. The average precision is maximised when documents closest to the selected phrase belong to the gold standard category. Table 3 shows the selected cluster descriptors aligned to the gold standard categories, the average precision and mean average precision scores achieved by the CEDL method and PV-based descriptive clustering models when applied to the Reuters and the 20 Newsgroups dataset.

The Reuters dataset presents a challenging case for descriptive clustering methods given that the distribution of gold standard categories is highly skewed, i.e., the majority categories (e.g., ‘earn’ and ‘acq’) correspond to more than one clusters while the remaining clusters cover multiple smaller categories. Nonetheless, we observe that the automatically selected cluster descriptors are related to the corresponding gold standard categories (e.g., ‘import coffee’ and ‘oil export’ for gold standard category ‘ship’). In practice, the skewed distribution of gold standard categories can be addressed by using a larger number of clusters in k-means, or by using a cluster algorithm more amenable to heterogeneously sized clusters.

The 20 Newsgroups dataset shows a more balanced distribution of categories than the Reuters

<sup>5</sup>The spectral clustering via normalised cut and the CEDL algorithm without document and phrase co-embeddings are document clustering methods but not descriptive clustering models and thus they are excluded from this experiment.

Table 3: Cluster descriptions and average precision (as percentages) achieved by descriptive clustering methods. *CE1*: CEDL, *PV1*: PV-DBOW-WP, *PV2*: PV-DBOW-W, *PV3*: PV-DM, *PV4*: PV-CAT. The average precision metric depends on not only the phrase but also the location of documents relative to the selected phrase; consequently, the average precision of a phrase may vary among the embeddings.

corpus, and we note that all descriptive clustering methods were able to identify meaningful cluster descriptors that have a clear correspondence to the gold standard categories (e.g., ‘window version’ and ‘dos app’ for the category ‘comp.os.ms-windows.misc’).

With regard to the mean average precision, we observe that the PV-DBOW-W and PV-CAT models obtained the best performance. Moreover, the PV-CAT model achieved statistically significant improvements over the CEDL baseline in terms of the average precision across the 28 categories while no significant<sup>6</sup> improvement was observed for the remaining three PV-based models.

The results that we obtained demonstrate that the PV-based co-embedding space can effectively capture semantic similarities between documents and phrases. An illustrative example of this is shown in Table 4. In this example, we selected two documents that neighbour the phrase “user interface” in the PV-CAT co-embedded feature space

<sup>6</sup>For significance testing, we used a paired sign-test, with a significance threshold of 0.05 and Bonferroni multiple test correction for the 4 tests; the uncorrected p-value for the PV-CAT model is 0.0009.

for the “20 Newsgroups” dataset. It can be noted that although neither of the two documents explicitly contain the input phrase, the first discusses a semantically similar topic, and the second uses the acronym GUI, i.e., graphical user interface.

As another example, we generate a two-dimensional visualisation of the document-phrase co-embeddings using t-SNE (van der Maaten and Hinton, 2008) that demonstrates how co-embedded phrases can be used as ‘landmarks’ for exploring a corpus. For this example, we use the ‘sci’ categories from the 20 Newsgroup corpus and select the 200 most frequent phrases in this subset. As input to t-SNE, we use the chordal distance defined by the cosine similarity in the co-embedding space and set the perplexity level to 40. Figure 1 in the supplementary material shows the visualisation with the cluster boundaries, location of the documents and co-embedded phrases.

## 5 Conclusion

Descriptive document clustering helps information retrieval tasks by automatically organising document collections into semantically coherent groups and assigning descriptive labels to each

Table 4: Two documents whose vector embeddings were the 5th and 6th nearest neighbours (according to the cosine of the angle of the corresponding vectors) to the phrase “user interface” in the PV-CAT based co-embedded space.

<i>Hi there, I'm looking for tools that can make X programming easy. I would like to have a tool that will enable to create X motif GUI Interactively. Currently I'm Working on a SGI with forms. A package that enables to create GUI with no coding at all (but the callbacks). Any help will be appreciated. Thanks Gabi.</i>

group. In this paper, we have presented a descriptive clustering method that uses paragraph vector models to support accurate clustering of documents and selection of meaningful and precise cluster descriptors. Our PV-based approach maps phrases and documents to a common feature space to enable the straightforward assignment of descriptive phrases to clusters. We have compared our approach to another state-of-the-art algorithm employing a co-embedding based on bag-of-word representations. The PV-based descriptive clustering method achieved superior clustering performance on both the Reuters and the 20 Newsgroups datasets. An evaluation of the selected cluster descriptors showed that our method selects informative phrases that accurately characterise the content of each cluster.

## A Supplementary Material

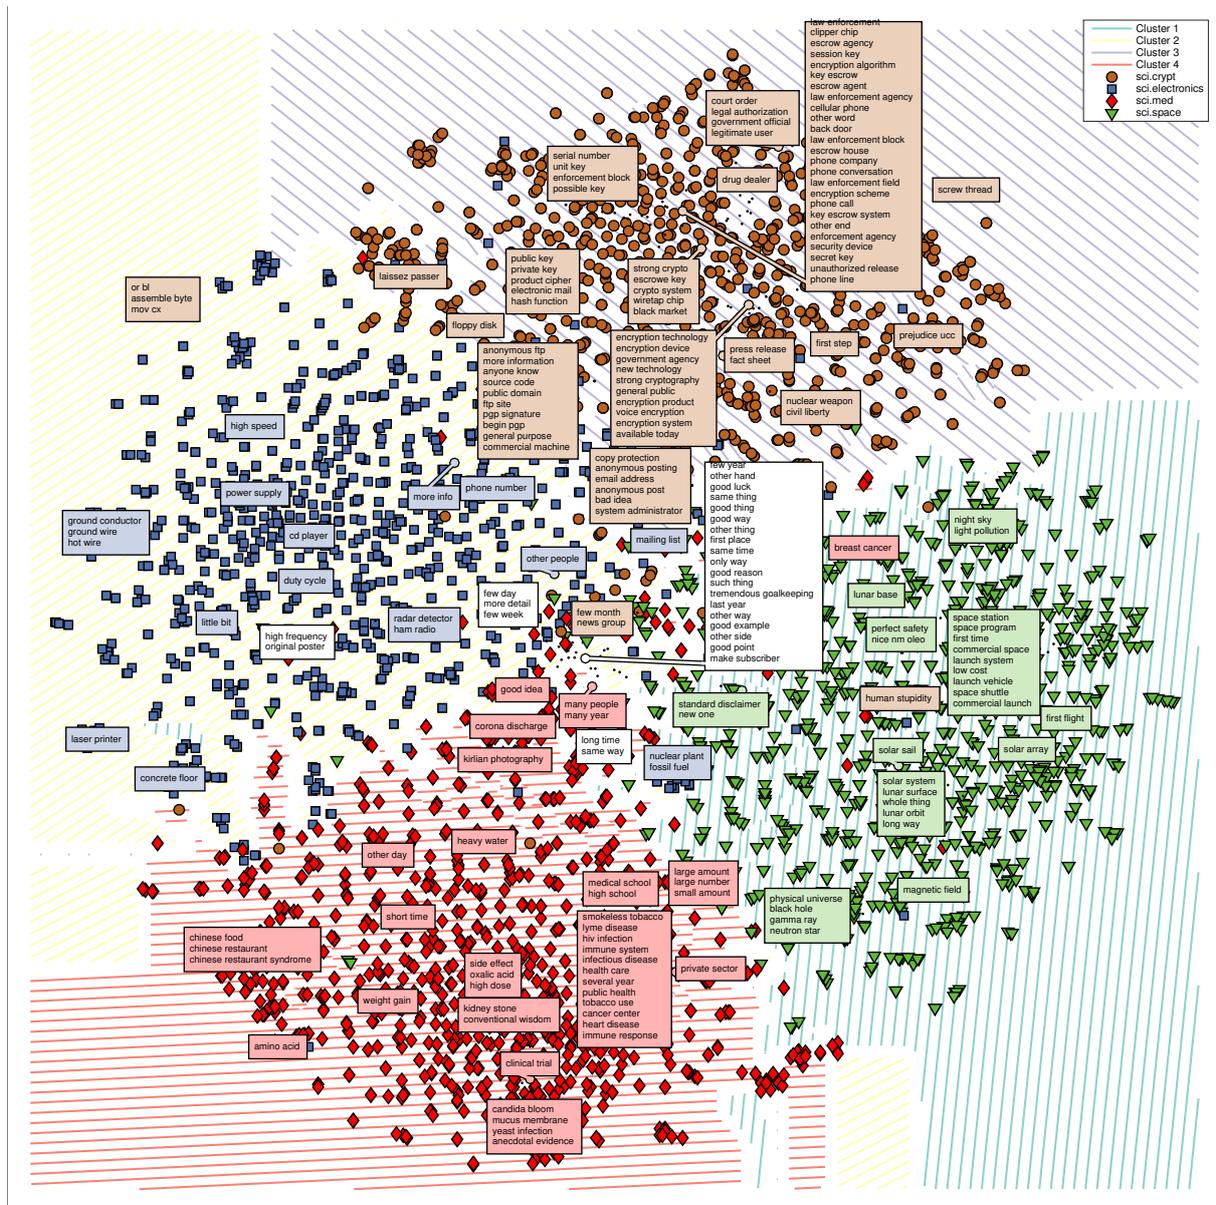

Figure 1: t-SNE visualisation of the PV-CAT co-embedding of the 20 Newsgroups ‘sci’ categories. Documents are represented by markers corresponding to the gold standard categories. Text boxes show the 200 most frequent phrases with nearby co-embedded phrases aggregated together. To show the correspondence between the categories and the phrase embedding, the text boxes are coloured based on the majority category of the documents nearest to each phrase. Sets of phrases with no majority category are left white. Hatch lines in the background denote the boundaries of each cluster, where the hatch angle (and colour) is based on the cluster. In the embedding space, each cluster is a convex set, but the t-SNE algorithm preserves local neighbourhoods and may fragment the clusters. (Best viewed with digital magnification.)

# SMARTies: Sentiment Models for Arabic Target entities

Noura Farra and Kathleen McKeown

Columbia University

Department of Computer Science

{noura, kathy}@cs.columbia.edu

## Abstract

We consider entity-level sentiment analysis in Arabic, a morphologically rich language with increasing resources. We present a system that is applied to complex posts written in response to Arabic newspaper articles. Our goal is to identify important entity “targets” within the post along with the polarity expressed about each target. We achieve significant improvements over multiple baselines, demonstrating that the use of specific morphological representations improves the performance of identifying both important targets and their sentiment, and that the use of distributional semantic clusters further boosts performances for these representations, especially when richer linguistic resources are not available.

## 1 Introduction

Target-specific sentiment analysis has recently become a popular problem in natural language processing. In interpreting social media posts, analysis needs to include more than just whether people feel positively or negatively; it also needs to include *what* they like or dislike. The task of finding all targets within the data has been called “open-domain targeted sentiment” (Mitchell et al., 2013; Zhang et al., 2015). If we could successfully identify the targets of sentiment, it would be valuable for a number of applications including sentiment summarization, question answering, understanding public opinion during political conflict, or assessing needs of populations during natural disasters.

In this paper, we address the open-domain targeted sentiment task. Input to our system consists of online posts, which can be comprised of one or multiple sentences, contain multiple entities with different sentiment, and have different

[Jealousy exists]- between [the Arab regimes]- since a long time and this is not the first time they disappoint us but this does not mess with the [Egyptians' love]+ for all the [Arab people]+ who have nothing to do with politics whatever their affiliations, and I am sure that [Egypt]+ will rise with the help of God and not [with the help of money from the Gulf]-.

[الغيرة موجودة]- بين [الأنظمة العربية]- من زمان ودي مش أول مرة يخيبوا ظننا لكن هذا لا يمس [حب المصريين]+ لكل [الشعوب العربية]+ التي لا علاقة لها بالسياسة وأيا كان انتماؤه ، وإني على يقين من أن [مصر]+ سوف تنهض بفضل الله لا [بفضل أموال الخليج]- .

Figure 1: Online post with annotated target entities and sentiment (green:pos, yellow:neg).

domains. Our goal is to identify the important entities towards which opinions are expressed in the post; these can include any nominal or noun phrase, including events, or concepts, and they are not restricted to named entities as has been the case in some previous work. The only constraint is that the entities need to be explicitly mentioned in the text. Our work also differs from much work on targeted sentiment analysis in that posts are long, complex, with many annotated targets and a lack of punctuation that is characteristic of Arabic online language. Figure 1 shows an example post, where targets are either labeled positive (green) if a positive opinion is expressed about them and negative (yellow) if a negative opinion is expressed.

To identify targets and sentiment, we develop two sequence labeling models, a target-specific model and a sentiment-specific model. Our models try to learn syntactic relations between entities and opinion words, but they also make use of (1) Arabic morphology and (2) entity semantics. Our use of morphology allows us to capture all “words” that play a role in identification of the target, while our use of entity semantics allows us to group together similar entities which may all be targets of the same sentiment; for example, if a commenter expresses negative sentiment towards

the United States, they may also express negative sentiment towards America or Obama.

Our results show that morphology matters when identifying entity targets and the sentiment expressed towards them. We find for instance that the attaching Arabic definite article *Al*+ **ال** is an important indicator of the presence of a target entity and splitting it off boosts recall of targets, while sentiment models perform better when less tokens are split. We also conduct a detailed analysis of errors revealing that the task generally entails hard problems such as a considerable amount of implicit sentiment and the presence of multiple targets with varying importance.

In what follows, we describe related work (§ 2), data and models (§ 3 and § 4), and linguistic decisions made for Arabic (§ 5). In § 6, we describe our use of word vector clusters learned on a large Arabic corpus. Finally, § 7 presents experiments and detailed error analysis.

## 2 Related Work

### Aspect-based and Entity-specific Analysis

Early work in target-based sentiment looked at identifying aspects in a restricted domain: product or customer reviews. Many of these systems used unsupervised and topical methods for determining aspects of products; Hu and Liu (2004) used frequent feature mining to find noun phrase aspects, Brody and Elhadad (2010) used topic modeling to find important keywords in restaurant reviews, and Somasundaran and Wiebe (2009) mined the web to find important aspects associated with debate topics and their corresponding polarities. SemEval 2014 Task 4 (Pontiki et al., 2014) ran several subtasks for identifying aspect terms and sentiment towards aspects and terms in restaurant and laptop reviews.

Entity-specific sentiment analysis has been frequently studied in social media and online posts. Jiang et al. (2011) proposed identifying sentiment of a tweet towards a specific named entity, taking into account multiple mentions of the given entity. Biyani et al. (2015) studied sentiment towards entities in online posts, where the local part of the post that contained the entity or mentions of it was identified and the sentiment was classified using a number of linguistic features. The entities were selected beforehand and consisted of known, named entities. More recent work uses LSTM and RNN networks to determine sentiment toward aspects in product reviews (Wang et al., 2016) and

towards entities in Twitter (Dong et al., 2014; Tang et al., 2015). SemEval 2016 ran two tasks on sentiment analysis (Nakov et al., 2016) and stance (Mohammad et al., 2016) towards pre-defined topics in Twitter, both on English data.

**Open domain targeted analysis** In early work. Kim and Hovy (2006) proposed finding opinion target and sources in news text by automatic labeling of semantic roles. Here, opinion-target relationships were restricted to relations that can be captured using semantic roles. Ruppenhofer et al. (2008) discussed the challenges of identifying targets in open-domain text which cannot be addressed by semantic role labeling, such as implicitly conveyed sentiment, global and local targets related to the same entity, and the need for distinguishing between entity and proposition targets.

Sequence labeling models became more popular for this problem: Mitchell et al. (2013) used CRF model combinations to identify named entity targets in English and Spanish, and Yang and Cardie (2013) used joint modeling to predict opinion expressions and their source and target spans in news articles, improving over several single CRF models. Their focus was on identifying directly subjective opinion expressions (e.g. "I *hate* [this dictator]" vs. "[This dictator] is *destroying* his country.") Recent work (Deng and Wiebe, 2015) identifies entity sources and targets, as well as the sentiment expressed by and towards these entities. This work was based on probabilistic soft logic models, also with a focus on direct subjective expressions.

There is also complementary work on using neural networks for tagging open-domain targets (Zhang et al., 2015; Liu et al., 2015) in shorter posts. Previous work listed did not consider word morphology, or explicitly model distributional entity semantics as indicative of the presence of sentiment targets.

**Related work in Arabic** Past work in Arabic machine translation (Habash and Sadat, 2006) and named entity recognition (Benajiba et al., 2008) considered the tokenization of complex Arabic words as we do in our sequence labeling task. Analysis of such segmentation schemes has not been reported for Arabic sentiment tasks, which cover mostly sentence-level sentiment analysis and where the lemma or surface bag-of-word representations have typically been sufficient.

There are now many studies on sentence-level

sentiment analysis in Arabic news and social media (Abdul-Mageed and Diab, 2011; Mourad and Darwish, 2013; Refaee and Rieser, 2014; Salameh et al., 2015). Elarnaoty et al. (2012) proposed identifying sources of opinions in Arabic using a CRF with a number of patterns, lexical and subjectivity clues; they did not discuss morphology or syntactic relations. Al-Smadi et al. (2015) developed a dataset and built a majority baseline for finding targets in Arabic book reviews of known aspects; Obaidat et al. (2015) also developed a lexicon-based approach to improve on this baseline. Abu-Jbara et al. (2013) created a simple opinion-target system for Arabic by identifying noun phrases in polarized text; this was done intrinsically as part of an effort to identify opinion subgroups in online discussions. There are no other sentiment target studies in Arabic that we know of. In our experiments, we compare to methods similar to these baseline systems, as well as to results of English work that is comparable to ours.

**Entity Clusters** It has been shown consistently that semantic word clusters improve the performance of named entity recognition (Täckström et al., 2012; Zirikly and Hagiwara, 2015; Turian et al., 2010) and semantic parsing (Saleh et al., 2014); we are not aware of such work for identifying entity targets of sentiment.

### 3 Data

We use the Arabic Opinion Target dataset developed by Farra et al. (2015), which is publicly available<sup>1</sup>. The data consists of 1177 online comments posted in response to *Aljazeera* Arabic newspaper articles and is part of the Qatar Arabic Language Bank (QALB) corpus (Habash et al., 2013; Zaghouani et al., 2014). The comments are 1-3 sentences long with an average length of 51 words. They were selected such that they included topics from three domains: politics, culture, and sports.

Targets are always noun phrases and they are either labeled positive if a positive opinion is expressed *about* them and negative if a negative opinion is expressed (as shown in Figure 1). Targets were identified using an incremental process where first *important* entities were identified, and then entities agreed to be neutral were discarded (the annotation does not distinguish between *neutral* and *subjective neutral*).

The data also contains ambiguous or ‘undeter-

<sup>1</sup>[www.cs.columbia.edu/~noura/Resources.html](http://www.cs.columbia.edu/~noura/Resources.html)

**The dictator is destroying his country**

T	T	O	O	O	O
N	N	∅	∅	∅	∅

Table 1: Example of CRF annotations.

mined’ targets where annotators did agree they were targets, but did not agree on the polarity. We use these targets for training our target model, but discard them when training our sentiment polarity model. There are 4886 targets distributed as follows: 38.2% positive, 50.5% negative, and 11.3% ambiguous. We divide the dataset into a training set (80%), development set (10%), and blind test set (10%), all of which represent the three different domains. We make the splits available for researchers to run comparative experiments.

## 4 Sequence Labeling Models

For modeling the data, we choose Conditional Random Fields (CRF) (Lafferty et al., 2001) for the ability to engineer Arabic linguistic features and because of the success of CRF models in the past for entity identification and classification related tasks.

We build two linear chain CRF models:

1. **Target Model** This model predicts a sequence of labels  $\vec{E}$  for a sequence of input tokens  $\vec{x}$ , where

$$E_i \in \{T(target), O(not\_target)\}$$

and each token  $x_i$  is represented by a feature vector  $\vec{f}_{i_t}$ . A token is labeled  $T$  if it is part of a target; a target can contain one or more consecutive tokens.

2. **Sentiment Model** This model predicts a sequence of labels  $\vec{S}$  for the sequence  $\vec{x}$ ,

$$S_i \in \{P(pos), N(neg), \emptyset(neutral)\}$$

and each token  $x_i$  is represented by a feature vector:

$$(\vec{f}_{i_s}, E_i); E_i \in \{T, O\}$$

Additionally, this model has the constraint:

$$if E_i = T, S_i \in \{P, N\}$$

and otherwise

$$S_i = \emptyset$$

The last constraint indicating that sentiment is either positive or negative is ensured by the training data, where we have no examples of target tokens having neutral sentiment. The two models are trained independently. Thus, if target words are already available for the data, the sentiment model can be run without training or running the target model. Otherwise, the sentiment model can be run on the output of the target predictor. The sentiment model uses knowledge of whether a word is a target and utilizes context from neighboring words whereby the entire sequence is optimized to predict sentiment polarities for the targets. An example sequence is shown in Table 1, where *the dictator* is an entity target towards which the writer implicitly expresses negative sentiment.

## 5 Arabic Morphology and Linguistics

### 5.1 Arabic Morphology

In Arabic, clitics and affixes can attach to the beginning and end of the word stem, making words complex. For example, in the sentence *فاستقبلوها* ‘*So they welcomed her*’, the discourse conjunction (*so* + ف), the opinion target (*her* ها+), opinion holder (*they* هاو), and the opinion expression itself (*welcomed* استقبل) are all collapsed in the same word.

Clitics, such as conjunctions +و *w+*, prepositions +ب *b+*, the definite article +ال *Al+* ‘*the*’ (all of which attach at the beginning), and possessive pronouns and object pronouns +هـ +*h* ها+ +*hA* ‘*his/her*’ or ‘*him/her*’ (which attach at the end) can all function as individual words. Thus, they can be represented as separate tokens in the CRF.

The morphological analyzer MADAMIRA (Pasha et al., 2014) enables the tokenization of a word using multiple schemes. We consider the following two schemes:

- **D3**: the Declitization scheme which splits off conjunction clitics, particles and prepositions, *Al+*, and all the enclitics at the end.
- **ATB**: the Penn Arabic Treebank tokenization, which separates all clitics above except the definite article *Al+*, which it keeps attached.

For a detailed description of Arabic concatenative morphology and tokenization schemes, the reader is referred to Habash (2010).

For each token, we add a part of speech feature. For word form (non-clitic) tokens, we use the part of speech (POS) feature produced by the morphological analyzer. We consider the surface word and the lemma for representing the word form. For the clitics that were split off, we use a detailed POS feature that is also extracted from the output of the analyzer and can take such forms as *DET* for *Al+* or *poss\_pron\_3MP* for third person masculine possessive pronouns. Table 2 shows the words and part of speech for the input sentence *فاستقبلوها* ‘*so they welcomed her*’ *fa-istaqbalu-ha*, using the lemma representation for the word form and the D3 tokenization scheme.

These lexical and POS features are added to both our target model and sentiment model.

### 5.2 Sentiment Features

The choice of sentiment lexicon is an important consideration when developing systems for new and/or low-resource languages. We consider three lexicons: (1) *SIFAAT*, a manually constructed Arabic lexicon of 3982 adjectives (Abdul-Mageed and Diab, 2011), (2) *ArSenL*, an Arabic lexicon developed by linking English SentiWordNet with Arabic WordNet and an Arabic lexical database (Badaro et al., 2014), and (3) the English MPQA lexicon (Wilson et al., 2005), where we look up words by matching on the English glosses produced by the morphological analyzer MADAMIRA.

For the target model, we add token-level binary features representing subjectivity, and for the sentiment model, we add both subjectivity and polarity features.

We also add a feature specifying respectively the subjectivity or polarity of the parent word of the token in the dependency tree in the target or sentiment model.

### 5.3 Syntactic Dependencies

We ran the CATiB (Columbia Arabic Treebank) dependency parser (Shahrour et al., 2015) on our data. CATiB uses a number of intuitive labels specifying the token’s syntactic role: e.g. *SBJ*, *OBJ*, *MOD*, and *IDF* for the Arabic *idafa* construct (e.g. *رئيس الحكومة* *president of government*), as well as its part of speech role. In addition to the sentiment dependency features specifying the sentiment of parent words, we added dependency features specifying the syntactic role of the token in relation to its parent, and the path from the token to the parent,

Word	English	Representation	POS	Token type
<i>f</i>	so	<i>f+</i>	conj	clitic
<i>Astqblw</i>	welcomed-they	<i>isotaqobal_1</i>	verb	lemma
<i>hA</i>	her	<i>+hA</i>	ivsuff_do:3FS	clitic

Table 2: Example of morphological representation. The encoded features will be *Representation* and *POS*. The POS for *her* represents an object pronoun. The word form represented is the lemma.

e.g *nom\_obj\_vrb* or *nom\_idf\_nom*, as well as the sentiment path from the token to the parent, e.g *nom(neutral)\_obj\_vrb(negative)*.

#### 5.4 Chunking and Named Entities

The morphological analyzer *MADAMIRA* also produces base phrase chunks (BPC) and named entity tags (NER) for each token. We add features for these as well, based on the hypothesis that they will help define the spans for entity targets, whether they are named entities or any noun phrases. We refer to the sentiment and target models that utilize Arabic morphology, sentiment, syntactic relations and entity chunks as **best-linguistic**.

### 6 Word Clusters and Entity Semantics

Similar entities which occur in the context of the same topic or the same larger entity are likely to occur as targets alongside each other and to have similar sentiment expressed towards them. They may repeat frequently in a post even if they do not explicitly or lexically refer to the same person or object. For example, someone writing about American foreign policy may frequently refer to entities such as *{the United States, America, Obama, the Americans, Westerners}*. Such entities can cluster together semantically and it is likely that a person expressing positive or negative sentiment towards one of these entities may also express the same sentiment towards the other entities in this set.

Moreover, cluster features serve as a denser feature representation with a reduced feature space compared to Arabic lexical features. Such features can benefit the CRF where a limited amount of training data is available for target entities.

To utilize the semantics of word clusters, we build word embedding vectors using the skip-gram method (Mikolov et al., 2013) and cluster them using the K-Means algorithm (MacQueen, 1967), with Euclidean distance as a metric. Euclidean distance serves as a semantic similarity metric and

has been commonly used as a distance-based measure for clustering word vectors.

The vectors are built on Arabic Wikipedia <sup>2</sup> on a corpus of 137M words resulting in a vocabulary of 254K words. We preprocess the corpus by tokenizing (using the schemes described in section 5) and lemmatizing before building the word vectors. We vary the number of clusters and use the clusters as binary features in our target and sentiment models.

## 7 Experiments and Results

### 7.1 Experiments

**Setup** To build our sentiment and target models, we use CRF++ (Kudo, 2005) to build linear-chain sequences. We use a context window of +/-2 for all features except the syntactic dependencies, where we use a window of +/-4 to better capture syntactic relations in the posts. For the sentiment model, we include the context of the previous predicted label, to avoid predicting consecutive tokens with opposite polarity.

We evaluate all our experiments on the development set which contains 116 posts and 442 targets, and present a final result with the best models on the unseen test. For the SentiWordNet-based lexicon ArSenL, we tune for the sentiment score threshold and use  $t=0.2$ . We use Google’s word2vec tool<sup>3</sup> for building and clustering word vectors with dimension 200. We vary the number of clusters  $k$  between 10 (25K words/cluster) and 20K (12 words/cluster).

**Baselines** For evaluating the **predicted targets**, we follow work in English (Deng and Wiebe, 2015) and use the *all-NP* baseline, where all nouns and noun phrases in the post are predicted as important targets.

For evaluating **sentiment towards targets**, we consider four baselines: the *majority* baseline which always predicts negative, and the *lexicon*

<sup>2</sup><https://dumps.wikimedia.org/arwiki/20160920/arwiki-20160920-pages-articles.xml.bz2>

<sup>3</sup><https://github.com/dav/word2vec>

baseline evaluated in the case of each of our three lexicons: manually created, WordNet-based, and English-translated. The strong lexicon baseline splits the post into sentences or phrases by punctuation, finds the phrase that contains the predicted target, and returns positive if there are more positive words than negative words, and negative otherwise. These baselines are similar to the methods of previously published work for Arabic targeted sentiment (Al-Smadi et al., 2015; Obaidat et al., 2015; Abu-Jbara et al., 2013).

We run our pipelined models for all morphological representation schemes: *surface word* (no token splits), *lemma* (no clitics), lemma with ATB clitics (contain all token splits except *Al+*), and lemma with D3 clitics (contains all token splits). We explore the effect of semantic word clusters in these scenarios. Finally we show our *best-linguistic* (high-resource) model, and the resulting integration with word clusters.

## 7.2 Results

Tables 3-5 show the results. Target F-measure is calculated using the *subset* metric (similar to metrics used by Yang and Cardie (2013), Irsoy and Cardie (2014)); if either the predicted or gold target tokens are a subset of the other, the match is counted when computing F-measure. Overlapping matches that are not subsets do not count (e.g. *موقف مصر* *Egypt's position* and *موقف إسرائيل* *Israel's position* do not match). For this task, in the case of multiple mentions of the same entity in the post, any mention will be considered correct if the subset matches<sup>4</sup> (e.g. if *فلسطين* *Palestine* is a gold target, and *دولة فلسطين* *state of Palestine* is predicted at a different position in the post, it is still correct). This evaluation is driven from the sentiment summarization perspective: we want to predict the overall opinion in the post towards an entity.

*F-pos*, *F-neg*, and *Acc-sent* show the performance of the sentiment model on only the *correctly predicted* targets<sup>5</sup>. Since the target and sentiment models are trained separately, this is meant to give an idea of how the sentiment model would perform in standalone mode, if targets were already provided.

*F-all* shows the overall F-measure showing the

<sup>4</sup>We have also computed the performance for mention-overlap; the difference in target F-measure is 2 points and consistent across the different systems.

<sup>5</sup>We exclude targets with ambiguous sentiment whose polarity was not agreed on by the annotators.

performance of correctly predicted targets with correct sentiment compared to the total number of polar targets. This evaluates the end-to-end scenario of both important target and sentiment prediction.

Best results are shown in bold. Significance thresholds are calculated for the best performing systems (Tables 4-5) using the approximate randomization test (Yeh, 2000) for target recall, precision, F-measure, *Acc-sent* and *F-all*. Significance over the method in the previous row is indicated by \* ( $p < 0.05$ ), \*\* ( $p < 0.005$ ), \*\*\* ( $p < 0.0005$ ). A confidence interval of almost four F-measure points is required to obtain  $p < 0.05$ . Our dataset is small; nonetheless we get significant results.

**Comparing Sentiment Lexicons** Table 3 shows the results comparing the different baselines. All targets are retrieved using *all-NP*; sentiment is determined using the lexical baselines. As expected, the *all-NP* baseline shows near perfect recall and low precision in predicting important targets. We observe that the gloss-translated MPQA lexicon outperforms the two other Arabic lexicons among the sentiment baselines.

We believe that the hit rate of MPQA is higher than that of the smaller, manually-labeled SIFAAT, and it is more precise than the automatically generated WordNet-based lexicon ArSenL. The performance of MPQA is, however, reliant on the availability of high-quality English glosses. We found MPQA to consistently outperform in the model results, so in our *best-linguistic* models, we only show results using the MPQA lexicon.

## Comparing Morphology Representations

Looking at table 4, we can see that using the lemma representation easily outperforms the sparser surface word, and that adding tokenized clitics as separate tokens outperforms representations which only use the word form. Moreover, upon using the **D3** decliticization method, we observe a significant increase in recall of targets over the **ATB** representation. This shows that the presence of the Arabic definite article *ال* *Al+* is an important indicator of a target entity; thus, even if an entity is not named, *Al+* indicates that it is a **known** entity and is likely more salient.

The more tokens are split off, the more targets are recalled, although this comes at the cost of a decrease in sentiment performance, where the lemma representation has the highest sentiment score and the D3 representation has the lowest af-

All-NP	Target			Sentiment			
	Recall	Precision	F-score	F-pos	F-neg	Acc-sent	F-all
Baseline1 Majority	98.4	29.2	45	0	72.4	56.8	12.4
Baseline2 ArSenL	98.4	29.2	45	50.6	<b>64.3</b>	58.6	12.7
Baseline3 SIFAAT	98.4	29.2	45	61	58	59.5	13.1
Baseline4 MPQA	98.4	29.2	45	<b>67</b>	63.7	<b>65.4</b>	<b>14.2</b>

Table 3: Target and sentiment results using baselines; *all-NP* for targets and lexicons for sentiment.

	Target			Sentiment			
	Recall	Precision	F-score	F-pos	F-neg	Acc-sent	F-all
Surface + POS	41	<b>60.6</b>	48.9	62.2	73.6	68.9	32.6
Lemma + POS	48.2**	60.5	53.7*	<b>65.4</b>	<b>77.6</b>	<b>72.8</b>	38.1**
+ATB tokens	52.4*	59.5	55.7	61.3	75.7	70.1	<b>38.2</b>
+D3 tokens	<b>59.6**</b>	55.7*	<b>57.6</b>	64.1	73	69.2	36.1

Table 4: Target and sentiment results using different morphological representations. All models use POS.

ter surface word. We believe the addition of extra tokens in the sequence (which are function words and have not much bearing on semantics) generates noise with respect to the sentiment model. All models significantly improve the baselines on F-measure; for *Acc-sent*, the surface word CRF does not significantly outperform the MPQA baseline.

**Effect of Word Clusters** Figures 2 - 5 show the performance of different morphological representations when varying the number of word vector clusters  $k$ . (Higher  $k$  means more clusters and fewer entities per semantic cluster.) Adding cluster features tends to further boost the recall of important targets for all morphological schemes, while more or less maintaining precision. The difference in different schemes is consistent with the results of Table 4; the D3 representation maintains the highest recall of targets, while the opposite is true for identifying sentiment towards the targets. The ATB representation shows the best overall F-measure, peaking at 41.5 using  $k=250$  (compare with 38.2 using no clusters); however, it recalls much fewer targets than the D3 representation.

The effect of clusters on sentiment is less clear; it seems to benefit the D3 and ATB schemes more than lemma (significant boosts in sentiment accuracy). The improvements in F-measure and *F-all* observed by using the best value of  $k$  is statistically significant for all schemes ( $k=10$  for lemma,  $k=250$  for lemma+ATB,  $k=500$  for lemma+D3, with *F-all* values of 40.7, 41.5, and 39.1 respectively). In general, the cluster performances tend to peak at a certain value of  $k$  which balances the

reduced sparsity of the model (fewer clusters) with the semantic closeness of entities within a cluster (more clusters).

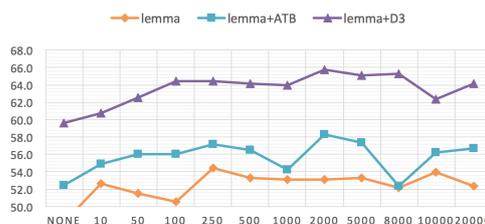

Figure 2: Target recall vs clusters.

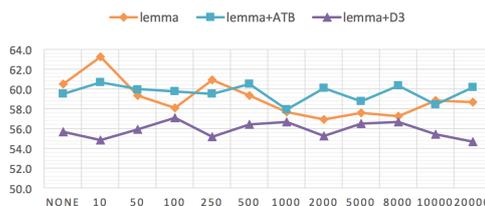

Figure 3: Target precision vs clusters.

**Performance of Best Linguistic Model** Table 5 shows the performance of our *best-linguistic* model, which in addition to the word form and part of speech, contains named entity and base phrase chunks, the syntactic dependency features, and the sentiment lexicon features. The best linguistic model is run using both **ATB** and **D3** tokenization schemes, and then using a combined **ATB+D3** scheme where we use D3 for the target model and remove the extra clitics before piping in the output to the sentiment model. This combined

	Target			Sentiment			
	Recall	Precision	F-score	F-pos	F-neg	Acc-sent	F-all
<b>best-linguistic-ATB</b>	53	<b>62.1</b>	57.2	68.6	79.4	75.1	40.7
<b>best-linguistic-D3</b>	64.2***	58.8	61.4*	62.7	75.6	70.5*	39.1
<b>best-linguistic-D3+ATB</b>	63.7	58.8	61.4	67.7	<b>80</b>	75.4***	43.1***
<b>best-linguistic+clusters</b>	<b>66.2</b>	57.8	<b>61.8</b>	<b>70</b>	<b>80</b>	<b>76</b>	<b>44.2</b>

Table 5: Performance of best linguistic model

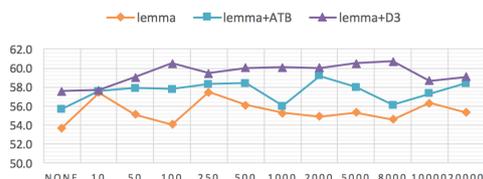

Figure 4: Target F-score vs clusters.

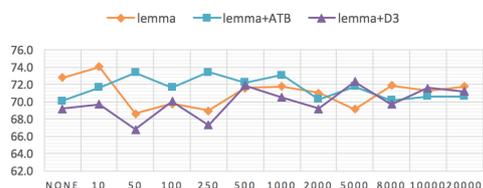

Figure 5: Sentiment accuracy vs clusters.

scheme results in the best results overall: F-score of 61.4 for targets, accuracy of 75.4 for sentiment and overall F-measure of 43.1.

Adding the richer linguistic resources results in both improved target precision, recall, and sentiment scores, with F-measure for positive targets reaching 67.7 for positive targets and 80 for negative targets. Performance exceeds that of the simpler models which use only POS and word clusters, but it is worth noting that using only the basic model with the word clusters can achieve significant boosts in recall and F-measure bringing it closer to the rich linguistic model.

The last row shows the best linguistic model **D3+ATB** combined with the clusters (best result for  $k=8000$ , or about 30 words per cluster). Adding the clusters improves target and F-measure scores, although this result is not statistically significant. We observe that it becomes more difficult to improve on the rich linguistic model using word clusters, which are more beneficial for low resource scenarios.

Our results are comparable to published work for most similar tasks in English: e.g. Yang and Cardie (2013) who reported target subset F-measure of ~65, Pontiki et al. (2014) where best

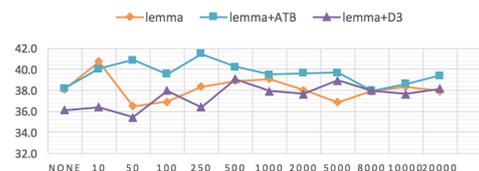

Figure 6: Overall F-score vs clusters.

	Target			Sentiment

performing SemEval systems reported 70-80% for sentiment given defined aspects, and (Mitchell et al., 2013; Deng and Wiebe, 2015) for overall F-measure; we note that our tasks differ as described in section 2.

**Results on blind test** Table 6 shows the results on unseen test data for *best-linguistic* using **D3**, **D3+ATB** and with clusters using  $k=8000$ . The results are similar to what was observed in the development data.

### 7.3 Error Analysis

We analyzed the output of our best linguistic models on the development set, and observed the following kind of errors:

**Implicit Sentiment** This was the most common kind of error observed. Commenters frequently expressed complex subjective language without using sentiment words, often resorting to sarcasm, metaphor, and argumentative language. We also observed persistent errors where positive sentiment was identified towards an entity because of misleading polar words; e.g. *minds العقول* was consistently predicted to be positive even though the post in question was using implicit language to express negative sentiment; the English gloss

<b>Example 1</b>
Till when will <b>[the world]-</b> wait before it intervenes against these <b>[crimes against humanity]-</b> committed by this <b>[criminal bloody regime]-</b> which will not stop doing that... because its presence has always been associated with oppression and murder and crime... But now it's time for it to disappear and descend into <b>[the trash of history]-</b> .

<b>Example 2</b>
<b>[Malaysia]+</b> is considered the most successful country in Eastern Asia, and its economic success has spread to other <b>[aspects of life in Malaysia]+</b> , for its <b>[services to its citizens]+</b> have improved, and there has been an increase in <b>[the quality of its health and educational and social and financial and touristic services]+</b> , which has made it excellent for foreign investments.
<b>Output</b> Malaysia:pos health:pos educational and social:neg financial:neg

Table 7: Good and bad examples of output by SMARTies. Gold annotations for targets are provided in the text with ‘-’ or ‘+’ reflecting negative and positive sentiment towards targets.

is *brains*, which appears as a positive subjective word in the MPQA lexicon. The posts also contained cases of complex coreference where subjective statements were at long distances from the targets they discussed.

**Annotation Errors** Our models often correctly predicted targets with reasonable sentiment which were not marked as important targets by annotators; this points to the subjective nature of the task.

**Sentiment lexicon misses** These errors resulted from mis-match between the sentiment of the English gloss and the intended Arabic meaning, leading to polar sentiment being missed.

**Primary Targets** The data contains multiple entity targets and not all are of equal importance. Out of the first 50 posts manually analyzed on the dev set, we found that in 38 out of 50 cases (76%) the correct *primary* targets were identified (the most important topical sentiment target(s) addressed by the post); in 4 cases, a target was predicted where the annotations contained no polar targets at all, and in the remaining cases the primary target was missed. Correct sentiment polarity was predicted for 31 out of the 38 correct targets (81.6%).

In general, our analysis showed that our system does well on posts where targets and subjective language are well formed, but that the important target identification task is difficult and made more complex by the long and repetitive nature of the posts. Table 7 shows two examples of the translated output of SMARTies, the first on more well-formed text and the second on text that is more difficult to parse.

## 8 Conclusions

We presented a linguistically inspired system that can recognize important entity targets along with sentiment in opinionated posts in Arabic. The targets can be any type of entity or event, and they are

not known beforehand. Both target and sentiment results significantly improve multiple lexical baselines and are comparable to previously published results in similar tasks for English, a similarly hard task. Our task is further complicated by the informal and very long sentences that are used in Arabic online posts. We showed that the choice of morphological representation significantly affects the performance of the target and sentiment models. This could shed light on further research in target-specific sentiment analysis for morphologically complex languages, an area little investigated previously. We also showed that the use of semantic clusters boosts performance for both target and sentiment identification. Furthermore, semantic clusters alone can achieve performance close to a more resource-rich linguistic model relying on syntax and sentiment lexicons, and would thus be a good approach for low-resource languages. Integrating different morphological preprocessing schemes along with clusters gives our best result.

Our code and data is publicly available<sup>6</sup>. Future work will consider cross-lingual clusters and morphologically different languages.

## Acknowledgments

This work was supported in part by grant NPRP 6-716-1-138 from the Qatar National Research Fund, by DARPA DEFT grant FA8750-12-2-0347 and by DARPA LORELEI grant HR0011-15-2-0041. ## Abstract

Spanish is the third-most used language on the Internet, after English and Chinese, with a total of 7.7% of Internet users (more than 277 million of users) and a huge users growth of more than 1,400%. However, most work on sentiment analysis has focused on English. This paper describes a deep learning system for Spanish sentiment analysis. To the best of our knowledge, this is the first work that explores the use of a convolutional neural network to polarity classification of Spanish tweets.

## 1 Introduction

Knowing the opinion of customers or users has become a priority for companies and organizations in order to improve the quality of their services and products. With the ongoing explosion of social media, it affords a significant opportunity to poll the opinion of many internet users by processing their comments. However, it should be noted that sentiment analysis, which can be defined as the automatic analysis of opinion in texts (Pang and Lee, 2008), is a challenging task because even different people often assign different polarities to a given text. Moreover, sentiment analysis can involve several Natural Language Processing (NLP) tasks such as negation or subjectivity detection, which have not been fully resolved by the NLP research community to date. On Twitter, the task is even more difficult, because the texts are small (only 140 characters) and are characterized by a informal style language utilized by users, many grammatical errors and spelling mistakes, slang and vulgar vocabulary, and plenty of abbreviations.

The shortage of training and testing data is one of the main bottlenecks for most NLP tasks in general, and for sentiment analysis in particular. This

drawback has been partially overcome thanks to the organization of shared tasks such as Sentiment Analysis in Twitter Task at SemEval 2013-2015 (Nakov et al., 2013; Rosenthal et al., 2014; Rosenthal et al., 2015; Nakov et al., 2016), which provided annotated corpora of tweets for sentiment analysis. Most research efforts in this task have focused on English texts, much less attention has been given to other languages (Abdul-Mageed et al., 2011; Kapukaranov and Nakov, 2015). However, Spanish is the third language most used on the internet, with a total of 7.7% (more than 277 million of users) and a huge internet growth of more than 1,400%.

Since its introduction in 2013, the workshop on Sentiment Analysis at SEPLN (Villena-Román et al., 2013; Villena-Román et al., 2015b; Villena-Román et al., 2015a; García Cumberras et al., 2016) has had as main goal to promote the development of methods and resources for sentiment analysis of tweets written in Spanish. In this task, the participating systems have to determine the global polarity of each tweet in the test dataset. A detailed description of the task can be found in the overview paper of TASS 2016 (García Cumberras et al., 2016).

As said above, sentiment analysis of tweets is a very challenging task because of their small size, and thereby, they usually contain very scarce contextual information. This shortage of contextual information can be supplied by exploiting knowledge from large collections of unlabelled texts. Our approach uses a convolutional neural network (CNN), which uses word embeddings as its only input. Word embeddings can be very useful for the sentiment analysis task because they are able to represent syntactic and semantic information of words (Collobert et al., 2011; Socher et al., 2013b). We do not only experiment with randomly initialized word vectors, but also explore the use of

pre-trained word embeddings. We also perform a detailed exploration of the hyper-parameters of the CNN and their effect on the results.

The paper is organized as follows. In Section 2, we discuss some related work. Section 3 describes our approach. The experimental results are presented and discussed in Section 4. We conclude in Section 5 with a summary of our findings and some directions for future work.

## 2 Related Work

For the past two decades, a remarkable amount of NLP research has been dedicated to the sentiment analysis task. Most of early works were focused on customer reviews of products and services, while more recently researches usually carry out the task on data from social media such as tweets and user comments. Polarity classification can be performed at three different levels: document, sentence and entity level, being the first one the one most addressed until now. However, it is increasingly demanded to know the opinion of users on specific topics (entities).

Both unsupervised and supervised approaches have been used to tackle this problem, using standard features such as unigram/bigrams, word counts or binary presence features, word position, POS tags and sentiment features from polarity lexicons such as SentiWordNet (Baccianella et al., 2010), AFFIN (Hansen et al., 2011) or iSOL (Molina-González et al., 2013). Additionally, attention has recently been directed to more complex linguistic processes such as negation and speculation detection (Pang and Lee, 2008; Cruz et al., 2015).

Only a few works have explored the use of neural networks for sentiment analysis. Socher and colleagues (2011) proposed a recursive model that is able to capture the recursive nature of sentences and learn auto-encoders for multi-word phrases. Later, they proposed a matrix-vector recursive neural network model to learn compositional vector representations for phrases and sentences of any length (Socher et al., 2012). A feed-forward neural network was designed by dos Santos and Gatti (2014) to learn relevant features from characters, words and sentences for the sentiment analysis task.

In the four editions of the TASS workshop, most systems have been based on the use of popular supervised machine learning classifiers (most

of them used SVM) and very extensive feature sets, which included lexical and morphosyntactic features (such as tokens, lemmas, n-grams, PoS tags) and sentiment features from the polarity lexicons (such as ElhPolar (Saralegi and San Vicente, 2013), iSOL (Molina-González et al., 2013) or AFFIN (Hansen et al., 2011)) to represent the information of each tweet. Only one of the systems (Vilares et al., 2015) proposed an approach based on deep learning, in particular, a neural network Long Short-Term Memory (LSTM) with a logistic function at the output layer. The evaluation of the task showed that this deep learning approach did not overcome the classical classifiers such as SVM. In TASS, there are two different evaluations: one based on 6 different polarity labels (P+, P, NEU, N, N+, NONE) and another based on just 4 labels (P, N, NEU, NONE). The state-of-art result for the task with 4 polarity levels is around 0.70 of accuracy. As expected, the best accuracy is lower (around 0.67) for the task with 6 polarity levels. A more in-depth analysis of the results and the different participating systems can be found in (Villena-Román et al., 2013; Villena-Román et al., 2015b; Villena-Román et al., 2015a; García Cumberas et al., 2016).

To the best of our knowledge, convolutional networks have not been applied to the sentiment analysis of Spanish tweets yet. Several works (dos Santos and Gatti, 2014; Severyn and Moschitti, 2015) have shown that they can be a valuable approach for English tweets, and thereby, the same could be expected also for Spanish. One of the main advantages of this architecture is that it does not require syntactic information from sentences. It should be noted that many tweets are grammatically incorrect, and thereby, those methods not based on syntactic information, could give better results.

## 3 Approach

### 3.1 The General Corpus

The General corpus was created for the TASS competition. It consists of 68,000 Spanish tweets, which were collected from November 2011 to March 2012, and covers a variety of topics such as economy, communication, politics, mass media and culture. The corpus was divided into training and test sets with a 10%-90% ratio. As said above, each tweet in the training set is classified with its polarity, which can take some of

the following values: strong positive (P+), positive (P), neutral (NEU), negative (N), strong negative (N+) and one additional for tweets without polarity (NONE). The annotation process of the training set was semi-automatic using a baseline machine learning model whose annotations were manually reviewed later by human experts. Although the test set has not been released with their gold annotations, the evaluation platform of the TASS competition is still open<sup>1</sup> for registered users. This platform allows participants to submit new runs and then obtain their scores.

### 3.2 A baseline approach

To start with, we developed a baseline based on the most common approach for polarity classification at document level: the use of very popular supervised machine learning algorithms such as SVM and logistic regression. Our goal is to compare this baseline with the CNN model.

Instead of using bag-of-words (BoW) to represent tweets, we exploited word embedding representation. A word embedding is a function to map words to low dimensional vectors, which are learned from a large collection of texts. At present, Neural Network is one of the most used learning techniques for generating word embeddings (Mikolov et al., 2013). The essential assumption of this model is that semantically close words will have similar vectors (in terms of cosine similarity). Word embeddings can help to capture semantic and syntactic relationships of the corresponding words. While the well-known BoW model involves a very large number of features (as many as the number of non-stopwords words with at least a minimum number of occurrences in the training data), the word embedding representation allows a significant reduction in the feature set size (in our case, from millions to just 300). The dimensionality reduction is a desirable goal, because it helps in avoiding over-fitting and leads to a reduction of the training and classification times, without any performance loss. Moreover, word embeddings have shown promising results in NLP tasks, such as named entity recognition (Segura-Bedmar et al., 2015), relation extraction (Alam et al., 2016), sentiment analysis (Socher et al., 2013b) or parsing (Socher et al., 2013a).

As a preprocessing step, tweets must be cleaned. First, all links, urls and usernames (these

<sup>1</sup>[www.sepln.org/workshops/tass/2016/private/evaluate.php](http://www.sepln.org/workshops/tass/2016/private/evaluate.php)

last ones can be easily recognized because their first character is always the symbol @) were removed. Then, the hashtags were transformed to words by removing its first character (that is, the symbol #). Taking advantage of regular expressions, the emoticons were detected and classified in order to count the number of positive and negative emoticons in each tweet and then were removed from the text. Table 1 shows the list of positive and negative emoticons, which have been taken from Wikipedia<sup>2</sup>. The tweets were converted to lower-case. Moreover, the misspelled accented letters were replaced by their correct ones (for instance á with a). We also treated elongations (that is, the repetition of a character) by removing the repetition of a character after its second occurrence (for example, hoooolaaaa would be translated to hola). We also took into account laughs (for instance jajaja) which turned out to be challenging because of the diverse ways they are expressed (i.e. expressions like "ja", "jaja", jajajaja, "jiji" or jejeje and even misspelled ones like jajja-jaaj). We addressed this using regular expressions to standardize the different forms (i.e. jajjjaaj to jajaja) and then replaced them with the Spanish translation of laugh: "risa". Finally we removed all non-letters characters and all stopwords present in tweets<sup>3</sup>.

Orientation	Emoticons
Positive	:-), :), :D, :o), :, D:3, :c), :>, =], 8), =), :}, :^), :-D, 8-D, 8D, x-D, xD, X-D, XD, =-D, =D, =-3, =3, B^D, :'), :'), :*, :-*, :^*, ;-), ;), *-), *), ;-], ;], ;D, ;^), >:P, :-P, :P, X-P, x-p, xp, XP, :-p, :p, =p, :-b, :b
Negative	>:[, :-(:, (:, :-c, :-<, <:, :-[, :[, :{, ;(, :-  , >:(, :^-(, :'(, D:<, D=, v.v

Table 1: List of positive and negative emoticons

Once the tweets were preprocessed, they were tokenized using the NLTK toolkit (a Python pack-

<sup>2</sup>[https://en.wikipedia.org/wiki/List\\_of\\_emoticons](https://en.wikipedia.org/wiki/List_of_emoticons)

<sup>3</sup><http://snowball.tartarus.org/algorithms/spanish/stop.txt>

age for NLP). To represent the tweets, we used Cardellino’s pre-trained model (Cardellino, 2016). This model is available for research community and was built from several Spanish collection texts such as Spanish Wikipedia (2015), the OPUS corpora (Tiedemann and Nygaard, 2004) or the Ancora corpus (Taulé et al., 2008), among others. It contains nearly 1.5 billion words (Cardellino, 2016). The dimension of its vectors is 300. Then, for each token, we searched its vector in the word embedding model. It should be noted that this model was trained on a collection of texts from different resources such as Spanish Wikipedia, WikiSource and Wikibooks, and none of them contains tweets. Therefore, it is possible that the main characteristics of the social media texts (such as informal style language, grammatical errors and spelling mistakes, slang and vulgar vocabulary, abbreviations, etc) are not correctly represented in this model. Indeed, we found that there was a significant number of words from the tweets (almost a 6%) that were not found in this word embedding model. We performed a review of a small sample of these words, showing that most of them were mainly hashtags.

In our baseline approach, a tweet of  $n$  tokens ( $T = w_1, w_2, \dots, w_n$ ) is represented as the centroid of the word vectors  $\vec{w}_i$  of its tokens, as shown in the following equation:

$$\vec{T} = \frac{1}{n} \sum_{i=1}^n \vec{w}_i = \frac{\sum_{j=1}^N \vec{w}_j \cdot TF(w_j, t)}{\sum_{j=1}^N TF(w_j, t)} \quad (1)$$

where  $N$  is the vocabulary size, that is, the total number of distinct words, while  $TF(w_j, t)$  refers to the number of occurrences of the  $j$ -th vocabulary word in the tweet  $T$ .

In addition to using the centroid, we completed the feature set with the following additional features:

- posWords: number of positive words present in the tweet.
- negWords: number of negative words present in the tweet.
- posEmo: number of positive emoticons present in the tweet.
- negEmo: number of negative emoticons present in the tweet.

For the posWords and negWords features we used the iSOL lexicon (Molina-González et al., 2013), a list composed by 2,509 positive words and 5,626 negative words. As described before, for the emoticons we used the listed in Table 1, but also added to the positive ones the number of laughs detected; and also, we included the number of recommendations present in the form of a “Follow Friday” hashtag (#FF), due to its ease of detection and its positive bias.

We also applied a set of emoticon’s rules as a pre-classification stage, similar to Chikersal et al. (2015), in which we determined a first stage polarity for each tweet as follows:

- If posEmo is greater than zero and negEmo is equal to zero, the tweet is marked as “P”.
- If negEmo is greater than zero and posEmo is equal to zero, the tweet is marked as “N”.
- If both posEmo and negEmo are greater than zero, the tweet is marked as “NEU”.
- If both posEmo and negEmo are equal to zero, the tweet is marked as “NONE”.

Then, the classification of tweets was performed using scikit-learn, a Python module for machine learning. This package provides many algorithms such as Random Forest, Support Vector Machine (SVM) and so on. One of its main advantages is that it is supported by extensive documentation. Moreover, it is robust, fast and easy to use. Initially, we performed experiments using three different classifiers: Random Forests, Support Vector Machines and Logistic Regression because these classifiers often achieved the best results for text classification and sentiment analysis (García Cumberas et al., 2016).

After the classification, we made three tests: i) applying no rule, ii) honoring the polarity defined by the rule, which means, we keep the predefined polarity if the tweet was marked as “P” or “N”, otherwise we take the value estimated by the classifier, and iii) a mixed approach where we give each polarity a value (N+: -2; N: -1; NEU, NONE: 0; P: 1; P+: 2) and performed an arithmetic sum of both the predefined and estimated polarity if and only if they are not equal; with that for instance, if the classifier marked a tweet as “N:-1” and the rules marked it as “P:1” the tweet will be classified as “NEU:0”.

In order to choose the best-performing classifiers, we used 10-fold cross-validation because there was no development dataset and this strategy has become the standard method in practical terms. Our experiments showed that, although the results were similar, the best settings were:

- SVM+MIX: Support Vector Machine and applying the mixed rules approach.
- LR+MIX: Logistic Regression and applying the mixed rules approach.

### 3.3 CNN Model

In this study, the CNN model proposed for sentiment analysis is based on the model for sentence classification described in Kim (2014). The model has been implemented using Google’s Tensorflow toolkit. Based on the fact that single level architectures seem to provide similar performance than larger networks (Kim, 2014), we decided to design our network with only a single convolutional layer, followed by a max-pooling layer and a softmax classifier as final layer. In this way, we were able to reduce the large amount of time needed to train a CNN on a large corpus as our training set (with almost 7,000 tweets).

Each tweet was represented by a matrix that concatenates the word embeddings of its words. This matrix is the input of the network. In our experiments, we learned our word embeddings from scratch, but also we tried with two different pre-trained word2vec models: Cardellino’s model, which was described above, and a pre-trained model from tweets. To train this second model of word embeddings, we used the corpus provided by the TASS organizers (68,000 tweets) as well as a very extensive collection of 8,774,487 tweets, which we collected during 2014. To do this, we used the word2vec tool, which implements the continuous bag-of-words and skip-gram architectures for computing vector representations of words (Mikolov et al., 2013). We used the continuous bag of words model with a context window of size 8. The size of the pre-trained model from tweets is 347,970 words. We randomly initialized those words that were not in the pre-trained model.

In the next layer, convolutions were performed over the word embeddings using multiple filter sizes. A filter is a sliding window of a given number of words. That is, different size windows are treated at a time. Then, a max pooling

layer extracted the most important feature (in our case, the maximum value) to reduce the computational complexity. In order to avoid over-fitting, dropout regularization was also used (Srivastava et al., 2014). This process randomly drops some units and their connections from the network during training. The final layer is a softmax prediction.

We used 10-fold cross-validation for parameter tuning. Many different combinations of hyperparameters of the neural network can be defined. Summarizing, we experimented with several variants of the model:

- CNN-rand: all words are randomly initialized and then learned during training.
- CNN-wiki: a model initialized with the word vectors from Cardellino’s pre-trained model. The word embeddings as well as the other parameters are fine-tuned for training.
- CNN-tweets: the network is initialized with the pre-trained model from tweets. As the previous model, both word embeddings and the other parameters are learned during the training.

## 4 Results

We adopt the same metrics used in the TASS shared task, which are the accuracy and the macro-averaged version of the precision, recall and F1.

One of our main goals is to study the effect of the word embeddings on the performance of our CNN model. Table 2 compares the models based on the type of word-embeddings used as input of the network: CNN-rand, CNN-wiki and CNN-Twitter. The other parameters of the model were set as follows: dimension of word embeddings = 300, number of filters = 128, size of filters = 3,4,5 dropout=0.5,  $\lambda = 0$ , batch size=64 and number of epochs=200. When the classification only considers 4 levels (POS, NEU, NEG, NONE), the best results are provided by the pre-trained model built from tweets, despite being much smaller (with less than 350,000 words) than Cardellino’s pre-trained model (with 1.5 million of words). Even the word vectors from scratch (CNN-rand) provided slightly higher performance than the CNN model trained with Cardellino’s pre-trained model. This may be due to the language style of tweets is completely different to the usual

4 polarity levels

Table 3: Results of the baseline systems and the best CNN model

one of text collections (for example Wikipedia) that make up Cardellino’s corpus. As expected, the results are lower when the classification is performed using 6 polarity levels because there are less examples in the training set for the classes: P, P+ and N, N+. The pre-trained model from tweets still provides the best F1, but the best accuracy is provided by Cardellino’s pre-trained model. The worst results are obtained when the word vectors are randomly initialized.

Once we evaluated the impact of word embeddings on the performance of the CNN model, we decided to focus on the rest of its parameters. The dropout regularization is parameterized by the dropout probability  $\in [0, 1]$ . Our experiments using 10-fold cross validation revealed that the best performance is achieved when it is set to 0.5. As expected, several experiments showed that the larger the number of training epochs used, the more accurate the model. The final number of training epochs was set to 200. The experiments also show that the learning rate is the parameter with a largest impact in the prediction performance. The best results were obtained when this parameter was set to 3. The size of filter also seems to have a significant effect on results. Thus, the model achieved better results when our setting also considered smaller size such as 2. This may be due to tweets are small texts whose average number of words is 12 (Li et al., 2011). The best results were obtained with the filter-size parameter equals to "2,3,4,5". In order to determine the best model, we performed a comprehensive series of experiments, showing that the best parameter setting is as follows: dimension of word embeddings = 300, number of filters = 300, size of filters = 2,3,4,5 dropout=0.5,  $\lambda = 3$ , batch size=500 and

number of epochs=200.

Table 3 shows the results of our baselines (using SVM or logistic regression trained with the feature set and the rules described above). It also presents the results of our best CNN model. We can observe that our CNN model provides slightly better results in terms of F1 than SVM and logistic regression. However, in terms of accuracy, these popular algorithms overcome CNN model. Meanwhile, SVM and Logistic regression provide results that are extremely similar. It is worth mentioning that the logistic regression’s performance was observably faster than the other two models. Although our CNN model worked acceptably, its performance is still far from the top ranking systems of TASS (see Table4).

Tables 5 and 6 show the scores for each polarity using the best CNN model. As expected, the lower results are obtained for those classes with less instances in the training dataset.

## 5 Conclusion and future work

This paper explores the use of a convolutional neural network in order to extract relevant features without the necessity of handcrafted features (such as stems, named entities, PoS tags, syntactic information, etc). Our paper shows that a convolutional neural network architecture can be an effective method for sentiment analysis of Spanish tweets. Although our performance is lower than top ranking systems of the TASS workshop, our CNN model provides promising results.

As future work, we also plan to study if the inclusion of external features (such as sentiment features from polarity lexicons) to the final layer (softmax layer) achieves to improve the results. Because the General Corpus of the TASS task covers very different domains, we will perform leave-one-domain-out cross validation in order to assess the generality of our CNN model. We also plan to explore how balanced corpora and bigger datasets could help to increase the performance classification of minority classes in the training dataset. Moreover, we would like to explore other deep learning that could effectively deal with the polarity classification of Spanish tweets.

## Abstract

Traditional learning-based approaches to sentiment analysis of written text use the concept of bag-of-words or bag-of- $n$ -grams, where a document is viewed as a set of terms or short combinations of terms disregarding grammar rules or word order. Novel approaches de-emphasize this concept and view the problem as a sequence classification problem. In this context, recurrent neural networks (RNNs) have achieved significant success. The idea is to use RNNs as discriminative binary classifiers to predict a positive or negative sentiment label at every word position then perform a type of pooling to get a sentence-level polarity. Here, we investigate a novel generative approach in which a separate probability distribution is estimated for every sentiment using language models (LMs) based on long short-term memory (LSTM) RNNs. We introduce a novel type of LM using a modified version of bidirectional LSTM (BLSTM) called contextual BLSTM (cBLSTM), where the probability of a word is estimated based on its full left and right contexts. Our approach is compared with a BLSTM binary classifier. Significant improvements are observed in classifying the IMDB movie review dataset. Further improvements are achieved via model combination.

## 1 Introduction

Sentiment analysis of text (also known as opinion mining) is the process of computationally identifying and categorizing opinions expressed in a piece of text in order to determine the writer's attitude towards a particular topic. Due to the tremendous

increase in web content, many organizations became increasingly interested in analyzing this big data in order to monitor the public opinion and assist decision making. Therefore, sentiment analysis attracted the interest of many researchers.

The task of sentiment analysis can be seen as a text classification problem. Depending on the target of the analysis, the classes can be described by continuous primitives such as valence, a polarity state (positive or negative attitude), or a subjectivity state (objective or subjective). In this work, we are interested in the binary classification of documents into a positive or negative attitude. Such detection of polarity is a non-trivial problem due to the existence of noise, comparisons, vocabulary changes, and the use of idioms, irony, and domain specific terminology (Schuller et al., 2015).

Traditional approaches to sentiment analysis rely on the concept of bag-of-words or bag-of- $n$ -grams, where a document is viewed as a set of terms or short combinations of terms disregarding grammar rules or word order. In this case, usually, the analysis involves: tokenization and parsing of text documents, careful selection of important features (terms), dimensionality reduction, and classification of the documents into categories. For example, Pang et al. (2002) have considered different classifiers, such as Naive Bayes (NB), maximum entropy (MaxEnt), and support vector machines (SVM) to detect the polarity of movie reviews. Pang and Lee (2004) have combined polarity and subjectivity analysis and proposed a technique to filter out objective sentences of movie reviews based on finding minimum cuts in graphs. In (Taboada et al., 2011; Ding et al., 2008), lexicon-based techniques are examined, where word-level sentimental orientation scores are used to evaluate the polarity of product reviews. More advanced approaches utilize word or  $n$ -gram vectors, like in (Maas et al., 2011; Dahl et al., 2012).

Novel approaches are mainly based on artificial neural networks (ANNs). These approaches de-emphasize the concept of bag-of-words or bag-of- $n$ -grams. A document is viewed as a set of sentences, each sentence is a sequence of words. The sentiment problem is rather considered as a sequence classification problem. For example, in (Dong et al., 2014; Dong et al., 2016), RNN classifiers are used with an adaptive method to select relevant semantic composition functions for obtaining vector representations of sentences. This is found to improve sentiment classification on the Stanford Sentiment Treebank (SST). Rong et al. (2014) have used a RNN model to learn word representation simultaneously with the sentiment distribution. Santos and Gatti (2014) have proposed a convolutional neural network (CNN) that exploits from character- to sentence-level information to perform sentiment analysis on the Stanford Twitter Sentiment (STS) corpus. Kalchbrenner et al. (2014) have used a dynamic convolutional neural network (DCNN) with a dynamic  $k$ -max pooling to perform sentiment analysis on the SST and Twitter sentiment datasets. Lai et al. (2015) have utilized a combination of RNNs and CNNs called recurrent convolutional neural network (RCNN) to perform text classification on multiple datasets including sentiment analysis on the SST dataset.

Other novel approaches use tree structured neural models instead of sequential models (like RNNs) in order to capture complex semantic relationships that relate words to phrases. Despite their good performance, these models rely on existing parse trees of the underlying sentences which are, in most cases, not readily available or not trivial to generate. For example, Socher et al. (2013) have introduced a recursive neural tensor network (RNTN) to predict the compositional semantic effects in the SST dataset. In (Tai et al., 2015; Le and Zuidema, 2015), tree-structured LSTMs are used to improve the earlier models.

Another perspective to the sentiment problem is to assume that each sentence with a positive or negative class is drawn from a particular probability distribution related to that class. Then, instead of estimating a discriminative model that learns how to separate sentiment classes in sentence space, we estimate a generative model that tells us how these sentences are generated. This generative approach can be better or complementary in some sense to the discriminative approach.

The probability distributions over word sequences are well known as language models (LMs). They have also been used for sentiment analysis. However, no trial is made to go beyond simple bigram models. For example, Hu et al. (2007b) have estimated two separate positive and negative LMs from training collections. Tests are performed by computing the Kullback-Leibler divergence between the LM estimated from the test document and the sentiment LMs. Therein, uni- and bigram models are shown to outperform SVM models in classifying a movie review dataset. In (Hu et al., 2007a), a batch of terms in a domain are identified. Then, two different unigram LMs representing classifying knowledge for every term are built up from subjective sentences. A classifying function based on the generation of a test document is defined for the sentiment classification. This approach has outperformed SVM on a Chinese digital product review dataset. Liu et al. (2012) have employed an emoticon smoothed unigram LM to perform sentiment classification.

In this paper, we compare the generative LM approach with the discriminative binary classification approach. We estimate a separate probability distribution for each sentiment using long-span LMs based on unidirectional LSTMs (Sundermeyer et al., 2012) trained to predict a word depending on its full left context. The probability scores from positive and negative LMs are used to classify unseen sentences. In addition, we introduce a novel type of LM using a modified version of the standard bidirectional LSTM called contextual bidirectional LSTM (cBLSTM). In contrast to the unidirectional model, this model is trained to predict a word depending on its full left and right contexts. Moreover, we combine the LM approach with the binary classification approach using linear interpolation of probabilities. We observe that the cBLSTM LM outperforms both the LSTM LM and the BLSTM binary classifier. Combining approaches together yields further improvements. Models are evaluated on the IMDB large movie review dataset<sup>1</sup> (Maas et al., 2011).

## 2 Language Models

A statistical LM is a probability distribution over word sequences that assigns a probability  $p(w_1^M)$  to any word sequence  $w_1^M$  of length  $M$ . Thus, it provides a way to estimate the relative likelihood

<sup>1</sup><http://ai.stanford.edu/~amaas/data/sentiment/>

of different phrases. It is a widely used model in many natural language processing tasks, like automatic speech recognition, machine translation, and information retrieval. Usually, to estimate a LM, the assumption of the  $(n - 1)^{th}$  order Markov process is used (Bahl et al., 1983), in which a current word  $w_m$  is assumed conditionally dependent on the preceding  $(n - 1)$  history words, such that:

$$p(w_1^M) \approx \prod_{m=1}^M p(w_m | w_{m-n+1}^{m-1}). \quad (1)$$

This is called an  $n$ -gram LM. A conventional approach to estimate these probabilities is the back-off LM which is based on count statistics collected from the training text. In addition to the initial  $n$ -gram approximation, a major drawback of this model is that it backs-off to a shorter history whenever insufficient statistics are observed for a given  $n$ -gram. Novel state-of-the-art LMs are based on ANNs like RNNs that provide long-span probabilities conditioned on all predecessor words (Mikolov et al., 2010; Kombrink et al., 2011).

### 3 Unidirectional RNN Models

#### 3.1 Standard RNN

A RNN maps from a sequence of input observations to a sequence of output labels. The mapping is defined by a set of activation weights and a non-linear activation function. Recurrent connections allow to access activations from past time steps. For an input sequence  $x_1^T$ , a RNN computes the hidden sequence  $h_1^T$  and the output sequence  $y_1^T$  by performing the following operations for time steps  $t = 1$  to  $T$  (Graves et al., 2013):

$$h_t = \mathcal{H}(W_{xh}x_t + W_{hh}h_{t-1} + b_h) \quad (2)$$

$$y_t = W_{hy}h_t + b_y, \quad (3)$$

where  $\mathcal{H}$  is the hidden layer activation function,  $W_{xh}$  is the weight matrix between the input and hidden layer,  $W_{hh}$  is the recurrent weight matrix between the hidden layer and itself,  $W_{hy}$  is the weight matrix between the hidden and output layer,  $b_h$  and  $b_y$  are the hidden and output layer bias vectors respectively.  $\mathcal{H}$  is usually an element-wise application of the sigmoid function.

#### 3.2 LSTM RNN

In (Hochreiter and Schmidhuber, 1997), an alternative RNN called Long Short-Term Memory (LSTM) is introduced where the conventional neuron is replaced with a so-called *memory cell* controlled by input, output and forget gates in order to

overcome the vanishing gradient problem of traditional RNNs. In this case,  $\mathcal{H}$  can be described by the following composite function:

$$i_t = \sigma(W_{xi}x_t + W_{hi}h_{t-1} + W_{ci}c_{t-1} + b_i) \quad (4)$$

$$f_t = \sigma(W_{xf}x_t + W_{hf}h_{t-1} + W_{cf}c_{t-1} + b_f) \quad (5)$$

$$c_t = f_t c_{t-1} + i_t \tanh(W_{xc}x_t + W_{hc}h_{t-1} + b_c) \quad (6)$$

$$o_t = \sigma(W_{xo}x_t + W_{ho}h_{t-1} + W_{co}c_t + b_o) \quad (7)$$

$$h_t = o_t \tanh(c_t), \quad (8)$$

where  $\sigma$  is the sigmoid function,  $i, f, o$ , and  $c$  are respectively the input, forget, output gates, and cell activation vectors (Graves et al., 2013).

#### 3.3 LSTM LM

In a LSTM LM, the time steps correspond to the word positions in a training sentence. At every time step, the network takes as input the word at the current position encoded as a 1-hot binary vector. The input vector is then passed to one or more recurrent hidden layers with self connections that implicitly take into account all the previous history words presented to the network. The output of the final hidden layer is passed to an output layer with a softmax activation function to produce a correctly normalized probability distribution. The target output at each word position is the next word in the sentence. A cross-entropy loss function is used which is equivalent to maximizing the likelihood of the training data. At the end, the network can predict the long-span conditional probability  $p(w_m | w_1^{m-1})$  for any word  $w_m \in V$  and a given history  $w_1^{m-1}$ , where  $V$  is the vocabulary. Fig. 1 shows an unfolded example of a LSTM LM over a sentence  $\langle s \rangle w_1 w_2 w_3 \langle /s \rangle$ , where  $\langle s \rangle$  and  $\langle /s \rangle$  are the sentence start and end symbols.

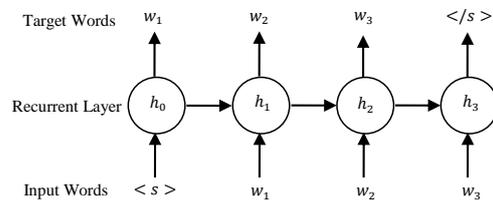

Figure 1: Architecture of a LSTM LM predicting a word given its full previous history.

### 4 Bidirectional RNN Models

#### 4.1 BLSTM RNN

A BLSTM processes input sequences in both directions with two sub-layers in order to account for the full input context. These two sub-layers

compute forward and backward hidden sequences  $\vec{h}$ ,  $\overleftarrow{h}$  respectively, which are then combined to compute the output sequence  $y$  (see Fig. 2), thus:

$$\vec{h}_t = \mathcal{H}(W_{x\vec{h}}x_t + W_{\vec{h}\vec{h}}\vec{h}_{t-1} + b_{\vec{h}}) \quad (9)$$

$$\overleftarrow{h}_t = \mathcal{H}(W_{x\overleftarrow{h}}x_t + W_{\overleftarrow{h}\overleftarrow{h}}\overleftarrow{h}_{t+1} + b_{\overleftarrow{h}}) \quad (10)$$

$$y_t = W_{\vec{h}y}\vec{h}_t + W_{\overleftarrow{h}y}\overleftarrow{h}_t + b_y \quad (11)$$

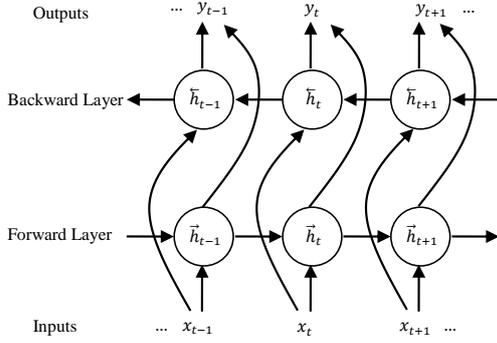

Figure 2: Architecture of a BLSTM, every output depends on the whole input sequence.

## 4.2 Contextual BLSTM LM

The standard BLSTM described in Section 4.1 is not suitable for estimating LMs. This is because it predicts every output symbol depending on the whole input sequence. Since a LM indeed uses the same word sequence in both input and target sides of the network, it would be incorrect to predict a word given the whole input sentence. Rather, it is required to predict a word given the full left and right context while excluding the predicted word itself from the conditional dependence. To allow for this, we modify the architecture of the standard BLSTM such that it accounts for a contextual dependence rather than a full sequence dependence. The new model is called a contextual BLSTM or cBLSTM in short. The architecture of this model is illustrated in Fig. 3.

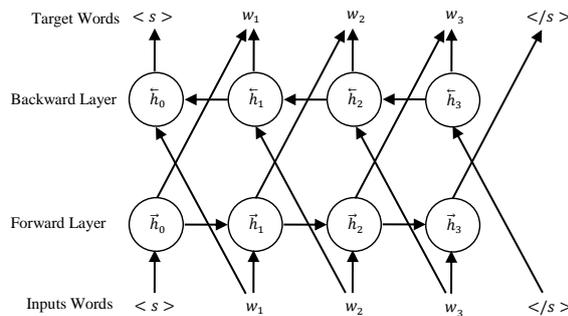

Figure 3: Architecture of a cBLSTM LM predicting a word given its full left and right contexts.

The model consists of a forward and a backward sub-layer. The forward sub-layer receives the encoded input words starting from the sentence start symbol up to the last word before the sentence end symbol (sequence  $\langle s \rangle w_1 w_2 w_3$  in Fig. 3). The forward hidden states are used to predict words starting from the first word after the sentence start symbol up to the sentence end symbol (sequence  $w_1 w_2 w_3 \langle /s \rangle$  in Fig. 3). The backward sub-layer does exactly the reverse operation. The two sub-layers are interleaved together in order to adjust the conditional dependence such that the prediction of any target word depends on the full left and right contexts. Note that the hidden state at the first as well as the last time step needs to be padded by zeros so that the size of the hidden vector is consistent across all time steps. At the end, the model can effectively predict the conditional probability  $p(w_m | w_1^{m-1}, w_{m+1}^M)$  for any word  $w_m \in V$ , left context  $w_1^{m-1}$  and right context  $w_{m+1}^M$ , where  $V$  is the vocabulary and  $M$  is the length of the sentence. Table 1 shows the predicted probability at each time step of Fig. 3. Note that one direction dependence is maintained at the start and end of sentence (time steps 1 and 5).

time step	predicted conditional prob.
1	$p(\langle s \rangle   w_1 w_2 w_3 \langle /s \rangle)$
2	$p(w_1   \langle s \rangle, w_2 w_3 \langle /s \rangle)$
3	$p(w_2   \langle s \rangle w_1, w_3 \langle /s \rangle)$
4	$p(w_3   \langle s \rangle w_1 w_2, \langle /s \rangle)$
5	$p(\langle /s \rangle   \langle s \rangle w_1 w_2 w_3)$

Table 1: Predicted conditional probabilities at every time step of the cBLSTM shown in Fig. 3.

Our implementation of the novel cBLSTM RNN model is integrated into our publicly available CURRENNT<sup>2</sup> toolkit initially introduced by Weninger et al. (2014). A new version of the toolkit with the novel implementations is planned to be available by the date of publication.

Here, it is worth noting that deep cBLSTM models can not be easily constructed by stacking multiple hidden bidirectional layers together. The reason is that the hidden states obtained after the first bidirectional layer are dependent on the full left and right contexts. If these states are utilized as inputs to a second bidirectional layer that identically repeats the same operation again, then the desired conditional dependence will not be correctly

<sup>2</sup><http://sourceforge.net/p/currentnt>

maintained. One method to solve this problem is to create deeper models by stacking multiple forward and backward sub-layers independently. The fusion of both sub-layers takes place at the end of the deep stack. The implementation of such a deep cBLSTM model is not yet available.

## 5 Dataset

Our experiments on sentiment analysis are performed on the IMDB large movie review dataset (v1.0) introduced by Maas et al. (2011). The labeled partition of the dataset consists of 50k balanced full-length movie reviews with 25k positive and 25k negative reviews extracted from the Internet Movie Database (IMDB)<sup>3</sup>.

Since the reviews are in a form of long paragraphs which are difficult to handle directly with RNNs, we break down these paragraphs into relatively short sentences based on punctuation clues. After breaking down the paragraphs, the average number of sentences per review is around 13 sentences. We randomly selected 1000 positive and 1000 negative reviews as our test set. A similar number of random reviews are selected as a development set. The remaining reviews are used as a training set. Note that this is not the official dataset division provided by Maas et al. (2011), where 25k balanced reviews are dedicated for training and the other 25k balanced reviews are dedicated for testing. The reasons not to follow the official division are firstly that, it does not provide a development set; secondly, our proposed models need much data to train well as revealed by initial experiments; thirdly, it would be very time consuming to use the whole data as one partition and perform multi-fold cross validation as usually adopted with large sentiment datasets (Schuller et al., 2015). A preprocessed version of the IMDB dataset with the modified partitioning is planned to be available for download by the date of publication.

A word list of the 10k most frequent words is selected as our vocabulary. This covers around 95% of the words in our development and test sets. Any out-of-vocabulary word is mapped to a special *unk* symbol. We use the classification accuracy as our evaluation measure. The unweighted average F1 scores over positive and negative classes are also calculated. However, their values are found almost similar to the classification accuracies. Therefore, only classification accuracies are reported.

<sup>3</sup><http://www.imdb.com>

## 6 Related Work

The work of this paper is closely related to several previous publications that report sentiment classification accuracy on the same dataset. For example, in (Maas et al., 2011), the IMDB dataset is introduced and a semi-supervised word vector induction framework is used, where an unsupervised probabilistic model similar to latent Dirichlet allocation (LDA) is proposed to learn word vectors. Another supervised model is utilized to constrain words expressing similar sentiment to have similar representations in vector space. In (Dahl et al., 2012), documents are treated as bags of  $n$ -grams. Restricted Boltzmann machines (RBMs) are used to extract vector representations for  $n$ -grams. Then, a linear SVM model is utilized to classify documents based on the resulting feature vectors. Wang and Manning (2012) have used a variant of SVM with Naive Bayes log-count ratios as well as word bigrams as features. This modified SVM model is referred to as NBSVM. In our previous publication (Schuller et al., 2015), LSTM LMs trained on 40% of the whole IMDB dataset are used for performing sentiment analysis. However, a carefully tuned MaxEnt classifier is found to perform better. Le and Mikolov (2014) have used a paragraph vector methodology with an unsupervised algorithm based on feed-forward neural networks that learns fixed-length vector representations from variable-length texts. All these publications use the official IMDB dataset division except for (Schuller et al., 2015), where a similar division as in this paper is used. To give a comprehensive idea about the aforementioned techniques, we show in Table 2 the classification results as reported in the related publications. Note that only the results of (Schuller et al., 2015) are directly comparable to our results.

experiment	Accuracy [%]
Maas et al. (2011)	88.89
Dahl et al. (2012)	89.23
Wang and Manning (2012)	91.22
Schuller et al. (2015)*	91.55
Le and Mikolov (2014)	92.58

Table 2: Sentiment classification accuracies from previous publications on the IMDB dataset.

In relation to our novel cBLSTM LM, previous trials have been made to estimate bidirectional

LMs. For example, in (Frinken et al., 2012), distinct forward and backward LMs are estimated for handwriting recognition. However, no trial is made to go beyond 4-gram models. In (Xiong et al., 2016), standard forward and backward RNN LMs are separately estimated for a conversational speech recognition task. The log probabilities from both models are added. In (Arisoy et al., 2015), bidirectional RNNs and LSTMs are used to estimate LMs for an English speech recognition task. Therein, the standard bidirectional architecture (as in Fig. 2) is used without modifications. This causes circular dependencies to arise when combining probabilities from multiple time steps. Therefore, pseudo-likelihoods are utilized rather than true likelihoods which is not perfect from the mathematical point of view. Not surprisingly, the BLSTM LMs do not yield any gain over the LSTM LMs. In addition, the perplexity of such a model becomes invalid. More importantly, in (Peris and Casacuberta, 2015), bidirectional RNN LMs are used for a statistical machine translation task. However, only standard RNNs but not LSTMs are utilized. Furthermore, no details are provided about how the model is exactly modified and how the left and right dependencies are maintained over time steps.

## 7 Sentiment Classification

### 7.1 Generative LM-based classifier

Our first approach to sentiment classification is the generative approach based on LMs. We either use LSTM LMs described in Section 3.3 or cBLSTM LMs described Section 4.2. Two separate LMs are estimated from positive and negative training data. We use networks with a single hidden layer that consists of 300 memory cells followed by a softmax layer with a dimension of  $10k + 3$ . This is equal to the full vocabulary size in addition to  $\langle s \rangle$ ,  $\langle /s \rangle$ , and  $unk$  symbols representing sentence start, sentence end, and unknown word symbols respectively. In case of using cBLSTM networks, a single hidden layer of 600 memory cells is used (300 cells for each forward and backward sub-layer). A cross-entropy loss function is used with a momentum of 0.9. We use sentence-level mini-batches of size 100 sentences computed in parallel. The learning rate is set initially to  $10^{-3}$  and then decreased gradually to  $10^{-6}$ . The training process is controlled by monitoring the cross-entropy error over the development set.

In addition, we use a data sub-sampling methodology during training. For this purpose, a traditional 5-gram backoff LM is created out of the development data, we call this a *ranking LM*. Then, all training sentences are ranked according to their perplexities with the ranking LM. Using these ranks, we divide our training sentences into three partitions that reflect the relative importance of the data, such that the first partition contains the 100k sentences with the lowest perplexities, the second partition contains the 100k sentences with next lowest perplexities. The third partition contains all the other sentences. Instead of using the whole training data in each epoch, we use a random sample with more sentences from the first two partitions than the third one. After a sufficient number of epochs, the whole training data is covered. The sub-sampling approach speeds up the training and makes it feasible with any size of training data. At the same time, the training is focused on the relatively more important examples. In addition, it adds a useful regularization to the training process. Yet, it leads to a less smoother convergence. To show the efficiency of our sentence ranking methodology, Table 3 shows examples of the highest and lowest ranked sentences from positive and negative training data.

<b>most +ve</b>	this is one of the best films ever made.
<b>least +ve</b>	cheap laughs but great value.
<b>most -ve</b>	this is one of the worst movies i have ever seen.
<b>least -ve</b>	life's too short.

Table 3: Examples of the highest/lowest ranked sentences from positive/negative training data.

After training the neural networks, each of the positive and negative sentiment LM estimates a probability distribution for the corresponding sentiment, we call these probability distributions  $p_+$  and  $p_-$ . To evaluate the sentiment of some test review, we calculate the perplexity of each model  $p_+$  and  $p_-$  with respect to the whole review. Thus, given a probability distribution  $p$ , and a review text  $S$  composed of  $K$  sentences  $S = s_1, \dots, s_K$ , each sentence  $s_k : 1 \leq k \leq K$  is composed of a sequence of  $M_k$  words  $s_k = w_1^k, w_2^k, \dots, w_{M_k}^k$ ; we calculate the perplexity  $PP_p(S)$  of a model  $p$  with respect to text  $S$ . It is a very common measure-

ment of how well a probability distribution predicts a sample. A low perplexity indicates that the probability distribution is good at predicting the sample. Perplexity is defined as the exponentiated negative average log-likelihood, or in other words, the inverse of the geometric average probability assigned by the model to each word in the sample. We calculate the Perplexity using Equation 12 if the model  $p$  is based on LSTM, and using Equation 13 if the model is based on cBLSTM:

$$PP_p(S) = \left[ \prod_{k=1}^K \prod_{m=1}^{M_k} p(w_m^k | w_1^k, w_2^k, \dots, w_{m-1}^k) \right]^{\frac{-1}{N}} \quad (12)$$

$$PP_p(S) = \left[ \prod_{k=1}^K \prod_{m=1}^{M_k} p(w_m^k | w_1^k, w_2^k, \dots, w_{m-1}^k; w_{m+1}^k, w_{m+2}^k, \dots, w_{M_k}^k) \right]^{\frac{-1}{N}}, \quad (13)$$

where  $N = \sum_{k=1}^K M_k$  is the total number of words in text  $S$ . Then, a sentiment polarity  $\mathcal{P} \in \{-1, +1\}$  is assigned to  $S$  according to the following decision rule:

$$\mathcal{P}(S) = \begin{cases} +1 & \text{if } PP_{p_+}(S) < PP_{p_-}(S) \\ -1 & \text{otherwise} \end{cases}. \quad (14)$$

## 7.2 Discriminative BLSTM-based Binary Classifier

Our second approach to sentiment classification is the discriminative approach based on BLSTM RNNs described in Section 4.1. We use BLSTM networks with a single hidden layer that consists of 600 memory cells (300 cells for each forward and backward sub-layer). Since the BLSTM performs a binary classification task, only a single output neuron is used with a sigmoid activation function. A cross-entropy loss function is used with a momentum of 0.9. The same training settings like the case of LSTM/cBLSTM LMs are used including sub-sampling with the same partitioning of the training data. However, a single training dataset with all positive and negative reviews is used. For a sentence with a positive sentiment, the target outputs are set to *ones* at all time steps. For a sentence with a negative sentiment, the target outputs are set to *zeros* at all time steps. Since the sigmoid function provides output values in the interval  $[0,1]$ ,

the network is trained to produce the probability of the positive class at every time step. Although the output of the BLSTM network at a given time step is dependent on the whole input sequence, it is widely known that every output is more affected by the inputs at closer time steps in both directions. Therefore, a sentence-level sentiment can be deduced by comparing the average probability mass assigned to the positive class over all time steps with the average probability mass assigned to the negative class. Thus, similar to Section 7.1, given a review text  $S$  composed of  $K$  sentences, each sentence is a sequence of  $M_k$  words, we calculate two probabilities  $p_+(S)$  and  $p_-(S)$  that the review  $S$  has a positive or negative sentiment using Equations 15 and 16 respectively:

$$p_+(S) = \frac{1}{N} \sum_{k=1}^K \sum_{m=1}^{M_k} p_+(w_m^k) \quad (15)$$

$$p_-(S) = \frac{1}{N} \sum_{k=1}^K \sum_{m=1}^{M_k} (1 - p_+(w_m^k)), \quad (16)$$

where  $N$  is the total number of words in text  $S$ , and  $p_+(w_m^k)$  is the probability that a positive class is assigned to the word at position  $m$  of the  $k^{th}$  sentence of the review  $S$ . Then, a sentiment polarity  $\mathcal{P} \in \{-1, +1\}$  is assigned to  $S$  according to the following decision rule:

$$\mathcal{P}(S) = \begin{cases} +1 & \text{if } p_+(S) > p_-(S) \\ -1 & \text{otherwise} \end{cases}. \quad (17)$$

## 7.3 Model Combination

The probability scores of the generative LM-based classifier and the discriminative BLSTM-based binary classifier discussed in Sections 7.1 and 7.2 can be combined together via linear interpolation. This is achieved by first normalizing the probabilities from the LMs such that the probabilities of positive and negative classes for a given review are summed up to 1.0. Note that this normalization property holds by default for the BLSTM-based binary classifier. Then, the probabilities of both models are linearly interpolated to obtain a single probability score. The interpolation weights are optimized on the development data.

## 8 Experimental Results

Table 4 shows the results of our experiments. All the neural networks in this work are trained

and optimized using our own CURRENNT toolkit (Weninger et al., 2014). Both the LSTM and cBLSTM LMs are linearly interpolated with two additional LMs, namely a 5-gram backoff LM smoothed with modified Kneser-Ney smoothing (Kneser and Ney, 1995), and another 5-gram MaxEnt LM (Alumäe and Kurimo, 2010). These two models are estimated using the SRILM language modeling toolkit (Stolcke, 2002).

classification model	Acc. [%]
LSTM LM	89.58
+ 5-grm backoff LM	91.05
+ 5-grm MaxEnt LM	91.23
cBLSTM LM	89.88
+ 5-grm backoff LM	91.38
+ 5-grm MaxEnt LM	91.48
BLSTM binary classifier	90.15
LSTM LM + BLSTM binary classifier	92.35
cBLSTM LM + BLSTM binary classifier	<b>92.83</b>
Schuller et al. (2015) LSTM + 5-grm LM	90.50
Schuller et al. (2015) MaxEnt classifier	91.55

Table 4: Sentiment classification accuracies measured on the IMDB dataset.

We observe that the use of cBLSTM LM as a generative sentiment classifier significantly outperforms the use of both LSTM LM and BLSTM discriminative binary classifiers. The statistical significance is verified using a bootstrap method of significance analysis described by Bisani and Ney (2004). The probability of improvement ( $POI_{boot}$ ) is around 95%. Combining LM-based classifiers with BLSTM-based binary classifiers via linear interpolation of probabilities achieves further improvements. Our best accuracy (92.83%) is obtained by combining the cBLSTM LM classifier with the BLSTM binary classifier. These results reveal that both the generative and discriminative approaches are complementary in solving the sentiment classification problem.

Finally, our best result is better than the best previously published result in (Schuller et al., 2015) on the same IMDB dataset with the same dataset partitioning. Even though they are not directly comparable, our results are better than other previously published results reported in Table 2 where a different dataset partitioning is used.

For illustration, Table 5 shows two examples of positive and negative reviews that could not be

correctly classified by the discriminative BLSTM binary classifier, however they are correctly classified by the cBLSTM LM classifier. We can observe the implicit indication of the writer’s attitude towards the movie which can not be easily captured by simple approaches. In this case, learning a separate long-span bidirectional probability distribution for each sentiment seems to help.

<b>+ve</b>	low budget mostly no name actors. this is what a campy horror flick is supposed to be all about. these are the types of movies that kept me on the edge of my seat as a kid staying up too late to watch cable. if you liked the eighties horror scene this is the movie for you.
<b>-ve</b>	i and a friend rented this movie. we both found the movie soundtrack and production techniques to be lagging. the movie’s plot appeared to drag on throughout with little surprise in the ending. we both agreed that the movie could have been compressed into roughly an hour giving it more suspense and moving plot.

Table 5: Examples of reviews correctly classified by the cBLSTM LM classifier.

## 9 Conclusions

We have introduced a generative approach to sentiment analysis in which a novel contextual BLSTM (cBLSTM) LM is used as a sentiment classifier. Separate LM probability distributions are estimated for positive and negative sentiment from the training data. Then, probability scores from these LMs are utilized to classify test data. Results have been compared with a discriminative sentiment classification approach that uses a BLSTM-based binary classifier. We have observed that the generative cBLSTM LM approach significantly outperforms other approaches. Models have been evaluated on the IMDB large movie review dataset. The proposed models have achieved better results than the previously published results on the same dataset with the same partitioning. In addition, indicative comparisons have been made with the previously published results on the same dataset with different partitioning. Using model combi-

nation, we could achieve further performance improvement indicating that both the generative and discriminative approaches are complementary in solving the sentiment analysis problem. Moreover, we have introduced an efficient methodology based on perplexity calculation to partition the training data according to relative importance to the learning task. This partitioning methodology has been combined with a sub-sampling technique to efficiently train the neural networks on large data. As a future work, we plan to investigate deeper cBLSTM as well as hybrid recurrent and convolutional models. Another direction is to experiment with pre-trained word vectors.

## Acknowledgments

The research leading to these results has received funding from the European Unions Horizon 2020 Programme through the Research and Innovation Action #645378 (ARIA-VALUSPA), the Innovation Action #644632 (MixedEmotions), as well as the German Federal Ministry of Education, Science, Research and Technology (BMBF) under grant agreement #16SV7213 (EmotAsS). We further thank the NVIDIA Corporation for their support of this research by Tesla K40 GPU donation.

## Abstract

We investigate the task of open domain opinion relation extraction. Given a large number of unlabelled texts, we propose an efficient distantly supervised framework based on pattern matching and neural network classifiers. The patterns are designed to automatically generate training data, and the deep learning model is designed to capture various lexical and syntactic features. The result algorithm is fast and scalable on large-scale corpus. We test the system on the Amazon online review dataset, and show that the proposed model is able to achieve promising performances without any human annotations.

## 1 Introduction

Opinion mining systems aim to detect and extract opinion-related information from texts. With the help of natural language processing algorithms and large-scale user generated contents, researchers could take a closer look at how people express their opinions on various objects and topics. Such observations are important both for applications (e.g., recommendation and retrieval) and linguistic studies.

In this paper, we address the task of opinion relation extraction. The task tries to identify opinion expressions (words indicating sentiments, emotions and comments), opinion targets (objects of opinions) and their relations (what opinion on which target). The following are two examples.

1. The unit is [well designed] and [perfect reception].

2. The Passion of The Christ will [touch your heart].

Opinion relations in the two sentences are (“well designed”, “unit”), (“perfect reception”, “unit”), and (“touch your heart”, “The Passion of The Christ”). Extracting opinion bearing relations is usually the first step towards fine-grained analysis of opinion in texts, and plays an important role in other sentiment related applications (e.g., sentiment summarization). The goal of this paper is to extract opinion relations from open domain large-scale opinion bearing texts.

Previous works on fine-grained opinion information extraction have achieved notable success on many aspects: various domains were examined (Pontiki et al., 2015), different types of relations were studied (Ganapathibhotla and Liu, 2008; Narayanan et al., 2009; Wu et al., 2011), and both supervised and unsupervised (pattern-based) algorithms were applied. But we have observed some difficulties when trying to use existing methods. The pattern based methods (both lexical patterns and syntactic patterns) are simple, fast, and scalable on large-scale datasets. However, the robustness of patterns is usually questionable in practice. For example, syntactic patterns are sensitive to errors in parse trees, which are common in user generated contents. Lexical patterns either have limited coverage (e.g., fixed set of patterns (Riloff and Wiebe, 2003)), or hard-to-control noise (e.g., bootstrapping approaches (Qiu et al., 2011)). On the other hand, supervised models can achieve better performances than patterns on manually labeled datasets, but it is often difficult to obtain large number of annotations for the relation extraction task, and the trained models are

also limited to specified domains. Thus, we still need an algorithm to better combine the power of syntactic and lexical patterns, while reduce manual annotations.

Another problem is that many existing systems rely on general purpose opinion lexicons to select candidate relations. If an opinion expression is not recognized by the lexicon, the systems are unable to extract the related relations. As an example, one weakness of many existing lexicons is the lack of support on multiword expressions (e.g., “more than what I expected”, “honest to the book” and “adrenaline pumping”), which are common in opinion bearing texts. Another example is that some true expressions could be ignored either due to errors from POS taggers and syntactic parsers. Thus, to enlarge the coverage of opinion relation extraction, we need some method to better detect opinion expressions.

Regarding above problems, we make efforts to contribute to following aspects.

First, we propose a distantly supervised algorithm for open domain opinion relation extraction. The algorithm first applies domain independent patterns to get a set of opinion relations, then trains a classifier on them. We show that, although the relations from pattern matching are not as accurate as gold standard annotations, the distantly supervised classifier still improves performances. Our algorithm significantly outperforms the double propagation algorithm (Qiu et al., 2011), which is the state-of-the-art unsupervised opinion relation extraction system.

Second, we develop a neural network model to learn representations for lexical and syntactic contexts. The model uses bidirectional LSTMs to capture global information and convolutional neural networks to get local low dimensional feature embeddings. Comparing with other neural network models on relation extraction, we learn representations for different contexts explicitly, which is inspired by features in traditional relation classifiers. Empirical results show that the proposed model outperforms a strong logistic regression baseline, which uses handcrafted features as state-of-the-art supervised relation classifiers.

Third, we explore an unsupervised classifier to detect multiword opinion expressions. Given an expression, the classifier looks adjacent words and predicts whether it is an opinion expression. The new classifier helps us to discover opinion expres-

sions which are not in general purpose opinion lexicons, and benefits the relation extractor.

We aim to make all algorithms simple, fast and scalable for large-scale corpus. Our system is tested on Amazon review data which contains 15 different domains and 33 million reviews. The output database contains 72.5 million pairs of opinion relations. Extensive experiments have been conducted on various aspects of the algorithm, and the performances of the proposed unsupervised models are even competitive with previous supervised models.

## 2 Related Works

Opinion relation extraction is an important task for fine-grained sentiment analysis. If human annotations are provided (e.g. MPQA corpus (Deng and Wiebe, 2015)), we could formulate the task into a supervised relation extraction problem as (Kobayashi et al., 2007; Johansson and Moschitti, 2013). Two types of models have been applied: pipeline models which first extract candidates of opinion expressions and targets then identify correct relations (Wu et al., 2009; Li et al., 2010; Yang and Cardie, 2012), and joint models which extract opinion expressions, targets and relations using a unified joint model (Yang and Cardie, 2013; Yang and Cardie, 2014). One consideration of applying supervised methods is their dependencies on the domains and human annotations.

Semi-supervised and unsupervised models are also applied for extracting opinion relations. Approaches include rule-based bootstrapping (Qiu et al., 2011), graph propagation algorithms (Xu et al., 2013; Liu et al., 2014; Brody and Elhadad, 2010), integer programming (Lu et al., 2011), and probabilistic topic models (Titov and McDonald, 2008; Mukherjee and Liu, 2012).

Our model is inspired by previous distantly supervised algorithms (Snow et al., 2004; Mintz et al., 2009). They use relations from WordNet or knowledge bases as distant supervision. Since we don't have similar resources for opinion relation extraction, we use patterns to generate relations. Neural network classifiers are popular for relation extraction recently. Many of them focus on fully supervised settings, recurrent neural networks (RNN) and convolutional neural networks (CNN) (Vu et al., 2016; Zeng et al., 2015; Xu et al., 2015a; Xu et al., 2015b; Zhang and Wang, 2015), sequence models and tree models

are investigated (Li et al., 2015; dos Santos et al., 2015). One similar network structure to our model is proposed in (Miwa and Bansal, 2016). They jointly extract entities and relations using two LSTM models. Another recent work (Jebbara and Cimiano, 2016) uses stacked RNNs and CNNs for aspect and opinion detection. Different from models there, we will learn representations for different lexical and syntactic features explicitly. Our formulation follows the features in traditional relation classifiers, which helps to interpret the learned vectors.

A closely related task is aspect-based opinion mining (Zhao et al., 2010; Yu et al., 2011; Wang et al., 2015). Instead of locating the opinion expressions, aspect-based opinion mining directly analyzes polarities of different opinion targets. The targets are usually constrained to be some predefined set. Shared tasks (SemEval2014, SemEval2015) have been held on the task, and various systems are proposed and evaluated (Pontiki et al., 2014; Pontiki et al., 2015). Comparing with aspect-based opinion mining, we will extract opinion expressions which are more informative, and we won't constrain opinion target types which helps us to handle open domain texts.

### 3 The Approach

Given an input sentence  $s = w_1, w_2, \dots, w_n$ , where  $w_i$  is a word, the opinion relation extraction task outputs  $(O, T)$  pairs, where  $O = w_i, w_{i+1}, \dots, w_j$  is an opinion expression,  $T = w_k, w_{k+1}, \dots, w_l$  is an opinion target and the pair  $(O, T)$  is an opinion relation which asserts that opinion  $O$  is directed to target  $T$ <sup>1</sup>. Both  $O$  and  $T$  could be multiword expressions.

#### 3.1 Patterns

Syntactic patterns have been shown to be effective for relation extraction. They are fast and can generalize well across domains, which are highly desirable for the open domain large-scale relation extraction task. However, despite of their advantages, two concerns are often raised: syntactic trees could be unreliable due to noise in texts and parsing errors, and the coverage of patterns is limited. To tackle the first problem, we deploy strong constraints on patterns in order to guarantee the quality of output. For the second problem, we en-

<sup>1</sup>We assume  $O, T$  are non-overlapped, and their distance in  $s$  is less than a threshold (10 in all experiments).

large the coverage by using a distantly supervised classifier (Section 3.2) and an opinion expression classifier (Section 3.3)

Table 1 lists the patterns used in our system. Like (Qiu et al., 2011), patterns are based on the dependency tree of input sentences, which basically capture adjective-noun, verb-complement and adverb-verb relations. The notation  $w_1 \xrightarrow{l} w_2$  denotes that there is a dependency relation between word  $w_1$  and  $w_2$  with dependency relation type  $l$ . For example, the pattern P1 is activated if  $w_1$  is the parent of  $w_2$  in the dependency tree, and the dependency type is `amod` or `dep`.

In order to overcome noise and errors in dependency trees, we constrain all patterns by predefined part-of-speech (POS) tag sets and a general purpose opinion lexicon  $L$ . For example, the pattern P1 only accepts nouns and adjectives as arguments, and the adjectives are required to be an opinion word in  $L$ .

We also design the patterns to be able to handle multiword opinion expressions and targets (about 30% of all annotated expressions). Two cases are considered here. First, when two words match a pattern, we expand them to the smallest phrases containing them. It helps to collect some local contexts of opinion relations. For example, in pattern P4, the matching words "case" and "choice" are expanded to "the case" and "an excellent choice". Second, a relation pair could be compiled to a new opinion expression, which may have relations with other opinion targets. For example, in pattern C2, ("perfectly", "fit") is a relation, and it can be compiled into "fit perfectly" which appears in a new relation ("fit perfectly", "the case"). The compiled expressions can bring more informative relations which are ignored in previous works.

As an alternative of pattern matching, we also investigate the bootstrapping setting like (Qiu et al., 2011). In this setting, the algorithm is allowed to add new words to the opinion lexicon, and use the updated lexicon for successive pattern matching. While the bootstrapping could discover new opinion words which are not in the original lexicon, we find that the errors caused by newly added words are hard to control, and the advantages of bootstrapping are suppressed by the noise as the corpus becomes large. We will show (in the experiment section) that the accuracy drops 30% comparing with the direct pattern matching.

Name	Pattern	Output	Example
P1	$w_1 \xrightarrow[\text{dep}]{\text{amod}} w_2$ $w_1.\text{pos} \in \text{NOUN}, w_2.\text{pos} \in \text{ADJ}$	$T = w_1.\text{np}$ $O = w_2$	It is a [cool] <u>case</u> . $\text{case} \xrightarrow{\text{amod}} \text{cool}$
P2	$w_1 \xrightarrow[\text{xcomp}]{\text{acomp}} w_2$ $w_1.\text{pos} \in \text{VERB}, w_2.\text{pos} \in \text{ADJ}$	$T = w_1.\text{vp}$ $O = w_2$	The case <u>looks</u> [great]. $\text{looks} \xrightarrow{\text{xcomp}} \text{great}$
P3	$w_1 \xrightarrow{\text{advmod}} w_2$ $w_1.\text{pos} \in \text{VERB}, w_2.\text{pos} \in \text{ADV}$	$T = w_1$ $O = w_2$	The cover <u>matches</u> [perfectly]. $\text{matches} \xrightarrow{\text{advmod}} \text{perfectly}$
P4	$w_1 \xrightarrow{\text{nsbj}} w_2$ $w_1.\text{pos} \in \text{NOUN},$ $w_2.\text{pos} \in \text{NOUN or VERB or ADJ}$ has a coplua verb between $w_1$ and $w_2$	$T = w_1.\text{np}$ $(O = w_2.\text{np}$ $O = w_2.\text{vp}$ $O = w_2.\text{adjp})$	<u>This case</u> is [an excellent choice]. $\text{case} \xleftarrow{\text{nsbj}} \text{choice}$
C1	$w_1 \xleftarrow{\text{conj}} (O', T')$ $O'.\text{pos.} \in \text{ADJ or ADV}$ $w_1.\text{pos} \in \text{ADJ or ADV}$	$T = T'$ $O = w_1$	The case <u>looks</u> [great] and very [cute]. $\text{cute} \xleftarrow{\text{conj}} (\text{great, looks})$
C2	$(O', T') \xrightarrow{\text{nsbj}} w_1$ $w_1.\text{pos} \in \text{NOUN}, T'.\text{pos} \in \text{VERB}$ $O'.\text{pos} \in \text{ADV}, T'$ and $O'$ are adjacent	$T = w_1$ $O = T'O'$	<u>The case</u> [fits perfectly]. $(\text{perfectly, fits}) \xrightarrow{\text{nsbj}} \text{the case}$

Table 1: Syntactic patterns in the system. We denote POS tag sets: NOUN = {NN, NNS}, VERB = {VB, VBD, VBN, VBP, VBZ}, ADJ = {JJ, JJR, JJS}, ADV = {RB, RBR, RBS}.  $w_i.\text{pos}$  is the POS tag of  $w_i$ .  $w_i.\text{np}$  ( $w_i.\text{vp}$ ,  $w_i.\text{adjp}$ ) is the smallest noun (verb, adjective) phrase containing  $w_i$  (return  $w_i$  if no such phrase exists).  $T, T'$  are opinion targets,  $O, O'$  are opinion expressions. “ $(O', T') \rightarrow$ ” and “ $\leftarrow (O', T')$ ” represent dependency relations on words  $O'$  and  $T'$  respectively.

### 3.2 Distant Supervision

Despite of the high precision, one well-known disadvantage of pattern-based methods is the low coverage. Consider the following example,

Ordered the k9ballistics Crate Pad and I  
am [so pleased].

No pattern in Table 1 is applicable on relation (“so pleased”, “Ordered the k9ballistics Crate Pad”), although it could be inferred from the context. In fact, the two expressions are close in distance, and “Ordered the k9ballistics Crate Pad ” is the only possible object of “please” in the sentence. Many similar cases appear in online review corpus which downgrade the performance of patterns. To further explore those relations, we develop distantly supervised classifiers to integrate various lexical and syntactic contexts. Our experiments show that classifiers help to increase coverage of patterns by 20%.

Given a candidate relation  $x = (O, T)$  in sentence  $s$ , the classifier outputs probability  $p(y|x), y \in \{1, -1\}$  telling whether  $x$  is a valid opinion relation. Since manually labelled corpus are costly and difficult to obtain for open domains, we would prefer unsupervised classifiers. On the other side, the pattern matching can generate a set of opinion relations without any human annota-

tions. Although the relations are not completely correct, they are almost free to collect and easily amount to a large set. Thus, we can take the relations from the pattern matching as the distant supervision, and hope the broad coverage could overcome the noise.

Formally, we take all relations extracted by patterns as positive samples. For each positive sample  $(O, T)$ , we add a negative sample  $(O, T')$  for  $T' \neq T$  ( $T'$  is NP, VP or ADJP). Similarly, we add negative samples  $(O', T)$  for all  $O' \neq O$ . At test time, we consider all VP and ADJP in  $s$  which contain at least one word in the general opinion lexicon  $L$  as candidate opinion expressions, all NP and VP as candidate opinion targets, and all possible pairs between them are candidate relations.

Our distantly supervised classifier is based on a neural network. Different from most previous deep learning models, the classifier learns representations for different lexical and syntactic contexts explicitly, which is inspired by features in traditional (non-neural-network-based) relation classifiers. We would observe from experiments that knowledge from previous feature engineering works can help neural network models to achieve better performances. Before explaining the model, we refresh some notations first. For  $x = (O, T)$  in sentence  $s$ , where

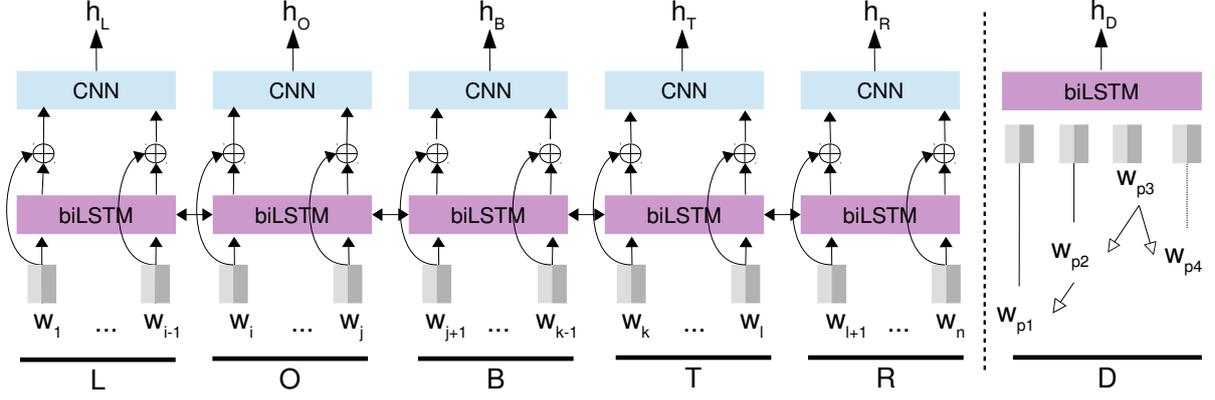

Figure 1: Representation learning of lexical and syntactic contexts. The left hand side is the five CNNs and the sentence level biLSTM for lexical contexts. For a word  $w$ , operator “ $\oplus$ ” concatenates word/POS embeddings of  $w$  and the output vectors of the biLSTM on  $w$ . The right hand side is the biLSTM for syntactic contexts.  $w_{p1}, \dots, w_{p4}$  is the dependency path  $D$ ,  $w_{p3}$  is the lowest common ancestor of head words of  $O$  and  $T$ .

$O = w_i, \dots, w_j, T = w_k, \dots, w_l$ , denote other parts of  $s$  to be  $L = w_1, \dots, w_{i-1}, B = w_{i+1}, \dots, w_{k-1}, R = w_{l+1}, \dots, w_n$ , where  $L, R$  are the left and right contexts of  $x$ ,  $B$  is the context between  $O$  and  $T$ <sup>2</sup>. Let  $D = w_{p1}, \dots, w_{pm}$  be the path connecting head words of  $O$  and  $T$  in the dependency tree.

To capture lexical contexts of  $x$ , we use five convolutional neural networks (CNN) to learn representations for  $L, O, B, T, R$ . Take  $B$  as an example, the output  $\mathbf{h}_B \in \mathbf{R}^d$  is the result of a single layer convolution of inputs with max-pooling. The input of the CNN includes word and POS tag embeddings of  $w_{i+1}, \dots, w_{k-1}$ . The five local CNN models can be independently trained before making the final predictions, however, it ignores global information of the sentence, and also the potential sharing of features among local models. In order to incorporate global structures, we build the five local models on top of a sentence level bidirectional long short term memory network (biLSTM). The recurrent structure and memory mechanism of biLSTM can propagate and share long distance features of  $s$ . We take outputs of memory cells as inputs of the CNN models (in addition to the embeddings). All representations  $\mathbf{h}_L, \mathbf{h}_O, \mathbf{h}_B, \mathbf{h}_T, \mathbf{h}_R$  use the same network structure in our experiments. Finally, to make a prediction on  $y$ , we use a softmax function  $p(y|x) = \frac{1}{Z} \exp\{\theta^T \Phi(x, y)\}$  on the weighted averaged fea-

<sup>2</sup>For simplicity, we assume  $O$  appears before  $T$ . In the implementation, an indicator dimension is set to identify whether  $O$  appears first.

ture vector  $\Phi(x, y)$ ,

$$\Phi(x, y) = a_L \mathbf{h}_L + a_O \mathbf{h}_O + a_B \mathbf{h}_B + a_T \mathbf{h}_T + a_R \mathbf{h}_R,$$

where  $a_L, a_O, a_B, a_T, a_R \in \mathbf{R}, \theta \in \mathbf{R}^d$  are parameters of the model.

We also try to incorporate dependency path  $D$  into the model as suggested by (Xu et al., 2015a; Xu et al., 2015b). We use a similar bidirectional LSTM like (Xu et al., 2015b), and concatenate the final outputs of the forward LSTM and the backward LSTM to get feature representation  $\mathbf{h}_D \in \mathbf{R}^d$ . The experiments show that, however,  $\mathbf{h}_D$  can not get further performance gains. We suspect that the errors from dependency parsing limited the contribution of this feature.

### 3.3 Opinion Expression Classifier

In above pattern matching and distant supervision algorithms, a candidate opinion expression is extracted if it contains at least one opinion word in the general purpose opinion lexicon  $L$ . Although the simple approach helps to handle multiword expressions, some expressions could also be ignored since they have no opinion words in  $L$  or their POS tags are wrongly assigned. In this section, we introduce our unsupervised opinion expression classifier, which predicts whether a phrase is an opinion expression based on its contexts.

Formally, for a candidate expression  $O = w_i, \dots, w_j$  in sentence  $s$ , we use context words  $w_{i-c}, \dots, w_{i-1}$  and  $w_{j+1}, \dots, w_{j+c}$  as inputs of a CNN classifier ( $c$  is the context window size, and

we set it to 5 in all experiments). After the convolution layer, max-pooling and softmax (similar to the CNNs in Section 3.2), the classifier outputs probability  $p(z|O)$  where  $z \in \{-1, 1\}$  indicates whether  $O$  is a valid opinion expression. In order to get the training set, we rely on the lexicon  $L$ . Given the unlabelled corpus and  $w \in L$ , we consider each appearance of  $w$  in the corpus as a positive example, and other randomly chosen words as negative examples.

To apply the opinion expression classifier in the opinion relation classifier, we add expressions which have  $p(z|O)$  greater than some threshold  $\gamma$  to the relation classifier.

## 4 Experiments

### 4.1 Configurations

We extract opinion relations on a subset of Amazon product review corpus provided by (McAuley et al., 2015), which contains 15 domains and 33 million reviews. The statistics of extracted relations are in Table 2.

For quantitative evaluation, we select four domains (Cell Phones, Movie and TV, Food, Pet Supplies) for detailed analyses. We manually label all correct opinion relations in 1000 sentences, and select 200 sentences as the development set, the rest 800 as the test set<sup>3</sup>. Furthermore, to compare with previous supervised methods, we also conduct experiments on USAGE corpus (Klinger and Cimiano, 2014) which annotates 4481 opinion relations for 8 products.

We use NLTK (Bird et al., 2009) for sentence splitting and word segmentation, Stanford parser<sup>4</sup> for getting POS tags, phrase chunks and dependency trees, and scikit-learn toolkit (Pedregosa et al., 2011) and TensorFlow<sup>5</sup> for machine learning algorithms. The general purpose opinion lexicon is from (Wilson et al., 2005).

### 4.2 Main Results

Table 4 shows results on four domains. The methods for comparison are:

- **Adjacent** is a simple baseline system from (Hu and Liu, 2004). It first identifies words in the general purpose opinion lexicon, then finds the nearest noun or verb phrase to them as their opinion targets.

All	33	223.9	72.5

Table 2: Statistics of the opinion relation database. The relations are extracted by patterns in Table 1 and normalized by removing leading articles, pronouns and copulas of opinion expressions and targets. All numbers are in  $10^6$ .

- **Bootstrapping** reimplements the double propagation in (Qiu et al., 2011), which is the state-of-the-art unsupervised opinion relation extraction algorithm. It also uses a set of patterns, but adds new opinion words discovered by the patterns to the existing lexicon on the fly. The updated lexicon is then used in following bootstrapping iterations.
- **Pattern** is the pattern matching method in Section 3.1.
- **LR** is a logistic regression trained with the same distant supervision as Section 3.2. We use standard relation extraction features (Table 3), which are used in state-of-the-art supervised relation classifiers (Mintz et al., 2009)<sup>6</sup>.
- **NN** is our neural network model in Section 3.2. We set the dimension  $d$  of outputs (e.g.,  $\mathbf{h}_B$ ) be 128, the output dimension of biLSTM be 128, the dimension of word/POS tag embeddings be 300. We use three convolution kernels with window size 1, 2, 3, and initialize word embeddings with pre-trained word vectors from word2vec tools<sup>7</sup>. By default, we use the five CNNs on the sentence level biLSTM and not include dependency path  $\mathbf{h}_D$  and the opinion expression classifier (the configuration of “NN” equals “biLSTM+LOBTR” in Table 5). In order to build

the training set, we run the pattern matching on  $6 \times 10^4$  unlabelled sentences.

- **NN+Pattern** stacks results of “Pattern” and “NN”.

We have several observations on Table 4. First, performances of “Adjacent” are poor, which means that we do need some advanced linguistic features for the task. Second, “Bootstrapping” underperforms “Pattern” in four domains. We examine the outputs of “Bootstrapping” and find that the newly added words bring a lot of noise into the opinion lexicon, which affect the accuracy negatively. Third, while “Pattern” has the highest precision in all systems, distantly supervised methods (“LR” and “NN”) help to improve recall and achieve better F1 values (except on the Pet domain). Hence, based on the distant supervision from patterns, classifiers cover more correct relations. Regarding the Pet domain, the precision of “Pattern” is low, so the number of errors in training set of “LR” and “NN” is large, and one could fail to learn reliable models. Fourth, the neural network model “NN” outperforms traditional classifier “LR” on all domains, which shows that learning feature representations has some advantages than handcrafting features on our experiment settings. Finally, simply stacking the results of “Pattern” and “NN” can improve the overall scores.

Next, we test our neural network model with various settings in Table 5. First, we compare models with different configurations on CNNs in row 1 to row 3. The setting “biLSTM+B” only uses the CNN corresponding to the words in  $B$  (i.e., the words between  $O$  and  $T$ ); “biLSTM+OBT” uses three CNN on words in  $B, O, T$ ; “biLSTM+LOBTR” involves all five CNNs (equals to “NN” in Table 4). We see

that, in general, the performances (especially recalls) increase as we introduce more CNNs. However, the dependency path feature  $\mathbf{h}_D$  (“biLSTM+LOBTR+D” in row 4) won’t help to get further improvements. Second, in row 5, we drop the sentence level biLSTM and only use the five CNNs, and observe some loss on performances compared with row “biLSTM+LOBTR”. Hence, the long distance information provided by the biLSTM is also helpful. Third, we test the opinion expression classifier in the last two rows. Recall that  $\gamma$  is the threshold that controls the output of the classifier. The result shows that when  $\gamma = 0.8$ , new opinion expressions added by the classifier can improve the scores, but when  $\gamma = 0.5$ , the noise can overwhelm the gains. We further show the precision-recall curves of “NN” and “LR” in the case of  $\gamma = 0.8$  in Figure 2. Some interesting opinion expressions added by the classifier are “not even enough”, “became extremely hot”, “\*just\* enough”, “arrived damaged”, “looks cool n cute”, which shows that the classifier could both discover opinion expressions without words in general purpose lexicons, and have some tolerance to noise.

### 4.3 Results on USAGE Corpus

In order to compare with fully supervised methods, we evaluate our models on USAGE corpus in Table 6. To build the distantly supervised models, we use untagged reviews which are about the 8 products of USAGE. The baseline systems are (Klinger and Cimiano, 2014) and (Jebbara and Cimiano, 2016), which are state-of-the-art systems on the dataset.

Results show that, with the same setting (“gold”) <sup>8</sup>, our fully unsupervised models achieve competitive precision scores against previous fully supervised methods. By examining the outputs, one reason for the performance gaps on recall may be the differences of annotation guidelines between USAGE and our dataset. For example, we don’t annotate pronouns as opinion targets while USAGE does (e.g., (“love”, “it”) is a proper annotation in USAGE). We can also observe that distant supervisions provide notable performances gains than direct pattern matching.

<sup>8</sup>Both baselines don’t report end-to-end performances. As a reference, in (Jebbara and Cimiano, 2016), the F1 of opinion expression and target extraction are 50% and 67%.

System	Phone			Movie			Food			Pet

#### 4.4 Error Analysis

Finally, we do some error analyses on the extracted relations. Taking movie domain as example, we find that for movie reviews, the opinions

from reviewers are mixed with plot and characters of movies, which makes it difficult to distinguish opinions and background topics with our simple opinion relation definition. For example,

Systems	P	R	F
Klinger et al. (2014)	-	-	65.0
Jebbara et al. (2016)	87.0	75.0	81.0
Pattern	51.4	20.7	29.5
LR (end-to-end)	49.5	27.8	35.6
NN (end-to-end)	43.3	40.1	41.6
LR (gold)	89.1	47.9	62.3
NN (gold)	81.4	62.8	70.9

Table 6: Results on USAGE corpus. First two rows are state-of-the-art systems on the dataset. Both of them assume gold annotations on opinion expressions and targets have been given. We report results with identical settings (“gold”), and also “end-to-end” results in which no gold annotations are provided.

in “Also said repeatedly how Tojo was [loyal to Emperor Hirohito]”, the word “loyal” indicates a wrong opinion relation since it’s a description of the story. A true comment from the reviewer is behind the word “repeatedly”, which is hard to be expressed with our opinion relations. We plan to introduce both more background knowledge and more powerful relation types in future work.

## 5 Conclusion

We investigate the task of large-scale opinion relation extraction. Our algorithm first uses syntactic patterns to get a set of opinion relations, then builds a neural network classifier based on these relations. We also develop an opinion expression classifier to better extract opinion words. Extensive experiments on Amazon review data show the effectiveness of the proposed methods.

# Decoding with Finite-State Transducers on GPUs

Arturo Argueta and David Chiang

Department of Computer Science and Engineering

University of Notre Dame

aargueta,dchiang@nd.edu

## Abstract

Weighted finite automata and transducers (including hidden Markov models and conditional random fields) are widely used in natural language processing (NLP) to perform tasks such as morphological analysis, part-of-speech tagging, chunking, named entity recognition, speech recognition, and others. Parallelizing finite state algorithms on graphics processing units (GPUs) would benefit many areas of NLP. Although researchers have implemented GPU versions of basic graph algorithms, limited previous work, to our knowledge, has been done on GPU algorithms for weighted finite automata. We introduce a GPU implementation of the Viterbi and forward-backward algorithm, achieving decoding speedups of up to 5.2x over our serial implementation running on different computer architectures and 6093x over OpenFST.

## 1 Introduction

Weighted finite automata (Mohri, 2009), including hidden Markov models and conditional random fields (Lafferty et al., 2001), are used to solve a wide range of natural language processing (NLP) problems, including phonology and morphology, part-of-speech tagging, chunking, named entity recognition, and others. Even models for speech recognition and phrase-based translation can be thought of as extensions of finite automata (Mohri et al., 2002; Kumar et al., 2005).

Although the use of graphics processing units (GPUs) is now *de rigueur* in applications of neural networks and made easy through toolkits like Theano (Theano Development Team, 2016), there has been little previous work, to our knowledge,

on acceleration of weighted finite-state computations on GPUs (Narasiman et al., 2011; Li et al., 2014; Peng et al., 2016; Chong et al., 2009). In this paper, we consider the operations that are most likely to have high speed requirements: decoding using the Viterbi algorithm, and training using the forward-backward algorithm. We present an implementation of the Viterbi and forward-backward algorithms for CUDA GPUs. We release it as open-source software, with the hope of expanding in the future to a toolkit including other operations like composition.

Most previous work on parallel processing of finite automata (Ladner and Fischer, 1980; Hillis and Steele, 1986; Mytkowicz et al., 2014) uses dense representations of finite automata, which is only appropriate if the automata are not too sparse (that is, most states can transition to most other states). But the automata used for natural language tend to be extremely large and sparse. In addition, the more recent work in this line assumes deterministic automata, but automata that model natural language ambiguity are generally nondeterministic.

Previous work has been done on accelerating particular NLP tasks on GPUs: in machine translation, phrase-pair retrieval (He et al., 2013) and language model querying (Bogoychev and Lopez, 2016); parsing (Hall et al., 2014; Canny et al., 2013); and speech recognition (Kim et al., 2012). Our aim here is for a more general-purpose collection of algorithms for finite automata.

Our work uses concepts from the work of Merrill et al. (2012), who show that GPUs can be used to accelerate breadth-first search in sparse graphs. Our approach is simple, but well-suited to the large, sparse automata that are often found in NLP applications. We show that it achieves a speedup of a factor of 5.2 on a GPU relative to a serial algorithm, and 6093 relative to OpenFST.

## 2 Graphics Processing Units

GPUs became known for their ability to render high quality images faster than conventional multi-core CPUs. Current off-the-shelf CPUs contain 8–16 cores while GPUs contain 1500–2500 simple CUDA cores built into the card. General Purpose GPUs (GPGPU) contain cores able to execute calculations that are not constrained to image processing. GPGPUs are now widely used across scientific domains to enhance the performance of diverse applications.

### 2.1 Architecture

CUDA cores (also known as scalar processors) are grouped into different Streaming Multiprocessors (SM) on the graphics card. The number of cores per SM varies depending on the GPU’s micro-architecture, ranging from 8 cores per SM (Tesla) up to 192 (Kepler). The overall number of SM on the chip varies, and it can range from 15 (Kepler) up to 24 (Maxwell). Streaming Multiprocessors are composed of the following components:

- **Special Function units (SFU)** These allow computations of functions such as sine, cosine, etc.
- **Shared Memory and L1 Cache** The size of the memory varies on the GPU model.
- **Warp Schedulers** assigns threads in an SM to be executed in a specific warp.

To execute a workload on the GPU, a kernel must be launched with a specified grid structure. The kernel must specify the number of threads to run on a block and the number of blocks in a grid before being executed on the device. The maximum number of threads per block and blocks per grid can vary depending on the GPU device. If the kernel is successfully launched, each block in the grid will get assigned to a SM. Each SM will execute 32 threads at a time (also called a warp) in its assigned block. If the number of threads in a block is not divisible by 32, the kernel will not launch on the device. Each SM contains a warp scheduler in charge of choosing the warps in a block to be executed in parallel. When the amount of blocks in a grid surpasses the amount of SM on the device, the SMs will execute a subset of blocks in parallel.

K40 Specs	
Global Memory	11520 MB
L2 cache size	1.57 MB
Shared memory per block	0.049 MB
Multiprocessors	15
Cores per MP	192
Registers per block	65536

Table 1: Device properties of a K40c GPU

The memory hierarchy on the device is laid out to maximize the data throughput. Table 1 shows the amount of cores available for execution as well as the amount of memory available on a Kepler based GPU. Registers are the fastest type of memory on the device, and this memory is private to each thread running on a block. Shared memory is the second fastest, and is shared by all threads running in the same block. The next type of memory is the L2 cache, which is shared among all streaming multiprocessors. The slowest and largest type of memory is global memory. Directly reading and writing to global memory affects performance significantly. Efficient memory management (reading and writing to and from contiguous addresses in memory) is important to fully utilize the memory hierarchy and increase performance.

### 2.2 Optimizations

Different factors such as number of threads in a block or coalesced memory accesses affect the performance on the GPU. In this section, we will cover the methods and modifications we used to improve the performance of our parallel implementations.

The optimal number of threads per block depends on the device configuration. The number of multiprocessors and cores per multiprocessor must be considered before launching a CUDA kernel on the device. Table 1 shows the number of streaming multiprocessors and the number of cores per multiprocessor on a K40 GPU. Multiple blocks in a kernel grid can get scheduled to be executed on a single streaming multiprocessor if the number of blocks in a grid exceeds the number of streaming multiprocessors. Each streaming multiprocessor will only execute one warp in a block in parallel during execution, and that is why choosing an appropriate number of blocks is important. For example, if two blocks get assigned to a multiprocessor and each block contains 192 threads, the

multiprocessor must execute 12 warps total where 1 warp gets executes at a time in parallel.

In our implementations, we take the following approach. The number of cores per multiprocessor is considered first to configure the block size. The block size is set to contain the same number of threads as the number of cores per multiprocessor of the graphics card used. If the number of threads needed to perform a computation is not divisible by the amount of cores per multiprocessor, the number of threads is rounded up to the closest dividend. Once the block size and number of threads are selected, the number of blocks is chosen by dividing the total number of threads by the block size.

Coalesced memory accesses are essential to maximize the use of resources running on the GPU. When data is requested by a warp executing on a streaming multiprocessor, a block from global memory will be accessed and allocated in shared memory. It is crucial to coalesce memory accesses so the number of blocks of global memory requested and the global memory access times decrease. This can be achieved by making all threads in a warp access contiguous spaces in memory. A similar speedup can be achieved if each thread in a block allocates all the data required from global memory into a compact data structure allocated in shared memory (size of the shared memory varies across devices). Section 4 describes the data structure used to coalesce memory reads. For each input symbol  $w_t$  the source states of all possible transitions can be read in a coalesced form and stored in shared memory allowing faster execution times.

Using special function units on the device can inhibit the performance of a program running on the GPU. Performance is affected because the number of SFU is lower than the amount of regular cores (e.g. The GK104 Kepler architecture contains 1536 regular cores and 256 special function units total). Also, the cycle penalty for using SFU rather than CUDA cores is higher than the penalty for regular cores on the device. For this work, the amount of instructions that use a specific SFU are kept to a minimum to obtain a higher speedup. By combining the mentioned techniques in this section, an application can significantly increase its performance.

### 3 Weighted Finite Automata

In this section, we review weighted finite automata, using a matrix formulation. A *weighted finite automaton* is a tuple  $M = (Q, \Sigma, s, F, \delta)$ , where

- $Q$  is a finite set of states.
- $\Sigma$  is a finite input alphabet.
- $s \in \mathbb{R}^Q$  is a one-hot vector: if  $M$  can start in state  $q$ , then  $s[q] = 1$ ; otherwise,  $s[q] = 0$ .
- $f \in \mathbb{R}^Q$  is a vector of final weights: if  $M$  can accept in state  $q$ , then  $f[q] > 0$  is the weight incurred; otherwise,  $f[q] = 0$ .
- $\delta : \Sigma \rightarrow \mathbb{R}^{Q \times Q}$  is the transition function: if  $M$  is in state  $q$  and the next input symbol is  $a$ , then  $\delta[a][q, q']$  is the weight of going to state  $q'$ .

Note that we currently do not allow transitions on empty strings or epsilon transitions. This definition can easily be extended to weighted finite transducers by augmenting the transitions with output symbols. See Figure 1 for an example FST.

Using this notation, the total weight of a string  $w = w_1 \cdots w_n$  can be written succinctly as:

$$\text{weight}(w) = s^\top \left( \prod_{t=1}^n \delta[w_t] \right) f. \quad (1)$$

Matrix multiplication is defined in terms of multiplication and addition of weights. It is common to redefine weights and their multiplication/addition to make the computation of (1) yield various useful values. When this is done, multiplication is often written as  $\otimes$  and addition as  $\oplus$ . If we define  $p_1 \otimes p_2 = p_1 p_2$  and  $p_1 \oplus p_2 = p_1 + p_2$ , then equation (1) gives the total weight of the string.

Or, we can make Equation (1) obtain the *maximum* weight path as follows. The weight of a transition is  $(p, k)$ , where  $p$  is the probability of the transition and  $k$  is (a representation of) the transition itself. Then

$$(p_1, k_1) \otimes (p_2, k_2) \equiv (p_1 p_2, k_1 k_2)$$

$$(p_1, k_1) \oplus (p_2, k_2) \equiv \begin{cases} (p_1, k_1) & \text{if } p_1 > p_2 \\ (p_2, k_2) & \text{otherwise.} \end{cases}$$

The Viterbi algorithm simply computes Equation (1) under the above definition of weights.

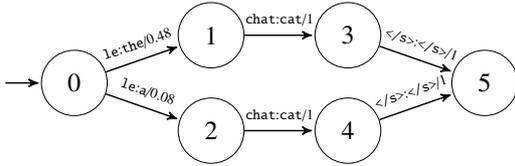

Figure 1: Example of a FST that translates the french string `le chat` to English.

#### 4 Serial Algorithm

Applications of finite automata use a variety of algorithms, but the most common are the Viterbi, forward, and backward algorithms. Several of these automata algorithms are related to one another and used for learning and inference. Speeding up these algorithms will allow faster training and development of large scale machine learning systems.

The forward and backward algorithms are used to compute weights (Eq. 1), in left-to-right (Reading an input utterance from left to right) and right-to-left order, respectively. Their intermediate values are used to compute expected counts during training by expectation-maximization (Eisner, 2002). They can be computed by Algorithm 2.

Algorithm 1 is one way of computing Viterbi using Equation (1). It is a straightforward algorithm, but the data structures require a brief explanation.

Throughout this paper, we use zero-based indexing for arrays. Let  $m = |\Sigma|$ , and number the input symbols in  $\Sigma$  consecutively  $0, \dots, m - 1$ . Then we can think of  $\delta$  as a three-dimensional array. In general, this array is very sparse. We store it using a combination of compressed sparse row (CSR) format and coordinate (COO) format, as shown in Figure 2 where:

- $z$  is the number of transitions with nonzero weight
- $R$  is an array of length  $(m + 1)$  containing offsets into the arrays  $S, T, O$ , and  $P$ . if  $a \in \Sigma$ , the transitions on input  $a$  can be found at positions  $R[a], \dots, R[a + 1] - 1$  (i.e. to access all transitions  $\delta[a]$ ). Note that  $R[m] = z$
- $S$  contains the source states for each transition  $0 \leq k < z \in \delta[a]$
- $T$  contains target states for transitions  $0 \leq k < z \in \delta[a]$

	le	chat	</s>			
$R$	0	2	4	6		
$S$	0	0	1	2	3	4
$T$	1	2	3	4	5	5
$O$	the	a	cat	cat	</s>	</s>
$P$	0.48	0.08	1	1	1	1

Figure 2: CSR/COO representation of FST in Figure 1.

- $O$  contains the output symbols for transitions from state  $S[k]$  to state  $T[k]$
- $P$  contains the probabilities for transitions from state  $S[k]$  to state  $T[k]$

The vector  $f$  of final weights is stored as a sparse vector: for each  $k$ ,  $S_f[k]$  is a final state with weight  $P_f[k]$ .

---

**Algorithm 1** Serial Viterbi algorithm (using CSR/COO representation).

---

```

1: for  $q \in Q$  do
2:    $\alpha[0][q] = 0$ 
3:  $\alpha[0][s] = 1$ 
4: for  $t = 1, \dots, n$  do
5:    $a \leftarrow w_t$ 
6:   for  $k = R[a], \dots, R[a + 1] - 1$  do
7:      $p \leftarrow \alpha[t - 1][S[k]] \otimes P[k]$ 
8:      $\alpha[t][T[k]] \leftarrow \alpha[t][T[k]] \oplus p$ 
9: return  $\bigoplus_k \alpha[n][S_f[k]] \otimes P_f[k]$ 

```

---

If the transition matrices  $\delta[a]$  are stored in compressed sparse row (CSR) format, which enables efficient traversal of a matrix in row-major order, then these algorithms can be written out as Algorithm 2 for the forward-backward algorithm and 1 for Viterbi. (Using compressed sparse columns (CSC) format, the loop over  $q'$  would be outside the loop over  $q$ , which is perhaps the more common way to implement these algorithms.)

#### 5 Parallel Algorithm

Our parallel implementation is based on Algorithm 1 for Viterbi and Algorithm 2 for forward-backward, but parallelizes the loop over  $t$ , that is, over the transitions on symbol  $w_t$ . The transitions

---

**Algorithm 2** Forward-Backward algorithm (row-major).

5:       p = forward[t][q]δ[wt+1][q, q']
6:       forward[t + 1][q'] += p
7:   for q ∈ Q do      ▶ backward pass
8:     backward[n][q] = f[q]
9:   for t = n - 1, ..., 0 do
10:    for q ∈ Q do
11:     for q' ∈ Q such that δ[wt+1][q, q'] > 0 do
12:      p = δ[wt+1][q, q']backward[t][q']
13:      backward[t][q] += p
14: Z = ∑q∈Q forward[n][q]f[q]
15: for t = 0, ..., n - 1 do
16:   for q, q' ∈ Q do
17:    α = forward[t][q]      ▶ Expected counts
18:    β = backward[t + 1][q']
19:    count[q, q'] += α × δ[w][q, q'] × β/Z

```

---

are stored in CSR/COO format as described above for Algorithm 1. The  $S$ ,  $T$ , and  $P$  arrays are stored on the GPU in global memory; the  $R$  and  $O$  arrays are kept on the host. For each input symbol  $a$ , the transitions on  $S$  and  $T$  are sorted first by source state and then by target state; this improves memory locality slightly. For the forward-backward algorithm, sorting by target improves the performance for the backward pass since the input is read from right to left.

For each input symbol  $w_t$ , one thread is launched per transition, that is, for each nonzero entry of the transition matrix  $\delta[w_t]$ . Equivalently, one thread is launched for each transition  $k$  such that  $R[w_t] \leq k < R[w_t + 1]$ , for a total of  $R[w_t + 1] - R[w_t]$  threads. Each thread looks up  $q = S[k]$ ,  $q' = T[k]$  and computes its corresponding operation.

For example, in Figure 2, input word “le” has index 0; since  $R[0] = 0$  and  $R[1] = 2$ , two threads are launched, one for  $k = 0$  (that is,  $0 \xrightarrow{\text{le:the}/0.48} 1$ ) and one for  $k = 1$  (that is,  $0 \xrightarrow{\text{le:a}/0.08} 2$ ).

## 5.1 Viterbi

At the time of computing a transition  $\delta[w_t][q, q']$ , if the probability (at line 8 in Algorithm 1) is higher than  $\alpha[t][q']$ , we store the probability in  $\alpha[t][q']$ . Because this update potentially involves

concurrent reads and writes at the same memory location, we use an atomic max operation (defined as `atomicMax` on the NVIDIA toolkit). However, `atomicMax` is not defined for floating-point values. Additionally, this update needs to store a back-pointer ( $k$ ) that will be used afterwards to reconstruct the highest-probability path. The problem is that the `atomicMax` provided by NVIDIA can only update a single value atomically.

We solve both problems with a trick: pack the Viterbi probability and the back-pointer into a single 64-bit integer, with the probability in the higher 32 bits and the back-pointer in the lower 32 bits. In IEEE 754 format, the mapping between nonnegative real numbers and their bit representations (viewed as integers) is order-preserving, so a max operation on this packed representation updates both the probability and the back-pointer simultaneously.

The reconstruction of the Viterbi path is not parallelizable, but is done on the GPU to avoid copying  $\alpha$  back to the host avoiding a slowdown. This generates a sequence of transition indices, which is moved back to the host. There, the output symbols can be looked up in array  $O$ .

## 5.2 Forward-Backward

The forward and backward algorithms 2 are similar to the Viterbi algorithm, but do not need to keep back-pointers. In the forward algorithm, when a transition  $\delta[w_t][q, q']$  is processed, we update the sum of probabilities reaching state  $q'$  in  $\text{forward}[t + 1][q']$ . Likewise, in the backward algorithm, we update the sum of probabilities starting from  $q$  in  $\text{backward}[t][q]$ . Both passes require atomic addition operations, but because we use log-probabilities to avoid underflow, the atomic addition must be implemented as:

$$\log(\exp a + \exp b) = b + \log 1p(\exp(a - b)), \quad (2)$$

assuming  $a \leq b$  and where  $\log 1p(x) = \log(1 + x)$ , a common function in math libraries which is more numerically stable for small  $x$ .

We implemented an atomic version of this log-add-exp operation. The two transcendentals are expensive, but CUDA’s fast math option (`-use_fast_math`) speeds them up somewhat by sacrificing some accuracy.

## 6 Other Approaches

### 6.1 Parallel prefix sum

We have already mentioned a line of work begun by (Ladner and Fischer, 1980) for unweighted, nondeterministic finite automata, and continued by (Hillis and Steele, 1986) and (Mytkowicz et al., 2014) for unweighted, deterministic finite automata. These approaches use *parallel prefix sum* to compute the weight (1), multiplying each adjacent pair of matrices in parallel and repeating until all the matrices have been multiplied together.

This approach could be combined with ours; we leave this for future work. A possible issue is that matrix-vector products are replaced with slower matrix-matrix products. Another is that prefix sum might not be applicable in a more general setting – for example, if a FST is composed with an input lattice rather than an input string.

### 6.2 Matrix libraries

The formulation of the Viterbi and forward-backward algorithms as a sequence of matrix multiplications suggests two possible easy implementation strategies. First, if transition matrices are stored as dense matrices, then the forward algorithm becomes identical to forward propagation through a rudimentary recurrent neural network. Thus, a neural network toolkit could be used to carry out this computation on a GPU. However, in practice, because our transition matrices are sparse, this approach will probably be inefficient.

Second, off-the-shelf libraries exist for sparse matrix/vector operations, like cuSPARSE.<sup>1</sup> However, such libraries do not allow redefinition of the addition and multiplication operations, making it difficult to implement the Viterbi algorithm or use log-probabilities. Also, parallelization of sparse matrix/vector operations depends heavily on the sparsity pattern (Bell and Garland, 2008), so that an off-the-shelf library may not provide the best solution for finite-state models of language. We test this approach below and find it to be several times slower than a non-GPU implementation.

## 7 Experiment

### 7.1 Setup

To test our algorithm, we constructed a FST for rudimentary French-to-English translation. We trained different unsmoothed bigram language

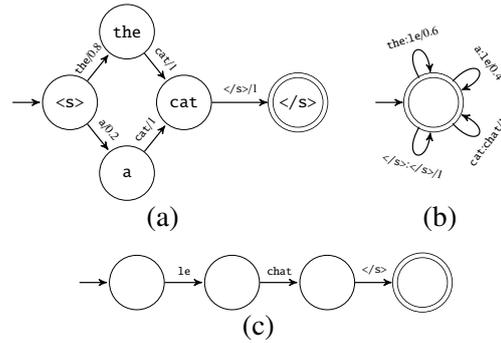

Figure 3: Example automata/transducers for (a) language model (b) translation model (c) input sentence. These three composed together form the transducer in Figure 1.

models on 1k/10k/100k/150k lines of French-English parallel data from the Europarl corpus and converted it into a finite automaton (see Figure 3a for a toy example).

GIZA++ was used to word-align the same data and generate word-translation tables  $P(f | e)$  from the word alignments, as in lexical weighting (Koehn et al., 2003). We converted this table into a single-state FST (Figure 3b). The language model automaton and the translation table transducer were intersected to create a transducer similar to the one in Figure 1.

For more details about the transducers (number of nodes, edges, and percentage of non-zero elements on the transducer) see Table 4.

We tested on a subset of 100 sentences from the French corpus with lengths of up to 80 words. For each experimental setting, we ran on this set 1000 times and report the total time. Our experiments were run on three different systems: (1) a system with an Intel Core i7-4790 8-core CPU and an NVIDIA Tesla K40c GPU, (2) a system with an Intel Xeon E5 16-core CPU and an NVIDIA Titan X GPU, and (3) a system with an Intel Xeon E5 24-core CPU and an NVIDIA Tesla P100 GPU.

### 7.2 Baselines

We compared against the following baselines:

**Carmel** is an FST toolkit developed at USC/ISI.<sup>2</sup>

**OpenFST** is a FST toolkit developed by Google as an open-source successor of the AT&T Finite State Machine library (Allauzen et al., 2007). For compatibility, our implementations read the OpenFST/AT&T text file format.

<sup>1</sup><http://docs.nvidia.com/cuda/cusparse/>

<sup>2</sup><https://github.com/graehl/carmel>

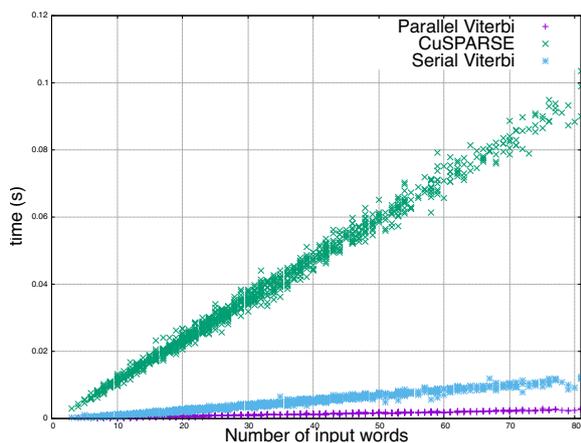

Figure 4: Viterbi decoding times for 1000 individual test sentences compared for our serial, parallel, and cuSPARSE implementations (Titan X).

**Our serial implementation** Algorithm 1 for Viterbi and Algorithm 2 for forward-backward.

**cuSPARSE** was used to implement the forward algorithm, using CSR format instead of COO for transition matrices. Since we can't redefine addition and multiplication, we could not implement the Viterbi algorithm. To avoid underflow, we rescaled the vector of forward values at each time step and kept track of the log of the scale in a separate variable.

To be fair, it should be noted that Carmel and OpenFST are much more general than the other implementations listed here. Both perform FST composition in order to decode an input string adding another layer of complexity to the process. The timings for OpenFST and Carmel on Table 2 include composition

### 7.3 Results

Table 2 shows the overall performance of our Viterbi algorithm and the baseline algorithms. Our parallel implementation does worse than our serial implementation when the transducer used is small (presumably due to the overhead of kernel launches and memory copies), but the speedups increase as the size of the transducer grows, reaching a speedup of 5x. The forward-backward algorithm with expected counts obtains a 5x speedup over the serial code on the largest transducer (See Table 3).

CuSPARSE does significantly worse than even our serial implementation; presumably, it would have done better if the transition matrices of our

transducers were sparser.

Figure 4 shows decoding times for three algorithms (our serial and parallel Viterbi, and cuSPARSE forward) on individual sentences. It can be seen that all three algorithms are roughly linear in the sentence length.

Viterbi is faster than either the forward or backward algorithm across the board. This is because the latter need to add log-probabilities (lines 6 and 13 of Algorithm 2), which involves expensive calls to transcendental functions.

### 7.4 Comparison across GPU architectures

Table 2 compares the performance of the Kepler-based K40, where we did most of our experiments, with the Maxwell-based Titan X and the Pascal-based Tesla P100. The performance improvement is due to different factors, such as a larger number of active thread blocks per streaming multiprocessor on a GPU architecture, the grid and block size selected to run the kernels, and memory management on the GPU. After the release of the Kepler architecture, the Maxwell architecture introduced an improved workload balancing, reduced arithmetic latency, and faster atomic operations. The Pascal architecture allows speedups over all the other architectures by introducing an increased floating point performance, faster data movement performance (NVLink), larger and more efficient shared memory, and improved atomic operations. Also, SMs on the pascal architecture are more efficient allowing speedups larger speedups than its predecessors. Our parallel implementations were compiled using architecture specific flags (`-arch=compute_XX`) to take full advantage of the architectural enhancements described in this section.

### 7.5 Comparison against a multi-core implementation

Table 2 shows how our parallel implementation on a GPU compares against a multi-core version of our serial Viterbi algorithm implemented in MPI. We chose MPI since it supports distributed and shared memory unlike OpenMP that supports shared memory only. Results show that a multi-core implementation of the algorithm leads to slower performance than the serial code due to the communication and synchronization overhead. Several cores must transfer information frequently and synchronize all messages on a single core. GPUs perform better than multi-core in this case

Method	Hardware	Training size (lines)

since all the memory is already on the graphics card and the cost of using global memory on the GPU is lower than synchronizing and sharing data between cores.

## 8 Conclusion

We have shown that our algorithm outperforms several serial implementations (our own serial implementation on a Intel Core i7 and Xeon E machines, Carmel and OpenFST) as well as a GPU implementation using cuSPARSE.

A system with newer and faster cores might achieve higher speedups than a GPU on smaller datasets. However, building a multi-core system that beats a GPU setup can be more expensive. For example, a 16 core Intel Xeon E5-2698 V3 can cost 3,500 USD (Bogoychev and Lopez, 2016). Newer GPU models offer previous generation CPU’s the opportunity to obtain speedups for a lower price (Titan X GPUs sell cheaper than Xeon E5 setups at US\$1,200). Speeding up computation on a GPU would allow users to speed up applications cheaper without investing on a newer multi-core system.

Our implementation has been open-sourced and is available online.<sup>3</sup> In the future, we plan to expand this software into a toolkit that includes other algorithms needed to run a full machine translation system.

## Abstract

Translating in real-time, a.k.a. simultaneous translation, outputs translation words before the input sentence ends, which is a challenging problem for conventional machine translation methods. We propose a neural machine translation (NMT) framework for simultaneous translation in which an agent learns to make decisions on when to translate from the interaction with a pre-trained NMT environment. To trade off quality and delay, we extensively explore various targets for delay and design a method for beam-search applicable in the simultaneous MT setting. Experiments against state-of-the-art baselines on two language pairs demonstrate the efficacy of the proposed framework both quantitatively and qualitatively.<sup>1</sup>

## 1 Introduction

Simultaneous translation, the task of translating content in real-time as it is produced, is an important tool for real-time understanding of spoken lectures or conversations (Fügen et al., 2007; Bangalore et al., 2012). Different from the typical machine translation (MT) task, in which translation quality is paramount, simultaneous translation requires balancing the trade-off between translation quality and time delay to ensure that users receive translated content in an expeditious manner (Mieno et al., 2015). A number of methods have been proposed to solve this problem, mostly in the context of phrase-based machine translation. These methods are based on a *segmenter*, which receives the input one word at a time, then decides when to send it to a MT system that translates each

<sup>1</sup>Code and data can be found at <https://github.com/nyu-dl/dl4mt-simul-trans>.

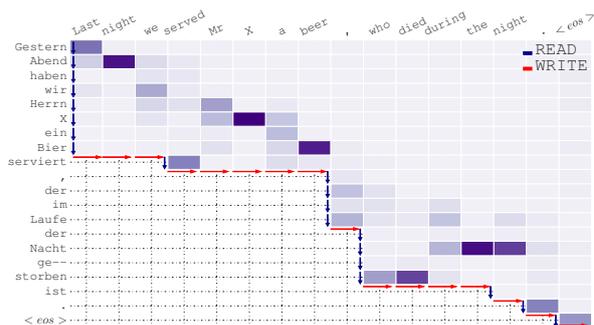

Figure 1: Example output from the proposed framework in DE  $\rightarrow$  EN simultaneous translation. The heat-map represents the soft alignment between the incoming source sentence (left, up-to-down) and the emitted translation (top, left-to-right). The length of each column represents the number of source words being waited for before emitting the translation. Best viewed when zoomed digitally.

segment independently (Oda et al., 2014) or with a minimal amount of language model context (Bangalore et al., 2012).

Independently of simultaneous translation, accuracy of standard MT systems has greatly improved with the introduction of neural-network-based MT systems (NMT) (Sutskever et al., 2014; Bahdanau et al., 2014). Very recently, there have been a few efforts to apply NMT to simultaneous translation either through heuristic modifications to the decoding process (Cho and Esipova, 2016), or through the training of an independent segmentation network that chooses when to perform output using a standard NMT model (Satija and Pineau, 2016). However, the former model lacks a capability to learn the appropriate timing with which to perform translation, and the latter model uses a standard NMT model as-is, lacking a holistic design of the modeling and learning within the simultaneous MT context. In addition, neither model has demonstrated gains over previ-

ous segmentation-based baselines, leaving questions of their relative merit unresolved.

In this paper, we propose a unified design for learning to perform neural simultaneous machine translation. The proposed framework is based on formulating translation as an interleaved sequence of two actions: READ and WRITE. Based on this, we devise a model connecting the NMT system and these READ/WRITE decisions. An example of how translation is performed in this framework is shown in Fig. 1, and detailed definitions of the problem and proposed framework are described in §2 and §3. To learn which actions to take when, we propose a reinforcement-learning-based strategy with a reward function that considers both quality and delay (§4). We also develop a beam-search method that performs search within the translation segments (§5).

We evaluate the proposed method on English-Russian (EN-RU) and English-German (EN-DE) translation in both directions (§6). The quantitative results show strong improvements compared to both the NMT-based algorithm and a conventional segmentation methods. We also extensively analyze the effectiveness of the learning algorithm and the influence of the trade-off in the optimization criterion, by varying a target delay. Finally, qualitative visualization is utilized to discuss the potential and limitations of the framework.

## 2 Problem Definition

Suppose we have a buffer of input words  $X = \{x_1, \dots, x_{T_s}\}$  to be translated in real-time. We define the simultaneous translation task as sequentially making two interleaved decisions: READ or WRITE. More precisely, the translator READs a source word  $x_\eta$  from the input buffer in chronological order as translation context, or WRITES a translated word  $y_\tau$  onto the output buffer, resulting in output sentence  $Y = \{y_1, \dots, y_{T_t}\}$ , and action sequence  $A = \{a_1, \dots, a_T\}$  consists of  $T_s$  READs and  $T_t$  WRITES, so  $T = T_s + T_t$ .

Similar to standard MT, we have a measure  $Q(Y)$  to evaluate the translation quality, such as BLEU score (Papineni et al., 2002). For simultaneous translation we are also concerned with the fact that each action incurs a time delay  $D(A)$ .  $D(A)$  will mainly be influenced by delay caused by READ, as this entails waiting for a human speaker to continue speaking (about 0.3s per word for an average speaker), while WRITE consists of generating a few words from a machine transla-

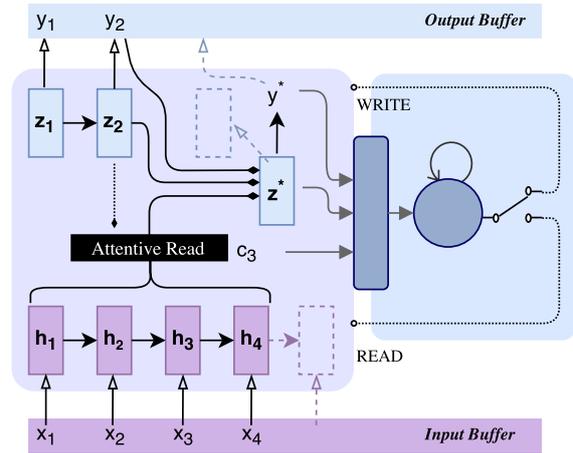

Figure 2: Illustration of the proposed framework: at each step, the NMT environment (left) computes a candidate translation. The recurrent agent (right) will the observation including the candidates and send back decisions—READ or WRITE.

tion system, which is possible on the order of milliseconds. Thus, our objective is finding an optimal policy that generates decision sequences with a good trade-off between higher quality  $Q(Y)$  and lower delay  $D(A)$ . We elaborate on exactly how to define this trade-off in §4.2.

In the following sections, we first describe how to connect the READ/WRITE actions with the NMT system (§3), and how to optimize the system to improve simultaneous MT results (§4).

## 3 Simultaneous Translation with Neural Machine Translation

The proposed framework is shown in Fig. 2, and can be naturally decomposed into two parts: environment (§3.1) and agent (§3.2).

### 3.1 Environment

**Encoder: READ** The first element of the NMT system is the encoder, which converts input words  $X = \{x_1, \dots, x_{T_s}\}$  into context vectors  $H = \{h_1, \dots, h_{T_s}\}$ . Standard NMT uses bi-directional RNNs as encoders (Bahdanau et al., 2014), but this is not suitable for simultaneous processing as using a reverse-order encoder requires knowing the final word of the sentence before beginning processing. Thus, we utilize a simple left-to-right unidirectional RNN as our encoder:

$$h_\eta = \phi_{\text{UNI-ENC}}(h_{\eta-1}, x_\eta) \quad (1)$$

**Decoder: WRITE** Similar with standard MT, we use an attention-based decoder. In contrast, we

only reference the words that have been read from the input when generating each target word:

$$\begin{aligned} c_\tau^\eta &= \phi_{\text{ATT}}(z_{\tau-1}, y_{\tau-1}, H^\eta) \\ z_\tau^\eta &= \phi_{\text{DEC}}(z_{\tau-1}, y_{\tau-1}, c_\tau^\eta) \\ p(y|y_{<\tau}, H^\eta) &\propto \exp[\phi_{\text{OUT}}(z_\tau^\eta)], \end{aligned} \quad (2)$$

where for  $\tau$ ,  $z_{\tau-1}$  and  $y_{\tau-1}$  represent the previous decoder state and output word, respectively.  $H^\eta$  is used to represent the incomplete input states, where  $H^\eta$  is a prefix of  $H$ . As the WRITE action calculates the probability of the next word on the fly, we need greedy decoding for each step:

$$y_\tau^\eta = \arg \max_y p(y|y_{<\tau}, H^\eta) \quad (3)$$

Note that  $y_\tau^\eta, z_\tau^\eta$  corresponds to  $H^\eta$  and is the candidate for  $y_\tau, z_\tau$ . The agent described in the next section decides whether to take this candidate or wait for better predictions.

### 3.2 Agent

A trainable agent is designed to make decisions  $A = \{a_1, \dots, a_T\}$ ,  $a_t \in \mathcal{A}$  sequentially based on observations  $O = \{o_1, \dots, o_T\}$ ,  $o_t \in \mathcal{O}$ , and then control the translation environment properly.

**Observation** As shown in Fig 2, we concatenate the current context vector  $c_\tau^\eta$ , the current decoder state  $z_\tau^\eta$  and the embedding vector of the candidate word  $y_\tau^\eta$  as the continuous observation,  $o_{\tau+\eta} = [c_\tau^\eta; z_\tau^\eta; E(y_\tau^\eta)]$  to represent the current state.

**Action** Similarly to prior work (Grissom II et al., 2014), we define the following set of actions:

- **READ:** the agent rejects the candidate and waits to encode the next word from input buffer;
- **WRITE:** the agent accepts the candidate and emits it as the prediction into output buffer;

**Policy** How the agent chooses the actions based on the observation defines the policy. In our setting, we utilize a stochastic policy  $\pi_\theta$  parameterized by a recurrent neural network, that is:

$$\begin{aligned} s_t &= f_\theta(s_{t-1}, o_t) \\ \pi_\theta(a_t|a_{<t}, o_{\leq t}) &\propto g_\theta(s_t), \end{aligned} \quad (4)$$

where  $s_t$  is the internal state of the agent, and is updated recurrently yielding the distribution of the action  $a_t$ . Based on the policy of our agent, the overall algorithm of greedy decoding is shown in Algorithm 1, The algorithm outputs the translation result and a sequence of observation-action pairs.

---

### Algorithm 1 Simultaneous Greedy Decoding

---

**Require:** NMT system  $\phi$ , policy  $\pi_\theta$ ,  $\tau_{\text{MAX}}$ , input buffer  $X$ , output buffer  $Y$ , state buffer  $S$ .

```

1: Init  $x_1 \leftarrow X, h_1 \leftarrow \phi_{\text{ENC}}(x_1), H^1 \leftarrow \{h_1\}$ 
2:    $z_0 \leftarrow \phi_{\text{INIT}}(H^1), y_0 \leftarrow \langle s \rangle$ 
3:    $\tau \leftarrow 0, \eta \leftarrow 1$ 
4: while  $\tau < \tau_{\text{MAX}}$  do
5:    $t \leftarrow \tau + \eta$ 
6:    $y_\tau^\eta, z_\tau^\eta, o_t \leftarrow \phi(z_{\tau-1}, y_{\tau-1}, H^\eta)$ 
7:    $a_t \sim \pi_\theta(a_t; a_{<t}, o_{<t}), S \leftarrow (o_t, a_t)$ 
8:   if  $a_t = \text{READ}$  and  $x_\eta \neq \langle /s \rangle$  then
9:      $x_{\eta+1} \leftarrow X, h_{\eta+1} \leftarrow \phi_{\text{ENC}}(h_\eta, x_{\eta+1})$ 
10:     $H^{\eta+1} \leftarrow H^\eta \cup \{h_{\eta+1}\}, \eta \leftarrow \eta + 1$ 
11:    if  $|Y| = 0$  then  $z_0 \leftarrow \phi_{\text{INIT}}(H^\eta)$ 
12:  else if  $a_t = \text{WRITE}$  then
13:     $z_\tau \leftarrow z_\tau^\eta, y_\tau \leftarrow y_\tau^\eta$ 
14:     $Y \leftarrow y_\tau, \tau \leftarrow \tau + 1$ 
15:    if  $y_\tau = \langle /s \rangle$  then break

```

---

## 4 Learning

The proposed framework can be trained using reinforcement learning. More precisely, we use policy gradient algorithm together with variance reduction and regularization techniques.

### 4.1 Pre-training

We need an NMT environment for the agent to explore and use to generate translations. Here, we simply pre-train the NMT encoder-decoder on full sentence pairs with maximum likelihood, and assume the pre-trained model is still able to generate reasonable translations even on incomplete source sentences. Although this is likely sub-optimal, our NMT environment based on uni-directional RNNs can treat incomplete source sentences in a manner similar to shorter source sentences and has the potential to translate them more-or-less correctly.

### 4.2 Reward Function

The policy is learned in order to increase a reward for the translation. At each step the agent will receive a reward signal  $r_t$  based on  $(o_t, a_t)$ . To evaluate a good simultaneous machine translation, a reward must consider both quality and delay.

**Quality** We evaluate the translation quality using metrics such as BLEU (Papineni et al., 2002). The BLEU score is defined as the weighted geometric average of the modified n-gram precision BLEU<sup>0</sup>, multiplied by the brevity penalty BP to punish a short translation. In practice, the vanilla

BLEU score is not a good metric at sentence level because being a geometric average, the score will reduce to zero if one of the precisions is zero. To avoid this, we used a smoothed version of BLEU for our implementation (Lin and Och, 2004).

$$\text{BLEU}(Y, Y^*) = \text{BP} \cdot \text{BLEU}^0(Y, Y^*), \quad (5)$$

where  $Y^*$  is the reference and  $Y$  is the output. We decompose BLEU and use the difference of partial BLEU scores as the reward, that is:

$$r_t^Q = \begin{cases} \Delta \text{BLEU}^0(Y, Y^*, t) & t < T \\ \text{BLEU}(Y, Y^*) & t = T \end{cases} \quad (6)$$

where  $Y^t$  is the cumulative output at  $t$  ( $Y^0 = \emptyset$ ), and  $\Delta \text{BLEU}^0(Y, Y^*, t) = \text{BLEU}^0(Y^t, Y^*) - \text{BLEU}^0(Y^{t-1}, Y^*)$ . Obviously, if  $a_t = \text{READ}$ , no new words are written into  $Y$ , yielding  $r_t^Q = 0$ . Note that we do not multiply BP until the end of the sentence, as it would heavily penalize partial translation results.

**Delay** As another critical feature, delay judges how much time is wasted waiting for the translation. Ideally we would directly measure the actual time delay incurred by waiting for the next word. For simplicity, however, we suppose it consumes the same amount of time listening for one more word. We define two measurements, global and local, respectively:

- **Average Proportion (AP):** following the definition in (Cho and Esipova, 2016),  $X, Y$  are the source and decoded sequences respectively, and we use  $s(\tau)$  to denote the number of source words been waited when decoding word  $y_\tau$ ,

$$0 < d(X, Y) = \frac{1}{|X||Y|} \sum_{\tau} s(\tau) \leq 1 \quad (7)$$

$$d_t = \begin{cases} 0 & t < T \\ d(X, Y) & t = T \end{cases}$$

$d$  is a global delay metric, which defines the average waiting proportion of the source sentence when translating each word.

- **Consecutive Wait length (CW):** in speech translation, listeners are also concerned with long silences during which no translation occurs. To capture this, we also consider on how many words were waited for (READ) consecutively between translating two words. For each action, where we initially define  $c_0 = 0$ ,

$$c_t = \begin{cases} c_{t-1} + 1 & a_t = \text{READ} \\ 0 & a_t = \text{WRITE} \end{cases} \quad (8)$$

- **Target Delay:** We further define ‘‘target delay’’ for both  $d$  and  $c$  as  $d^*$  and  $c^*$ , respectively, as different simultaneous translation applications may have different requirements on delay. In our implementation, the reward function for delay is written as:

$$r_t^D = \alpha \cdot [\text{sgn}(c_t - c^*) + 1] + \beta \cdot [d_t - d^*]_+ \quad (9)$$

where  $\alpha \leq 0, \beta \leq 0$ .

**Trade-off between quality and delay** A good simultaneous translation system requires balancing the trade-off of translation quality and time delay. Obviously, achieving the best translation quality and the shortest translation delays are in a sense contradictory. In this paper, the trade-off is achieved by balancing the rewards  $r_t = r_t^Q + r_t^D$  provided to the system, that is, by adjusting the coefficients  $\alpha, \beta$  and the target delay  $d^*, c^*$  in Eq. 9.

### 4.3 Reinforcement Learning

**Policy Gradient** We freeze the pre-trained parameters of an NMT model, and train the agent using the policy gradient (Williams, 1992). The policy gradient maximizes the following expected cumulative future rewards,  $J = \mathbb{E}_{\pi_\theta} \left[ \sum_{t=1}^T r_t \right]$ , whose gradient is

$$\nabla_{\theta} J = \mathbb{E}_{\pi_\theta} \left[ \sum_{t'=1}^T \nabla_{\theta} \log \pi_{\theta}(a_{t'} | \cdot) R_t \right] \quad (10)$$

$R_t = \sum_{k=t}^T [r_k^Q + r_k^D]$  is the cumulative future rewards for current observation and action. In practice, Eq. 10 is estimated by sampling multiple action trajectories from the current policy  $\pi_\theta$ , collecting the corresponding rewards.

**Variance Reduction** Directly using the policy gradient suffers from high variance, which makes learning unstable and inefficient. We thus employ the variance reduction techniques suggested by Mnih and Gregor (2014). We subtract from  $R_t$  the output of a baseline network  $b_\varphi$  to obtain  $\hat{R}_t = R_t - b_\varphi(o_t)$ , and centered re-scale the reward as  $\tilde{R}_t = \frac{\hat{R}_t - b}{\sqrt{\sigma^2 + \epsilon}}$  with a running average  $b$  and standard deviation  $\sigma$ . The baseline network is trained to minimize the squared loss as follows:

$$L_\varphi = \mathbb{E}_{\pi_\theta} \left[ \sum_{t=1}^T \|R_t - b_\varphi(o_t)\|^2 \right] \quad (11)$$

We also regularize the negative entropy of the policy to facilitate exploration.

---

**Algorithm 2** Learning with Policy Gradient

---

**Require:** NMT system  $\phi$ , agent  $\theta$ , baseline  $\varphi$

- 1: Pretrain the NMT system  $\phi$  using MLE;
  - 2: Initialize the agent  $\theta$ ;
  - 3: **while** stopping criterion fails **do**
  - 4:   Obtain a translation pairs:  $\{(X, Y^*)\}$ ;
  - 5:   **for**  $(Y, S) \sim \text{Simultaneous Decoding}$  **do**
  - 6:     **for**  $(o_t, a_t)$  in  $S$  **do**
  - 7:       Compute the quality:  $r_t^Q$ ;
  - 8:       Compute the delay:  $r_t^D$ ;
  - 9:       Compute the baseline:  $b_\varphi(o_t)$ ;
  - 10:    Collect the future rewards:  $\{R_t\}$ ;
  - 11:    Perform variance reduction:  $\{\tilde{R}_t\}$ ;
  - 12:    Update:  $\theta \leftarrow \theta + \lambda_1 \nabla_\theta [J - \kappa \mathcal{H}(\pi_\theta)]$
  - 13:    Update:  $\varphi \leftarrow \varphi - \lambda_2 \nabla_\varphi L$
- 

The overall learning algorithm is summarized in Algorithm 2. For efficiency, instead of updating with stochastic gradient descent (SGD) on a single sentence, both the agent and the baseline are optimized using a minibatch of multiple sentences.

## 5 Simultaneous Beam Search

In previous sections we described a simultaneous greedy decoding algorithm. In standard NMT it has been shown that beam search, where the decoder keeps a beam of  $k$  translation trajectories, greatly improves translation quality (Sutskever et al., 2014), as shown in Fig. 3 (A).

It is non-trivial to directly apply beam-search in simultaneous machine translation, as beam search waits until the last word to write down translation. Based on our assumption WRITE does not cost delay, we can perform a simultaneous beam-search when the agent chooses to consecutively WRITE: keep multiple beams of translation trajectories in temporary buffer and output the best path when the agent switches to READ. As shown in Fig. 3 (B) & (C), it tries to search for a relatively better path while keeping the delay unchanged.

Note that we do not re-train the agent for simultaneous beam-search. At each step we simply input the observation of the current best trajectory into the agent for making next decision.

## 6 Experiments

### 6.1 Settings

**Dataset** To extensively study the proposed simultaneous translation model, we train and evaluate it on two different language pairs: “English-

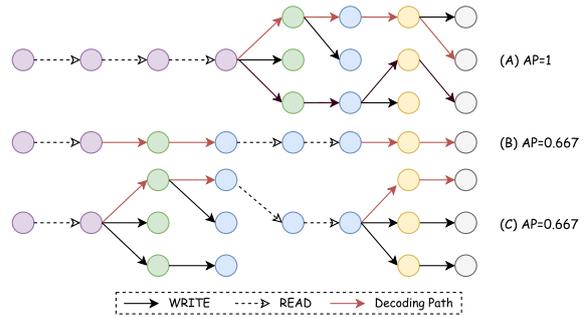

Figure 3: Illustrations of (A) beam-search, (B) simultaneous greedy decoding and (C) simultaneous beam-search.

German (EN-DE)” and “English-Russian (EN-RU)” in both directions per pair. We use the parallel corpora available from WMT’15<sup>2</sup> for both pre-training the NMT environment and learning the policy. We utilize newstest-2013 as the validation set to evaluate the proposed algorithm. Both the training set and the validation set are tokenized and segmented into sub-word units with byte-pair encoding (BPE) (Sennrich et al., 2015). We only use sentence pairs where both sides are less than 50 BPE subword symbols long for training.

**Environment & Agent Settings** We pre-trained the NMT environments for both language pairs and both directions following the same setting from (Cho and Esipova, 2016). We further built our agents, using a recurrent policy with 512 GRUs and a softmax function to produce the action distribution. All our agents are trained using policy gradient using Adam (Kingma and Ba, 2014) optimizer, with a mini-batch size of 10. For each sentence pair in a batch, 5 trajectories are sampled. For testing, instead of sampling we pick the action with higher probability each step.

**Baselines** We compare the proposed methods against previously proposed baselines. For fair comparison, we use the same NMT environment:

- **Wait-Until-End (WUE):** an agent that starts to WRITE only when the last source word is seen. In general, we expect this to achieve the best quality of translation. We perform both greedy decoding and beam-search with this method.
- **Wait-One-Step (WOS):** an agent that WRITES after each READS. Such a policy is problematic when the source and target language pairs have different word orders or lengths (e.g. EN-DE).

<sup>2</sup><http://www.statmt.org/wmt15/>

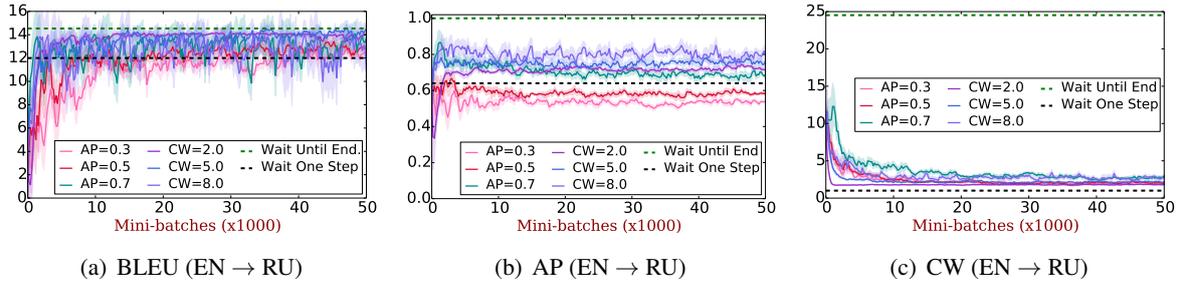

Figure 4: Learning progress curves for variant delay targets on the validation dataset for EN  $\rightarrow$  RU. Every time we only keep one target for one delay measure. For instance when using target AP, the coefficient of  $\alpha$  in Eq. 9 will be set 0.

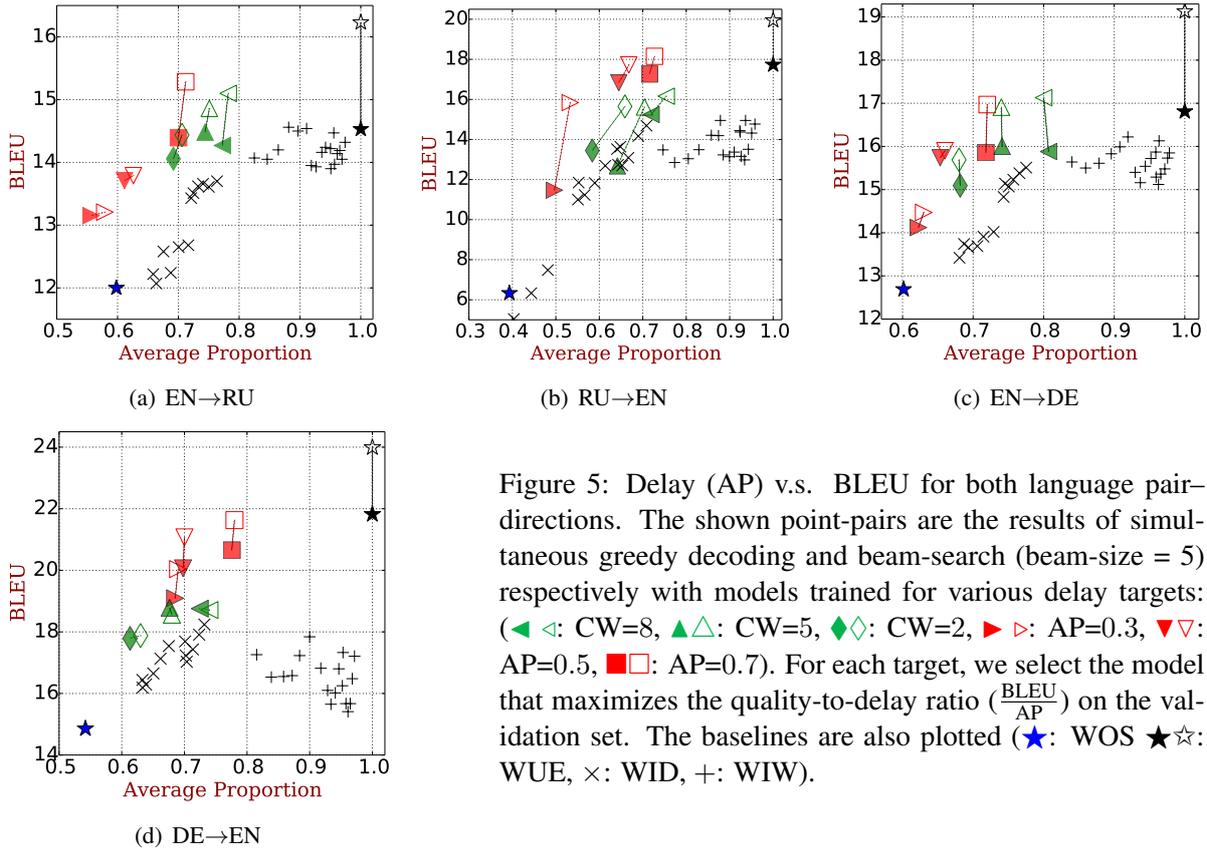

Figure 5: Delay (AP) v.s. BLEU for both language pair-directions. The shown point-pairs are the results of simultaneous greedy decoding and beam-search (beam-size = 5) respectively with models trained for various delay targets: ( $\triangleleft$ : CW=8,  $\triangle$ : CW=5,  $\diamond$ : CW=2,  $\blacktriangleright$ : AP=0.3,  $\blacktriangledown$ : AP=0.5,  $\blacksquare$ : AP=0.7). For each target, we select the model that maximizes the quality-to-delay ratio ( $\frac{\text{BLEU}}{\text{AP}}$ ) on the validation set. The baselines are also plotted ( $\star$ : WOS  $\star$ : WUE,  $\times$ : WID,  $+$ : WIW).

- **Wait-If-Worse/Wait-If-Diff (WIW/WID)**: as proposed by Cho and Esipova (2016), the algorithm first pre-READS the next source word, and accepts this READ when the probability of the most likely target word decreases (WIW), or the most likely target word changes (WID).
- **Segmentation-based (SEG)** (Oda et al., 2014): a state-of-the-art segmentation-based algorithm based on optimizing segmentation to achieve the highest quality score. In this paper, we tried the simple greedy method (SEG1) and the greedy method with POS Constraint (SEG2).

## 6.2 Quantitative Analysis

In order to evaluate the effectiveness of our reinforcement learning algorithms with different re-

ward functions, we vary the target delay  $d^* \in \{0.3, 0.5, 0.7\}$  and  $c^* \in \{2, 5, 8\}$  for Eq. 9 separately, and trained agents with  $\alpha$  and  $\beta$  adjusted to values that provided stable learning for each language pair according to the validation set.

**Learning Curves** As shown in Fig. 4, we plot learning progress for EN-RU translation with different target settings. It clearly shows that our algorithm effectively increases translation quality for all the models, while pushing the delay close, if not all of the way, to the target value. It can also be noted from Fig. 4 (a) and (b) that there exists strong correlation between the two delay measures, implying the agent can learn to decrease both AP and CW simultaneously.

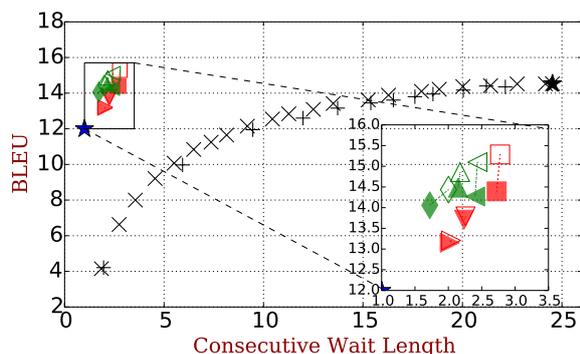

Figure 6: Delay (CW) v.s. BLEU score for EN  $\rightarrow$  RU, ( $\triangleleft$ : CW=8,  $\triangle$ : CW=5,  $\diamond$ : CW=2,  $\blacktriangleright$ : AP=0.3,  $\blacktriangledown$ : AP=0.5,  $\blacksquare$ : AP=0.7), against the baselines ( $\star$ : WOS  $\star$ : WUE,  $+$ : SEG1,  $\times$ : SEG2).

**Quality v.s. Delay** As shown in Fig. 5, it is clear that the trade-off between translation quality and delay has very similar behaviors across both language pairs and directions. The smaller delay (AP or CW) the learning algorithm is targeting, the lower quality (BLEU score) the output translation. It is also interesting to observe that, it is more difficult for “ $\rightarrow$ EN” translation to achieve a lower AP target while maintaining good quality, compared to “EN $\rightarrow$ ”. In addition, the models that are optimized on AP tend to perform better than those optimized on CW, especially in “ $\rightarrow$ EN” translation. German and Russian sentences tend to be longer than English, hence require more consecutive waits before being able to emit the next English symbol.

**v.s. Baselines** In Fig. 5 and 6, the points closer to the upper left corner achieve better trade-off performance. Compared to WUE and WOS which can ideally achieve the best quality (but the worst delay) and the best delay (but poor quality) respectively, all of our proposed models find a good balance between quality and delay. Some of the proposed models can achieve good BLEU scores close to WUE, while have much smaller delay.

Compared to the method of Cho and Esipova (2016) based on two hand-crafted rules (WID, WIW), in most cases our proposed models find better trade-off points, while there are a few exceptions. We also observe that the baseline models have trouble controlling the delay in a reasonable area. In contrast, by optimizing towards a given target delay, our proposed model is stable while maintaining good translation quality.

We also compared against Oda et al. (2014)’s

state-of-the-art segmentation algorithm (SEG). As shown in Fig 6, it is clear that although SEG can work with variant segmentation lengths (CW), the proposed model outputs high quality translations at a much smaller CW. We conjecture that this is due to the independence assumption in SEG, while the RNNs and attention mechanism in our model makes it possible to look at the whole history to decide each translated word.

**w/o Beam-Search** We also plot the results of simultaneous beam-search instead of using greedy decoding. It is clear from Fig. 5 and 6 that most of the proposed models can achieve an visible increase in quality together with a slight increase in delay. This is because beam-search can help to avoid bad local minima. We also observe that the simultaneous beam-search cannot bring as much improvement as it did in the standard NMT setting. In most cases, the smaller delay the model achieves, the less beam search can help as it requires longer consecutive WRITE segments for extensive search to be necessary. One possible solution is to consider the beam uncertainty in the agent’s READ/WRITE decisions. We leave this to future work.

### 6.3 Qualitative Analysis

In this section, we perform a more in-depth analysis using examples from both EN-RU and EN-DE pairs, in order to have a deeper understanding of the proposed algorithm and its remaining limitations. We only perform greedy decoding to simplify visualization.

**EN $\rightarrow$ RU** As shown in Fig 8, since both English and Russian are Subject-Verb-Object (SVO) languages, the corresponding words may share the same order in both languages, which makes simultaneous translation easier. It is clear that the larger the target delay (AP or CW) is set, the more words are read before translating the corresponding words, which in turn results in better translation quality. We also note that very early WRITE commonly causes bad translation. For example, for AP=0.3 & CW=2, both the models choose to WRITE in the very beginning the word “The”, which is unreasonable since Russian has no articles, and there is no word corresponding to it. One good feature of using NMT is that the more words the decoder READS, the longer history is saved, rendering simultaneous translation easier.

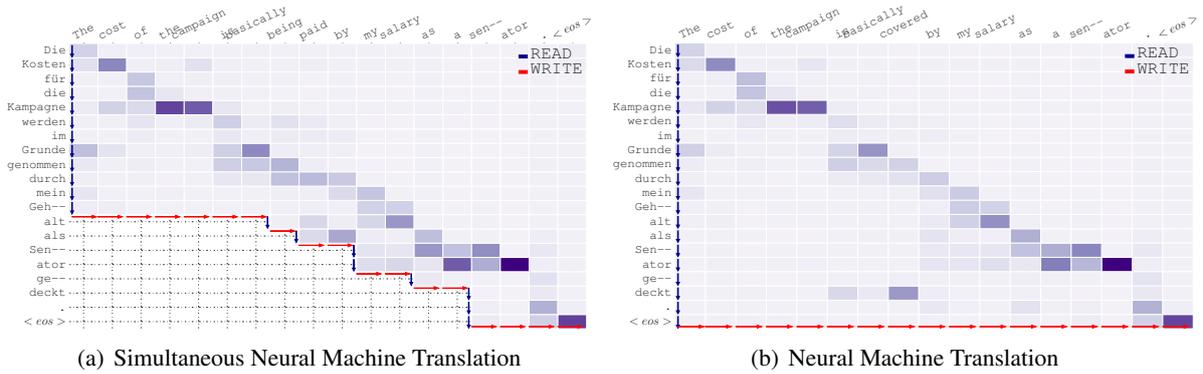

Figure 7: Comparison of DE→EN examples using the proposed framework and usual NMT system respectively. Both the heatmaps share the same setting with Fig. 1. The verb “gedeckt” is incorrectly translated in simultaneous translation.

Figure 8: Given the example input sentence (leftmost column), we show outputs by models trained for various delay targets. For these outputs, each row corresponds to one source word and represents the emitted words (maybe empty) after reading this word. The corresponding source and target words are in the same color for all model outputs.

**DE→EN** As shown in Fig 1 and 7 (a), where we visualize the attention weights as soft alignment between the progressive input and output sentences, the highest weights are basically along the diagonal line. This indicates that our simultaneous translator works by waiting for enough source words with high alignment weights and then switching to write them.

DE-EN translation is likely more difficult as German usually uses Subject-Object-Verb (SOV) constructions a lot. As shown in Fig 1, when a sentence (or a clause) starts the agent has learned such policy to READ multiple steps to approach the verb (e.g. serviert and gestorben in Fig 1). Such a policy is still limited when the verb is very far from the subject. For instance in Fig. 7, the simultane-

ous translator achieves almost the same translation with standard NMT except for the verb “gedeckt” which corresponds to “covered” in NMT output. Since there are too many words between the verb “gedeckt” and the subject “Kosten für die Kampagne werden”, the agent gives up reading (otherwise it will cause a large delay and a penalty) and WRITES “being paid” based on the decoder’s hypothesis. This is one of the limitations of the proposed framework, as the NMT environment is trained on complete source sentences and it may be difficult to predict the verb that has not been seen in the source sentence. One possible way is to fine-tune the NMT model on incomplete sentences to boost its prediction ability. We will leave this as future work.

## 7 Related Work

Researchers commonly consider the problem of simultaneous machine translation in the scenario of real-time speech interpretation (Fügen et al., 2007; Bangalore et al., 2012; Fujita et al., 2013; Rangarajan Sridhar et al., 2013; Yarmohammadi et al., 2013). In this approach, the incoming speech stream required to be translated are first recognized and segmented based on an automatic speech recognition (ASR) system. The translation model then works independently based on each of these segments, potentially limiting the quality of translation. To avoid using a fixed segmentation algorithm, Oda et al. (2014) introduced a trainable segmentation component into their system, so that the segmentation leads to better translation quality. Grissom II et al. (2014) proposed a similar framework, however, based on reinforcement learning. All these methods still rely on translating each segment independently without previous context.

Recently, two research groups have tried to apply the NMT framework to the simultaneous translation task. Cho and Esipova (2016) proposed a similar waiting process. However, their waiting criterion is manually defined without learning. Satija and Pineau (2016) proposed a method similar to ours in overall concept, but it significantly differs from our proposed method in many details. The biggest difference is that they proposed to use an agent that passively reads a new word at each step. Because of this, it cannot consecutively decode multiple steps, rendering beam search difficult. In addition, they lack the comparison to any existing approaches. On the other hand, we per-

form an extensive experimental evaluation against state-of-the-art baselines, demonstrating the relative utility both quantitatively and qualitatively.

The proposed framework is also related to some recent efforts about online sequence-to-sequence (SEQ2SEQ) learning. Jaitly et al. (2015) proposed a SEQ2SEQ ASR model that takes fixed-sized segments of the input sequence and outputs tokens based on each segment in real-time. It is trained with alignment information using supervised learning. A similar idea for online ASR is proposed by Luo et al. (2016). Similar to Satija and Pineau (2016), they also used reinforcement learning to decide whether to emit a token while reading a new input at each step. Although sharing some similarities, ASR is very different from simultaneous MT with a more intuitive definition for segmentation. In addition, Yu et al. (2016) recently proposed an online alignment model to help sentence compression and morphological inflection. They regarded the alignment between the input and output sequences as a hidden variable, and performed transitions over the input and output sequence. By contrast, the proposed READ and WRITE actions do not necessarily to be performed on aligned words (e.g. in Fig. 1), and are learned to balance the trade-off of quality and delay.

## 8 Conclusion

We propose a unified framework to do neural simultaneous machine translation. To trade off quality and delay, we extensively explore various targets for delay and design a method for beam-search applicable in the simultaneous MT setting. Experiments against state-of-the-art baselines on two language pairs demonstrate the efficacy both quantitatively and qualitatively.

## Abstract

We aim to shed light on the strengths and weaknesses of the newly introduced neural machine translation paradigm. To that end, we conduct a multifaceted evaluation in which we compare outputs produced by state-of-the-art neural machine translation and phrase-based machine translation systems for 9 language directions across a number of dimensions. Specifically, we measure the similarity of the outputs, their fluency and amount of reordering, the effect of sentence length and performance across different error categories. We find out that translations produced by neural machine translation systems are considerably different, more fluent and more accurate in terms of word order compared to those produced by phrase-based systems. Neural machine translation systems are also more accurate at producing inflected forms, but they perform poorly when translating very long sentences.

## 1 Introduction

A new paradigm to statistical machine translation, neural MT (NMT), has emerged very recently and has already surpassed the performance of the mainstream approach in the field, phrase-based MT (PBMT), for a number of language pairs, e.g. (Sennrich et al., 2016b; Luong et al., 2015; Costa-Jussà and Fonollosa, 2016; Chung et al., 2016).

In PBMT (Koehn, 2010) different models (translation, reordering, target language, etc.) are trained independently and combined in a log-linear scheme in which each model is assigned a

different weight by a tuning algorithm. On the contrary, in NMT all the components are jointly trained to maximise translation quality. NMT systems have a strong generalisation power because they encode translation units as numeric vectors that represent concepts, whereas in PBMT translation units are encoded as strings. Moreover, NMT systems are able to model long-distance phenomena thanks to the use of recurrent neural networks, e.g. long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) or gated recurrent units (Chung et al., 2014).

The translations produced by NMT systems have been evaluated thus far mostly in terms of overall performance scores, be it by means of automatic or human evaluations. This has been the case of last year's news translation shared task at the First Conference on Machine Translation (WMT16).<sup>1</sup> In this translation task, outputs produced by participant MT systems, the vast majority of which fall under either the phrase-based or neural approaches, were evaluated (i) automatically with the BLEU (Papineni et al., 2002) and TER (Snover et al., 2006) metrics, and (ii) manually by means of ranking translations (Federmann, 2012) and monolingual semantic similarity (Graham et al., 2016). In all these evaluations, the performance of each system is measured by means of an overall score, which, while giving an indication of the general performance of a given system, does not provide any additional information.

In order to understand better the new NMT paradigm and in what respects it provides better (or worse) translation quality than state-of-the-art PBMT, Bentivogli et al. (2016) conducted a detailed analysis for the English-to-German language direction. In a nutshell, they found out that NMT (i) decreases post-editing effort, (ii) de-

\*Work partly done at his previous position in Dublin City University, Ireland.

<sup>1</sup><http://www.statmt.org/wmt16/translation-task.html>

grades faster than PBMT with sentence length and (iii) results in a notable improvement regarding re-ordering.

In this paper we delve further in this direction by conducting a multilingual and multifaceted evaluation in order to find answers to the following research questions. Whether, in comparison to PBMT, NMT systems result in:

- considerably different output and higher degree of variability;
- more or less fluent output;
- more or less monotone translations;
- translations with better or worse word order;
- better or worse translations depending on sentence length;
- less or more errors for different error categories: inflectional, reordering and lexical;

Hereunder we specify the main differences and similarities between this work and that of Bentivogli et al. (2016):

- Language directions. They considered 1 while our study comprises 9.
- Content. They dealt with transcribed speeches while we work with news stories. Previous research has shown that these two types of content pose different challenges for MT (Ruiz and Federico, 2014).
- Size of evaluation data. Their test set had 600 sentences while our test sets span from 1 999 to 3 000 depending on the language direction.
- Reference type. Their references were both independent from the MT output and also post-edited, while we have access only to single independent references.
- Analyses. While some analyses overlap, some are novel in our experiments. Namely, output similarity, fluency and degree of re-ordering performed.

Our analyses are conducted on the best PBMT and NMT systems submitted to the WMT16 translation task for each language direction. This (i) guarantees the reproducibility of our results as all the MT outputs are publicly available, (ii) ensures

that the systems evaluated are state-of-the-art, as they are the result of the latest developments at top MT research groups worldwide, and (iii) allows the conclusions that will be drawn to be rather general, as 6 languages from 4 different families (Germanic, Slavic, Romance and Finno-Ugric) are covered in the experiments.

The rest of the paper is organised as follows. Section 2 describes the experimental setup. Subsequent sections cover the experiments carried out in which we measured different aspects of NMT, namely: output similarity (Section 3), fluency (Section 4), degree of reordering and quality of word order (Section 5), sentence length (Section 6), and amount of errors for different error categories (Section 7). Finally, Section 8 holds the conclusions and proposals for future work.

## 2 Experimental Setup

The experiments are run on the best PBMT and NMT constrained systems submitted to the news translation task of WMT16. We selected such systems according to the human evaluation (Bojar et al., 2016, Sec. 3.4).<sup>2</sup> We noted that many of the PBMT systems contain neural features, mainly in the form of language models. If the best PBMT submission contains any neural features we use this as the PBMT system in our analyses as long as none of these features is a fully-fledged NMT system. This was the case of the best submission in terms of BLEU for RU→EN (Junczys-Dowmunt et al., 2016).

Out of the 12 language directions at the translation task, we conduct experiments on 9.<sup>3</sup> These are the language pairs between English (EN) and Czech (CS), German (DE), Finnish (FI), Romanian (RO) and Russian (RU) in both directions (except for Finnish, where only the EN→FI direction is covered as no NMT system was submitted for the opposite direction, FI→EN). Finally, there was an additional language at the shared task, Turkish, that is not considered here, as either none of the systems submitted was neural (Turkish→EN), or there was one such system but its performance

<sup>2</sup>When there are not statistically significant differences between two or more NMT or PBMT systems (i.e. they belong to the same equivalence class), we pick the one with the highest BLEU score. If two NMT or PBMT systems were the best according to BLEU (draw), we pick the one with the best TER score.

<sup>3</sup>Some experiments are run on a subset of these languages due to the lack of required tools for some of the languages involved.

<b>Language Pair</b>	<b>MT Paradigm</b>	<b>System details</b>
EN→CS	PBMT NMT	Phrase-based, word clusters (Ding et al., 2016) Unsupervised word segmentation and backtranslated monolingual corpora (Sennrich et al., 2016a)
EN→DE	hierarchical PBMT NMT	String-to-tree, neural and dependency language models (Williams et al., 2016) Same as for EN→CS
EN→FI	PBMT  NMT	Phrase-based, rule-based and unsupervised word segmentation, operation sequence model (Durrani et al., 2011), bilingual neural language model (Devlin et al., 2014), re-ranked with a recurrent neural language model (Sánchez-Cartagena and Toral, 2016) Rule-based word segmentation, backtranslated monolingual corpora (Sánchez-Cartagena and Toral, 2016)
EN→RO	PBMT  NMT	Phrased-based, operation sequence model, monolingual and bilingual neural language models (Williams et al., 2016) Same as for EN→CS
EN→RU	PBMT  NMT	Phrase-based, word clusters, bilingual neural language model (Ding et al., 2016) Same as for EN→CS
CS→EN	PBMT NMT	Same as for EN→CS Same as for EN→CS
DE→EN	PBMT NMT	Phrase-based, pre-reordering, compound splitting (Williams et al., 2016) Same as for EN→CS plus reranked with a right-to-left model
RO→EN	PBMT  NMT	Phrase-based, operation sequence model, monolingual neural language model (Williams et al., 2016) Same as for EN→CS
RU→EN	PBMT  NMT	Phrase-based, lemmas in word alignment, sparse features, bilingual neural language model and transliteration (Lo et al., 2016) Same as for EN→CS

Table 1: Details of the best systems pertaining to the PBMT and NMT paradigms submitted to the WMT16 news translation task for each language direction.

was extremely low (EN→Turkish) and hence most probably not representative of the state-of-the-art in NMT.

Table 1 shows the main characteristics of the best PBMT and NMT systems submitted to the WMT16 news translation task. It should be noted that all the NMT systems listed in the table fall under the encoder-decoder architecture with attention (Bahdanau et al., 2015) and operate on subword units. Word segmentation is carried out with the help of a lexicon in the EN→FI direction (Sánchez-Cartagena and Toral, 2016) and in an unsupervised way in the remaining directions (Sennrich et al., 2016a).

## 2.1 Overall Evaluation

First, and in order to contextualise our analyses below, we report the BLEU scores achieved by the best NMT and PBMT systems for each language direction at WMT16’s news translation task in Table 2.<sup>4</sup> The best NMT system clearly outperforms the best PBMT system for all language directions out of English (relative improvements range from 5.5% for EN→RO to 17.6% for EN→FI) and the human evaluation (Bojar et al., 2016, Sec. 3.4) confirms these results. In the opposite direction, the human evaluation shows that the best NMT system outperforms the best PBMT system for all language directions except when the source language is Russian. This slightly differs from the automatic evaluation, according to which NMT outperforms PBMT for translations from Czech (3.3% relative improvement) and German (9.9%) but underperforms PBMT for translations from Romanian (-3.7%) and Russian (-3.8%).

## 3 Output Similarity

The aim of this analysis is to assess to which extent translations produced by NMT systems are different from those produced by PBMT systems. We measure this by taking the outputs of the top  $n$ <sup>5</sup> NMT and PBMT systems submitted to each language direction and checking their pairwise overlap in terms of the chrF1 (Popović, 2015)

<sup>4</sup>We report the official results from <http://matrix.statmt.org/matrix> for the test set *newstest2016* using normalised BLEU (column  $z$  *BLEU-cased-norm*).

<sup>5</sup>The number of systems considered is different for each language direction as it depends on the number of systems submitted. Namely, we have considered 2 NMT and 2 PBMT into Czech, 3 NMT and 5 PBMT into German, 2 NMT and 4 PBMT into Finnish, 2 NMT and 4 PBMT into Romanian and 2 NMT and 3 PBMT into Russian.

System	CS	DE	FI	RO	RU
	From EN				
PBMT	23.7	30.6	15.3	27.4	24.3
NMT	<b>25.9</b>	<b>34.2</b>	<b>18.0</b>	<b>28.9</b>	<b>26.0</b>
	Into EN				
PBMT	30.4	35.2	23.7	<b>35.4</b>	<b>29.3</b>
NMT	<b>31.4</b>	<b>38.7</b>	-	34.1	28.2

Table 2: BLEU scores of the best NMT and PBMT systems for each language pair at WMT16’s news translation task. If the difference between them is statistically significant according to paired bootstrap resampling (Koehn, 2004) with  $p = 0.05$  and 1 000 iterations, the highest score is shown in bold.

automatic evaluation metric.<sup>6</sup> In order to make sure that all systems considered are truly different (rather than different runs of the same system) we consider only 1 system per paradigm (NMT and PBMT) submitted by each team for each language direction.

We would consider NMT outputs considerably different (with respect to PBMT) if they resemble each other (i.e. high pairwise overlap between NMT outputs) more than they do to PBMT systems (i.e. low overlap between an output by NMT and another by PBMT). This analysis is carried out only for language directions out of English, as for all the language directions into English there was, at most, 1 NMT submission.

TL	2 NMT	2 PBMT	NMT & PBMT
CS	68.66	77.63	64.34
DE	72.10	72.97	66.80
FI	56.03	57.42	55.55
RO	69.47	75.96	68.77
RU	35.52	43.35	29.87

Table 3: Average of the overlaps between pairs of outputs produced by the top  $n$  NMT and PBMT systems for each language direction from English to the target language (TL). The higher the value, the larger is the overlap.

Table 3 shows the results. We can observe the same trends for all the language directions, namely: (i) the highest overlaps are between pairs

<sup>6</sup>Throughout our analyses we use this metric as it has been shown to correlate better with human judgements than the *de facto* standard automatic metric, BLEU, when the target language is a morphologically rich language such as Finnish, while its correlation is on par with BLEU for languages with simpler morphology such as English (Popović, 2015).

of PBMT systems; (ii) next, we have overlaps between NMT systems; (iii) finally, overlaps between PBMT and NMT are the lowest.

We can conclude then that NMT systems lead to considerably different outputs compared to PBMT. The fact that there is higher inter-system variability in NMT than in PBMT (i.e. overlaps between pairs of NMT systems are lower than between pairs of PBMT systems) may surprise the reader, considering the fact that all NMT systems belong to the same paradigm (encoder-decoder with attention) while for some language directions (EN→DE, EN→FI and EN→RO) there are PBMT systems belonging to two different paradigms (pure phrase-based and hierarchical). However, the higher variability among NMT translations can be attributed, we believe, to the fact that NMT systems use numeric vectors that represent concepts instead of strings as translation units.

#### 4 Fluency

In this experiment we aim to find out whether the outputs produced by NMT systems are more or less fluent than those produced by PBMT systems. To that end, we take perplexity of the MT outputs on neural language models (LMs) as a proxy for fluency. The LMs are built using TheanoLM (Enarvi and Kurimo, 2016). They contain 100 units in the projection layer, 300 units in the LSTM layer, and 300 units in the *tanh* layer, following the setup described by Enarvi and Kurimo (2016, Sec. 3.2). The training algorithm is Adagrad (Duchi et al., 2011) and we used 1 000 word classes obtained with `mkcls` from the training corpus. Vocabulary is limited to the most frequent 50 000 tokens.

LMs are trained on a random sample of 4 million sentences selected from the News Crawl 2015 monolingual corpora, available for all the languages considered.<sup>7</sup>

Table 4 shows the results. For all the language directions considered but one, perplexity is higher on the PBMT output compared to the NMT output. The only exception is translation into Finnish, in which perplexity on the PBMT output is slightly lower, probably because its fluency was improved by reranking it with a neural LM similar to the one

<sup>7</sup><http://data.statmt.org/wmt16/translation-task/training-monolingual-news-crawl.tgz>

Language direction	PBMT	NMT	Rel. diff.
EN→CS	202.91	173.33	-14.58%
EN→DE	131.54	107.08	-18.60%
EN→FI	214.10	222.40	3.88%
EN→RO	124.66	116.33	-6.68%
EN→RU	158.18	127.83	-19.19%
CS→EN	110.08	102.36	-7.01%
DE→EN	122.26	104.72	-14.35%
RO→EN	106.08	102.18	-3.68%
RU→EN	123.86	106.75	-13.81%
Average	143.74	129.22	-10.45%

Table 4: Perplexity scores for the outputs of the best NMT and PBMT systems on language models built on 4 million sentences randomly selected from the News Crawl 2015 corpora.

we use in this experiment (Sánchez-Cartagena and Toral, 2016). The average relative difference, i.e. considering all language directions, is notable at -10.45%. Thus, our experiment shows that the outputs produced by NMT systems are, in general, more fluent than those produced by PBMT systems.

One may argue that the perplexity obtained for NMT outputs is lower than that for PBMT outputs because the LMs we used to measure perplexity follow the same model as the decoder of the NMT architecture (Bahdanau et al., 2015) and hence perplexity on a neural LM is not a valid proxy for fluency. However, the following facts support our strategy:

- The manual evaluation of fluency carried out at the WMT16 shared translation task (Bogiar et al., 2016, Sec. 3.5) already confirmed that NMT systems consistently produce more fluent translations than PBMT systems. That manual evaluation only covered language directions into English. In this experiment, we extend that conclusion to language directions out of English.
- Neural LMs consistently outperform *n*-gram based LMs when assessing the fluency of *real* text (Kim et al., 2016; Enarvi and Kurimo, 2016). Thus, we have used the most accurate automatic tool available to measure fluency.

Language direction	Monotone vs.			PBMT vs. Ref.	NMT vs. Ref.
	PBMT	NMT	Ref.		
EN→CS	0.9273	0.9029	0.8295	<b>0.8008</b>	0.7964
EN→DE	0.8006	0.8229	0.7740	0.7560	<b>0.7791</b>

Table 5: Average Kendall’s tau distance between the word alignments obtained after translating the test set with each MT system being evaluated and a monotone alignment (left); and average Kendall’s tau distance between the word alignments obtained for each MT system’s translation and the word alignments of the reference translation (right). Larger values represent more similar alignments. If the difference between the distances depicted in the two last columns is statistically significant according to paired bootstrap resampling (Koehn, 2004) with  $p = 0.05$  and 1 000 iterations, the largest distance is shown in bold.

## 5 Reordering

In this section we measure the amount of reordering performed by PBMT and NMT systems. Our objective is to empirically determine whether: (i) the recurrent neural networks in NMT systems produce more changes in the word order of a sentence than an PBMT decoder; and whether (ii) these neural networks make the word order of the translations closer to that of the reference.

In order to measure the amount of reordering, we used the *Kendall’s tau distance* between word alignments obtained from pairs of sentences (Birch, 2011, Sec. 5.3.2). As the distance needs to be computed from permutations,<sup>8</sup> we turned word alignments into permutations by means of the algorithm defined by Birch (2011, Sec. 5.2).

For each language direction, we computed word alignments between the source-language side of the test set and the target-language reference, the PBMT output and the NMT output by means of MGIZA++ (Gao and Vogel, 2008). As the test sets are rather small for word alignment (1 999 to 3 000 sentence pairs depending on the language pair), we append bigger parallel corpora to help ensure accurate word alignments and avoid data sparseness. For languages for which in-domain

(news) parallel training data is available (German and Russian), we append that dataset (News Commentary). For the remaining languages (Finnish and Romanian) we use the whole Europarl corpus.

The amount of reordering performed by each system can be estimated as the distance between the word alignments produced by that system and a monotone word alignment. The similarity between the reorderings produced by each MT system and the reorderings in the reference translation can also be estimated as the distance between the corresponding word alignments. Table 5 shows the value of these distances for the language pairs included in our evaluation. The average over all the sentences in the test set of the distance proposed by Birch (2011) is depicted.

It can be observed that the amount of reordering introduced by both types of MT systems is lower than the quantity of reordering in the reference translation. NMT generally produces more changes in the structure of the sentence than PBMT. This is the case for all language pairs but two (EN→DE and EN→FI). A possible explanation for these two exceptions is the following: in the former language pair, the PBMT system is hierarchical (Williams et al., 2016) while in the latter, the output was reranked with neural LMs.

Concerning the similarity between the reorderings produced by both MT systems and those in the reference translation, out of 9 directions, in 5 directions the NMT system performs a reordering

<sup>8</sup>A permutation between a source-language sentence and a target-language sentence is defined as the set of operations that need to be carried out over the words in the source-language sentence to reflect the order of the words in the target-language sentence (Birch, 2011, Sec. 5.2).

closer to the reference, in 1 direction the PBMT system performs a reordering closer to the reference and in the remaining 3 directions the differences are not statistically significant. That is, NMT generally produces reorderings which are closer to the reference translation. The exceptions to this trend, however, do not exactly correspond to the language pairs for which NMT underperformed PBMT.

In summary, NMT systems achieve, in general, a higher degree of reordering than pure, phrase-based PBMT systems, and, overall, this reordering results in translations whose word order is closer to that of the reference translation.

## 6 Sentence Length

In this experiment we aim to find out whether the performances of NMT and PBMT are somehow sensitive to sentence length. In this regard, Bentivogli et al. (2016) found that, for transcribed speeches, NMT outperformed PBMT regardless of sentence length while also noted that NMT’s performance degraded faster than PBMT’s as sentence length increases. It should be noted, however, that sentences in our content type, news, are considerably longer than sentences in transcribed speeches.<sup>9</sup> Hence, the current experiment will determine to what extent the findings on transcribed speeches stand also for texts made of longer sentences.

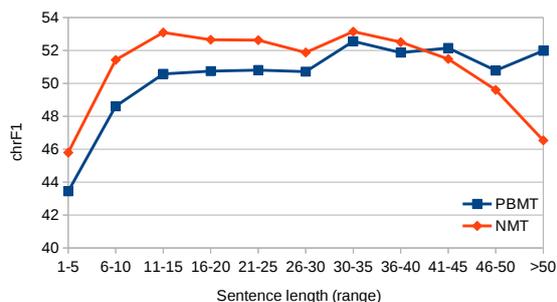

Figure 1: NMT and PBMT chrF1 scores on subsets of different sentence length for the language direction EN→FI.

We split the source side of the test set in subsets of different lengths: 1 to 5 words (1-5), 6 to 10 and so forth up to 46 to 50 and finally longer than 50 words (> 50). We then evaluate the out-

<sup>9</sup>According to Ruiz et al. (2014), sentences of transcribed speeches in English average to 19 words while sentences in news average to 24 words.

puts of the top PBMT and NMT submissions for those subsets with the chrF1 evaluation metric. Figure 1 presents the results for the language direction EN→FI. We can observe that NMT outperforms PBMT up to sentences of length 36-40, while for longer sentences PBMT outperforms NMT, with PBMT’s performance remaining fairly stable while NMT’s clearly decreases with sentence length. The results for the other language directions exhibit similar trends.

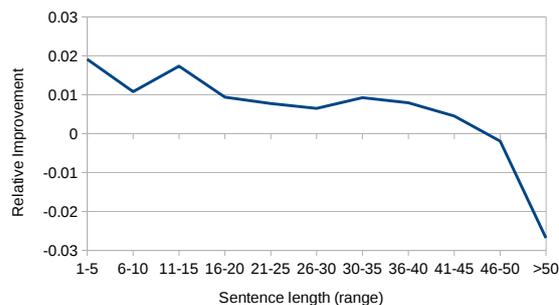

Figure 2: Relative improvement of the best NMT versus the best PBMT submission on chrF1 for different sentence lengths, averaged over all the language pairs considered.

Figure 2 shows the relative improvements of NMT over PBMT for each sentence length subset, averaged over all the 9 language directions considered. We observe a clear trend of this value decreasing with sentence length and in fact we found a strong negative Pearson correlation (-0.79) between sentence length and the relative improvement (chrF1) of the best NMT over the best PBMT system.

The correlations for each language direction are shown in Table 6. We observe negative correlations for all the language directions except for DE→EN.

Direction	CS	DE	FI	RO	RU
From EN	-0.72	-0.26	-0.89	-0.01	-0.74
Into EN	-0.19	0.10	-	-0.36	-0.70

Table 6: Pearson correlations between sentence length and relative improvement (chrF1) of the best NMT over the best PBMT system for each language pair.

## 7 Error Categories

In this experiment we assess the performance of NMT versus PBMT systems on a set of error

Error type	EN→CS	EN→DE	EN→FI	EN→RO	EN→RU	Average
Inflection	-16.18%	-13.26%	-11.65%	-15.13%	-16.79%	-14.60%
Reordering	-7.97%	-21.92%	-12.12%	-15.91%	-6.18%	-12.82%
Lexical	-0.44%	-3.48%	-1.09%	2.17%	-0.09%	-0.59%

Table 7: Relative improvement of NMT versus PBMT for 3 error categories, for language directions out of English.

Error type	CS→EN	DE→EN	RO→EN	RU→EN	Average
Inflection	-4.38%	-2.47%	-3.65%	-21.12%	-7.91%
Reordering	-8.68%	-21.09%	-9.48%	-8.50%	-11.94%
Lexical	-1.92%	-4.91%	-3.90%	5.32%	-1.35%

Table 8: Relative improvement of NMT versus PBMT for 3 error categories, for language directions into English.

categories that correspond to five word-level error classes: inflection errors, reordering errors, missing words, extra words and incorrect lexical choices. These errors are detected automatically using the edit distance, word error rate (WER), precision-based and recall-based position-independent error rates (hPER and rPER, respectively) as implemented in Hjerison (Popović, 2011). These error classes are then defined as follows:

- Inflection error (hINFer). A word for which its full form is marked as a hPER error while its base form matches the base form in the reference.
- Reordering error (hRer). A word that matches the reference but is marked as a WER error.
- Missing word (MISer). A word that occurs as deletion error in WER, is also a rPER error and does not share the base form with any hypothesis error.
- Extra word (EXTer). A word that occurs as insertion error in WER, is also a hPER error and does not share the base form with any reference error.
- Lexical choice error (hLEXer). A word that belongs neither to inflectional errors nor to missing or extra words.

Due to the fact that it is difficult to disambiguate between three of these categories, namely missing words, extra words and lexical choice errors (Popović and Ney, 2011), we group them in

a unique category, which we refer to as lexical errors.

As input, the tool requires the full forms and base forms of the reference translations and MT outputs. For base forms, we use stems for practical reasons. These are produced with the Snowball stemmer from NLTK<sup>10</sup> for all languages except for Czech, which is not supported. For this language we used the aggressive variant in `czech_stemmer`.<sup>11</sup>

Tables 7 and 8 show the results for language directions out of English and into English, respectively. For all language directions, we observe that NMT results in a notable decrease of both inflection (-14.6% on average for language directions out of EN and -7.91% for language directions into EN) and reordering (-12.82% from EN and -11.94 into EN) errors. The reduction of reordering errors is compatible with the results of the experiment presented in Section 5.<sup>12</sup>

Differences in performance for the remaining error category, lexical errors, are much smaller. In addition, the results for that category show a mixed picture in terms of which paradigm is better, which makes it difficult to derive conclusions that apply regardless of the language pair. Out of En-

<sup>10</sup><http://www.nltk.org>

<sup>11</sup>[http://research.variancia.com/czech\\_stemmer/](http://research.variancia.com/czech_stemmer/)

<sup>12</sup>Although the results depicted both in this section and in Section 5 show that NMT performs better reordering in general, results for particular language pairs are not exactly the same in both sections. This is due to the fact that the quality of the reordering is computed in different ways. In this section, only those words that match the reference are considered when identifying reordering errors, while in Section 5 all the words in the sentence are taken into account. That said, in Section 5 the precision of the results depends on the quality of word alignment.

glish, NMT results in slightly less errors (0.59% decrease on average) for all target languages except for RO (2.17% increase). Similarly, in the opposite language direction, NMT also results in slightly better performance overall (1.35% error reduction on average), and looking at individual language directions NMT outperforms PBMT for all of them except RU→EN.

## 8 Conclusions

We have conducted a multifaceted evaluation to compare NMT versus PBMT outputs across a number of dimensions for 9 language directions. Our aim has been to shed more light on the strengths and weaknesses of the newly introduced NMT paradigm, and to check whether, and to what extent, these generalise to different families of source and target languages. Hereunder we summarise our findings:

- The outputs of NMT systems are considerably different compared to those of PBMT systems. In addition, there is higher inter-system variability in NMT, i.e. outputs by pairs of NMT systems are more different between them than outputs by pairs of PBMT systems.
- NMT outputs are more fluent. We have corroborated the results of the manual evaluation of fluency at WMT16, which was conducted only for language directions into English, and we have shown evidence that this finding is true also for directions out of English.
- NMT systems introduce more changes in word order than pure PBMT systems, but less than hierarchical PBMT systems.<sup>13</sup> Nevertheless, for most language pairs, including those for which the best PBMT system is hierarchical, NMT's reorderings are closer to the reorderings in the reference than those of PBMT. This corroborates the findings on reordering by Bentivogli et al. (2016).
- We have found negative correlations between sentence length and the improvement brought by NMT over PBMT for the majority of the languages examined. While for most sentence lengths NMT outperforms PBMT, for very long sentences PBMT outperforms

<sup>13</sup>The latter finding applies only to one language direction as only for that one the best PBMT system is hierarchical.

NMT. The latter was not the case in the work by Bentivogli et al. (2016). We believe the reason behind this different finding is twofold. Firstly, the average sentence length in their evaluation dataset was considerably shorter; and secondly, the NMT systems included in our evaluation operate on subword units, which increases the effective sentence length they have to deal with.

- NMT performs better in terms of inflection and reordering consistently across all language directions. We thus confirm that the findings of Bentivogli et al. (2016) regarding these two error types apply to a wide range of language directions. Differences regarding lexical errors are much smaller and inconsistent across language directions; for 7 of them NMT outperforms PBMT while for the remaining 2 the opposite is true.

The results for some of the evaluations, especially error categories (Section 7) have been analysed only superficially, looking at what conclusions can be derived that apply regardless of language direction. Nevertheless, all our data is publicly released,<sup>14</sup> so we encourage interested parties to use this resource to conduct deeper language-specific studies.

## Acknowledgments

The research leading to these results is supported by the European Union Seventh Framework Programme FP7/2007-2013 under grant agreement PIAP-GA-2012-324414 (Abu-MaTran) and by Science Foundation Ireland through the CNGL Programme (Grant 12/CE/I2267) in the ADAPT Centre ([www.adaptcentre.ie](http://www.adaptcentre.ie)) at Dublin City University.

## Abstract

The language that we produce reflects our personality, and various personal and demographic characteristics can be detected in natural language texts. We focus on one particular personal trait of the author, *gender*, and study how it is manifested in original texts and in translations. We show that author's gender has a powerful, clear signal in original texts, but this signal is obfuscated in human and machine translation. We then propose simple domain-adaptation techniques that help retain the original gender traits in the translation, without harming the quality of the translation, thereby creating more personalized machine translation systems.

## 1 Introduction

Among many factors that mold the makeup of a text, gender and other authorial traits play a major role in our perception of the content we face. Many studies have shown that these traits can be identified by means of automatic classification methods. Classical examples include gender identification (Koppel et al., 2002), and authorship attribution and profiling (Seroussi et al., 2014). Most research, however, addressed texts in a single language, typically English.

We investigate a related but different question: we are interested in understanding what happens to personality and demographic textual markers during the translation process. It is generally agreed that good translation goes beyond transformation of the original content, by preserving more subtle and implicit characteristics inferred by author's personality, as well as era, geography, and various cultural and sociological aspects. In this work we explore whether translations preserve the

stylistic characteristic of the author and, furthermore, whether the prominent signals of the source are retained in the target language.

As a first step, we focus on *gender* as a demographic trait (partially due to the absence of parallel data annotated for other traits). We evaluate the accuracy of automatic gender classification on original texts, on their manual translations and on their automatic translations generated through statistical machine translation (SMT). We show that while gender has a strong signal in originals, this signal is obfuscated in human and machine translation. Surprisingly, determining gender over manual translation is even harder than over SMT; this may be an artifact of the translation process itself or the human translators involved in it.

Mirkin et al. (2015) were the first to show that authorial gender signals tend to vanish through both manual and automatic translation, using a small TED talks dataset. We use their data and extend it with a version of Europarl that we annotated with age and gender (§3). Furthermore, we conduct experiments with two language pairs, in both directions (§4). We also adopt a different classification methodology based on the finding that the translation process itself has a stronger signal than the author's gender (§4.1).

We then move on to assessing gender traits in SMT (§5). Since SMT systems typically do not take personality or demographic information into account, we hypothesize that the author's style, affected by their personality, will fade. Furthermore, we propose simple domain-adaptation techniques that do consider gender information and can therefore better retain the original traits. We build "gender-aware" SMT systems, and show (§6) that they retain gender markers while preserving general translation quality. Our findings therefore suggest that SMT can be made much more personalized, leading to translations that are more faith-

ful to the style of the original texts.

Finally, we analyze the prominent features that reflect gender in originals and translations (§7). Our experiments reveal that gender markers differ greatly by language, and the specific source language has a significant impact on the features and classification accuracy of the translated text. In particular, gender traits of the original language overshadow those of the target language in both manual and automatic translation products.

The **main contributions** of this paper are thus: (i) a new parallel corpus annotated with gender and age information, (ii) an in-depth assessment of the projection of gender traits in manual and automatic translation, and (iii) experiments showing that gender-personalized SMT systems better project gender traits while maintaining translation quality.

## 2 Related work

While modeling of demographic traits has been proven beneficial in some NLP tasks such as sentiment analysis (Volkova et al., 2013) or topic classification (Hovy, 2015), very little attention has been paid to translation. We provide here a brief summary of research relevant to our work.

**Machine translation (MT)** Virtually no previous work in MT takes into account personal traits. State-of-the-art MT systems are built from examples of translations, where the general assumption is that the more data available to train models, the better, and a single model is usually produced. Exceptions to this assumption revolve around work on domain adaption, where systems are customized by using data that comes from a particular text domain (Hasler et al., 2014; Cuong and Sima'an, 2015); and work on data cleaning, where spurious data is removed from the training set to ensure the quality of the final models (Cui et al., 2013; Simard, 2014). Personal traits, sometimes well marked in the translation examples, are therefore not explicitly addressed. Learning from different, sometimes conflicting writing styles can hinder model performance and lead to translations that are unfaithful to the source text.

Focusing on reader preferences, Mirkin and Meunier (2015) used a collaborative filtering approach from recommender systems, where a user's preferred translation is predicted based on the preferences of similar users. However, the user preferences in this case refer to the overall choice

between MT systems of a specific reader, rather than a choice based on traits of the writer. Mirkin et al. (2015) motivated the need for personalization of MT models by showing that automatic translation does not preserve demographic and psychometric traits. They suggested treating the problem as a domain adaptation one, but did not provide experimental results of personalized MT models.

**Gender classification** A large body of research has been devoted to isolating distinguishing traits of male and female linguistic variations, both theoretically and empirically. Apart from content, male and female speech has been shown to exhibit stylistic and syntactic differences. Several studies demonstrated that literary texts and blog posts produced by male and female writers can be distinguished by means of automatic classification, using (content-independent) function words and n-grams of POS tags (Koppel et al., 2002; Schler et al., 2006; Burger et al., 2011).

Although the tendencies of *individual word* usage are a subject of controversy, distributions of *word categories* across male and female English speech is nearly consensual: pronouns and verbs are more frequent in female texts, while nouns and numerals are more typical to male productions. Newman et al. (2008) carried out a comprehensive empirical study corroborating these findings with large and diverse datasets.

However, little effort has been dedicated to investigating the variation of individual markers of demographic traits across different languages. Johannsen et al. (2015) conducted a large-scale study on linguistic variation over age and gender across multiple languages in a social media domain. They showed that gender differences captured by shallow syntactic features were preserved across languages, when examined by linguistic categories. However, they did not study the distribution of individual gender markers across domains and languages. Our work demonstrates that while marker categories are potentially preserved, individual words typical to male and female language vary across languages and, more prominently, across different domains.

**Authorial traits in translationese** A large body of previous research has established that translations constitute an autonomic *language variety*: a special dialect of the target language, often re-

ferred to as *translationese* (Gellerstam, 1986). Recent corpus-based investigations of translationese demonstrated that originals and translations are distinguishable by means of supervised and unsupervised classification (Baroni and Bernardini, 2006; Volansky et al., 2015; Rabinovich and Wintner, 2015). The identification of machine-translated text has also been proven an easy task (Arase and Zhou, 2013; Aharoni et al., 2014).

Previous work has investigated how gender artifacts are carried over into human translation in the context of social and gender studies, as well as cultural transfer (Simon, 2003; Von Flotow, 2010). Shlesinger et al. (2009) conducted a computational study exploring the implications of the translator’s gender on the final product. They conclude that “the computer could not be trained to accurately predict the gender of the translator”. Preservation of authorial style in literary translations was studied by Lynch (2014), identifying Russian authors of translated English literature, by using (shallow) stylistic and syntactic features. Forsyth and Lam (2014) investigated authorial discriminability in translations of French originals into English, inspecting two distinct human translations, as well as automatic translation of the same sources.

Our work, to the best of our knowledge, is the first to automatically identify speaker gender in manual, and more prominently, automatic translations over multiple domains and language-pairs, examining distribution of gender markers in source and target languages.

### 3 Europarl with demographic info

We created a resource<sup>1</sup> based on the parallel corpus of the European Parliament (Europarl) Proceedings (Koehn, 2005). More specifically, we utilize the extension of its *en-fr* and *en-de* parallel versions (Rabinovich et al., 2015), where each sentence-pair is annotated with speaker name, the original language the sentence was uttered in, and the date of the corresponding session protocol. To extend speaker information with demographic properties, we used the Europarl website’s MEP information pages<sup>2</sup> and applied a procedure of gender and age identification, as further detailed in §3.1.

The final resource comprises *en-fr* and *en-de* parallel bilingual corpora where metadata of mem-

bers of the European Parliament (MEPs) is enriched with their gender and age at the time of the corresponding session. The data is restricted to sentence-pairs originally produced in English, French, or German. Table 1 provides statistics on the two datasets. We also release the full list of 3,586 MEPs with their meta information.

	<i>en-fr</i>	<i>fr-en</i>	<i>en-de</i>	<i>de-en</i>
male	100K	67K	101K	88K
female	44K	40K	61K	43K
total	144K	107K	162K	131K

Table 1: Europarl corpora (EP) statistics (# of sentence-pairs); gender refers to an author of the source utterance.

#### 3.1 Identification of MEP gender

Gender annotation was conducted using three different resources: Wikidata, Genderize and AlchemyVision, which we briefly describe below.

**Wikidata** (Vrandečić and Krötzsch, 2014) is a human-curated knowledge repository of structured data from Wikipedia and other Wikimedia projects. Wikidata provides an API<sup>3</sup> through which one can retrieve details about people in the repository, including place and date of birth, occupation, and gender. For MEPs found in the Wikidata, we first verified that the person holds (or held) a position of Member of the European Parliament and if so, retrieved the gender. Wikidata information is not complete: not all MEP names, positions or gender data is included. In total we obtained gender information for 2,618 MEPs (73% of the total 3,586), of which 1,882 (72%) are male and 736 female (28%).

**Genderize**<sup>4</sup> is an open resource containing over 2 million distinct names grouped by countries. It determines people’s gender based on their first name and the country of origin. Provided with the first name and the country a MEP represents.<sup>5</sup> Genderize was able to predict the gender of 2,785 MEPs, the vast majority of them with a probability of 0.9 or higher. We filtered out the 55 lower-confidence entries, keeping 2,730 MEPs (76% of total), of which 2001 (73%) are male and 729 (27%) female.

<sup>3</sup><https://www.mediawiki.org/wiki/Wikibase/API>

<sup>4</sup><https://genderize.io/>

<sup>5</sup>We assume that the country MEPs represent is highly correlated, if not strictly identical, to their country of origin.

<sup>1</sup>Available at <http://cl.haifa.ac.il/projects/pmt>

<sup>2</sup><http://www.europarl.europa.eu/meps/en/>

**AlchemyVision** The European Parliament website maintains a page for every MEP, including personal photos. We classified MEP personal images using AlchemyVision,<sup>6</sup> a publicly available image recognition service. In total, we retrieved the gender of 2,236 MEPs using AlchemyVision. Similarly to Genderize, we filtered out all predictions with a confidence score below 0.9, thus obtaining the gender of 2,138 MEPs (60% of total), of which 1,528 are male and 610 female (71% and 29%, respectively).

### 3.2 Resource evaluation and statistics

Even though Wikidata was created manually, to verify its correctness, we manually annotated the gender of 100 randomly selected MEPs with available Wikidata gender information; we found the metadata perfectly accurate. We therefore rely on Wikidata as a gold-standard against which we can assess the accuracy of the two other resources. Table 2 presents the accuracy and coverage of each resource based on this methodology.

resource	Wikidata	Genderize	Alchemy
coverage	73.0	76.1	59.6
accuracy	100.0	99.6	99.1

Table 2: Gender prediction performance (%).

Given information obtained from the three resources, we assign each MEP with a single gender prediction in the following way: whenever it is found in Wikidata (2,618 MEPs), the gender is determined by this resource. Otherwise, if both Genderize and AlchemyVision produced agreed-upon gender information (336 out of 338 cases), we set gender according to this prediction; the same applies to the case where only one of Genderize or AlchemyVision provided a prediction (346 and 178, respectively). We ended up with gender annotation for a total of 3,478 out of 3,586 members. The remaining 108 MEPs (92 male, 16 female) were annotated manually, a rather labor-intensive annotation in this case.

In total, the resource includes 947 (26%) female and 2,639 (74%) male MEPs. Based on the above accuracy estimations, and assuming that manual annotation is correct, the overall accuracy of gender information in this resource is 99.88%.

Utilizing the information on session dates and

<sup>6</sup><https://www.ibm.com/smarterplanet/us/en/ibmwatson/developercloud/alchemy-vision.html>

MEPs dates of birth available in the metadata, we also annotated each sentence-pair with the age of the MEP at the time the sentence was uttered. To summarize, we release the following resources: (i) meta information for 3,586 MEPs, as described above, (ii) bilingual parallel *en-fr* and *en-de* corpora, where each sentence-pair metadata is enriched with speaker MEPID, gender and age.

## 4 Experimental setup

We evaluate the extent to which gender traits are preserved in translation by evaluating the accuracy of gender classification of original and translated texts. The rationale is that the more prominent gender markers are in the text, the easier it is to classify the gender of its author.

### 4.1 Translationese vs. gender traits

Since we use the accuracy of gender identification as our evaluation metric, we isolate the dimension of gender in our data: the classification experiments are carried out separately on original, human translated text, as well as on each one of the MT products. Human, and more prominently, machine translations constitute distinct and distinguishable language variation, characterized by unique feature distributions (§2). We posit that in both human and machine translation products, the differences between original texts and translations overshadow the differences in gender. We corroborate this assumption by analysing a sample data distribution by two dimensions: (i) translation status and (ii) gender. Figure 1 presents the results for the English Europarl corpus. Both charts display data distributions of the same four classes: original (O) and translated (T) English<sup>7</sup> by male (M) and female (F) speakers (OM, OF, TM, TF). For the sake of visualization, the dimension of function words feature vectors was reduced to 2, using principal component analysis (Jolliffe, 2002). The left graph depicts color-separation by gender (male vs. female), while the right one by translation status (original vs. translated). Evidently, the linguistic variable of translationese stands out against the weaker signal of gender.

### 4.2 Datasets

In addition to the Europarl corpus annotated for gender (§3), we experimented with a corpus of

<sup>7</sup>This experiment refers to English translated from French; other language-pairs exhibited similar trends.

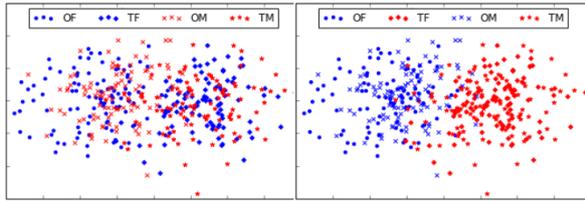

Figure 1: English EP data distributions across two dimensions: gender (left) and trans. status (right).

TED talks (transcripts and translations): a collection of texts from a completely different genre, where demographic traits may manifest differently. Testing the potential benefits of personalized SMT models on these two very diverse datasets allows us to examine the robustness of our approach. We used the TED gender-annotated data from Mirkin et al. (2015).<sup>8</sup> This corpus contains annotation of the speaker’s gender included in the English-French corpus of the IWSLT 2014 Evaluation Campaign’s MT track (Cettolo et al., 2012). We annotated 68 additional talks from the development and test sets of IWSLT 2014, 2015 and 2016. Using the full set, we split the TED parallel corpora by gender to obtain sub-corpora of 140K and 43K sentence pairs for male and female speakers, respectively.

The sizes of the datasets used for training, tuning and testing of SMT models are shown in Table 3. Relatively large test sets are used for evaluation of the MT results for the sake of reliable per-outcome gender classification (§4.1).

Although the size of the training/tuning/test sets in either direction for any language-pair is the same, their content is different. We use data in both translation directions (i.e., *en-fr* and *fr-en*, or *en-de* and *de-en*) for both SMT experiments. Out of these data, 2K and 15K sentence-pairs (for each gender) are held out for tuning and test, respectively, where they comply with the translation direction. That is, for *en-fr* experiments, tuning and test sets are sampled from the *en-fr* direction only and vice-versa. The additional bilingual data (ADD) for training the models comes from the gender-unannotated portion of Europarl (all but the gender-annotated sub-corpus detailed in §3) for the EP experiments, and from combining TED’s male and female data for the experiments with TED.

<sup>8</sup>Downloaded from <http://cm.xrce.xerox.com/>.

### 4.3 Classification setting

All datasets were split by sentence, filtering out sentence alignments other than one-to-one. For POS tagging, we employed the Stanford implementation<sup>9</sup> with its models for English, French and German. We divided all datasets into chunks of approximately 1,000 tokens, respecting sentence boundaries, and normalized the values of lexical features by the actual number of tokens in each chunk. For classification, we used Platt’s sequential minimal optimization algorithm (Keerthi et al., 2001) to train support vector machine classifiers with the default linear kernel (Hall et al., 2009). In all experiments we used (the maximal) equal amount of data from each category (M and F), specifically, 370 chunks for each gender.

Aiming to abstract away from content and capture instead stylistic and syntactic characteristics, we used as our feature set the combination of function words (FW)<sup>10</sup> and (the top-1,000 most frequent) POS-trigrams. We employ 10-fold cross-validation for evaluation of classification accuracy.

### 4.4 SMT setting

We trained phrase-based SMT models with Moses (Koehn et al., 2007), an open source SMT system. KenLM (Heafield, 2011) was used for language modeling. We trained 5-gram language models with Kneser-Ney smoothing (Chen and Goodman, 1996). The models were tuned using Minimum Error Rate Tuning (MERT) (Och, 2003). Our preprocessing included cleaning (removal of empty, long and misaligned sentences), tokenization and punctuation normalization. The Stanford tokenizer (Manning et al., 2014) was used for tokenization and standard Moses scripts were used for other preprocessing tasks. We used BLEU (Papineni et al., 2002) to evaluate MT quality against one reference translation.

## 5 Personalized SMT models

In order to investigate and improve gender traits transfer in MT, we devise and experiment with gender-aware SMT models. We demonstrate that despite their simplicity, these models lead to better preservation of gender traits, while not harming the general quality of the translations.

<sup>9</sup><http://nlp.stanford.edu/software/tagger.shtml>

<sup>10</sup>We used the lists of function words available at <https://code.google.com/archive/p/stop-words>.

	<i>en-de</i> & <i>de-en</i>	170K	86K	1.50M	2K	2K	15K	15K
TED	<i>en-fr</i>	117K	21K	138K	2K	2K	20K	20K

Table 3: MT datasets split for train, tuning and test, after cleaning.

We treat the task of personalizing SMT models as a domain adaptation task, where the *domain* is the gender. We applied two common techniques: (i) gender-specific model components (phrase table and language model (LM)) and (ii) gender-specific tuning sets. These personalized configurations are further compared to a baseline model where gender information is disregarded, as described below. In all cases, we use a single re-ordering table built from the entire training set.

**Baseline** The baseline (*MT-B*) system was trained using the complete parallel corpus available for a language-pair. The training set contained both gender-specific and unannotated data, but no distinction was made between them. A single translation model and a single LM were built, and the model was tuned using a random sample of 2K sentence-pairs from the mixed data dedicated for tuning, preserving, therefore, the gender distribution of the underlying dataset.

**Personalized models** These models use three datasets: male, female, and additional in-domain bilingual data. Two configurations were devised: *MT-P1*, a model with three phrase tables and three LMs trained on the three datasets; and *MT-P2*, where for each gender a phrase table and a language model were built using only the gender-specific data, as well as a general phrase table and LM. In both configurations, each of the two genderized model variants was tuned using the gender-specific tuning set. In order to evaluate the translation quality of a personalized model, we separately translated the male and female source segments, merged the outputs and evaluated the merged result.

## 6 Results

Recall that we use the accuracy of gender classification as a measure of the strength of gender markers in texts. We assessed this accuracy below on originals and (human and machine) translations. First, however, we establish that the quality of SMT is not harmed with our personalized

models.

**MT evaluation** We trained a baseline (*MT-B*) and two personalized models (*MT-P1* and *MT-P2*) for each language pair as detailed in §5. The BLEU scores of *en-fr* and *fr-en* personalized models were 38.42, 38.34 and 37.16, 37.16, with the baseline models scoring 38.65 and 37.35, respectively. Similarly, for experiments with *en-de* and *de-en* and the TED data, the baseline scores (21.95, 26.37 and 33.25) were only marginally higher than those of the personalized models (21.65, 21.80; 26.35, 26.21; and 33.19, 33.16), with differences ranging from 0.02 to 0.3. Neither *MT-P1* nor *MT-P2* was consistently better than the other. We conclude, therefore, that all MT systems are comparable in terms of general quality.

**Classification accuracy** Tables 4 and 5 present the results of gender classification accuracy in original (O), human- (HT) and machine-translated texts in the EP corpus. Female texts are distinguishable from their male counterparts with 77.3% and 77.1% accuracy for English originals, in line with accuracies reported in the literature (Koppel et al., 2002). Classification of original French and German texts reach 81.4% (Table 4) and 76.1% (Table 5), respectively.

<i>en-de MT-P2</i>	66.7	67.7	68.6	65.7	67.2

Table 5: EP *en-de*, *de-en* classification scores (%).

chine translation. The relatively low accuracy for human translation can be (partially) explained by the extensive editing procedure applied on Europarl proceedings prior to publishing (Cucchi, 2012), as well as the potential “fingerprints” of (male or female) human translators left on the final product.

Both *MT-P1* and *MT-P2* models yield translations that better preserve gender traits, compared to their manual and gender-agnostic automatic counterparts: accuracy improvements vary between 3.8 for *fr-en* translations to 7.0 percent points for *de-en*<sup>11</sup> (*MT-P1* vs *MT-B* in both cases). Per-class precision and recall scores do not exhibit significant differences, despite the unbalanced amount of per-gender data used for training the MT models.

Gender classification results in the TED dataset are presented in Table 6. The classification accuracy of English originals is 80.4%. While, similarly to Europarl, the gender signal is generally weakened in human translations<sup>12</sup> and baseline MT, overall accuracies are in most cases higher than in Europarl across all models. We attribute this difference to the more emotional and personal nature of TED speeches, compared with the formal language of the EP proceedings. Both personalized SMT models significantly outperform their baseline counterpart, as well as the manual translation, yielding 77.2% and 77.7% accuracy for *MT-P1* and *MT-P2*, respectively.

<sup>11</sup>All differences between *MT-P1* and *MT-P2* and baseline models are statistically significant.

<sup>12</sup>TED talks are subtitled, rather than transcribed, undergoing some editing and rephrasing.

## 7 Analysis

**Analysis of gender markers** To analyze the extent to which personal traits are preserved in translations, we extract the set of most discriminative FWs in various texts by employing the InfoGain feature selection procedure (Gray, 1990). Gender markers vary across *original* languages (with few exceptions); in EP, the most discriminating English features are *also*, *very*, *perhaps*, *as*, *its*, *others*, *you*. The French list includes *on*, *vous*, *dire*, *afin*, *doivent*, *doit*, *aussi*, *avait*, *voilà*, *je*, while the German list consists of *wir*, *man*, *wirklich*, *sollten*, *von*, *für*, *dass*, *allen*, *ob*. The list of discriminative markers in the TED English dataset contains mainly personal pronouns: *she*, *her*, *I*, *you*, *my*, *our*, *me*, *and*, *who*, *it*.

Figure 2 (top) presents weights assigned to various gender markers by the InfoGain attribute evaluator in originals and translations. Gender markers are carried over to (both manual and machine) translations to an extent that overshadows the original markers of the target language. In particular, the markers observed in translated English mirror their original French counterparts, in the same marker role: *I* (M) in English translations reflecting the original French *je* (M), *say* (M) reflecting *dire* (M), *must* (F) translated from *doit* (F) and *doivent* (F); the latter contradicting the original English *must* which characterizes M speech. The original English prominent gender markers (e.g., *also*, *very*) almost completely lose their discriminative power in translations. A similar phenomenon is exhibited by English translations from German, as depicted in Figure 2 (bottom): the German *wir* (*we*), *für* (*for*) and *ob* (*whether*) are preserved in (both manual and machine) English translations, in the same marker role.

We conclude that (i) gender traits in translation are weakened, compared to their originals. Furthermore, (ii) translations tend to embrace gender tendencies of the original language, thus resulting

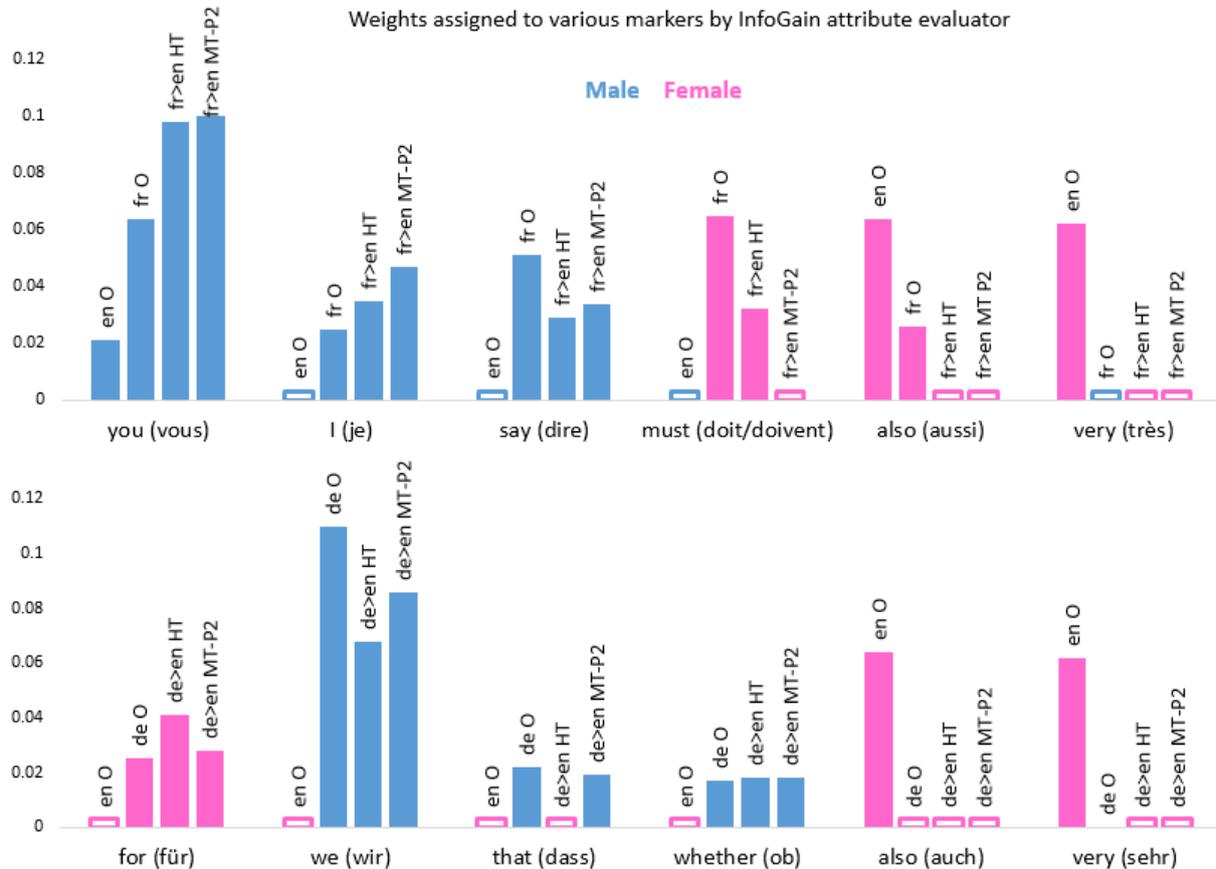

Figure 2: Persistence of *en* and *fr* markers in *fr-en* translations (top); *en* and *de* markers in *de-en* translations (bottom). The transparent bars refer to (weak) F/M markers, assigned weight  $< 0.01$  by InfoGain.

in a *hybrid* outcome, where male and female traits are affected both by markers of the source and (to a much lesser extent) the target language.

**Capturing the “personalization” effect** Both manual- and all machine-translations of Europarl are tested on a strictly identical set of sentences; therefore, the performance gap introduced by personalized SMT models can be captured by a subset of sentences misclassified by the baseline model, but classified correctly when applying a more personalized approach. The inspection of differences in these translations can shed some light on the underlying nature of our personalized models. Table 7 (top) shows manual, baseline, and personalized machine translations of examples of French and German sentences. The translation of the French word “vraiment” (in a *male* utterance) varies in English as “really” or “exactly”, where the former is more frequent in female English texts, and the latter is a male marker. The choice of a *male* English marker over its *female* equivalent by the gender-aware SMT model demonstrates the

effect of personalization as proposed in this paper. The translations of the German *female* sentence into English, as presented in Table 7 (bottom), further highlight this phenomenon by choosing the English *female* marker *think* in its personalized translation over the more neutral *consider* and *believe* in the manual and baseline versions, respectively.

## 8 Conclusions

We presented preliminary results of employing personalized SMT models for better preservation of gender traits in automatic translation. This work leaves much room for further research and practical activities. Authors’ personal traits are utilized by recommendation systems, conversational agents and other personalized applications. While resources annotated for personality traits mainly exist for English (and recently, for a small set of additional languages), they are scarce or missing from most other languages. Employing MT models that are sensitive to authors’ personal traits can

<i>fr O</i>	... on a corrigé la traduction du mot qui a été traduit en français par “propriété” qui n’est pas <b>vraiment</b> la même chose qu’ “appropriation”.
<i>fr-en HT</i>	... it had been translated into French using the word for “property”, which is not <b>really</b> the same thing as “ownership”.
<i>fr-en MT-B</i>	... it was corrected the translation of the word which has been translated into French as “ownership”, which is not <b>really</b> the same as “ownership”.
<i>fr-en MT-P1</i>	... it has corrected the translation of the word which has been translated into French as “ownership”, which is not <b>exactly</b> the same as “ownership”.
<i>de O</i>	Entsprechend <b>halte ich es auch für notwendig</b> , daß die Kennzeichnung möglichst schnell und verpflichtend eingeführt wird, und zwar für Rinder und für Rindfleisch .
<i>de-en HT</i>	Accordingly, <b>I consider it essential</b> that both the identification of cattle and the labelling of beef be introduced as quickly as possible on a compulsory basis.
<i>de-en MT-B</i>	Similarly, <b>I believe that it is necessary</b> , as quickly as possible and that compulsory labelling will be introduced, and for bovine animals and for beef and veal.
<i>de-en MT-P1</i>	Accordingly, <b>I also think it is essential</b> that the labelling and become mandatory as quickly as possible, and for bovine animals and for beef.

Table 7: Translation of *fr* (M) and *de* (F) sentences into English manually, and by different MT models.

facilitate user modeling in other languages as well as augment English data with translated content.

Our future plans include experimenting with more sophisticated MT models, and with additional demographic traits, domains and language-pairs.

## Acknowledgments

This research was partly supported by the H2020 QT21 project (645452, Lucia Specia). We are grateful to Sergiu Nisoi for sharing the initial collection of properties of Members of the European Parliament. We also thank our anonymous reviewers for their constructive feedback.

## Abstract

We study the problem of bilingual lexicon induction (BLI) in a setting where some translation resources are available, but unknown translations are sought for certain, possibly domain-specific terminology. We frame BLI as a classification problem for which we design a neural network based classification architecture composed of recurrent long short-term memory and deep feed forward networks. The results show that word- and character-level representations each improve state-of-the-art results for BLI, and the best results are obtained by exploiting the synergy between these word- and character-level representations in the classification model.

## 1 Introduction

Bilingual lexicon induction (BLI) is the task of finding words that share a common meaning across different languages. Automatically induced bilingual lexicons support a variety of tasks in information retrieval and natural language processing, including cross-lingual information retrieval (Lavrenko et al., 2002; Levow et al., 2005; Vulić and Moens, 2015; Mitra et al., 2016), statistical machine translation (Och and Ney, 2003; Zou et al., 2013), or cross-lingual entity linking (Tsai and Roth, 2016). In addition, they serve as a natural bridge for cross-lingual annotation and model transfer from resource-rich to resource-impooverished languages, finding their application in downstream tasks such as cross-lingual POS tagging (Yarowsky and Ngai, 2001; Täckström et al., 2013; Zhang et al., 2016), dependency parsing (Zhao et al., 2009; Durrett et al., 2012; Upadhyay et al., 2016), semantic role labeling (Padó and Lapata, 2009; van der Plas et al., 2011), to name only a few.

Current state-of-the-art BLI results are obtained by cross-lingual word embeddings (Mikolov et al., 2013b; Faruqui and Dyer, 2014; Gouws et al., 2015; Vulić and Moens, 2016; Duong et al., 2016, inter alia). They significantly outperform traditional count-based baselines (Gaussier et al., 2004; Tamura et al., 2012). Although cross-lingual word embedding models differ on the basis of a bilingual signal from parallel, comparable or monolingual data used in training (e.g., word, sentence, document alignments, translation pairs from a seed lexicon),<sup>1</sup> they all induce word translations in the same manner. (1) They learn a *shared bilingual semantic space* in which all source language and target language words are represented as dense real-valued vectors. The shared space enables words from both languages to be represented in a uniform language-independent manner such that similar words (regardless of the actual language) have similar representations. (2) Cross-lingual semantic similarity between words  $w$  and  $v$  is then computed as  $SF(\vec{w}, \vec{v})$ , where  $\vec{w}$  and  $\vec{v}$  are word representations in the shared space, and  $SF$  denotes a similarity function operating in the space (cosine similarity is typically used). A target language word  $v$  with the highest similarity score  $\arg \max_v SF(\vec{w}, \vec{v})$  is then taken as the correct translation of a source language word  $w$ .

In this work, we detect two major gaps in current representation learning for BLI. First, the standard embedding-based approach to BLI learns representations solely on the basis of word-level information. While early BLI works already established that character-level orthographic features may serve as useful evidence for identifying translations (Melamed, 1995; Koehn and Knight, 2002;

---

<sup>1</sup>See recent comparative studies on cross-lingual word embedding learning (Upadhyay et al., 2016; Vulić and Korhonen, 2016) for an in-depth discussion of the differences in modeling and bilingual supervision.

Haghighi et al., 2008), there has been no attempt to learn character-level bilingual representations automatically from the data and apply them to improve on the BLI task. Moreover, while prior work typically relies on simple orthographic distance measures such as edit distance (Navarro, 2001), we show that such character-level representations can be induced from the data. Second, Irvine and Callison-Burch (2013; 2016) demonstrated that bilingual lexicon induction may be framed as a classification task where multiple heterogeneous translation clues/features may be easily combined. Yet, all current BLI models still rely on straightforward similarity computations in the shared bilingual word-level semantic space (see Sect. 2).

Motivated by these insights, we propose a *novel bilingual lexicon induction (BLI) model* that combines automatically extracted word-level and character-level representations in a classification framework. As the seminal bilingual representation model of Mikolov et al. (2013b), our bilingual model learns from a set of training translation pairs, but we demonstrate that the synergy between word-level and character-level features combined within a deep neural network based classification framework leads to improved BLI results when evaluated in the medical domain. BLI has a large value in finding translation pairs in specialized domains such as the medical domain, where general translation resources are often insufficient to capture translations of all domain terminology.

This paper has several contributions:

- (C1)** *On the word level*, we show that framing BLI as a classification problem, that is, using word embeddings as features for classification leads to improved results compared to standard embedding-based BLI approaches (Mikolov et al., 2013b; Vulić and Korhonen, 2016) which rely on similarity metrics in a bilingual semantic space.
- (C2)** *On the character level*, we find that learning character-level representations with an RNN architecture significantly improves results over standard distance metrics used in previous BLI research to operationalize orthographic similarity.
- (C3)** We finally show that it is possible to effectively *combine word- and character-level signals* using a deep feed-forward neural network. The combined model outperforms “single” word-level and character-level BLI models which rely on only one set of features.

## 2 Background

**Word-Level Information for BLI** Bilingual lexicon induction is traditionally based on word-level features, aiming at quantifying cross-lingual word similarity on the basis of either (1) context vectors, or (2) automatically induced bilingual word representations. A typical context-vector approach (Rapp, 1995; Fung and Yee, 1998; Gaussier et al., 2004; Laroche and Langlais, 2010; Vulić and Moens, 2013b; Kontonatsios et al., 2014, inter alia) constructs context vectors in two languages using weighted co-occurrence patterns with other words, and a bilingual seed dictionary is then used to translate the vectors. Second-order BLI approaches which represent a word by its monolingual semantic similarity with other words were also proposed, e.g., (Koehn and Knight, 2002; Vulić and Moens, 2013a), as well as models relying on latent topic models (Vulić et al., 2011; Liu et al., 2013).

Recently, state-of-the-art BLI results were obtained by a suite of *bilingual word embedding (BWE)* models. Given source and target language vocabularies  $V^S$  and  $V^T$ , all BWE models learn a representation of each word  $w \in V^S \sqcup V^T$  as a real-valued vector:  $\vec{w} = [ft_1, \dots, ft_d]$ , where  $ft_k \in \mathbb{R}$  denotes the value for the  $k$ -th cross-lingual feature for  $w$  within a  $d$ -dimensional shared bilingual embedding space. Semantic similarity  $sim(w, v)$  between two words  $w, v \in V^S \sqcup V^T$  is then computed by applying a similarity function (SF), e.g. cosine ( $cos$ ) on their representations in the bilingual space:  $sim(w, v) = SF(\vec{w}, \vec{v}) = cos(\vec{w}, \vec{v})$ .

A plethora of variant BWE models were proposed, differing mostly in the strength of bilingual supervision used in training (e.g., word, sentence, document alignments, translation pairs) (Zou et al., 2013; Mikolov et al., 2013b; Hermann and Blunsom, 2014; Chandar et al., 2014; Sjøgaard et al., 2015; Gouws et al., 2015; Coulmance et al., 2015; Vulić and Moens, 2016, inter alia). Although the BLI evaluation of the BWE models was typically performed on Indo-European languages, none of the works attempted to learn character-level representations to enhance the BLI performance.

In this work, we experiment with two BWE models that have demonstrated a strong BLI performance using only a small seed set of word translation pairs (Mikolov et al., 2013b), or document alignments (Vulić and Moens, 2016) for bilingual supervision.

It is also important to note that other word-level

translation evidence was investigated in the literature. For instance, the model of Irvine and Callison-Burch (2016) relies on raw word frequencies, temporal word variations, and word burstiness. As the main focus of this work is investigating the combination of automatically induced word-level and character-level representations, we do not exploit the whole space of possible word-level features and leave this for future work. However, we stress that our framework enables the inclusion of these additional word-level signals.

**Character-Level Information for BLI** For language pairs with common roots such as English-Dutch or English-Spanish, translation pairs often share orthographic character-level features, and regularities (e.g., *ideal:ideaal*, *apparition:aparición*). Orthographic translation clues are even more important in certain domains such as medicine, where words with the same roots (from Greek and Latin), and abbreviations are frequently encountered (e.g., *D-dimer:D-dimeer*, *meiosis:meiose*). When present, such orthographic clues are typically strong indicators of translation pairs (Haghighi et al., 2008). This observation was exploited in BLI, applying simple string distance metrics such as Longest Common Subsequence Ratio (Melamed, 1995; Koehn and Knight, 2002), or edit distance (Mann and Yarowsky, 2001; Haghighi et al., 2008). Irvine and Callison-Burch (2016) showed that these metrics may be used with languages with different scripts: they transliterate all words to the Latin script before calculating normalized edit distance.

**BLI as a Classification Task** Irvine and Callison-Burch (2016) demonstrate that BLI can be observed as a classification problem. They train a linear classifier to combine similarity scores from different signals (e.g., temporal word variation, normalized edit distance, word burstiness) using a set of training translation pairs. The approach outperforms an unsupervised combination of signals based on a mean reciprocal rank aggregation, as well as the matching canonical correlation analysis algorithm of Haghighi et al. (2008). A drawback of their classification framework is that translation signals are processed (i.e., converted to a similarity score) and weighted independently.

In contrast to their work, we propose to learn character-level representations instead of using the simple edit distance signal between candidate translations. In addition, our model identifies

translations by jointly processing and combining character-level and word-level translation signals.

### 3 Methodology

In this paper we frame BLI as a classification problem as it supports an elegant combination of word-level and character-level representations. Let  $V^S$  and  $V^T$  denote the sets of all unique source and target words respectively, and  $C^S$  and  $C^T$  denote the sets of all unique source and target characters. The goal is to learn a function  $g : X \rightarrow Y$ , where the input space  $X$  consists of all candidate translation pairs  $V^S \times V^T$  and the output space  $Y$  is  $\{-1, +1\}$ . We define  $g$  as:

$$g(w^S, w^T) = \begin{cases} +1 & , \text{ if } f(w^S, w^T) > t \\ -1 & , \text{ otherwise} \end{cases}$$

Here,  $f$  is a function realized by a neural network that outputs a classification score between 0 and 1;  $t$  is a threshold tuned on a validation set. When the neural network is confident that  $w^S$  and  $w^T$  are translations,  $f(w^S, w^T)$  will be close to 1. The reason for placing a threshold  $t$  on the output of  $f$  is twofold. First, it allows balancing between recall and precision. Second, the threshold naturally accounts for the fact that words might have multiple translations: if two target language words  $w_1^T$  and  $w_2^T$  both have high scores when paired with  $w^S$ , both may be considered translations of  $w^S$ .

Since neural network parameters are trained using a set of positive translation pairs  $D_{lex}$ , one way to interpret  $f$  is to consider it an automatically trained similarity function. For each positive training translation pair  $\langle w^S, w^T \rangle$ , we create  $2N_s$  noise or negative training pairs. These negative samples are generated by randomly sampling  $N_s$  target language words  $w_{neg,S,i}^T, i = 1, \dots, N_s$  from  $V^T$  and pairing them with the source language word  $w^S$  from the true translation pair  $\langle w^S, w^T \rangle$ .<sup>2</sup> Similarly, we randomly sample  $N_s$  source language words  $w_{neg,T,i}^S$  and pair them with  $w^T$  to serve as negative samples. We then train the network by minimizing cross-entropy loss, expressed by Eq. (1):

<sup>2</sup>If we accidentally construct a negative pair which occurs in the set of positive pairs  $D_{lex}$ , we re-sample until we obtain exactly  $N_s$  negative samples.

$$\mathcal{L}_{ce} = \sum_{\langle w_s, w_t \rangle \in D_{lex}} \left( \log(f(w^S, w^T)) - \sum_{i=1}^{N_s} \log(f(w_{neg,T,i}^S, w^T)) - \sum_{i=1}^{N_s} \log(f(w^S, w_{neg,S,i}^T)) \right) \quad (1)$$

We further explain the architecture of the neural network and the strategy we use to identify candidate translations during prediction. Four key components may be distinguished: (1) the input layer; (2) the character-level encoder; (3) the word-level encoder; and (4) a feed-forward network that combines the output representations from the two encoders into the final classification score.

### 3.1 Input Layer

The goal is to exploit the knowledge encoded in both the word and character levels. Therefore, the raw input representation of a word  $w \in V^S$  of character length  $M$  consists of (1) its *one-hot* encoding on the word level, labeled  $x_w^S$ ; and (2) a sequence of  $M$  one-hot encoded vectors  $x_{c_0}^S, \dots, x_{c_i}^S, \dots, x_{c_M}^S$  on the character level, representing the character sequence of the word.  $x_w^S$  is thus a  $|V^S|$ -dimensional word vector with all zero entries except for the dimension that corresponds to the position of the word in the vocabulary.  $x_{c_i}^S$  is a  $|C^S|$ -dimensional character vector with all zero entries except for the dimension that corresponds to the position of the character in the character vocabulary  $C^S$ .

### 3.2 Character-Level Encoder

To encode a pair of character sequences  $x_{c_0}^S, \dots, x_{c_i}^S, \dots, x_{c_n}^S, x_{c_0}^T, \dots, x_{c_i}^T, \dots, x_{c_m}^T$  we use a two-layer long short-term memory (LSTM) recurrent neural network (RNN) (Hochreiter and Schmidhuber, 1997) as illustrated in Fig. 1. At position  $i$  in the sequence, we feed the concatenation of the  $i^{th}$  character of the source language and target language word from a training pair to the LSTM network. The characters are represented by their one-hot encoding. To deal with the possible difference in word length, we append special padding characters at the end of the shorter word (see Fig. 1).  $s_{1i}$ , and  $s_{2i}$  denote the states of the first and second layer of the LSTM. We found that a two-layer LSTM performed better than a shallow LSTM. The output at the final state  $s_{2N}$  is the character-level representation  $r_c^{ST}$ . We apply dropout regularization (Srivastava et al., 2014) with a keep probability of 0.5 on the output connections of the LSTM (see

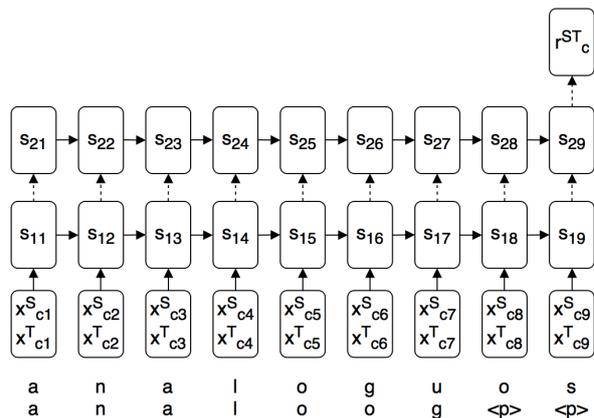

Figure 1: An illustration of the character-level LSTM encoder architecture using the example EN-NL translation pair  $\langle analogous, analog \rangle$ .

the dotted lines in Fig. 1). We will further refer to this architecture as CHAR-LSTM<sub>joint</sub>.<sup>3</sup>

### 3.3 Word-Level Encoder

We define the word-level representation of a word pair  $\langle w^S, w^T \rangle$  simply as the concatenation of word embeddings for  $w^S$  and  $w^T$ :

$$r_w^{ST} = W^S \cdot x_w^S \parallel W^T \cdot x_w^T \quad (2)$$

Here,  $r_w^{ST}$  is the representation of the word pair, and  $W^S, W^T$  are word embedding matrices looked up using one-hot vectors  $x_w^S$  and  $x_w^T$ . The first variant of the architecture assumes that  $W^S$  and  $W^T$  are obtained in advance using any state-of-the-art word embedding model, e.g., (Mikolov et al., 2013b; Vulić and Moens, 2016). They are then kept *fixed* when minimizing the loss from Eq. (1). In Sect. 5.3, however, we investigate another variant architecture where word embeddings are optimized *jointly* with their unsupervised context-prediction objective and the cross-entropy loss from Eq. (1).

To test the generality of our approach, we experiment with two well-known embedding models: (1) the model from Mikolov et al. (2013b), which trains monolingual embeddings using skipgram with negative sampling (SGNS) (Mikolov et al., 2013a); and (2) the model of Vulić and Moens (2016) which learns word-level bilingual embeddings from document-aligned comparable

<sup>3</sup>A possible modification to the architecture would be to swap the (unidirectional) LSTM for a bidirectional LSTM. In preliminary experiments on the development set this did not yield improvements over the proposed architecture, we thus do not discuss it further.

data (BWESG). For both models, the top layers of our proposed classification network should learn to relate the word-level features stemming from these word embeddings using a set of annotated translation pairs.

### 3.4 Combination: Feed-Forward Network

To combine representations on word- and character-level we use a fully connected feed-forward neural network  $r_h$  on top of the concatenation of  $r_w^{ST}$  and  $r_c^{ST}$  which is fed as the input to the network:

$$r_{h_0} = r_w^{ST} \parallel r_c^{ST} \quad (3)$$

$$r_{h_i} = \sigma(W_{h_i} \cdot r_{h_{i-1}} + b_{h_i}) \quad (4)$$

$$\text{score} = \sigma(W_o \cdot r_{h_H} + b_o) \quad (5)$$

$\sigma$  denotes the sigmoid function and  $H$  denotes the number of layers between the representation layer and the output layer. In the simplest architecture,  $H$  is set to 0 and the word-pair representation  $r_{h_0}$  is directly connected to the output layer (see Fig. 2A). In this setting each dimension from the concatenated representation is weighted independently. This architecture induces undesirable patterns in the combined activation of features, and consequently does not learn generalizable relationships between source and target language inputs. On the word level, for instance, it is obvious that the classifier needs to combine the embeddings of the source and target word to make an informed decision and not merely calculate a weighted sum of them. Therefore, we opt for an architecture with hidden layers instead (see Fig. 2B). Unless stated otherwise, we use two hidden layers, while in Section 5.3 we further analyze the influence of parameter  $H$ .

### 3.5 Candidate Generation

To identify which word pairs are translations, one could enumerate all translation pairs and feed them to the classifier  $g$ . The time complexity of this brute-force approach is  $O(|V^S| \times |V^T|)$  times the complexity of  $g$ . For large vocabularies this can be a prohibitively expensive procedure. Therefore, we have resorted to a heuristic which uses a noisy classifier: it generates  $2N_c \ll |V^T|$  translation candidates for each source language word  $w^S$  as follows. It generates (1) the  $N_c$  target words closest to  $w^S$  measured by edit distance as translations, and (2)  $N_c$  target words measured closest to  $w^S$  based on the cosine distance between their word-level embeddings in a bilingual space induced by the embedding model of Vulić and Moens (2016).

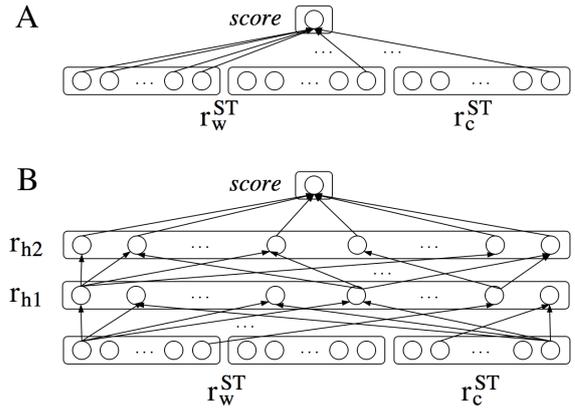

Figure 2: Illustrations of the classification component with feed-forward networks of different depths. A:  $H = 0$ . B:  $H = 2$  (our model). All layers are fully connected.

## 4 Experimental Setup

**Data** One of the main advantages of automatic BLI systems is their portability to different languages and domains. However, current standard BLI evaluation protocols still rely on general-domain data and test sets (Mikolov et al., 2013a; Gouws et al., 2015; Lazaridou et al., 2015; Vulić and Moens, 2016, inter alia). To tackle the lack of quality domain-specific data for training and evaluation of BLI models, we have constructed a new English-Dutch (EN-NL) text corpus in the *medical* domain. The corpus contains topic-aligned documents (i.e., for a given document in the source language, we provide a link to a document in the target language that has comparable content). The domain-specific document collection was constructed from the English-Dutch aligned Wikipedia corpus available online<sup>4</sup>, where we retain only document pairs with at least 40% of their Wikipedia categories classified as *medical*.<sup>5</sup>

The simple selection heuristic ensures that the main topic of the corpus lies in the medical domain, yielding a final collection of 1198 training document pairs. Following a standard practice (Koehn and Knight, 2002; Haghghi et al., 2008; Prochasson and Fung, 2011), the corpus was then tokenized and lowercased, and words occurring less than five times were filtered out.

**Translation Pairs: Training, Development, Test** We construct semi-automatically a set of EN-NL translation pairs by translating all words that occur

<sup>4</sup><http://linguatoools.org/tools/corpora/>

<sup>5</sup>[https://www.dropbox.com/s/hlewabrap1b9p5n/medicine\\_en.txt?dl=0](https://www.dropbox.com/s/hlewabrap1b9p5n/medicine_en.txt?dl=0)

in our pre-processed corpus. This process relied on Google Translate and manual corrections done by fluent EN and NL speakers. Translating the EN vocabulary yields 13,856 translation pairs in total, while the reverse process of translating the NL vocabulary yields 6,537 translation pairs. Taking the union of both lexicons results in 17,567 unique translation pairs, where 7,368 translation pairs (41.94%) have both the source and target language word occurring in our corpus.<sup>6</sup>

We perform a 80/20 random split of the obtained subset of 7,368 translation pairs to construct a training and test set respectively. We make another 80/20 random split of the training set into training and validation data. We note that 20.31% of the source words have more than one translation.

**Word-Level Embeddings** Skip-gram word embeddings with negative sampling (SGNS) (Mikolov et al., 2013b) are obtained with the `word2vec` toolkit with the subsampling threshold set to  $10e-4$  and window size to 5. BWESG embeddings (Vulić and Moens, 2016) are learned by merging topic-aligned documents with length-ratio shuffling, and then by training a SGNS model over the merged documents with the subsampling threshold set to  $10e-4$  and the window size set to 100. The dimensionality of all word-level embeddings is  $d = 50$ .

**Classifier** The model is implemented in Python using Tensorflow (Abadi et al., 2015). For training we use the Adam optimizer with default values (Kingma and Ba, 2015) and mini-batches of 10 examples. We used  $2N_s = 10$  negative samples and we generated  $2N_c = 10$  candidate translation pairs during prediction. The classification threshold  $t$  is tuned measuring  $F_1$  scores on the validation set using a grid search in the interval  $[0.1, 1]$  in steps of 0.1.

**Evaluation Metric** The metric we use is  $F_1$ , the harmonic mean between recall and precision. While prior work typically proposes only one translation per source word and reports  $Accuracy@1$  scores accordingly, here we also account for the fact that words can have multiple translations. We evaluate all models using two different modes: (1) *top* mode, as in prior work, identifies only one translation per source word (i.e., it is the target word with the highest classification score), (2) *all*

<sup>6</sup>Since we use a comparable corpus in our experiments, not all translations of the English vocabulary words occur in the Dutch part of the corpus and vice versa.

mode identifies as translation pairs all pairs for which the classification score exceeds threshold  $t$ .

## 5 Results and Discussion

**A Roadmap to Experiments** We first study automatically extracted word-level and character-level representations and their contribution to BLI in isolation (Sect. 5.1 and Sect. 5.2). It effectively means that for such single-component experiments Eq. 3 is simplified to  $r_{h_o} = r_w^{ST}$  (word-level) and  $r_{h_o} = r_c^{ST}$  (character-level). Following that, we investigate different ways of combining word-level and character-level representations into improved BLI models (Sect. 5.3). There, we conduct additional analyses which investigate the influence of (i) the number of hidden layers of the classifier, (ii) training data size, and (iii) other variant architectures (i.e., training word-level and character-level representations separately vs. training character-level representations jointly with the classifier vs. training all components jointly).

### 5.1 Experiment I: Word Level

The goal of this experiment is twofold. First, we want to analyze the potential usefulness of standard word embeddings in a classification framework. Second, we want to compare the BLI approach based on classification to standard BLI approaches that simply compute similarities in a shared bilingual space. All classification NNs are trained for 150 epochs. The results are shown in Tab. 1.

The top two rows are BLI baselines that apply cosine similarity (SIM) in a bilingual embedding space to score translation pairs. For SGNS-based embeddings, we follow (Mikolov et al., 2013b) and align two monolingual embedding spaces by learning a linear mapping using the same set of training translation pairs as used by our classification framework. The BWESG-based embeddings do not exploit available translation pairs, but rely on document alignments during training. The bottom two rows of Tab. 1 use the classification framework we proposed (CLASS).

As the main finding, we see that the classification framework using word-level features outperforms the standard similarity-based framework. BWESG in the similarity-based approach works best in *top*-mode, i.e., it is good at finding a single translation for a source word.<sup>7</sup> The classification-based ap-

<sup>7</sup>Surprisingly, the similarity-based approach with SGNS embeddings (Mikolov et al., 2013b) reports extremely low

Representation		development		test	
		$F_1$ (top)	$F_1$ (all)	$F_1$ (top)	$F_1$ (all)
SIM	BWESG	15.71	11.56	13.43	9.84
	SGNS	0.43	0.40	0.56	0.37
CLASS	BWESG	11.51	16.02	12.12	15.09
	SGNS	<b>17.67</b>	<b>20.67</b>	<b>17.25</b>	<b>19.79</b>

Table 1: Comparison of different BLI systems which use only word-level information.

proach is consistently better in translating words with multiple translations as evident from higher *all*-mode scores in Tab. 1.

When comparing BWESG and SGNS embeddings within the classification framework, we observe that we obtain significantly better results with SGNS embeddings. A plausible explanation is that SGNS embeddings better capture properties related to the local context of a word like syntax information since they are trained with much smaller context windows.<sup>8</sup> We also note that SGNS also has a practical advantage over BWESG concerning the data requirements as the former does not assume document-level alignments.

## 5.2 Experiment II: Character Level

Here, we compare the representation learned by the character-level encoder with manually extracted features that are commonly used. The following character-level methods are evaluated:

- CHAR-LSTM<sub>joint</sub>, the output of the architecture described in Sect. 3.2
- ED<sub>norm</sub>, the edit distance between the word pair normalized by the average of the number of characters of  $w_s$  and  $w_t$  as used in prior work (Irvine and Callison-Burch, 2013; Irvine and Callison-Burch, 2016).
- log(ED<sub>rank</sub>), the logarithm of the rank of  $w_t$  in a list sorted by the edit distance w.r.t.  $w_s$ . This means that the target word that is nearest in edit distance w.r.t.  $w_s$  will have a feature value of  $\log(1) = 0$ , words that are more distant from  $w_s$  will get higher feature values.

results. A possible explanation for such results is that the model is not able to learn a decent linear mapping between two monolingual embedding spaces induced from a small monolingual corpus relying on low-frequency word translation pairs (Vulić and Korhonen, 2016). We verified the influence of low-frequency word pairs by gradually decreasing the amount of pairs in the seed lexicon, keeping only the most frequent word pairs: e.g., limiting the seed lexicon to the 1000 most frequent word pairs, we obtain better results, which are still well below other models in our comparison.

<sup>8</sup>Large window sizes are inherent to the BWESG model.

Representation		development		test	
		$F_1$ (top)	$F_1$ (all)	$F_1$ (top)	$F_1$ (all)
ED <sub>norm</sub>		30.35	31.36	30.89	28.43
log(ED <sub>rank</sub> )		29.01	26.14	29.48	22.25
ED <sub>norm</sub> + log(ED <sub>rank</sub> )		31.32	30.32	32.27	30.04
CHAR-LSTM <sub>joint</sub>		<b>33.93</b>	<b>35.26</b>	<b>33.89</b>	<b>34.93</b>

Table 2: Comparison of character-level BLI methods from prior work with automatically learned character-level representations.

Target words with the same edit distance score are assigned the same rank.

- ED<sub>norm</sub> + log(ED<sub>rank</sub>), the concatenation of the ED<sub>norm</sub> and log(ED<sub>rank</sub>) features. The combined model results in a stronger baseline.

For the ED-based features we use the same classification framework. However, we use hidden layers only for ED<sub>norm</sub> + log(ED<sub>rank</sub>) as hidden layers do not make the the one-dimensional feature models (ED<sub>norm</sub> and log(ED<sub>rank</sub>)) any more expressive. The ED-based models were additionally tuned by performing a grid search to find the optimal values for the number of negative samples  $2N_s$  and the number of generated translation candidates  $2N_c$ . Both  $2N_s$  and  $2N_c$  are chosen from the interval [10, 100] in steps of 10 based on the performance on the validation set. The ED-based models converge quickly and were only trained for 25 epochs. For the CHAR-LSTM<sub>joint</sub> representation, we use 512 memory cells per layer, we train the model for 300 epochs, and the parameters  $2N_s$  or  $2N_c$  were set to the default values (10) without any additional fine-tuning.

The results are displayed in Tab. 2. The overall performance is high compared to the results of the word-level models. The importance of character-level information in this data set is explained by the large amount of medical terminology and expert abbreviations (e.g., *amynoglicosides*, *aphasics*, *nystagmus*, *EPO*, *EMDR*), which due to its etymological processes, typically contain recurring morphological patterns across languages. It also further supports the need of models that are able to exploit and combine word-level and character-level features. Results also indicate that learning character-level representations from the data is beneficial as the CHAR-LSTM<sub>joint</sub> model significantly outperforms the baselines used in prior work. The CHAR-LSTM<sub>joint</sub> shows consistent improvements over baselines across evaluation modes, while the largest gains are again in the *all*-mode.

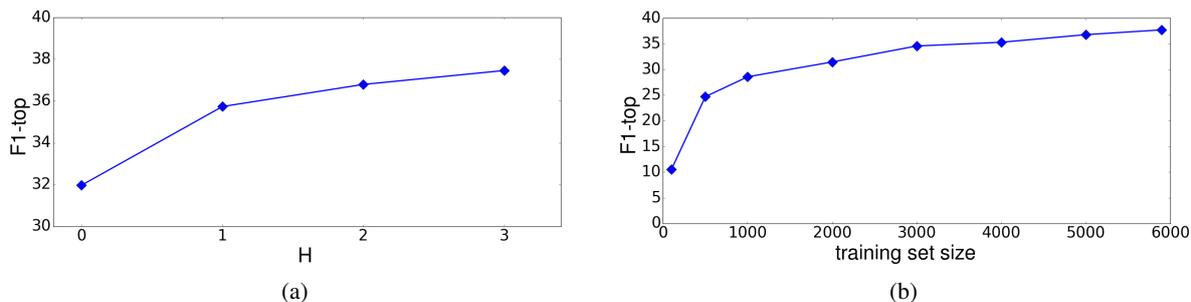

Figure 3: (a) The influence of the number of layers  $H$  between the representations and the output layer on the BLI performance; (b) The influence of the training set size (the number of training pairs).

### 5.3 Experiment III: Combined Model

Encouraged by the excellent results of single-component word-level and character-level BLI models in the classification framework, we also evaluate the combined model. As word-level representations we choose SGNS embeddings and the LSTM consists of 128 in memory cells in each layer in all further experiments.<sup>9</sup> We compare three alternative strategies to learn the parameters of the neural network used for classification:

(1) SEPARATE: Word-level and character-level representations are trained separately. Word-level embeddings and LSTM weights for character-level representations are kept fixed when training the hidden and output layers are simply appended on top of the fixed representations.

(2) CHAR JOINT: Word-level embeddings are trained separately, while character-level representations are trained together with the hidden layers and output layer. This can encourage the network to learn new information on the character-level, different from word-level representations.

(3) ALL JOINT: Motivated by recent work (Ferreira et al., 2016) which proposed a joint formulation for learning task-specific BWEs in a document classification task, all components in our BLI framework are now trained jointly. The joint training objective now consists of two components: the context prediction objective (i.e., SGNS-style objective) and the translation objective described by Eq. (1).

The results are shown in Tab. 3. The CHAR JOINT strategy significantly improves on the best single word-level/character-level models. SEPARATE and ALL JOINT, however, do not improve on the CHAR-LSTM<sub>joint</sub> model. CHAR JOINT allows the character-level representations to learn features that are complementary to word-level information,

<sup>9</sup>We found that in this setting, where we use both word-level and character-level representations, it is beneficial to use a smaller LSTM than in the character-level only setting.

training	development		test	
	$F_1$ (top)	$F_1$ (all)	$F_1$ (top)	$F_1$ (all)
SEPARATE	35.35	35.09	33.60	33.17
CHAR JOINT	<b>36.78</b>	<b>35.85</b>	<b>37.73</b>	<b>36.61</b>
ALL JOINT	33.02	33.75	32.86	33.31

Table 3: Results of the combined model (word-level SGNS plus CHAR-LSTM<sub>joint</sub>). Three different strategies of information fusion are compared.

which seems crucial for an optimal combination of both representations. Learning word-level embeddings jointly with the rest of the network is not beneficial. This can be explained by the fact that the translation objective deteriorates the generalization capabilities of word embeddings.

Another crucial parameter is the number of hidden layers  $H$ . Fig. 3(a) shows the influence of  $H$  on  $F_1$  in *top* mode. BLI performance increases with  $H$ . As expected, we see the largest improvement from  $H = 0$  to  $H = 1$ . With  $H = 0$  the network is not able to model dependencies between features. More hidden layers allow the network to learn more complex, abstract relations between features, resulting in an improved BLI performance.

**Influence of Training Set Size** In practice, for various language pairs and domains, one may have at disposal only a limited number of readily available translation pairs. Fig. 3(b) shows the influence of the size of the training set on performance: while it is obvious that more training data leads to a better BLI performance, the results suggest that a competitive BLI performance may be achieved with smaller training sets (e.g., the model reaches up to 77% of the best performance with only 1K training pairs, and > 80% with 2K pairs).

## 6 Conclusion and Future work

We have introduced a neural network based classification architecture for the task of bilingual lexicon

induction (BLI). We have designed, implemented and evaluated a character-level encoder in the form of a two-layer long short-term memory network and have experimented with different word-level representations. The resulting encodings were used in a deep feed-forward neural network. The results show that especially this combination of character- and word-level knowledge is very successful in the BLI task when evaluated in the medical domain.

Our novel method for learning character-level representations will raise the interest in studying character-level encoders which could be tested in different tasks where string comparisons are important. In future work, we intend to further propose and compare with alternative character-level encoding architectures, and combine additional useful BLI signals in our BLI classification framework.

## Acknowledgments

This research has been carried out in the framework of the Smart Computer-Aided Translation Environment (SCATE) project (IWT-SBO 130041). IV is supported by ERC Consolidator Grant LEXICAL (no 648909). The authors are grateful to the anonymous reviewers for their helpful suggestions.

# Grouping business news stories based on salience of named entities

Llorenç Escoter, Lidia Pivovarova, Mian Du, Anisia Katiskaya and Roman Yangarber

Department of Computer Science  
University of Helsinki, Finland

first.last@cs.helsinki.fi

## Abstract

In news aggregation systems focused on broad news domains, certain stories may appear in multiple articles. Depending on the relative importance of the story, the number of versions can reach dozens or hundreds within a day. The text in these versions may be nearly identical or quite different. Linking multiple versions of a story into a single group brings several important benefits to the end-user—reducing the cognitive load on the reader, as well as signaling the relative importance of the story. We present a grouping algorithm, and explore several vector-based representations of input documents: from a baseline using keywords, to a method using *salience*—a measure of importance of named entities in the text. We demonstrate that features beyond keywords yield substantial improvements, verified on a manually-annotated corpus of business news stories.

## 1 Introduction

We address the problem of grouping multiple versions of the same story in a system that continuously processes articles incoming from a large number of news streams. Our problem setting is PULS—an on-line information extraction (IE) system, which analyses news in the business domain.<sup>1</sup> PULS collects articles from over 1000 on-line sources that provide RSS feeds. Among approximately 4000–6000 articles arriving daily, some of the stories appear multiple times.

The role of the aggregation component is to cluster the articles into a set of *stories*—a story is a set of articles that report the same piece of news.

<sup>1</sup><http://puls.cs.helsinki.fi/>

The purpose of grouping is that when a user issues a query, the system should show one item per story, rather than one item per article, so the same fact is not shown over and over again. Information should be presented in a way that minimizes redundancy of the returned results; this implies narrowly clustering news articles that describe the same events or facts.

Another goal is to identify *trending* stories. In the business domain, if a story is globally important, it will appear in many feeds. When repeated news items are identified, the number and variety of sources covering the story is an indicator of that story's relative importance.

Thus, from the end-user's perspective, we have at least two motivations for grouping different news that describe the same story: reducing redundancy and ranking stories by importance.

The main contributions of this paper are:

- We try to identify the most effective document representation for news clustering. We demonstrate that automatically extracted *named entities* (NE) are better features than words. Moreover, considering the *salience* of NEs—a measure that combines frequency and prominence of the NE—gives further improvement in clustering performance. We introduce a novel salience weighting scheme, which in our experiments outperforms TF-IDF and raw count weighting.
- For word representation, we compare pre-trained *word2vec* vectors with vectors trained on a domain-specific news corpus. Although the corpus-specific word embeddings alone give lower performance on the clustering task, we show that they work better in combination with NE features.
- We analyze two measures for evaluation of clustering performance—Rand index and V-

measure—and a standard way of adjusting them for “chance.” We demonstrate that adjusting favors clustering with a smaller number of clusters. We propose a new type of normalization, which avoids this problem.

- We publish the *data-set*, consisting of nearly 4000 articles collected by our system for one day, grouped into clusters manually. The data-set represents a real task, which the aggregation component must solve daily. We also provide a command-line *annotation tool*, to facilitate manual clustering. We also publish the *word embeddings*.

Although in this paper we deal only with business news, we consider redundancy and the tendency to repeat the more important events to be general properties of news streams. Thus, we believe that our task and the proposed solution generalize to many other news-monitoring settings.

The paper is organized as follows. Section 2 discusses related work. Section 3 presents the NE extraction system and introduces salience for NE weighting. Section 4 describes the algorithm and features. Section 5 describes the data and annotation process. Section 6 discusses evaluation methods and results. Section 7 contains conclusions and future work.

## 2 Related work

A general overview of text clustering techniques can be found in (Aggarwal and Zhai, 2012). Many results on document clustering are published in IR literature, where these techniques are used to cluster search results (Carpineto et al., 2009).

News are clustered for various purposes: finding breaking news in streams (Kumaran and Allan, 2004), linking duplicates or articles about the same story (Vadrevu et al., 2011), tracking threads of news over time (van Erp et al., 2014; Azzopardi and Staff, 2012; Steinberger and Pouliquen, 2008), or facilitating access to information (Zhang et al., 2013; Toda and Kataoka, 2005).

The main techniques for clustering documents are: agglomerative clustering (Steinberger and Pouliquen, 2008) and partitioning clustering, such as k-means, buckshot, and *fractionation* (Azzopardi and Staff, 2012; Sankaranarayanan et al., 2009; Cutting et al., 1992). Hierarchical agglomerative clustering is commonly used in practice, though in general it has a complexity of  $O(n^2 \log(n))$ , (Berkhin, 2006). All objects start

in their own, trivial cluster. The closest pair of clusters is merged, iteratively, until the hierarchy is complete. Partitional algorithms can also be used to create a hierarchical solution, e.g., *bisecting k-means*, which is better than standard k-means and comparable to agglomerative hierarchical approaches, (Steinbach et al., 2000).

On the other hand, determining the number of clusters might be a tricky task for partitional algorithms (Gialampoukidis et al., 2016).

Suffix Tree Clustering (STC) is a linear-time algorithm based on identifying common phrases within groups of documents, (Zamir and Etzioni, 1999). Spectral clustering models the documents as an undirected graph, where each node represents a document, assigns a similarity between documents as a weight on the edges, and tries to find the best cuts of the graph, (Shi and Malik, 2000). Xu et al. (2003) identify document clusters in the latent semantic space derived by non-negative factorization of the term-document matrix of the given corpus.

A common procedure for agglomerative clustering (also used in this paper) can be summarized as follows: convert documents into a vector representation, then use a metric to compute pairwise similarity between documents—often, cosine similarity. In this procedure, clustering quality crucially depends on document representation.

Traditionally, a common way of representing documents for clustering is by a vector of TF-IDF weights for each keyword, e.g., (Iglesias et al., 2016; Azzopardi and Staff, 2012; Vadrevu et al., 2011). Steinberger and Pouliquen (2008) use log-likelihood (LL) for weighting keywords rather than TF-IDF. LL statistics can be computed for each word in the corpus, relative to a separate, “reference” corpus (Rayson and Garside, 2000). Staff et al. (2015) claim that for search results, using raw term frequencies outperforms TF-IDF. Recent lines of research use word embeddings (Mikolov et al., 2013b) to represent documents. Sophisticated deep learning algorithms can also be applied to text clustering (Xu et al., 2015), but to date they require labeled training data, while the method proposed in this paper is unsupervised.

In contrast to bag-of-words (BOW) schemes, named entities (NEs) can be used as features (Montalvo et al., 2012). In most cases, NEs are also weighted according to TF-IDF (Toda and Kataoka, 2005) or its variants (Cheng et al., 2012;

Kiritoshi and Qiang, 2016).

Kumaran and Allan (2004) combined three vector representations for a document, namely: all words, NEs, and all words except NEs. This is similar to the series of experiments in this paper; the difference is that Kumaran and Allan (2004) used TF-IDF in all three cases, while we compare TF-IDF with several alternatives.

Popular clustering data sets target much coarser categorization tasks. For instance, 20 News-group<sup>2</sup> and Reuters' RCV1<sup>3</sup> categorize news into business sectors such as "Fruit Growing" or "comp.graphics." TDT2<sup>4</sup> classifies news related to certain topics—a phenomenon or a big event—such as "Asian Economic Crisis" or "1998 Winter Olympics." Our task focuses on more focused groups; stories about business activities that occurred within a given industry sector or that are related to a broader phenomenon are not considered the same story. If the same entities engage in two different activities, we consider that as two distinct stories. Therefore, we manually annotated a sample of our corpus, which is more suitable for evaluating our methods.

### 3 Named Entities and Saliency

We use a Named Entity Recognition module as part of the PULS news monitoring system. (Yangarber and Steinberger, 2009; Huttunen et al., 2013; Du et al., 2016) It uses patterns and rules to extract NEs; currently the system uses about a thousand patterns, some of which were learned (Yangarber, 2003) and some manually constructed. The system assigns a *type* to each NE—company, person, product, etc.—but the NE types are not used for grouping to reduce the effect of mistakes in analysis, e.g., when an entity is classified with different types across multiple documents. Rather, we consider clustering to be an earlier step in the overall processing pipeline (Yangarber, 2006). Ji and Grishman (2008) show that performance of an IE system can be improved by using clusters of topically-related documents. In PULS we use grouping to improve NE classification: we assign each entity a type based on the majority within the set of clustered documents.

<sup>2</sup><http://www-2.cs.cmu.edu/~TextLearning/datasets.html>

<sup>3</sup><http://about.reuters.com/researchandstandards/corpus/>

<sup>4</sup><https://catalog.ldc.upenn.edu/LDC2001T57>

Our definition of *saliency* relies on the general nature of news articles. Authors typically mention the main event in the title, in condensed form; then, the main information is elaborated in the first few sentences, followed by further detail and background. Thus, the most important NEs are mentioned early in the text and then repeated, whereas less important NEs are mentioned in the later paragraphs and are less frequent.

We compute *saliency* as a combination of *prominence* and *frequency* of an entity in a document. Prominence captures the importance of the *first* mention of entity  $e$  in document  $d$ :

$$prominence(e, d) = \frac{ns(d) - fs(e, d)}{ns(d)}$$

where  $ns(d)$  is the total number of sentences in the document,  $fs(e, d)$  is the number of the sentence (starting at zero) of the first mention of  $e$  in  $d$ . Thus, the prominence of entities mentioned in the title is 1. Prominence also takes into account the total length of the document, to capture diversity of news sources in the collection. For example, the second sentence in a two-page article is more important than the second sentence in a short article, where all crucial information must be condensed at the very beginning.

Frequency is the ratio of mentions of a given NE over all NE mentions:

$$frequency(e, d) = \frac{C(e, d)}{\sum_{e' \in NE(d)} C(e', d)}$$

where  $C(e, d)$  is the count of  $e$  in  $d$ ,  $NE(d)$  is the set of all NEs in  $d$ . Note that we compute the NE frequency relative to the other NEs only and ignore all the other words in the document, since NEs and common words have rather different distributions: important terms are usually repeated more times than names.

We define saliency as the geometric mean of prominence and frequency:

$$S(e, d) = \sqrt{prominence(e, d) \cdot frequency(e, d)}$$

Saliency lies between 0 and 1, but the saliencies in a document need not add up to one—there may be more than one salient entity in the document, or none. In the business domain, the majority of events involve some NEs (often, companies).

We make extensive use of saliency in the PULS system to aggregate and present information to

users. For example, we represent each group as a list of salient companies, with the least salient companies removed. Similarly, when a user searches for a name, the system returns only documents where the entity salience is above a certain threshold.

We compare salience to two other weighting strategies: namely, frequency alone, and TF-IDF.

## 4 Clustering algorithm

The experiments follow the same structure. We start with a collection of documents and transform it into a collection of vectors, by one of the methods described below. We apply agglomerative clustering to the collection of document vectors, using cosine distance between vectors. The agglomerative algorithm produces a dendrogram with the documents as leaves, and we obtain a clustering by cutting at a distance threshold  $\theta \in (0, 1)$ . We use the *complete* metric, meaning that the distance between clusters  $A$  and  $B$  is the *maximum* of the distances between any two vectors in  $A$  and  $B$  (Aggarwal and Zhai, 2012). The threshold  $\theta$  imposes a limit on the maximum distance between any two documents in a cluster.

### 4.1 Mapping documents to $\mathbb{R}^k$

To represent documents as vectors we use two types of features: all words, or named entities. For words, we use three representations: TF-IDF, *word2vec* embeddings pre-trained on a large general corpus, and embeddings trained on our business-news corpus. For NEs, we use raw counts, TF-IDF and salience. Thus, we experiment with six vector representations.

**Word-based representations:** For each word  $w$ , we compute TF-IDF as:

$$\text{TF-IDF}(w, d) = \frac{C(w, d)}{\sum_{w' \in W(d)} C(w', d)} \cdot \log \frac{|D|}{|D_w|}$$

where  $C(w, d)$  counts how many times the word  $w$  appears in document  $d$ ,  $W(d)$  is all words in  $d$ ,  $D$  is all documents in the corpus, and  $|D_w|$  are all documents in  $D$  which contain word  $w$ . Then the vector representation for the document is:

$$\text{TF-IDF}(d) = \sum_{w \in W(d)} \text{TF-IDF}(w, d) \hat{u}_w$$

where  $\hat{u}_w$  is the *one-hot* vector, whose length is the size of the vocabulary, and which contains zeros in all positions but the one corresponding to

$w_1$	$w_2$	Google News	Business
jump	climb	0.55	<b>0.85</b>
recall	remember	<b>0.43</b>	0.13

Table 1: Cosine similarity for sample word vectors.

$w$ . The vector  $\text{TF-IDF}(d)$  contains TF-IDF values for its words and zeros in all other positions. We use only content words—nouns, adjectives and verbs—in the TF-IDF representations.

Another approach is to represent each word as a vector in a low-dimensional vector space. We can then represent documents by adding their corresponding word vectors. We use word vectors produced by the CBOW approach—continuous bag-of-words (Mikolov et al., 2013a). The vector representing document  $d$  is then:

$$\text{CBOW}(d) = \sum_{w \in W(d)} C(w, d) e_w$$

where  $e_w$  is the *embedding* vector representing  $w$ .

In this paper we use the “standard” word2vec embeddings built on the Google News data-set<sup>5</sup> (referred to as “CBOW-st”), and embeddings trained on our business-news corpus “CBOW-b”. Our corpus is relatively small (4.5 million documents), but it contains only documents relevant to business news. We do not know *a priori* which set of embeddings is more suitable for our task. Although the two embeddings produce similar results, the resulting word vectors have noticeable differences, as can be seen in Table 1. The business-domain embeddings for *jump* and *climb* are much closer than in the general corpus, since both are used to denote *increases*; meanwhile, embeddings for *recall* and *remember* are much closer in the general corpus, because, in the business domain, *recall* frequently refers to product recalls.

**Named entity-based representations:** Another natural representation for a document  $d$  can be obtained by using only named entity counts:

$$\text{NEC}(d) = \sum_{e \in \text{NE}(d)} C(e, d) \hat{u}_e$$

where  $\text{NE}(d)$  is the set of all named entities in document  $d$ ,<sup>6</sup> and  $\hat{u}_e$  is the one-hot vector. TF-IDF for NEs is computed in the same way as for keywords

<sup>5</sup>[code.google.com/archive/p/word2vec](https://code.google.com/archive/p/word2vec)

<sup>6</sup>Here we use counts instead of frequencies since there are equivalent when cosine similarity is used.

but using only NEs, ignoring common words. We refer to this representation as **NE-TFIDF**. Finally, a salience-based document representation leverages the *salience*  $S$  of the NEs, described in Section 3:

$$\text{NES}(d) = \sum_{e \in \text{NE}(d)} S(e, d) \hat{u}_e$$

## 4.2 Combining representations

Named entities are crucial for news clustering. In some reporting, journalists use standardized language and even article templates to describe similar events. In such cases, the article’s NEs are the only way to obtain a meaningful document similarity. On the other hand, NEs can be misleading, e.g., if two different events take place in the same location (see (Kumaran and Allan, 2004) for examples in both kinds of problems). Thus, we try to *combine* NE and other textual features.

To that end, we use the best-performing methods in their respective categories—see results in Section 6—namely CBOW for words and salience for NEs. We use two methods of combining of CBOW and NES representation: *juxtaposition* and the *AND* function.

Juxtaposing means simply appending together the vectors corresponding to the NEs and the keywords, to form longer document vectors:

$$\text{NES\_CBOW}_\alpha(d) = \left[ \alpha k_d \frac{\text{NES}(d)}{\|\text{NES}(d)\|}, \frac{\text{CBOW}(d)}{\|\text{CBOW}(d)\|} \right] \quad (1)$$

where first, we normalize both representations by their respective Euclidean distances,  $\|\cdot\|$ ; then, we scale by  $\alpha$ , which controls the relative weight of NES vs. CBOW. We further scale NES by  $k_d$ —the number of NEs found in  $d$ . The rationale behind this is that if a document contains more NEs, then the NES representation conveys more information; whereas if  $d$  has only one NE, then grouping should rely much more on the keywords. We apply the same agglomerative clustering procedures as in other experiments to these juxtaposed vectors. We experiment with both vector representations, CBOW-st and CBOW-b.

The second method, similar to that used in (Kumaran and Allan, 2004), requires that both word distance *and* NE distance should be sufficiently close—closer than corresponding thresholds. In this case, we cannot use the *complete* linkage metric since a maximum of distances is not defined if the distance is a *pair* of numbers. Thus, unlike all

other experiments described in this paper, for the *AND* combination method we use the *single* metrics (Aggarwal and Zhai, 2012). This is equivalent to finding connected components of the graph where the nodes are documents and there is an edge between two nodes if and only if both distances are below their respective thresholds.

## 5 Data and annotation scheme

From our business news corpus (Pivovarov et al., 2013) we selected one “typical” day for annotation, with a total of 3959 documents.<sup>7</sup> We manually annotated all of these documents via a specialized interface, which displays documents pairwise and allows an annotator to make three main decisions: documents can be

- Grouped: if their main stories are the same.
- Not grouped: if their stories are not the same.
- Partially grouped: if their main stories are not the same, but may partially overlap. For example, one article might mention the other’s main story toward the end.

The interface provides other helpful options, for example, the annotator can use regular expressions to search for all documents similar to a given one; another option is to mark the document as invalid if the document is *malformed*.<sup>8</sup>

We use a triangular matrix  $M$  to keep track of the pairwise relations among documents. Since annotation is an extremely time-consuming process, the key aim is to reduce the amount of data shown to the annotator as far as possible. We initialize  $M$  by pre-marking all pairs of documents that do have no NE in common as un-grouped; this decision may later be reversed by the annotator.

Another idea that allows us to minimize manual work is *decision propagation*. Document grouping—that is, documents having the same main story—can be viewed as an equivalence relation. This means that (ideally) only one member of a group needs to be checked against a member of another group to decide whether both groups

<sup>7</sup>Some sites publish “summary” articles, which contain an overview of 10 or more (possibly unrelated) stories, with as little as one sentence per story. In this paper, summaries are filtered out, to make the grouping task well defined. Filtering is performed by a simple segmentation algorithm, which checks whether the text is separable into contiguous segments, containing *non-overlapping* sets of named entities.

<sup>8</sup>This includes documents where some *broken* content was retrieved, such as a login page or advertisement.

should be merged. Every time a user groups two documents, the decision is propagated so that two corresponding groups are merged, and other pairs from the merged group are never shown to the user. Sometimes this leads to a contradiction, including cases when the initialization was wrong—i.e., when initialization suggests that two documents cannot be in the same group, but the annotator decides to merge two groups they belong to. In such a case, the annotator is warned and has to resolve the contradiction. Negative decisions can also be propagated: when an annotator marks a pair of documents as ungrouped, this affects all documents in both groups. Partial relations, on the other hand, are not equivalence relations, and require more manual annotation.

Our annotation tool keeps track of annotators’ decisions,  $U$ , and reconstructs the annotation from them. This process can be viewed as applying each  $u \in U$  to successive versions of  $M$ :

$$M_i = u_i(M_{i-1})$$

In this scenario, mistakes—which will appear as contradictions in  $M$ —are much easier to detect and correct. Given  $U$  that generates contradictions, a minimal subset  $U' \subset U$  that generates the same contradiction can be more easily inspected. Then, the offending input can be corrected and we can proceed with the annotation.<sup>9</sup>

In total four members of our team were involved in the annotation process. Most of the instances were annotated by one person. In the beginning of the process we annotated several cases together and discussed difficult ones to work out general guidelines. Annotators also checked some random part of others’ annotations, and corrected several cases during error analysis, by looking at misclassified instances with the highest confidence.<sup>10</sup>

Of the 3959 documents annotated in this manner, all documents marked as either invalid or *partially related* to others were removed (402 documents), leaving 3557 documents that can be grouped unambiguously. This constitutes the ground-truth clustering against which we test our system. Figure 1 shows how the documents are distributed among cluster sizes: the vast majority of them (2249) are in a cluster by themselves,<sup>11</sup>

<sup>9</sup>We arrived at this annotation scheme through trial and error, since annotating thousands of documents is a complex and tedious task. This seems to be an effective approach.

<sup>10</sup>Overall, the annotation process spanned across two calendar months.

<sup>11</sup>Leftmost bar is cut off at 500 to improve readability.

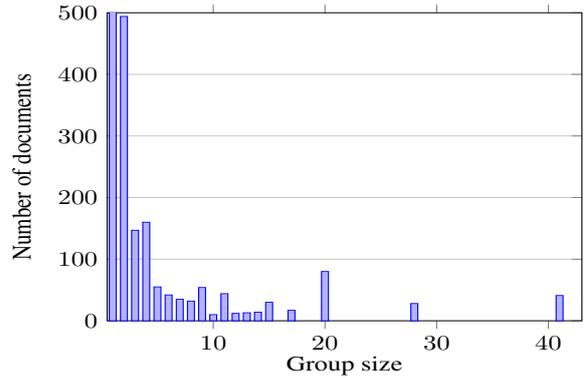

Figure 1: Distribution of annotated data (the leftmost bar goes up to 2249: 2249 documents are not clustered with any other document)

and the rest form larger ones. This is expected, as most of the data has been gathered from specialized business RSS feeds (mining news, dairy news, and so on); these sources usually report all news related to their industry including less important events that do not appear in other sources.

## 6 Evaluation and results

### 6.1 Evaluation methods

We evaluate our resulting clusters using Rand index (RI) and V-Measure. Rand index considers all possible pairs of documents, and is the proportion of correctly classified pairs—grouped or ungrouped—among all pairs (Rand, 1971). RI can be adjusted for chance, as described in (Hubert and Arabie, 1985):

$$ARI(S_{rep}) = \frac{RI(S_{rep}) - \mathbb{E}[RI(S_{chance})]}{1 - \mathbb{E}[RI(S_{chance})]} \quad (2)$$

where  $S_{rep}$  is the clustering strategy based on a document representation  $rep$ — $rep$  is one of the representation strategies described in Section 4. The strategy  $S_{chance}$  is a *random* clustering strategy;  $RI(S)$  is the RI of applying strategy  $S$  to the data; and  $\mathbb{E}$  is expectation, which is estimated as described in (Hubert and Arabie, 1985).

V-Measure is the harmonic mean of homogeneity ( $H$ ) and completeness ( $C$ ) (Rosenberg and Hirschberg, 2007).

$$H = 1 - \frac{\mathbb{H}(C|K)}{\mathbb{H}(C)} \quad C = 1 - \frac{\mathbb{H}(K|C)}{\mathbb{H}(K)} \quad V = \frac{2HC}{H + C}$$

where  $\mathbb{H}$  denotes entropy,  $K$  are predicted labels,

and  $C$  are the true labels. Completeness, homogeneity and V-measure are analogous to recall, precision and F-measure respectively.

Figures 2 and 3 show the measures we wish to optimize, namely the Rand index (*unadjusted for chance*) and the V-Measure. RI adjusted for chance (ARI) is shown in Figure 4.

From figures 2 and 3 it is relatively difficult to see the maxima of the measures. In both, most of the *interesting* information lies in a very small region, which is difficult to visualize. If we zoomed into these regions sufficiently, we would find that the maxima in these figures correspond to similar values  $\theta$ , which are different from the maxima in Figure 4. This highlights several problems.

Adjustment for chance depends on the number of clusters, which in turn depends on the threshold value ( $\theta$ ); a random clustering that produces a very large number of clusters will have a very high RI value (which is the adjustment penalty) and the ARI will be very low, because the penalty for the adjustment is high. Therefore, the ARI measure favors higher values of  $\theta$ , where the number of resulting clusters will be smaller.

We consider this a shortcoming of the ARI measure and propose another function to maximize. We rather adjust for the **naïve** strategy,  $S_{\text{naïve}}$ , which assigns each document to its own cluster. In other words, we try to measure what is the gain of clustering some documents compared to “doing nothing.”

We transform Equation 2 to adjust for  $S_{\text{naïve}}$  rather than chance. Suppose  $f(S)$  is a scoring measure for a clustering strategy  $S$ ; in our case,  $f$  is RI or V-measure. Now,  $f(S) \in [0, 1]$ , and 1 is the perfect score, and 0 is the worst score. We can adjust  $f$  as follows:

$$\begin{aligned} \hat{f}_{\text{naïve}}(S_{\text{rep}}) &= \frac{f(S_{\text{rep}}) - \mathbb{E}[f(S_{\text{naïve}})]}{1 - \mathbb{E}[f(S_{\text{naïve}})]} \\ &= \frac{f(S_{\text{rep}}) - f(S_{\text{naïve}})}{1 - f(S_{\text{naïve}})} \end{aligned} \quad (3)$$

Equation 3 adjusts the score for the naïve strategy—which shows how much better than the naïve the given strategy performs; if it performs worse than naïve adjusted score is less than zero.

The naïve strategy produces high scores: V-measure of 0.965 and RI of 0.9993. Homogeneity for the naïve strategy is 1, and completeness for our corpus is also quite high because the majority of documents do not belong to any group, as

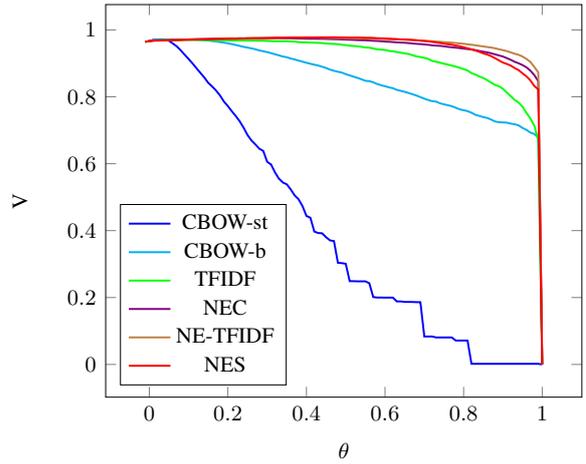

Figure 2: V-Measure

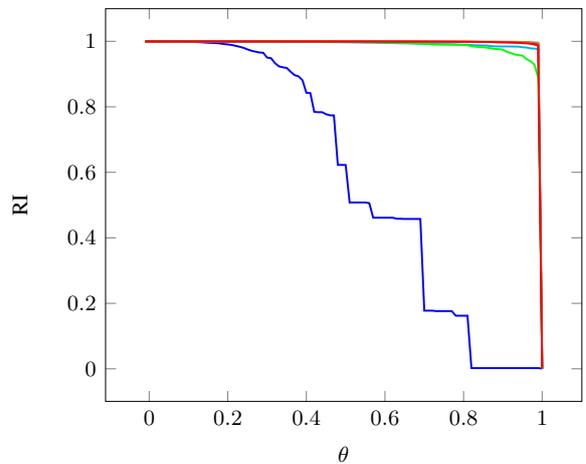

Figure 3: Rand index

shown in Figure 1. Rand index considers all possible pairings and yields a high score since most must belong to different clusters.

Using the naïve adjustment, Figures 5 and 6 show a much clearer picture of how each document representation behaves.<sup>12</sup> The figures show that the two measures—RI and V-measure—behave similarly, and reach their maxima at very similar values of  $\theta$ . Because the measures indicate the same maximum, we do not need to prefer one measure over the other.

## 6.2 Results

As seen in Figure 5 and 6, the NE-based strategies outperform the word-based ones. Even the worst-performing NE-based measure (raw count, NEC) is better than the word-based strategies. TF-IDF, which is the most frequently mentioned strategy in the literature, outperforms raw counts. We can

<sup>12</sup>In these figures we show only positive values.

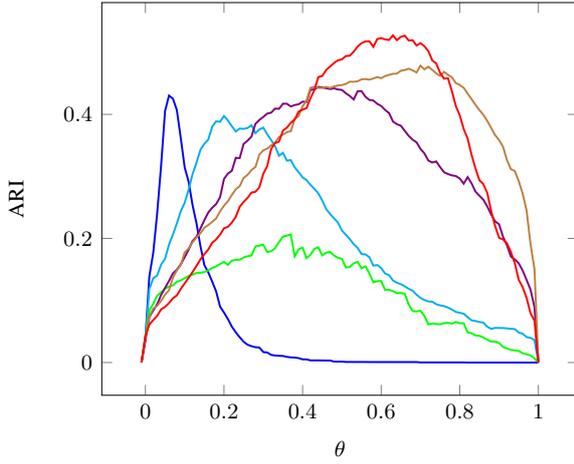

Figure 4: Adjusted Rand index

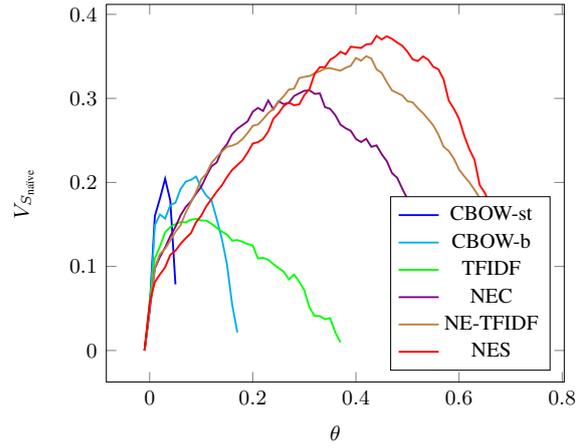

Figure 6: V Measure adjusted for  $S_{naive}$

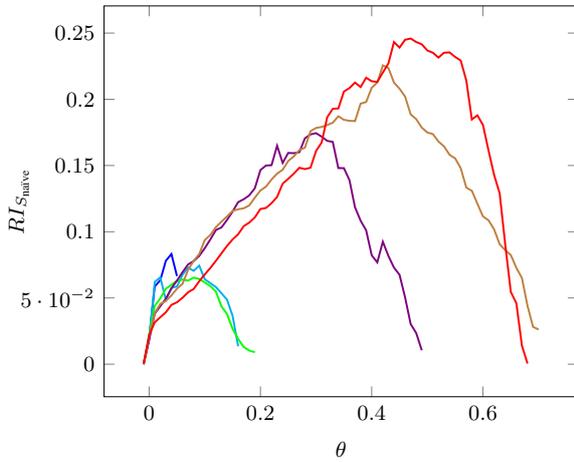

Figure 5: Rand index adjusted for  $S_{naive}$

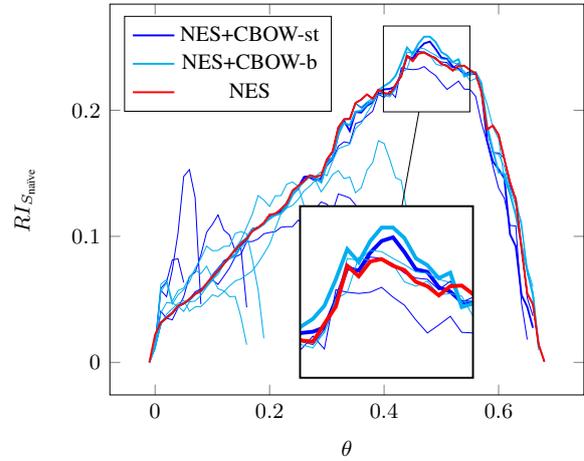

Figure 7: Rand index adjusted for  $S_{naive}$

argue for and against TF-IDF. For example, it is clear that locations that rarely pop up in news are more informative than popular country names. On the other hand, big companies, such as Google, are involved in many different activities and often appear in the news, which should not affect their relevance in a particular event. The best-performing measure, which is based on *saliency* (NES), completely ignores the overall distribution of NEs in the corpus. However, it takes into account the *position* of the entity mentions in the text, and manages to outperform both raw counts and TF-IDF.

Among word-based measures, embeddings—CBOw-st and CBOw-b—outperform TF-IDF, and pre-trained embeddings, CBOw-st, are slightly better than the ones trained on our small business corpus, CBOw-b. It is also interesting how concave the CBOw plots are, as can be seen in Figures 5 and 6; this shows that the embedding representation has a clear, well-defined, threshold.

Figures 7 and 8 show the measures obtained by combining embedding-based representations and saliency, according to Equation 1—juxtaposing combination method. We tested several values of  $\alpha$ , on a logarithmic scale from  $\frac{1}{1000}$  to 1000, some of them are shown using thin blue lines, dark for CBOw-st and light for CBOw-b. The thick lines present the best performing combinations, which correspond to  $\alpha = 1$  for CBOw-st and  $\alpha = 0.5$  for CBOw-b; the red curves present the values obtained by NES in figures 5 and 6.

It can be seen, from Figures 7 and 8, that, when combined with saliency, the embeddings trained on our small domain-specific corpus outperform those trained on a much larger general corpus, even though CBOw-b alone performs worse than CBOw-st. It is interesting that, in the case of business-specific embeddings, it is better to give less weight to the NE features: the best  $\alpha$  for CBOw-st is half of the best  $\alpha$  for CBOw-b.

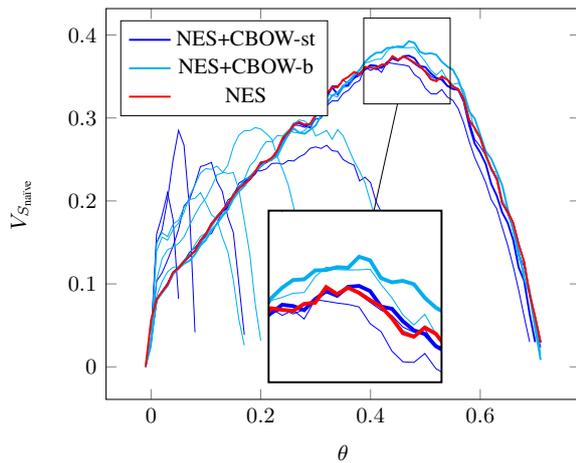

Figure 8: V-Measure adjusted for  $S_{naive}$

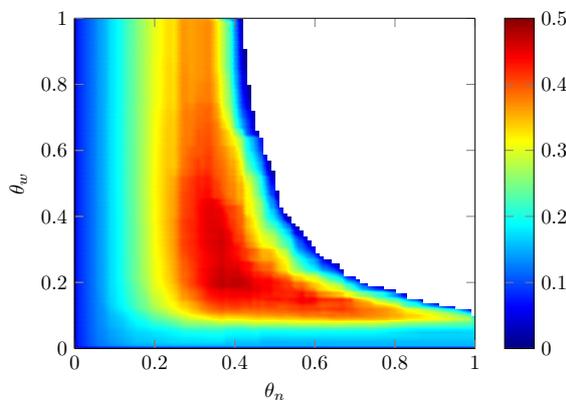

Figure 9: V-Measure adjusted for  $S_{naive}$

However, as can be seen from these figures, juxtaposed representations does not yield significant improvements over simply using a single set of features. Figures 9 and 10 show, respectively, the V-measure and Rand-index for CBOW-b and NES combined using the *AND* function: two documents are in the same group if and only if both distances are below their corresponding thresholds— $\theta_n$  for NEs and  $\theta_w$  for words. Since we are optimizing these two parameters, we plot the results in a heat map. It can be seen that this approach to combination yields a significant improvement: up to 0.39 for  $S_{naive}$ -adjusted Rand index and 0.47 for V-measure.

This significant improvement can be explained by the distribution of our corpus, presented in Figure 1, and by the fact that we use two representations of documents with different information. By using the *AND* function to combine them, we can filter out the cases where using only one representation would result in a false positive. In other

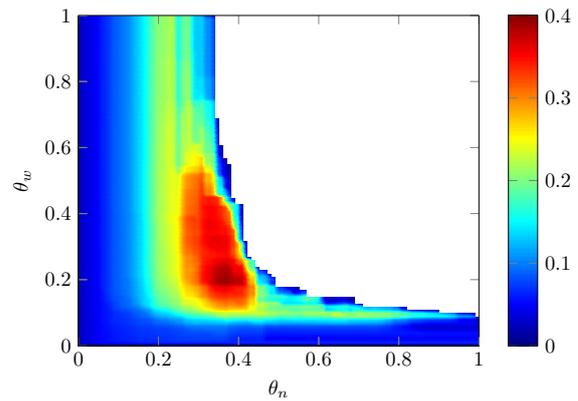

Figure 10: Rand index adjusted for  $S_{naive}$

words, two documents are grouped only if both their names and their common keywords are similar. We hypothesize that this can be a reasonable method for event-based clustering of news streams: the trending events are reported in many sources, while each source tries to produce some unique content. On the other hand, this may be not an appropriate strategy for topic classification.

## 7 Conclusions and future work

We have shown how considering the relative importance of named entities, in the form of *saliency*, can be used to improve detection of related stories in different news articles. We have introduced an effective adjustment for the clustering metrics, and a method for combining different document vector representations, which outperforms the base representations alone. We make public the annotation interface, the news data, and the word embeddings used in this work, on our project page.<sup>13</sup>

We plan to explore other, more *user-oriented* metrics, which could take into account what a potential user might expect from a news-aggregating system. Other representations using the relative importance of named entities in a given news article should also be considered, such as a continuous-vector representation for documents where named entities play a role. Zhao and Karypis (2002) claim that agglomerative clustering may not be the best algorithm for this kind of task; therefore we plan to explore how the representations behave under other clustering algorithms.

## Abstract

The dominant approach for many NLP tasks are recurrent neural networks, in particular LSTMs, and convolutional neural networks. However, these architectures are rather shallow in comparison to the deep convolutional networks which have pushed the state-of-the-art in computer vision. We present a new architecture (VD-CNN) for text processing which operates directly at the character level and uses only small convolutions and pooling operations. We are able to show that the performance of this model increases with the depth: using up to 29 convolutional layers, we report improvements over the state-of-the-art on several public text classification tasks. To the best of our knowledge, this is the first time that very deep convolutional nets have been applied to text processing.

## 1 Introduction

The goal of natural language processing (NLP) is to process text with computers in order to analyze it, to extract information and eventually to represent the same information differently. We may want to associate categories to parts of the text (e.g. POS tagging or sentiment analysis), structure text differently (e.g. parsing), or convert it to some other form which preserves all or part of the content (e.g. machine translation, summarization). The level of granularity of this processing can range from individual characters to subword units (Sennrich et al., 2016) or words up to whole sentences or even paragraphs.

After a couple of pioneer works (Bengio et al. (2001), Collobert and Weston (2008), Collobert et al. (2011) among others), the use of neural networks for NLP applications is attracting huge in-

terest in the research community and they are systematically applied to all NLP tasks. However, while the use of (deep) neural networks in NLP has shown very good results for many tasks, it seems that they have not yet reached the level to outperform the state-of-the-art by a large margin, as it was observed in computer vision and speech recognition.

Convolutional neural networks, in short *ConvNets*, are very successful in computer vision. In early approaches to computer vision, handcrafted features were used, for instance “*scale-invariant feature transform (SIFT)*” (Lowe, 2004), followed by some classifier. The fundamental idea of ConvNets (LeCun et al., 1998) is to consider feature extraction and classification as one jointly trained task. This idea has been improved over the years, in particular by using many layers of convolutions and pooling to sequentially extract a *hierarchical representation* (Zeiler and Fergus, 2014) of the input. The best networks are using more than 150 layers as in (He et al., 2016a; He et al., 2016b).

Many NLP approaches consider words as basic units. An important step was the introduction of continuous representations of words (Bengio et al., 2003). These *word embeddings* are now the state-of-the-art in NLP. However, it is less clear how we should best represent a sequence of words, e.g. a whole sentence, which has complicated syntactic and semantic relations. In general, in the same sentence, we may be faced with local and long-range dependencies. Currently, the mainstream approach is to consider a sentence as a sequence of tokens (characters or words) and to process them with a recurrent neural network (RNN). Tokens are usually processed in sequential order, from left to right, and the RNN is expected to “*memorize*” the whole sequence in its internal states. The most popular and successful RNN variant are certainly LSTMs (Hochreiter and Schmid-

huber, 1997) – there are many works which have shown the ability of LSTMs to model long-range dependencies in NLP applications, e.g. (Sundermeyer et al., 2012; Sutskever et al., 2014) to name just a few. However, we argue that LSTMs are generic learning machines for sequence processing which are lacking task-specific structure.

We propose the following analogy. It is well known that a fully connected one hidden layer neural network can in principle learn any real-valued function, but much better results can be obtained with a deep problem-specific architecture which develops hierarchical representations. By these means, the search space is heavily constrained and efficient solutions can be learned with gradient descent. ConvNets are namely adapted for computer vision because of the compositional structure of an image. Texts have similar properties : characters combine to form n-grams, stems, words, phrase, sentences etc.

We believe that a challenge in NLP is to develop deep architectures which are able to learn hierarchical representations of whole sentences, jointly with the task. In this paper, we propose to use deep architectures of many convolutional layers to approach this goal, using up to 29 layers. The design of our architecture is inspired by recent progress in computer vision, in particular (Simonyan and Zisserman, 2015; He et al., 2016a).

This paper is structured as follows. There have been previous attempts to use ConvNets for text processing. We summarize the previous works in the next section and discuss the relations and differences. Our architecture is described in detail in section 3. We have evaluated our approach on

several sentence classification tasks, initially proposed by (Zhang et al., 2015). These tasks and our experimental results are detailed in section 4. The proposed deep convolutional network shows significantly better results than previous ConvNets approach. The paper concludes with a discussion of future research directions for very deep approach in NLP.

## 2 Related work

There is a large body of research on sentiment analysis, or more generally on sentence classification tasks. Initial approaches followed the classical two stage scheme of extraction of (hand-crafted) features, followed by a classification stage. Typical features include bag-of-words or  $n$ -grams, and their TF-IDF. These techniques have been compared with ConvNets by (Zhang et al., 2015; Zhang and LeCun, 2015). We use the same corpora for our experiments. More recently, words or characters, have been projected into a low-dimensional space, and these embeddings are combined to obtain a fixed size representation of the input sentence, which then serves as input for the classifier. The simplest combination is the element-wise mean. This usually performs badly since all notion of token order is disregarded.

Another class of approaches are recursive neural networks. The main idea is to use an external tool, namely a parser, which specifies the order in which the word embeddings are combined. At each node, the left and right context are combined using weights which are shared for all nodes (Socher et al., 2011). The state of the top node is fed to the classifier. A recurrent neural net-

work (RNN) could be considered as a special case of a recursive NN: the combination is performed sequentially, usually from left to right. The last state of the RNN is used as fixed-sized representation of the sentence, or eventually a combination of all the hidden states.

First works using convolutional neural networks for NLP appeared in (Collobert and Weston, 2008; Collobert et al., 2011). They have been subsequently applied to sentence classification (Kim, 2014; Kalchbrenner et al., 2014; Zhang et al., 2015). We will discuss these techniques in more detail below. If not otherwise stated, all approaches operate on words which are projected into a high-dimensional space.

A rather shallow neural net was proposed in (Kim, 2014): one convolutional layer (using multiple widths and filters) followed by a max pooling layer over time. The final classifier uses one fully connected layer with drop-out. Results are reported on six data sets, in particular Stanford Sentiment Treebank (SST). A similar system was proposed in (Kalchbrenner et al., 2014), but using five convolutional layers. An important difference is also the introduction of multiple *temporal k-max pooling* layers. This allows to detect the  $k$  most important features in a sentence, independent of their specific position, preserving their relative order. The value of  $k$  depends on the length of the sentence and the position of this layer in the network. (Zhang et al., 2015) were the first to perform sentiment analysis entirely at the character level. Their systems use up to six convolutional layers, followed by three fully connected classification layers. Convolutional kernels of size 3 and 7 are used, as well as simple max-pooling layers. Another interesting aspect of this paper is the introduction of several large-scale data sets for text classification. We use the same experimental setting (see section 4.1). The use of character level information was also proposed by (Dos Santos and Gatti, 2014): all the character embeddings of one word are combined by a max operation and they are then jointly used with the word embedding information in a shallow architecture. In parallel to our work, (Yang et al., 2016) proposed a based hierarchical attention network for document classification that perform an attention first on the sentences in the document, and on the words in the sentence. Their architecture performs very well on datasets whose samples contain multiple sen-

tences.

In the computer vision community, the combination of recurrent and convolutional networks in one architecture has also been investigated, with the goal to “*get the best of both worlds*”, e.g. (Pinheiro and Collobert, 2014). The same idea was recently applied to sentence classification (Xiao and Cho, 2016). A convolutional network with up to five layers is used to learn high-level features which serve as input for an LSTM. The initial motivation of the authors was to obtain the same performance as (Zhang et al., 2015) with networks which have significantly fewer parameters. They report results very close to those of (Zhang et al., 2015) or even outperform ConvNets for some data sets.

In summary, we are not aware of any work that uses VGG-like or ResNet-like architecture to go deeper than than six convolutional layers (Zhang et al., 2015) for sentence classification. Deeper networks were not tried or they were reported to not improve performance. This is in sharp contrast to the current trend in computer vision where significant improvements have been reported using much deeper networks (Krizhevsky et al., 2012), namely 19 layers (Simonyan and Zisserman, 2015), or even up to 152 layers (He et al., 2016a). In the remainder of this paper, we describe our very deep convolutional architecture and report results on the same corpora than (Zhang et al., 2015). We were able to show that performance improves with increased depth, using up to 29 convolutional layers.

### 3 VDCNN Architecture

The overall architecture of our network is shown in Figure 1. Our model begins with a look-up table that generates a 2D tensor of size  $(f_0, s)$  that contain the embeddings of the  $s$  characters.  $s$  is fixed to 1024, and  $f_0$  can be seen as the “RGB” dimension of the input text.

We first apply one layer of 64 convolutions of size 3, followed by a stack of temporal “convolutional blocks”. Inspired by the philosophy of VGG and ResNets we apply these two design rules: (i) for the same output temporal resolution, the layers have the same number of feature maps, (ii) when the temporal resolution is halved, the number of feature maps is doubled. This helps reduce the memory footprint of the network. The networks contains 3 pooling operations (halving the tempo-

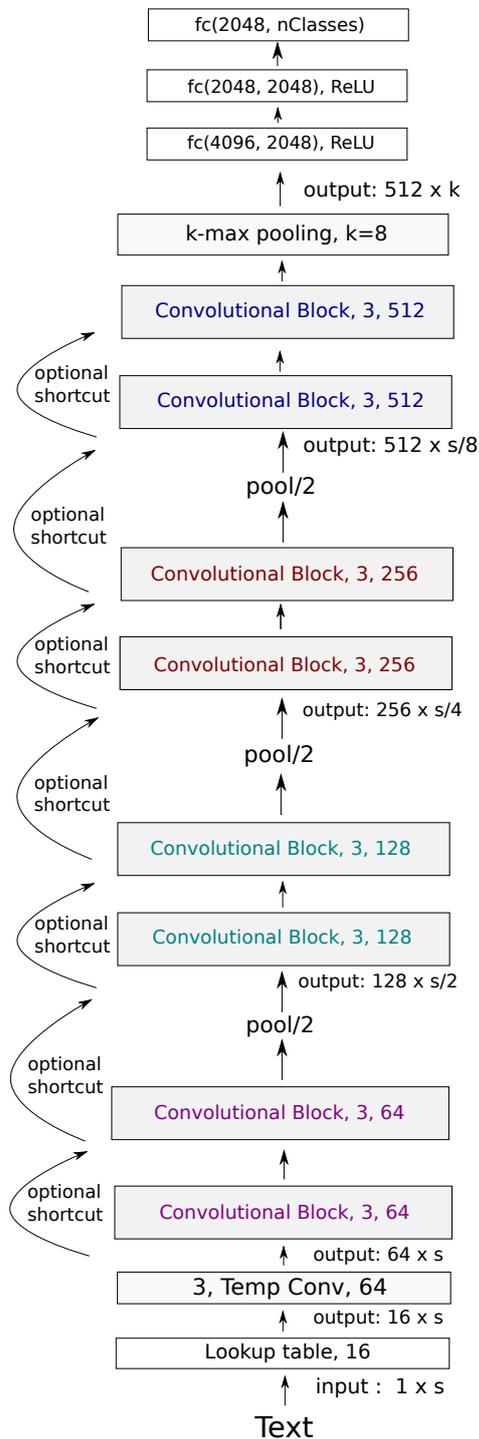

Figure 1: VDCNN architecture.

ral resolution each time by 2), resulting in 3 levels of 128, 256 and 512 feature maps (see Figure 1). The output of these convolutional blocks is a tensor of size  $512 \times s_d$ , where  $s_d = \frac{s}{2^p}$  with  $p = 3$  the number of down-sampling operations. At this level of the convolutional network, the resulting tensor can be seen as a high-level representation of the input text. Since we deal with padded input text of fixed size,  $s_d$  is constant. However, in the case of variable size input, the convolutional encoder provides a representation of the input text that depends on its initial length  $s$ . Representations of a text as a set of vectors of variable size can be valuable namely for neural machine translation, in particular when combined with an attention model. In Figure 1, temporal convolutions with kernel size 3 and  $X$  feature maps are denoted "3, Temp Conv,  $X$ ", fully connected layers which are linear projections (matrix of size  $I \times O$ ) are denoted "fc( $I$ ,  $O$ )" and "3-max pooling, stride 2" means temporal max-pooling with kernel size 3 and stride 2.

Most of the previous applications of ConvNets to NLP use an architecture which is rather shallow (up to 6 convolutional layers) and combines convolutions of different sizes, e.g. spanning 3, 5 and 7 tokens. This was motivated by the fact that convolutions extract  $n$ -gram features over tokens and that different  $n$ -gram lengths are needed to model short- and long-span relations. In this work, we propose to create instead an architecture which uses many layers of small convolutions (size 3). Stacking 4 layers of such convolutions results in a span of 9 tokens, but the network can learn by itself how to best combine these different "3-gram features" in a deep hierarchical manner. Our architecture can be in fact seen as a temporal adaptation of the VGG network (Simonyan and Zisserman, 2015). We have also investigated the same kind of "ResNet shortcut" connections as in (He et al., 2016a), namely identity and  $1 \times 1$  convolutions (see Figure 1).

For the classification tasks in this work, the temporal resolution of the output of the convolution blocks is first down-sampled to a fixed dimension using  $k$ -max pooling. By these means, the network extracts the  $k$  most important features, independently of the position they appear in the sentence. The  $512 \times k$  resulting features are transformed into a single vector which is the input to a three layer fully connected classifier with ReLU

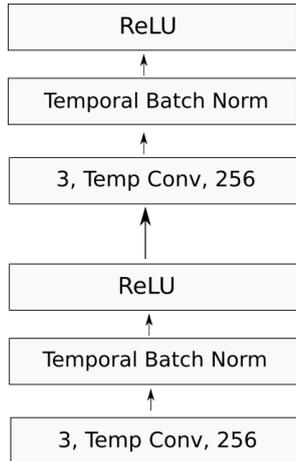

Figure 2: Convolutional block.

hidden units and softmax outputs. The number of output neurons depends on the classification task, the number of hidden units is set to 2048, and  $k$  to 8 in all experiments. We do not use drop-out with the fully connected layers, but only temporal batch normalization after convolutional layers to regularize our network.

### Convolutional Block

Each convolutional block (see Figure 2) is a sequence of two convolutional layers, each one followed by a temporal BatchNorm (Ioffe and Szegedy, 2015) layer and an ReLU activation. The kernel size of all the temporal convolutions is 3, with padding such that the temporal resolution is preserved (or halved in the case of the convolutional pooling with stride 2, see below). Steadily increasing the depth of the network by adding more convolutional layers is feasible thanks to the limited number of parameters of very small convolutional filters in all layers. Different depths of the overall architecture are obtained by varying the number of convolutional blocks in between the pooling layers (see table 2). Temporal batch normalization applies the same kind of regularization as batch normalization except that the activations in a mini-batch are jointly normalized over temporal (instead of spatial) locations. So, for a mini-batch of size  $m$  and feature maps of temporal size  $s$ , the sum and the standard deviations related to the BatchNorm algorithm are taken over  $|\mathcal{B}| = m \cdot s$  terms.

We explore three types of down-sampling between blocks  $K_i$  and  $K_{i+1}$  (Figure 1) :

- (i) The first convolutional layer of  $K_{i+1}$  has stride 2 (ResNet-like).

Depth:	9	17	29	49
conv block 512	2	4	4	6
conv block 256	2	4	4	10
conv block 128	2	4	10	16
conv block 64	2	4	10	16
First conv. layer	1	1	1	1
#params [in M]	2.2	4.3	4.6	7.8

Table 2: Number of conv. layers per depth.

- (ii)  $K_i$  is followed by a  $k$ -max pooling layer where  $k$  is such that the resolution is halved (Kalchbrenner et al., 2014).
- (iii)  $K_i$  is followed by max-pooling with kernel size 3 and stride 2 (VGG-like).

All these types of pooling reduce the temporal resolution by a factor 2. At the final convolutional layer, the resolution is thus  $s_d$ .

In this work, we have explored four depths for our networks: 9, 17, 29 and 49, which we define as being the number of convolutional layers. The depth of a network is obtained by summing the number of blocks with 64, 128, 256 and 512 filters, with each block containing two convolutional layers. In Figure 1, the network has 2 blocks of each type, resulting in a depth of  $2 \times (2 + 2 + 2 + 2) = 16$ . Adding the very first convolutional layer, this sums to a depth of 17 convolutional layers. The depth can thus be increased or decreased by adding or removing convolutional blocks with a certain number of filters. The best configurations we observed for depths 9, 17, 29 and 49 are described in Table 2. We also give the number of parameters of all convolutional layers.

## 4 Experimental evaluation

### 4.1 Tasks and data

In the computer vision community, the availability of large data sets for object detection and image classification has fueled the development of new architectures. In particular, this made it possible to compare many different architectures and to show the benefit of very deep convolutional networks. We present our results on eight freely available large-scale data sets introduced by (Zhang et al., 2015) which cover several classification tasks such as sentiment analysis, topic classification or news categorization (see Table 3). The number of training examples varies from 120k up to 3.6M, and the number of classes is comprised between 2

Data set	#Train	#Test	#Classes	Classification Task
AG’s news	120k	7.6k	4	English news categorization
Sogou news	450k	60k	5	Chinese news categorization
DBPedia	560k	70k	14	Ontology classification
Yelp Review Polarity	560k	38k	2	Sentiment analysis
Yelp Review Full	650k	50k	5	Sentiment analysis
Yahoo! Answers	1 400k	60k	10	Topic classification
Amazon Review Full	3 000k	650k	5	Sentiment analysis
Amazon Review Polarity	3 600k	400k	2	Sentiment analysis

Table 3: Large-scale text classification data sets used in our experiments. See (Zhang et al., 2015) for a detailed description.

and 14. This is considerably lower than in computer vision (e.g. 1 000 classes for ImageNet). This has the consequence that each example induces less gradient information which may make it harder to train large architectures. It should be also noted that some of the tasks are very ambiguous, in particular sentiment analysis for which it is difficult to clearly associate fine grained labels. There are equal numbers of examples in each class for both training and test sets. The reader is referred to (Zhang et al., 2015) for more details on the construction of the data sets. Table 4 summarizes the best published results on these corpora we are aware of. We do not use “Thesaurus data augmentation” or any other preprocessing, except lower-casing. Nevertheless, we still outperform the best convolutional neural networks of (Zhang et al., 2015) for all data sets. The main goal of our work is to show that it is possible and beneficial to train very deep convolutional networks as text encoders. Data augmentation may improve our results even further. We will investigate this in future research.

## 4.2 Common model settings

The following settings have been used in all our experiments. They were found to be best in initial experiments. Following (Zhang et al., 2015), all processing is done at the character level which is the atomic representation of a sentence, same as pixels for images. The dictionary consists of the following characters “abcdefghijklmnopqrstuvwxyz0123456789-.,;.:?:'"/|\_#\$\$%^&\*~\`+=<>()[]{}” plus a special padding, space and unknown token which add up to a total of 69 tokens. The input text is padded to a fixed size of 1014, larger text are truncated. The character embedding is

of size 16. Training is performed with SGD, using a mini-batch of size 128, an initial learning rate of 0.01 and momentum of 0.9. We follow the same training procedure as in (Zhang et al., 2015). We initialize our convolutional layers following (He et al., 2015). One epoch took from 24 minutes to 2h45 for depth 9, and from 50 minutes to 7h (on the largest datasets) for depth 29. It took between 10 to 15 epoches to converge. The implementation is done using Torch 7. All experiments are performed on a single NVidia K40 GPU. Unlike previous research on the use of ConvNets for text processing, we use temporal batch norm without dropout.

## 4.3 Experimental results

In this section, we evaluate several configurations of our model, namely three different depths and three different pooling types (see Section 3). Our main contribution is a thorough evaluation of networks of increasing depth using an architecture with small temporal convolution filters with different types of pooling, which shows that a significant improvement on the state-of-the-art configurations can be achieved on text classification tasks by pushing the depth to 29 convolutional layers.

**Our deep architecture works well on big data sets in particular, even for small depths.** Table 5 shows the test errors for depths 9, 17 and 29 and for each type of pooling : convolution with stride 2,  $k$ -max pooling and temporal max-pooling. For the smallest depth we use (9 convolutional layers), we see that our model already performs better than Zhang’s convolutional baselines (which includes 6 convolutional layers and has a different architecture) on the biggest data sets : Yelp Full, Yahoo Answers and Amazon Full and Polarity. The most important decrease in classification error can

Table 5: Testing error of our models on the 8 data sets. No data preprocessing or augmentation is used.

be observed on the largest data set Amazon Full which has more than 3 Million training samples. We also observe that for a small depth, temporal max-pooling works best on all data sets.

**Depth improves performance.** As we increase the network depth to 17 and 29, the test errors decrease on all data sets, for all types of pooling (with 2 exceptions for 48 comparisons). Going from depth 9 to 17 and 29 for Amazon Full reduces the error rate by 1% absolute. Since the test is composed of 650K samples, 6.5K more test samples have been classified correctly. These improvements, especially on large data sets, are significant and show that increasing the depth is useful for text processing. Overall, compared to previous state-of-the-art, our best architecture with depth 29 and max-pooling has a test error of 37.0 compared to 40.43%. This represents a gain of 3.43% absolute accuracy. The significant improvements which we obtain on all data sets compared to Zhang’s convolutional models do not include any data augmentation technique.

**Max-pooling performs better than other pooling types.** In terms of pooling, we can also see that max-pooling performs best overall, very close to convolutions with stride 2, but both are significantly superior to  $k$ -max pooling.

Both pooling mechanisms perform a max operation which is local and limited to three consec-

utive tokens, while  $k$ -max pooling considers the whole sentence at once. According to our experiments, it seems to hurt performance to perform this type of max operation at intermediate layers (with the exception of the smallest data sets).

**Our models outperform state-of-the-art ConvNets.** We obtain state-of-the-art results for all data sets, except AG’s news and Sogou news which are the smallest ones. However, with our very deep architecture, we get closer to the state-of-the-art which are ngrams TF-IDF for these data sets and significantly surpass convolutional models presented in (Zhang et al., 2015). As observed in previous work, differences in accuracy between shallow (TF-IDF) and deep (convolutional) models are more significant on large data sets, but we still perform well on small data sets while getting closer to the non convolutional state-of-the-art results on small data sets. The very deep models even perform as well as ngrams and ngrams-TF-IDF respectively on the sentiment analysis task of Yelp Review Polarity and the ontology classification task of the DBpedia data set. Results of Yang et al. (only on Yahoo Answers and Amazon Full) outperform our model on the Yahoo Answers dataset, which is probably linked to the fact that their model is task-specific to datasets whose samples that contain multiple sentences like (question, answer). They use a hierarchical attention mecha-

nism that apply very well to documents (with multiple sentences).

### **Going even deeper degrades accuracy. Shortcut connections help reduce the degradation.**

As described in (He et al., 2016a), the gain in accuracy due to the increase of the depth is limited when using standard ConvNets. When the depth increases too much, the accuracy of the model gets saturated and starts degrading rapidly. This *degradation* problem was attributed to the fact that very deep models are harder to optimize. The gradients which are backpropagated through the very deep networks vanish and SGD with momentum is not able to converge to a correct minimum of the loss function. To overcome this degradation of the model, the *ResNet model* introduced shortcut connections between convolutional blocks that allow the gradients to flow more easily in the network (He et al., 2016a).

We evaluate the impact of shortcut connections by increasing the number of convolutions to 49 layers. We present an adaptation of the ResNet model to the case of temporal convolutions for text (see Figure 1). Table 6 shows the evolution of the test errors on the Yelp Review Full data set with or without shortcut connections. When looking at the column “without shortcut”, we observe the same degradation problem as in the original ResNet article: when going from 29 to 49 layers, the test error rate increases from 35.28 to 37.41 (while the training error goes up from 29.57 to 35.54). When using shortcut connections, we observe improved results when the network has 49 layers: both the training and test errors go down and the network is less prone to underfitting than it was without shortcut connections.

While shortcut connections give better results when the network is very deep (49 layers), we were not able to reach state-of-the-art results with them. We plan to further explore adaptations of residual networks to temporal convolutions as we think this a milestone for going deeper in NLP. Residual units (He et al., 2016a) better adapted to the text processing task may help for training even deeper models for text processing, and is left for future research.

### **Exploring these models on text classification tasks with more classes sounds promising.**

Note that one of the most important difference between the classification tasks discussed in this

depth	without shortcut	with shortcut
9	37.63	40.27
17	36.10	39.18
29	35.28	36.01
49	37.41	36.15

Table 6: Test error on the Yelp Full data set for all depths, with or without residual connections.

work and ImageNet is that the latter deals with 1000 classes and thus much more information is back-propagated to the network through the gradients. Exploring the impact of the depth of temporal convolutional models on categorization tasks with hundreds or thousands of classes would be an interesting challenge and is left for future research.

## **5 Conclusion**

We have presented a new architecture for NLP which follows two design principles: 1) operate at the lowest atomic representation of text, i.e. characters, and 2) use a deep stack of local operations, i.e. convolutions and max-pooling of size 3, to learn a high-level hierarchical representation of a sentence. This architecture has been evaluated on eight freely available large-scale data sets and we were able to show that increasing the depth up to 29 convolutional layers steadily improves performance. Our models are much deeper than previously published convolutional neural networks and they outperform those approaches on all data sets. To the best of our knowledge, this is the first time that the “*benefit of depths*” was shown for convolutional neural networks in NLP.

Eventhough text follows human-defined rules and images can be seen as raw signals of our environment, images and small texts have similar properties. Texts are also compositional for many languages. Characters combine to form n-grams, stems, words, phrase, sentences etc. These similar properties make the comparison between computer vision and natural language processing very profitable and we believe future research should invest into making text processing models deeper. Our work is a first attempt towards this goal.

In this paper, we focus on the use of very deep convolutional neural networks for sentence classification tasks. Applying similar ideas to other sequence processing tasks, in particular neural machine translation is left for future research. It needs to be investigated whether these also benefit from having deeper convolutional encoders.

# “PageRank” for Argument Relevance

Henning Wachsmuth and Benno Stein and Yamen Ajjour

Faculty of Media, Bauhaus-Universität Weimar, Germany

{henning.wachsmuth, benno.stein, yamen.ajjour}@uni-weimar.de

## Abstract

Future search engines are expected to deliver pro and con arguments in response to queries on controversial topics. While argument mining is now in the focus of research, the question of how to retrieve the *relevant* arguments remains open. This paper proposes a radical model to assess relevance objectively at web scale: the relevance of an argument’s conclusion is decided by what other arguments reuse it as a premise. We build an argument graph for this model that we analyze with a recursive weighting scheme, adapting key ideas of PageRank. In experiments on a large ground-truth argument graph, the resulting relevance scores correlate with human average judgments. We outline what natural language challenges must be faced at web scale in order to stepwise bring argument relevance to web search engines.

## 1 Introduction

What stance should I take? What are the best arguments to back up my stance? Information needs of people aim more and more at arguments in favor of or against a given controversial topic (Cabrio and Villata, 2012b). As a result, future information systems, above all search engines, are expected to deliver pros and cons in response to respective queries (Rinott et al., 2015). Recently, argument mining has become emerging in research, also being studied for the web (Al-Khatib et al., 2016a). Such mining finds and relates units of arguments (i.e., premises and conclusions) in natural language text, but it does not assess what arguments are *relevant* for a topic. Consider the following arguments (with implicit conclusions) for a query “reasons against capital punishment”:

**Example  $a_1$ .** “*The death penalty legitimizes an irreversible act of violence. As long as human justice remains fallible, the risk of executing the innocent can never be eliminated.*”

**Example  $a_2$ .** “*Capital punishment produces an unacceptable link between the law and violence.*”<sup>1</sup>

While both arguments are on-topic,  $a_1$  seems more clear, concrete, and targeted, potentially making it more relevant. First approaches to assess argument quality exist (see Section 2). However, they hardly account for the problem that argument quality (and relevance in particular) is often perceived subjectively. Whether  $a_3$ , e.g., is more relevant than  $a_1$  or less depends on personal judgment:

**Example  $a_3$ .** “*The death penalty doesn’t deter people from committing serious violent crimes. The thing that deters is the likelihood of being caught and punished.*”

In this paper, we study from a retrieval perspective how to assess argument relevance *objectively*, i.e., without relying on explicit human judgments. Following argumentation theory, we see relevance as a dialectical quality that depends on how beneficial all participants of a discussion deem the use of an argument for the discussion (Walton, 2006). In the context of web search, an objective assessment hence at best takes place at web scale. We propose the radical model that relevance is not decided by the content of arguments, but structurally by how many arguments across the web use the conclusion of an argument as a premise and by how relevant these are in turn. The rationale is that an author cannot control who “cites” his or her argument in this way, so each citation can be assumed to add to relevance. Thereby, we achieve to decouple relevance from the soundness of the inference an argument makes to draw its conclusion.

<sup>1</sup>All example arguments in Sections 1–4 are derived from [www.bbc.co.uk/ethics/capitalpunishment/against\\_1.shtml](http://www.bbc.co.uk/ethics/capitalpunishment/against_1.shtml).

Given algorithms that mine arguments from the web and that decide if two argument units mean the same, an argument graph can be built where nodes represent arguments and each edge the reuse of a conclusion as a premise (Section 3). Based on the graph, we devise an adaptation of the PageRank algorithm (Page et al., 1999) to assess argument relevance. Originally, PageRank recursively processes the web link graph to infer the objective relevance of each web page from what other pages link to that page. In an according manner, we process the argument graph to compute a score for each argument unit. An argument’s relevance then follows from the scores of its premises (Section 4). Analogue to the supportive nature of web links, our new *PageRank for argument relevance* counts any use of a conclusion as a premise as a support of relevance. In principle, balancing support and attack relations would also be possible, though.

At web scale, mining arguments from natural language text raises complex challenges. Since not all have been solved reliably yet, we here derive an argument graph from the complete *Argument Web* (Bex et al., 2013), a large ground-truth database consisting of about 50,000 argument units. This way, we can evaluate PageRank without the noise induced by mining errors. Moreover, we provide a first argument relevance benchmark dataset, where seven experts ranked arguments for 32 conclusions of general interest (Section 5). On the dataset, the PageRank scores beat several intuitive baselines and correlate with human average judgments of relevance—even though they ignore an argument’s content and inference—indicating the impact of our approach (Section 6). We discuss how to bring argument relevance to web search engines, starting from the technologies of today (Section 7).

**Contributions** To summarize, the work at hand provides three main contributions to research:

1. An approach to structurally and hence objectively assess argument relevance at web scale.
2. A first benchmark ranking dataset for the evaluation of argument relevance assessment.
3. Evidence that argument relevance depends on the reuse of conclusions in other arguments.

## 2 Related Work

Argument relevance can be seen as one dimension of argumentation quality. In argumentation theory, two relevance types are distinguished: *Local* rele-

vance means that an argument’s premises actually help accepting or rejecting its conclusion. Such relevance is one prerequisite of a cogent argument, along with the acceptability of the premises and their sufficiency for drawing the conclusion (Johnson and Blair, 2006). Here, we are interested in an argument’s *global* relevance, which refers to the benefit of the argument in a discussion (Walton, 2006): An argument is more globally relevant the more it contributes to resolving an issue (van Eemeren, 2015). While Blair (2012) deems both types as vague and resisting analysis so far, we assess global relevance using objective statistics.

In (Wachsmuth et al., 2017), we comprehensively survey theories on argumentation quality as well as computational approaches to specific quality dimensions. Among the latter, Persing and Ng (2015) rely on manual annotations of essays to predict how strong an essay’s argument is—a naturally subjective and non-scalable assessment. For scalability, Habernal and Gurevych (2016) learn on crowdsourced labels, which of two arguments is more convincing. Similar to us, they construct a graph to rank arguments, but since their graph is based on the labels, the subjectivity remains. This also holds for (Braunstein et al., 2016) where classical retrieval and argument-related features serve to rank argument units by the level of support they provide in community question answering.

More objectively, Boltužić and Šnajder (2015) find popular arguments in online debates. However, popularity alone is often not correlated with merit (Govier, 2010). We additionally analyze dependencies between arguments—like Cabrio and Villata (2012a) who classify attack relations between debate portal arguments. From these, they derive accepted arguments in the logical argumentation framework of Dung (1995). Relevance and acceptability are orthogonal dimensions: an argument may be relevant even if far from everyone accepts it. While probabilistic extensions of Dung’s framework exist (Bistarelli et al., 2011; Dondio, 2014), they aim at the probability of logical truth. In contrast, relevance reflects the importance of arguments, for which we take on a retrieval view.

In information retrieval, relevance represents a fundamental concept, particularly in the context of search engines. A web page is seen as relevant for a search query if it contains information the querying person was looking for (Croft et al., 2009). To assess argument relevance objectively, we adapt

a core retrieval technique, recursive link analysis. Due to its wide use, we build upon Google’s original PageRank algorithm (Page et al., 1999), but alternatives such as (Kleinberg, 1999) would also apply. PageRank is sensitive to certain manipulations, such as link farms (Croft et al., 2009). Some of them will affect argument graphs, too. Improvements of the original algorithm should therefore be taken into account in future work. In this paper, we omit them on purpose for simplicity and clarity.

We already introduced our PageRank approach in (Al-Khatib et al., 2016a), but we only roughly sketched its general idea there. Recursive analyses have also been proposed for fact finding, assuming that trustworthy web pages contain many true facts, and that true facts will be found on many trustworthy web pages (Yin et al., 2007; Galland et al., 2010). Pasternack and Roth (2010) model a user’s prior knowledge in addition. Close to argumentation, Samadi et al. (2016) evaluate claims using a credibility graph derived from evidence found in web pages. All these works target truth. In order to capture relevance, we base PageRank on the reuse of argument units instead.

In particular, we construct a graph from all arguments found in web pages. Both complex argument models from theory (Toulmin, 1958; Reisert et al., 2015) and simple proprietary models (Levy et al., 2014) have been studied for web text. Some include quality-related concepts, such as evidence types (Al-Khatib et al., 2016b). Others represent the overall structure of argumentation (Wachsmuth et al., 2015). Like Mochales and Moens (2011), we consider only premises and conclusions as units of arguments here. This is the common ground of nearly all argument-level models, and it will allow an integration with approaches to analyze argument inference (Feng and Hirst, 2011) based on the argumentation schemes of Walton et al. (2008). Edges in our graph emerge from the usage of units in different arguments. Alternatively, it would be possible to mine support and attack relations between arguments (Park and Cardie, 2014; Peldszus and Stede, 2015).

Not all mining steps work robustly on web text yet (Al-Khatib et al., 2016a). To focus on the impact of PageRank, we thus rely on ground-truth data in our experiments. In isolation, existing argument corpora do not adequately mimic web context, as they are small and dedicated to a specific genre (Stab and Gurevych, 2014), or restricted to

flat relations between units (Aharoni et al., 2014). To maximize size and heterogeneity, we here refer to the Argument Web (Bex et al., 2013), which is to our knowledge the largest ground-truth argument database available so far. It includes relation-rich corpora, e.g., AraucariaDB (Reed and Rowe, 2004), as well as much annotated web text, e.g., from (Walker et al., 2012) and (Wacholder et al., 2014). Thus, it serves as a suitable basis for constructing an argument graph.

### 3 The Web as an Argument Graph

We now present the model that we envision as the basis for argument relevance in future web search, targeting information needs of the following kind: “*What are the most relevant arguments to support or attack my stance?*” The model relies on three principles that aim at the separation of concerns:

- I. *Freedom of Inference.* No inference from argument premises to conclusions is challenged.
- II. *Freedom of Mining.* No restrictions are made for how to mine and relate argument units.
- III. *Freedom of Assessment.* No graph processing method is presupposed to assess relevance.<sup>2</sup>

#### 3.1 Definition of the Argument Graph

Let  $D = \{d_1, d_2, \dots\}$  be the set of all considered web pages. Each  $d \in D$  may contain zero or more arguments. Given  $D$ , we model the web as an argument graph in three incremental building blocks:

**Canonical Argument Structure** A canonical structure that represents each argument in  $D$  as a tuple  $a = \langle c, P \rangle$  where  $c$  denotes the conclusion of  $a$  and  $P = \{c_1, \dots, c_k\}$  its premises,  $k \geq 0$ . Both conclusions and premises form argument units.

**Reuse Interpretation Function** An interpretation function  $\mathcal{I}$  that assigns one label from the set  $\{\approx, \not\approx\}$  to each pair of argument units  $(c, c')$  from all arguments in  $D$ .

**Argument Graph** A graph  $G = (A, E)$  such that

$A = \{a_1, \dots, a_n\}$  is a set of nodes where each  $a \in A$  corresponds to one argument in  $D$ ;

$E \subseteq A \times A$  is a set of edges where  $(a, a') \in E$  iff.  $\mathcal{I}(c, c_i) = \approx$  holds for the conclusion  $c$  of  $a$  and any premise  $c_i$  of  $a'$ .<sup>3</sup>

<sup>2</sup>We will introduce a specific method in Section 4. Nevertheless, other methods would also be applicable in principle.

<sup>3</sup>In order to keep the definition of the argument graph simple, we include *all* possible pairs of arguments for the edges here. In practice, some pairs should rather be excluded in order to counter manipulation, e.g., those *within* a web page.

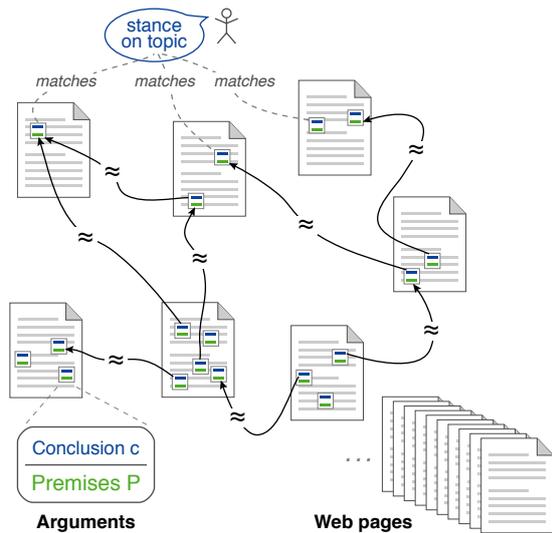

Figure 1: A small argument graph with three potentially relevant arguments for a queried stance.

Figure 1 sketches an argument graph. Given a user query with a stance on a controversial topic, as shown, each argument whose (maybe implicit) conclusion  $c$  matches the stance is potentially relevant. Stance classification is outside the scope of this paper. We assess the relevance of arguments with conclusion  $c$ . The reuse of such conclusions in other arguments is exemplified in Figure 2.

### 3.2 Properties of the Argument Graph Model

In accordance with Principle I, the canonical structure implicitly accepts the inference that an argument draws to arrive at its conclusion. This separates soundness from relevance, reducing the latter to an argument’s units. We even permit “arguments” that have no premise. The reason is that argument units can be relevant without justification (e.g., when serving as axioms for others).

In accordance with Principle II, we do not detail the semantics of the concepts that we propose to construct arguments and their relations, leaving the exact interpretation to the mining algorithms at hand. For arguments, premises and conclusions denote the common ground, and they are generally identifiable in various web texts. For relations, the definition based on the reuse of argument units actually refines previous rather vague relation models, such as (Dung, 1995)—this is possible due to the abstraction from inference.

In accordance with Principle III, we do not pre-define how to assess relevance given an argument graph (and the web pages). In addition to a conclu-

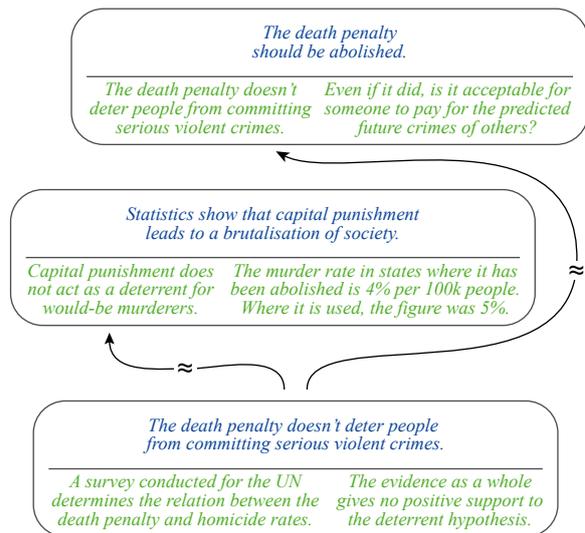

Figure 2: Example for the reuse of an argument’s conclusion as a premise in two other arguments.

sion, e.g., its opposite can be generated (Bilu et al., 2015) to balance support and attack somehow. In general, the usage of conclusions as premises favors a monotonous assessment (the more the better), which we implement in Section 4. Note that we allow circles in the graph. This might look unwanted as it enables circular reasoning. However, not all arguments use the same inference rule (say, modus ponens). Hence, it is reasonable that they, directly or indirectly, refer to each other.

Altogether, our model defines a *framework* for assessing argument relevance. It is instantiated by concrete mining and graph processing algorithms. An analysis of argument inference should complement this, e.g., to filter out unsound arguments. Despite its framework nature, the model suggests a recursive assessment where an argument is more relevant the more relevant arguments it relates to.

## 4 PageRank for Argument Relevance

Given an argument graph  $G = (A, E)$ , we propose to assess argument relevance structurally and thus objectively. In the following, we first develop how to adapt PageRank in order to recursively compute relevance scores for all units of the arguments in  $A$  based on  $E$ . Then, we discuss how to derive the relevance of each argument from these scores.

### 4.1 PageRank for Conclusion Relevance

PageRank revolutionized web search, because it introduced “a method for rating web pages objectively and mechanically, effectively measuring the

*human interest and attention*” (Page et al., 1999). The original method assigns a high PageRank  $p(d)$  to a web page  $d$  if  $d$  is linked by many other web pages with a high PageRank. This value corresponds to the probability that a web surfer, who either follows a link on a visited web page or randomly chooses a new page, enters  $d$ . In particular, based on the link graph induced by a set of web pages  $D$ ,  $p(d)$  is computed recursively as:

$$p(d) = (1 - \alpha) \cdot \frac{1}{|D|} + \alpha \cdot \sum_i \frac{p(d_i)}{|D_i|}$$

Here,  $p(d_i)$  is the PageRank score of a web page  $d_i \in D$  that links to  $d$ , and  $D_i$  is the set of all web pages that  $d_i$  links to. According to the right summand, a web page linking to  $d$  contributes to  $p(d)$  more the less outgoing links it has, in order to reward the focus on specific links. The left summand specifies an equal ground relevance  $\frac{1}{|D|}$  for all web pages  $d$ , summing up to 1. The factor  $\alpha \in [0, 1]$  weights the two summands.

Based on an argument graph  $G = (A, E)$ , we adapt the PageRank idea in order to analogously rate the conclusion  $c$  of each argument  $a \in A$  “objectively and mechanically”. Recall that an edge  $(a, a') \in E$  states that  $c$  is a premise in another argument  $a' \in A$ . Now, we assign a high PageRank  $\hat{p}(c)$  to  $c$  if  $c$  serves as a premise for many conclusions  $c_i$  with high  $\hat{p}(c_i)$ . For this, we adjust the equation above in two ways:

**Ground Relevance** Originally, PageRank works on the lowest layer of the web, the link graph. This layer has no specific entry point, which is why the ground relevance of all pages  $d \in D$  is the same in  $p(d)$  above. Working with arguments on web pages, however, adds a new layer on top. Therefore, we start with the original PageRank as the ground relevance, i.e., we postulate that the higher  $p(d)$  is, the more relevant is a conclusion  $c$  found on  $d$  by default. In order to maintain a sum of 1 for all arguments, we normalize  $p(d)$  with the average number of arguments per web page. This results in the ground relevance  $\frac{p(d) \cdot |D|}{|A|}$  for each  $c$ .

**Recursive Relevance** The author of a web page  $d$  can specify the web pages that  $d$  links to, but the author cannot control which pages eventually link to  $d$ . This contrast is a cornerstone of the original PageRank to model relevance objectively. By analogy, the author of an argument specifies which argument units to use as premises for the argument’s conclusion  $c$ , but the author cannot control

which arguments use  $c$  as a premise for their conclusion  $c_i$ . This contrast is a cornerstone of our “PageRank for arguments” to model relevance objectively. In order to reward a focus on specific conclusions, we normalize the impact of the relevance  $\hat{p}(c_i)$  of each conclusion  $c_i$ , for which  $c$  serves as a premise, on the relevance of  $c$  by the number of premises  $|P_i|$  given for  $c_i$ . This results in the contribution  $\frac{\hat{p}(c_i)}{|P_i|}$  for each  $c_i$ .

Altogether, we compute the PageRank of a conclusion  $c$  that is contained in a web page  $d$  as:

$$\hat{p}(c) = (1 - \alpha) \cdot \frac{p(d) \cdot |D|}{|A|} + \alpha \cdot \sum_i \frac{\hat{p}(c_i)}{|P_i|}$$

## 4.2 Properties of the PageRank Approach

For space reasons, we only sketch that the adapted PageRank  $\hat{p}(c)$  maintains two important properties of the original PageRank (Page et al., 1999).

First, by construction, the original scores  $p(d)$  of all web pages sum up to 1. The left summand of  $\hat{p}(c)$  shares this sum among all arguments. The right summand ensures that the total contribution of conclusion usages is normalized with the total number of premises. Thus, the sum of all adapted PageRank scores is also 1.

Second, as the original PageRank,  $\hat{p}(c)$  reflects the idea of a citation ranking: Basic conclusions that serve as a premise for many arguments get a high score. They take the role of fundamental literature, say, “*human life is valuable*” in the context of death penalty. At the other end, each conclusion of a leaf argument in the graph is assigned only its ground relevance, since it is never reused. Without citations, relevance can still be estimated based on authorship, e.g., finding an argument on the BBC page from Footnote 1 might suffice to deem it relevant. We model this by including  $p(d)$  in  $\hat{p}(c)$ .

## 4.3 From Conclusion to Argument Relevance

Given a conclusion  $c$ , all arguments  $\langle c, P \rangle$  compete in terms of relevance. Since each such argument has the same conclusion, its relevance needs to be derived from its premises  $P$ . Intuitively, an argument proves only as strong at its weakest premise, so the minimum premise PageRank score could govern relevance. This fits our model, as we have “outsourced” the soundness of the inference based on the premises. However, it favors arguments with few premises. In order to find the best derivation, we compare four different premise aggregation methods in Section 6:

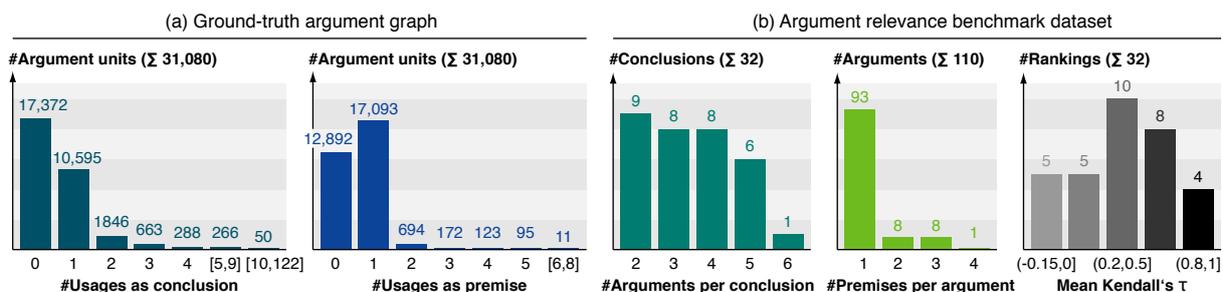

Figure 3: (a) Histograms of the usages of all argument units in the ground-truth argument graph as a conclusion or premise, respectively. (b) Histograms of the arguments per conclusion and the premises per argument in the benchmark dataset as well as the mean Kendall's  $\tau$  rank correlation of all seven rankers.

- Minimum.* The relevance of an argument corresponds to its minimum premise PageRank.
- Average.* The relevance of an argument corresponds to its average premise PageRank.
- Maximum.* The relevance of an argument corresponds to its maximum premise PageRank.
- Sum.* The relevance of an argument corresponds to the sum of its premise PageRanks.

In general, as for web pages (Croft et al., 2009), PageRank should certainly not be seen as the ultimate way of assessing argument relevance, especially because it fully ignores the content and inference of arguments. Rather, it provides an objective means to identify arguments commonly referred to for a given conclusion.

## 5 The Webis-ArgRank-17 Dataset

This section describes our construction of a large ground-truth argument graph as well as our creation of manual relevance rankings of arguments from the graph. The resulting *Webis-ArgRank-17 dataset* is not meant for training statistical ranking approaches. Rather, it serves as a first benchmark for evaluating argument relevance assessment.<sup>4</sup>

### 5.1 A Large Ground-Truth Argument Graph

As discussed in Section 2, the *Argument Web* is the largest existing argument database. It contains structured argument corpora (several from published research) with diverse types of mostly English text, often web content.<sup>5</sup> The *Argument Web* stores annotations in a standard format, so called argument maps. Each map specifies nodes that

correspond to argument units or to inference rules. Edges connect one of each in either direction. Implicitly, incoming edges of an inference node define premises of an argument, the single outgoing edge an argument's conclusion. At the last date we accessed the *Argument Web* (June 2, 2016), it contained 57 corpora with 8479 maps, summing up to 49,504 argument units and 26,012 arguments.

In order to get a ground-truth argument graph of maximum size, we merged all argument maps except for duplicates. We created one argument node for each inference node while maintaining argument units not connected to any inference node for completeness. For the edges of the argument graph, we assumed two units to be the same if and only if they capture exactly the same text, thereby minimizing the number of falsely detected usages of conclusions. Figure 3(a) shows how many units are used how often as a premise and as a conclusion respectively.<sup>6</sup>

The constructed graph contains 31,080 different argument units, 28,795 of which participate in 17,877 arguments. For convenience, we already precomputed the adapted PageRank score  $\hat{p}(c)$  of each argument unit  $c$  as well as the frequency of  $c$  in the graph. As no original PageRank score  $p(d)$  can be accessed for  $c$ , we started with the same ground relevance  $\frac{1}{31,080}$  for all units.

### 5.2 Benchmark Argument Rankings

3113 conclusions in the constructed graph have more than one argument and, so, are candidates for ranking. From these, we selected all 498 conclusions for which at least one argument has multiply

<sup>4</sup>The dataset and the Java code for reproducing all experiment results are freely available at: <http://www.arguana.com>

<sup>5</sup>All corpora contained in the *Argument Web* can be found at: <http://www.arg.dundee.ac.uk/aif-corpora>

<sup>6</sup>We tested some high-precision heuristics to match units that occur multiple times in different manifestations, such as ignoring capitalization or discourse connectives. However, the effect was little, which is why we decided to stick with exact matches to avoid false positives in the ground-truth graph.

Conclusion	Argument	Premises of Argument	Rank	$\emptyset$
Strawberries are the best choice for your breakfast meal!	$a_1$ (pro)	“Berries are superfoods because they’re so high in antioxidants without being high in calories”, says Giovinazzo <sub>[premise 1]</sub> MS, RD, a nutritionist at Clay health club and spa, in New York City. <sub>[premise 2]</sub>	1	1.43
	$a_2$ (pro)	One cup of strawberries, for instance, contains your full recommended daily intake of vitamin C, along with high quantities of folic acid and fiber.	2	1.57
	$a_3$ (pro)	Strawberries are good for your ticker.	3	3.00
Technology has enhanced the daily life of humans.	$a_4$ (pro)	The internet has enabled us to widen our knowledge.	1	2.00

	$a_9$ (con)	There’s a ton of information on the internet that is entirely useless.	6	5.42

Table 1: Two argument conclusions in the benchmark dataset, together with the premises of all alternative pro and con arguments, the arguments’ ranks in the dataset, and the mean ranks assigned by the 7 rankers.

used premises, as all others show no structural difference in the graph. We then let two experts from computational linguistics classify for each conclusion as to whether it denotes (a) a claim that internet users might search arguments for or (b) not such a claim for any of five reasons: (1) It is not of general interest but comes from a personal or any other too specific context, e.g., “*Viv needs to be allowed to prove herself*”, (2) its meaning is unclear, e.g., “*we need to get back to the classics*”, (3) it is not in English, (4) it mixes multiple conclusions, or (5) it is not a real conclusion but a topic, anecdote, question, or description, e.g., “*fingerprinting at the airport*” or “*what!?*”.

The experts could access the premises to see if unclear references can be resolved. They chose the same class 451 times (90.6%) with a substantial Cohen’s  $\kappa$  agreement of 0.69. In 136 cases, no expert saw a real claim, indicating some noise in the data. For the rankings, we selected only those conclusions that both saw as claims. We disregarded multiple instances of an argument and the few conclusions where only one argument was left then.

Next, each of the 264 arguments for the remaining 70 conclusions was classified by the same experts as to whether it is (a) a correct argument for the conclusion, (b) a correct counterargument, or (c) not correct for lack of real premises. Restatements of the conclusion as well as ad-hominem attacks were not seen as premises, while the experts were asked to ignore an argument’s strength.

The experts agreed in 201 cases (76.1%) with  $\kappa = 0.63$ . An example that they saw differently is “*I agree... the thrill is gone*” for the conclusion “*a tweet is fundamentally valueless*”. To al-

low for a reasonable but tractable ranking, we kept only conclusions where the experts agreed on two to six arguments and/or counterarguments, and we discarded one conclusion that paraphrased another one. The resulting dataset covers 32 conclusions. We included all 110 arguments for these conclusions, since their relevance is assessed via ranking. Figure 3(b) shows the distribution of arguments over conclusions and the premises per argument. For two conclusions, all premises are listed in Table 1. The ranks resulted from the final step.

In particular, since we expected argument relevance to be perceived subjectively, a total of seven experts from computational linguistics and information retrieval ranked all arguments (in terms of a strict ordering) for each conclusion by how much they contribute to the acceptance or rejection of the conclusion. In order not to bias the experts, they received arguments with corrected grammar, resolved references, and merged premises. They should follow their own view but acknowledge that there may be relevant counterarguments.

The highest agreement of two experts on all 32 rankings was 0.59 in terms of Kendall’s  $\tau$  rank correlation (Pearson coefficient 0.63), the mean over all expert pairs 0.36 (Pearson 0.40). This gap supports the subjectivity hypothesis. Figure 3(b) shows that five rankings had a negative  $\tau$ -value for all experts (the lowest  $\tau$  was  $-0.14$ ), whereas in 12 cases  $\tau$  was above 0.5, in four cases above 0.8. Overall, the resulting ranks thus largely qualify as benchmark average relevance judgments.<sup>7</sup>

<sup>7</sup>We are aware that the seven chosen experts are certainly not representative of average web users. In order to achieve a controlled setting, however, we preferred to rely on experts, e.g., to avoid misconceptions of terms such as “argument”.

# Approach	(a) Minimum			(b) Average			(c) Maximum			(d) Sum			(e) Best results		
	$\tau$	best	worst	$\tau$	best	worst									
1 PageRank	<b>0.01</b>	<b>11</b>	<b>6</b>	0.02	<b>12</b>	<b>6</b>	0.11	<b>11</b>	<b>4</b>	<b>0.28</b>	<b>15</b>	<b>3</b>	<b>0.28</b>	<b>15</b>	3
2 Frequency	-0.10	5	9	-0.03	8	10	-0.01	7	9	0.10	11	9	0.10	11	9
3 Similarity	-0.13	7	12	-0.05	8	11	0.01	9	10	0.02	9	10	0.02	9	10
4 Sentiment	<b>0.01</b>	8	<b>6</b>	<b>0.11</b>	<b>12</b>	4	<b>0.12</b>	10	5	0.12	12	4	0.12	12	4
5 Most premises	n/a	n/a	n/a	n/a	n/a	n/a	n/a	n/a	n/a	n/a	n/a	n/a	0.19	6	<b>1</b>
6 Random	n/a	n/a	n/a	0.00	8	7									

Table 2: (a–d) Mean Kendall’s  $\tau$  correlation of each approach with all benchmark argument rankings and counts of the *best* / *worst* rankings, once for each premise aggregation method. (e) Best observed results.

## 6 Evaluation

Finally, we report on an experiment that we carried out on the whole argument graph from Section 5 in order to provide first evidence that our PageRank approach objectively assesses argument relevance. Here, we assume that the average judgments of our benchmark rankings reflect objective relevance.

**Approaches** We compare six ranking approaches below. In case of 1.–4., we evaluate all premise aggregation methods from Section 4: (a) *Minimum*, (b) *Average*, (c) *Maximum*, and (d) *Sum*. While we are aware that more sophisticated ranking approaches are possible, the considered selection captures principle properties of arguments:

1. *PageRank*. An argument’s relevance corresponds to the PageRank of its premises. This is the approach that we propose.
2. *Frequency*. An argument’s relevance corresponds to the frequency of its premises in the graph. This baseline captures popularity, as proposed in related work (see Section 2).
3. *Similarity*. An argument’s relevance corresponds to the similarity of its premises to its conclusion. We use the Jaccard similarity between all words in the premises and the conclusion. This basic content-oriented baseline quantifies the support of premises.
4. *Sentiment*. An argument’s relevance corresponds to the positivity of its premises. Here, we sum up the positive values of all premise words in SentiWordNet (Baccianella et al., 2010) and subtract all negatives. Also this baseline quantifies the support of premises.
5. *Most premises*. An argument’s relevance corresponds to its number of premises. This simple baseline captures the amount of support.
6. *Random*. The relevance is decided randomly. This baseline helps interpreting the results.

**Experiment** For all 32 conclusions of our benchmark rankings, we assessed the relevance of every associated argument with all six approaches—in case of 1.–4. once for each premise aggregation method. For all approaches, we then compared the resulting ranks with the respective benchmark ranks and computed the mean correlation over all conclusions in terms of Kendall’s  $\tau$ . Kendall’s  $\tau$  is most suitable here, as it is meant for ranks and as it applies even when all arguments are ranked equally (unlike, e.g., the Pearson coefficient).

**Results** Table 2 shows that the highest rank correlation is clearly achieved by our *PageRank* approach, namely, when using the *Sum* aggregation. While a Kendall’s  $\tau$  of 0.28 is not very high, it can be interpreted as noncoincidental, and it is close to the low mean  $\tau$  of all experts (0.36) resulting from subjectivity (see Section 5). *PageRank Sum* proves best in 15 of 32 cases. *Most premises*, which has the second highest  $\tau$  (0.19), produced fewer worst rankings, but this is because it ranks all arguments equally for those 22 of the 32 conclusions where all have the same number of premises.

Matching the notion that popularity is not correlated with merit (see Section 2), *Frequency* hardly achieves anything. In fact, each frequency approach is outperformed by the PageRank approach with the respective aggregation method. The same holds for *Similarity*, which even seems to correlate rather negatively with relevance. An explanation may be that similarity rewards redundancy, which is why, e.g., all four similarity approaches falsely ranked the redundancy-free argument  $a_1$  in Table 1 lowest. However, this requires further investigation, including an analysis of more sophisticated similarity measures. *Sentiment*, finally, performs comparably strong with  $\tau > 0.1$  in three cases. In accordance with the second ranking in Table 1, this suggests that naming positive aspects (which support a conclusion) benefits relevance.

Regarding the four premise aggregation methods, we point out that their success might be partly affected by the scale of our data: 31,080 argument units is still tiny compared to the web argument graph we envision. In case of the first conclusion in Table 1, e.g., both *Minimum* and *Average* under-rate the relevance of  $a_1$ , since *premise 1* fails to counter the low PageRank score of *premise 2* (resulting in  $\tau = -0.82$ ). Summing up scores makes sense for these strongly connected premises, and it increases  $\tau$  to 0.82. In contrast, *Maximum* assigns the same rank to all three arguments, which would be unlikely if web-scale data was given.

We conclude that a final judgment about our approach will require a web-scale analysis. Still, we saw first evidence for the impact of assessing argument relevance with PageRank. Considering that PageRank fully ignores an argument’s content and inference—unlike our human expert rankers—its observed dominance is quite intriguing.

## 7 Towards Argument Search Engines

From an application viewpoint, the long-term goal of our research on argument relevance is to enable web search engines to provide the most important arguments in response to queries on controversial topics. In this regard, the proposed PageRank approach serves to retrieve relevant candidate arguments. These arguments should then be further assessed, e.g., in terms of the soundness of their inference or other quality dimensions (Wachsmuth et al., 2017). At web scale, however, our approach poses several challenges of processing natural language text, most of which refer to the construction of a reliable argument graph.

The kind of construction process that we foresee starts with the language identification and content extraction of web pages, followed by linguistic preprocessing (sentence splitting, part-of-speech tagging, etc.). For major languages, the respective technologies are not perfect but reliable (Gottron, 2008). Then, argument mining is needed in order to segment and classify argument units as well as to compose arguments. While some mining approaches for web content exist, their robustness still needs improvement (Al-Khatib et al., 2016a). The most complex step is to identify the reuse of a conclusion as a premise in another argument. Ultimately, this implies that the units are semantically equivalent (or contradictory). Both textual entailment and paraphrasing help but are themselves un-

solved in general. At least, promising results with about 70% accuracy are reported for ground-truth arguments (Cabrio and Villata, 2012a).

Nevertheless, the goal of bringing argument relevance to practice is not at all a dream of the far future. The decisive observation is here that the size of the web allows preferring precision over recall. In particular, an initial high-precision, lower-recall argument graph may be obtained by focusing on “low-hanging fruits”. For instance, reliable arguments can be derived from those web sources that are directly cited in online debate portals, such as <http://www.debatepedia.org>. Generally, the mining process can be tailored to narrow domains and to well-structured text genres first. In order to limit the noise from mining errors, simple and unambiguous sentence-level arguments may be focused on and mined only if the respective approaches have a high confidence. Similarly, the recognition of equivalent argument units may be restricted to near-duplicates based on high-precision heuristics, such as ignoring capitalization, discourse connectives and other filler words, or similar.

From there on, the framework nature of the defined argument graph allows a stepwise refinement of the process, integrating new approaches to any process step as available. Research towards argument search engines can hence start now.

## 8 Conclusion

This paper proposes a model to integrate argument relevance in future web search, and it lays theoretical ground for research on argument relevance. In particular, we have defined how to construct an argument graph at web scale as well as how to adapt PageRank for arguments in order to objectively assess relevance given the graph. The results on our new, freely available Webis-ArgRank-17 benchmark dataset with a ground-truth argument graph of notable size suggest that PageRank outperforms both frequency-based and simple content-based relevance assessment approaches.

An evaluation at web scale is left to future work. Currently, we are working on approaches that robustly mine arguments from web pages, preferring precision over recall in order to obtain a more reliable argument graph. In general, several considerable challenges exist towards the argument search engines we envision, not only in terms of argument mining. We propose to face these challenges in order to shape the future of web search together.

## Abstract

As the number of people receiving psychotherapeutic treatment increases, the automatic evaluation of counseling practice arises as an important challenge in the clinical domain. In this paper, we address the automatic evaluation of counseling performance by analyzing counselors' language during their interaction with clients. In particular, we present a model towards the automation of Motivational Interviewing (MI) coding, which is the current gold standard to evaluate MI counseling. First, we build a dataset of hand labeled MI encounters; second, we use text-based methods to extract and analyze linguistic patterns associated with counselor behaviors; and third, we develop an automatic system to predict these behaviors. We introduce a new set of features based on semantic information and syntactic patterns, and show that they lead to accuracy figures of up to 90%, which represent a significant improvement with respect to features used in the past.

## 1 Introduction

Effective behavioral counseling is an essential element in combating public health issues such as mental health, substance abuse, and nutrition among others. A key component in training addiction counselors and other health care providers is providing detailed clinical feedback and evaluation. In clinical psychotherapy, this is done through behavioral coding, a labor intensive and time consuming process that requires highly trained practitioners who observe the counseling interactions via audio/video or reading transcripts and, then provide detailed evaluative feed-

back based on a set of predefined behaviors.

Recently, research efforts have been made towards implementing automatic means to assist this process and provide clinicians with tools to code and analyze counseling narratives (Atkins et al., 2014; Xiao et al., 2014; Klonek et al., 2015). Such tools can enable analyzes at larger scale by providing faster, cheaper, and more reliable methods for coding and data summarizing tasks.

Following this line of work, this paper presents a text-based approach for the automatic coding of counselor's verbal behaviors during counseling encounters. We focus our analysis on counseling conducted using Motivational Interviewing (MI), a well established evidence-based psychotherapy style, and the Motivational Interviewing Treatment Integrity (MITI) coding scheme.

## 2 Background on Motivational Interviewing

Miller and Rollnick define MI as a collaborative, goal-oriented style of psychotherapy with particular attention to the language of change (Miller and Rollnick, 2013). MI has been widely used as treatment method in clinical trials on psychotherapy research to address addictive behaviors such as alcohol, tobacco and drug use; promote healthier habits such as nutrition and fitness; and help clients with psychological problems such as depression and anxiety (Rollnick et al., 2008; Polak et al., 2010; Lundahl et al., 2010; Vader et al., 2010; Apodaca et al., 2014; Magill et al., 2014; Moyers and Martin, 2006; Moyers et al., 2009; Glynn and Moyers, 2010; Barnett et al., 2014). In addition, MI has been successfully applied in different practice settings including social work in behavioral health centers, education, and criminal justice (Wahab, 2005; McMurrin, 2009).

MI implementation requires effective counselor

training, supervision, and evaluation. Counselor's competence in MI delivery is measured by either focusing on counselor behaviors, client behaviors, or both (Jelsma et al., 2015).

The MITI coding system is currently the gold standard instrument for this task (Moyers et al., 2005). MITI focuses on counselors verbal behaviors and measures their MI proficiency by evaluating the use of reflective listening; questions; counselor strategies to engage clients such as seeking collaboration, affirming, and emphasizing autonomy; behaviors that indicate counselor deficiencies while delivering MI such as confronting and persuading without permission; and finally, neutral behaviors such as providing information and persuading with permission.

### 3 Related Work

Recently there have been a number of efforts on building computational tools that assist clinical psychotherapy on behavioral coding tasks.

(Can et al., 2012) proposed a linguistic based approach to automatically detect and code counselor reflections that is based on analyzing n-grams patterns, similarity features between counselor and client speech, and contextual meta-features, which aim to represent the dialog sequence between the client and counselor. A method based on labeled topic models is presented in (Atkins et al., 2012; Atkins et al., 2014), where authors focus on automatically identifying topics related to MI behaviors from the MISC scheme such as reflections, questions, support, and empathy. Unlike their work, we introduce and experiment with richer sets of features that represent more accurately the linguistic structure of counselor behaviors, including syntactic patterns and semantic information. Moreover, although we also focus on the recognition of the two most frequently encountered behaviors (reflections and questions), we also apply and evaluate our system on the other MI behaviors measures by the MITI coding scheme. Speech and linguistic based methods have also been proposed to evaluate overall MI quality. For instance, (Xiao et al., 2014) presents a study on the automatic evaluation of counselor empathy. The method is based on analyzing correlations between prosody patterns and empathy showed by the therapist during the counseling interactions.

Although most of the work on coding of MI

within session language has focused on modeling the counselor language, there is also work that investigates the client language. (Tanana et al., 2015) addresses the identification of counselor's statements discussing client's change talk. Their approach uses recursive neural networks to model sequences of counselor and client verbal exchanges. (Lord et al., 2015b) analyze the language style synchrony between therapist and client during MI encounters. They rely on the psycholinguistic categories from the Linguistic Inquiry and Word Count lexicon to measure the degree in which counselor language matches the client language.

Also related to our research is work on the social interaction domain. (Danescu-Niculescu-Mizil et al., 2012) studied power differences from language coordination in group discussions by measuring the similarity of word usage across different linguistic categories. Stylistic influence and symmetry have also been explored in social media interactions (Danescu-Niculescu-Mizil et al., 2011). More recently, (Althoff et al., 2016) explored these phenomena in the mental health domain by analyzing text-message-based counseling and observed that counselors who are more successful act with more control in the conversations and coordinate in a lower degree than their less successful counterparts.

In summary, research findings have shown that natural language processing approaches can be successfully applied to clinical narratives for the automatic annotation and analysis of therapists' and clients' behaviors. However, developed methods have not yet explored the use of linguistic features that incorporate semantic or syntactic information. In this paper we seek to explore new linguistic representations that can improve the identification of MITI counselor behaviors. Furthermore, we also experiment with features that measure participants linguistic accommodation during the counseling interaction.

### 4 MI Narratives Dataset

The data used in this study consists of 277 MI sessions conducted in several medical settings, including randomized control trials in clinical research for smoking cessation and medication adherence; MI training from a graduate-level MI course; wellness coaching phone calls; and brief medical encounters in dental practice and student

counseling. The full set comprises 97.8 hours of audio with an average session length of 20.8 minutes with a standard deviation of 11.5 minutes.

#### 4.1 Transcription

Before transcribing, all the counseling recordings were preprocessed to remove any personal identifiers. This includes manually trimming the audio to remove introductions and replacing references to participant's name and location with silences.

Sessions were transcribed via Mechanical Turk (Marge et al., 2010) using the following guidelines: 1) transcribe speech turn by turn, 2) clearly identify the speaker (either client or counselor), 3) include speech disfluences, such as false starts, repetitions of whole words or parts of words, prolongations of sounds, fillers, long pauses. Transcriptions were manually verified at random points to avoid spam and ensure their quality. The final transcript set contains 22,719 utterances.

#### 4.2 MI Coding

MITI coding was conducted by a team of three counselors who have extensive experience with MI.<sup>1</sup> Prior to the annotation phase, annotators participated in a coding calibration step where they discussed the criteria for sentence parsing, the correct assignment of behavior codes, and conducted team coding in a set of sample sessions.

As suggested in the MI literature, we evaluated the coding reliability on a sample of ten double-coded sessions, which were coded by our staff and by MITI developers (Moyers et al., 2005).

We measured the inter-annotator agreement at both session and utterance level. For the session level, we measured the Intraclass Correlation Coefficient (ICC), which indicates how much of the total variation in MITI scores is due to differences among annotators (Dunn et al., 2015). The utterance level agreement was measured using the Kappa score (Lord et al., 2015a).

The ICC values reported in Table 1 show noticeable high agreement for the Question and Reflection codes with scores ranging between 0.89 to 0.97, which are considered excellent agreement in the MI literature (Jelsma et al., 2015). The remaining codes show lower agreement values due to low frequency counts in the sample. This was particularly the case for the Giving Information, Affirm

<sup>1</sup>Annotators were trained in the use of MITI 4.1 by expert trainers from the Motivational Interviewing Network of Trainers

and Emphasizing Autonomy codes, for which we were unable to obtain ICC scores (NA). Confront, and Persuading without Permission codes are not reported as they did not appear in our sample. The main reason for this is that the dataset was derived from sessions conducted by experienced counselors who avoided such codes as they indicate bad MI practice.

Overall, the ICC scores suggest that the annotators do not show significant variations at session level coding, i.e., the total frequency counts of each code per session did not differ significantly between coders. Furthermore, the Kappa scores suggest that annotators have fair to good pairwise agreement at utterance level coding.

Since the inter-reliability analysis showed reasonable agreement among the coding team members, we moved forward to the annotation phase. The 277 sessions are randomly distributed among the three members of the coding team. Annotations are conducted using the session audio recording along with its transcript using Nvivo,<sup>2</sup> a quantitative analysis suite for behavioral coding that allows selecting free text and assigning it to a given category. Table 2 presents an excerpt of a session transcript. As observed, a talk-turn can comprise multiple utterances.

The team annotated approximately 20 sessions per week. The entire annotation process took nearly three months. After the annotation phase, the annotated transcripts were processed to extract the verbal content of each MITI annotation; non-coded utterances were also extracted and labeled as neutral speech. In the coded set 33% (5262) are Questions, 17% (2690) are Simple Reflections, 18% (2876) are Complex Reflections, and 32% (5058) are other MITI codes: Seeking Collaboration (614), Emphasizing Autonomy (141), Affirm (499), Confront (141), Persuading without Permission (598), Giving information (1017), and Persuading with Permission (2100).

### 5 Linguistic Features for MI behaviors

In order to explore linguistic patterns related to counselor behaviors, we analyze their definitions and usage. For instance, the use of reflective statements helps counselors understand client's statements through hypothesis testing (Miller and Rollnick, 2013); questions help counselor elicit information and engage the clients in the conversation;

and so on. Considering these guidelines, we derive the following features that aim to capture the linguistic differences among these behaviors.

*N-grams*: These features represent the language used by the counselor and include all the unique words and word-pairs present in counselor speech. We extract a vector containing the frequencies of each word and word pair present in each utterance.

*Semantic information*: These features attempt to bring semantic information into the analysis of counselor language by identifying words as belonging to certain semantic categories that are potential markers of counseling style. For instance, semantic categories related to reflective language include tentative language e.g., maybe, perhaps, looks, as well as anxiety words e.g., afraid, tense, worried. We use two groups of semantic features. The first consists of features derived from the LIWC lexicon (Tausczik and Pennebaker, 2010), a psycholinguistic resource that contains 70 semantic categories representing psy-

chological cues to human thought processes, emotional states, intentions, and motivations. The second is a self-acquired reflection lexicon consisting of 146 words frequently present during reflective statements. These features are represented as the total frequency counts of all the words in a word category that are present in the annotation.

*Similarity*: Since reflective listening includes repetition and rephrasing, we can expect to observe linguistic similarity between client and counselor speech. Thus, we measure the degree to which the counselor matches the client language by using Linguistic Style Matching (LSM) (Gonzales et al., 2009), a technique that allows to quantify the extent to which one person uses comparable types of words to another person. We measure LSM at a turn-by-turn level using the LIWC word categories, e.g., positive words, pronouns, negations, quantifiers. In order to capture information from return statements, we combine client speech from the previous and current turn along with the counselor utterance. The features are represented by a score ranging between 0 and 1 indicating the degree to which the counselor and client use the same type of words.

*Syntactic features*: These features aim to represent the syntactic structure of the clinician statements. We use these features to encode information about the word order in the sentence. We expect syntactic patterns with high occurrence will likely capture reflection starters commonly used

Features	Acc.	P	R	F

Table 3: Classification results for counselor reflections (REFL), other MITI codes (OTHER), other MITI codes + transition (unannotated) utterances (ALL)

by the counselor such as “it sounds like ...”. First, we use the Stanford parser to generate the Context Free Grammar parse trees of counselor utterances and extract all production rules present in the trees. Second, we derive features for each lexicalized and unlexicalized production rule augmented with its grandparent node; this means we also include chunk tags such as noun phrases, adverb phrases, prepositional phrases, and so on. Third, each feature is calculated by counting how many times a production rule or production-rule-sequence occurs in the utterance.

## 6 Experiments and Results

After the feature extraction, we explore whether these features can be used as predictors of counselor behaviors. We first focus on the prediction of reflections and questions, as they represent the most frequent behaviors in counseling narratives; we then experiment with the use of these features for the prediction of the other behavior codes.

### 6.1 Predicting Counselor Reflections

We conduct learning experiments where we explore the use of n-grams, syntactic, semantic, and similarity features to build reflection classifiers at three levels of detail.

First, we attempt to mimic the process human coders follow while MITI annotating a session, i.e., the coder goes through each counselor utterance and chooses the most appropriate code according to the MITI guidelines. Hence, we focus on the identification of Reflection utterances regardless of being complex or simple. The learning

task aims to classify a counselor utterance either as a Reflection, or a Not-reflection, i.e., any other counselor utterance. Second, given that a large portion of the verbal exchanges between the counselor and the client consists of transition or facilitative statements (e.g., yeah, right), we decided to remove this content from the analysis thus focusing on the task of discriminating between Reflection and any other MITI code. Third, we aim to discriminate between Simple and Complex reflection. In MI, counselors use both types of reflections to understand the client’s perspective, feelings, and values. However, in general, complex reflections are preferable over simple reflections as they show counselor’s deeper understanding of the issues being discussed. In a real setting, distinguishing between these two behaviors and understanding their linguistic differences is important in order to provide the counselor with feedback on the nature of their reflective statements.

During our experiments we employ the Support Vector Machines (SVM) (Cortes and Vapnik, 1995) classifier as the main classifier. We use the version implemented in the LibLinear library with the default parameters. We build several classification models using each of the different sets of linguistic features. We evaluate the ability of such models to predict the target behavior using a five-fold cross-validation. As reference value, we use a majority class baseline, which is the percentage of instances correctly classified when selecting by default the most frequent category in the training data.

Table 3 summarizes the classification performance for each set of features in the detection of reflections. During our experiments we used F-score as the main evaluation metric. This metric considers both the proportion of reflections identified from the training set (recall) and the proportion of reflections correctly identified as such (precision). From this table, we can observe that the syntactic model accurately captures differences between reflective and non-reflective content. This difference is even more noticeable when discriminating between syntactic structures associated to reflective statements versus syntactic structures associated to other MITI codes (REFL vs OTHER column).

Table 4 presents the classification performance for the simple (S-Refl) and complex reflections (C-Refl). F-scores among the classification mod-

N-grams	63.24%	0.61	0.65	0.64	0.66	0.62	0.63
Semantic	67.21%	0.63	0.65	0.64	0.67	0.70	0.69
Similarity	63.22%	0.62	0.59	0.58	0.67	0.58	0.63
Syntax	65.06%	0.63	0.66	0.64	0.67	0.70	0.657
All features	62.52%	0.60	0.62	0.61	0.64	0.62	0.63

Table 4: Classification results for Simple Reflections (S-Refl) and Complex Reflections (C-Refl)

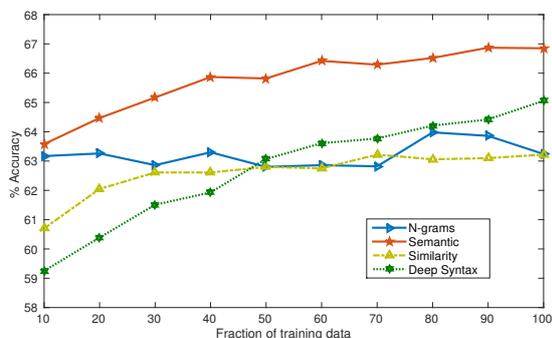

Figure 1: Learning curve for Simple (S-Refl) and Complex Reflection (C-Refl) detection using different amounts of training data and four feature sets.

els do not show noticeable improvement gain for the syntactic model. This suggests that the syntactic features might not have enough discriminative power to accurately differentiate between Complex and Simple reflections as the differences among these behavior codes are mostly semantic. This could be also attributed to the similarity of syntactic constructions for Simple and Complex reflections, i.e., common starters such as *it sounds like*, *it looks like*, and other similar syntactic constructions. Note that this task is also challenging for humans, as reported pairwise inter-annotator agreements for Simple and Complex reflections in our sample ranges between fair to good levels (see Kappa values in Table 1).

Finally, we investigate whether larger amounts of training data can be helpful to discriminate between Simple and Complex reflections, in particular with the use of syntax-based features. We plot the learning curves of the different sets of features using incremental amounts of data as shown in Figure 1. The learning trend suggests the classification performance while distinguishing between Complex and Simple Reflection improves when increasing the number of training examples. Notably, the syntactic features curve shows consistent growth, suggesting that larger quantities of train-

Target Behavior Change	Sessions	REF	OTHER

Smoking Cessation	95	2290	3745
Dietary Changes	72	2045	2669

Table 5: Class distribution for three target behavior changes

ing data might improve the classification performance for this task.

## 6.2 The Role of Behavior Change Target

During MI encounters, counselors follow specific strategies to guide the client towards behavior change. For instance, reflective listening strategies include generic starters to reformulate, rephrase, or intensify client’s statements, which are used regardless of the behavior change target. Considering that MI has proven to be effective on addressing a wide range of application domains, this might suggest a certain degree of domain independence, which can be of importance for the development of natural language processing strategies for the automatic coding of MI sessions.

Aiming to explore the role played by the health issue being discussed during the counseling encounter, we conduct an additional set of experiments on three target behavior changes present in our dataset, namely medication adherence, smoking cessation, and dietary changes. The class distribution for each set is shown in Table 5. We exclude 16 sessions as they correspond to miscellaneous change goals.

Using this data, we build reflection classifiers using the linguistic features described before. Results are shown in Table 6. From this table, we can derive interesting observations. First, following a similar trend as in our previous experiments, syntactic features offer improved performance over the n-grams, similarity, and semantic feature sets. Second, we observe more steady improvement when using a combination of different feature sets, as compared to our previous experi-

Target Behavior Change	Baseline	N-grams	Semantic	Similarity	Syntax	All Features
Medication adherence	57.52%	83.56%	61.48%	57.52%	85.31%	88.78%
Smoking cessation	62.05%	82.41%	66.16%	62.96%	83.41%	85.34%
Dietary changes	56.51%	82.75%	66.50%	59.56%	82.42%	85.41%

Table 6: Classification performance for reflection detection (REFL VS. ALL) on sessions aiming at three behavior changes

Category	Medication Adherence	Smoking Cessation	Dietary Changes
Noun	health, family, routine, life	children, control, past, role, parent	pre-diabetes, people, husband, future
Verb	live, imagine, see, eat, help	see, affect, feel, want, talk	care, affect, concern, leave
Adjective	difficult, responsible, important	concern, hard, helpful	scary, busy, difficult, willing

Table 7: Counselor word usage across different health issues

ments. Still, the performance for both sets of experiments is comparable, thus suggesting that the task is not heavily affected by the health issue being discussed. This further suggests that training data on the same behavior target is desirable but not essential.

Since we did not observe noticeable differences in language constructions used by counselors across different health issues, we decided to analyze whether counselors differ in their word choices. We thus looked at the top syntactic features generated for each classification model and their corresponding terminal nodes and part of speech tags. Table 7 shows sample words for nouns, verbs, and adjectives used by counselors while formulating reflections for three target behavior changes. From this table we notice that counselor word usage does vary with the health issue being addressed. For instance, when discussing smoking cessation, counselor emphasize verbs and nouns that evoke clients’ desire to change (affect, want, feel) and discuss client values that are related to how they are perceived by others (role, parent, control).

### 6.3 Prediction of Counselor Questions

Our next set of experiments aims to predict counselor questioning statements. As before, we build different prediction models using the developed feature sets and attempt to discriminate between 1) Questions and any other counselor utterance (QUEST vs ALL), and 2) Questions and other MITI codes (QUEST vs OTHER). Classification performances for these models are shown in Table 8. The best performing feature set is the syntactic followed by the n-grams model.

Note that in addition to the experiments reported in this table, we attempted to combine different features sets. However, we did not observe

Features	Acc.	P	R	F
QUEST vs. ALL				
Baseline	76.83%	0.00	0.00	0.00
N-grams	87.81%	0.91	0.92	0.76

Syntax	90.48%	0.92	0.92	0.87
All features	86.57%	0.82	0.82	0.82
GRU	92.8%	0.89	0.92	0.90

Table 8: Classification results for counselor questions (QUEST), other MITI codes + transition (unannotated) utterances (ALL), and other MITI codes (OTHER).

substantial improvement over our best performing model consisting of syntactic features.

### 6.4 Prediction of Other MI Codes

Aiming to identify potential predictors for the remaining MI codes, we conduct a set of experiments where we use our linguistic feature sets to build multiclass classifiers. Table 9 shows the precision and recall figures obtained for the different classification models. Note that the results using semantic and similarity features are not reported, as the resulting classifiers showed very low recall values. From these results we observe that both syntactic features and n-grams aid the identification of other counselor behavior codes, particularly Giving Information, Affirm, and Seeking Collaboration. However, the prediction accuracy of the syntactic models is slightly lower than the n-grams models. We believe that the more verbose nature of these codes, in contrast to reflections, makes it difficult to benefit from syntactic patterns.

Features	GI		AF		SEEK		AUTO		PWP		PWOP		CON	
	P	R	P	R	P	R	P	R	P	R	P	R	P	R
N-grams	0.56	0.47	0.42	0.37	0.55	0.49	0.29	0.26	0.23	0.15	0.29	0.22	0.10	0.07
Syntax	0.52	0.47	0.41	0.35	0.54	0.50	0.26	0.19	0.18	0.14	0.28	0.22	0.10	0.04
GRU	0.48	0.79	0.28	0.75	0.41	0.80	0.24	0.30	0.09	0.47	0.21	0.38	0.05	0.17

Table 9: Classification results for seven MI behaviors: Giving Information (GI), Affirm (AF), Seeking Collaboration (SEEK), Emphasizing Autonomy (AUTO), Persuading with Permission (PWP), Persuading without Permission (PWOP), Confront (CON)

	QUEST	REFL	S-REFL	C-REFL
1	*. ^ S → ?	*VBZ ^ VP → sounds	ROOT ^ ROOT → S	VP ^ S → TO_VP
2	*. ^ SBARQ → ?	*IN ^ SBAR → since	*VBD ^ VP → mentioned	NP ^ PP → PRP\$ _NN
3	ROOT ^ ROOT → SBARQ	*IN ^ S → so	ROOT ^ ROOT → FRAG	*VBZ ^ VP → sounds
4	NP ^ SQ → PRP	S ^ ROOT → IN _NP	ROOT ^ ROOT → NP	*VB ^ VP → be
5	*.SQ → ?	VP ^ S → VBZ _SBAR	VP ^ S → VBD _SBAR	*TO ^ VP → to
6	ROOT ^ ROOT → SQ	*PRP ^ NP → it	*RB ^ ADVP → so	*RB ^ ADVP → really
7	*WP ^ WHNP → what	*RB ^ ADVP → really	VP ^ S → VBD _NP	*PRP ^ NP → it
8	*IN ^ PP → about	S ^ ROOT → CC _ADVP	*NN ^ NP → ok	*IN ^ SBAR → like
9	*DT ^ NP → any	ADJP ^ VP → RBR _JJ	*UH ^ INTJ → okay	*IN ^ PP → like
10	*. ^ FRAG → ?	VP ^ S → VBP _PRT	VP ^ S → VBD _PP	*DT ^ NP → this

Table 10: Most discriminative syntactic features for Questions (QUEST), Reflections (REFL), Simple reflection (S-REFL) and Complex reflection (C-REFL).

Also, note that Emphasizing Autonomy, Persuading With And Without Permission, and the Confront codes lead to low precision and recall values, which can be partially attributed to having a smaller number of training examples as compared to the other codes.

## 7 Discussion

Our experimental results support the use of automatic means to predict MITI counselor behaviors. Unsurprisingly, better results are obtained for the more frequent behaviors such as reflections and questions. Unlike previous studies that focused on the identification of reflective content in psychotherapy narratives (Atkins et al., 2014; Xiao et al., 2014), we build prediction models that predict all the MITI behavior codes. We also introduce and leverage new features consisting of semantic and syntactic patterns; our experimental results suggest the effectiveness of these new features.

To gain further insight into the syntactic patterns, we extract the most predictive features for each classification model. Table 10 presents a summary of the top ten production rules associated to Question (Quest), Reflection (Refl), Simple Reflection (S-Refl), and Complex Reflection (C-Refl). As expected, question production rules include the question mark as a clear indicator of questions. However, we also observe clause tags and phrase tags that capture more complex questioning structures such as direct questions in-

troduced by a wh-word or a wh-phrase *SBARQ*, inverted yes/no questions *SQ*, question personal pronoun *WP* (wh-pronoun, personal), and noun phrases *WHNP*.

Similarly, the most predictive rules for Reflections (REFL column) include adverbs (*RB*, *RBR*), adjectives (*JJ*), present tense verbs (*VBZ*), personal pronouns (*PRP*); as well as adverb and adjective phrases (*ADVP*, *ADJP*). We observe that the syntactic similarity of reflective statements is well represented by the syntactic model as they include verbal structures that are frequently used by the counselor to formulate reflective statements; for instance, generic reflection starters such as “So, it sounds like ...” (see rules 1, 3, 5, and 6 in column REFL), and word categories, such as adjectives, conjunctions and comparative adverbs (see rules 8, 9, and 10 in column REFL). Moreover, we observe an interesting difference in the verb tense usage for Simple and Complex Reflection detection: production rules for Simple Reflection include present tense while production rules for Complex Reflection include past tense.

Overall, our experimental results show the potential of applying linguistic methods in the prediction of counselor behaviors, and in particular those that incorporate syntactic information into the analysis.

## 8 Conclusions

In this paper, we presented a classification model towards the automation of MI coding using the MITI coding system.

We made two important contributions. First, we introduced a novel large psychotherapy dataset derived from MI interventions, consisting of 277 MI sessions with a total of 22,719 utterances. The dataset was manually transcribed and annotated with ten counselor verbal behaviors. Second, using several features, we applied the classification model to the recognition of MI counseling behaviors, with an emphasis on the two most frequently encountered behaviors: reflections and questions. We showed how a richer feature set, and in particular a set consisting of semantic and syntactic patterns, can lead to accuracy figures of up to 90%, which represents a significant improvement with respect to the bag-of-word features used in the past.

We also presented several analyses, including an exploration of the role of the behavior change target in the prediction of reflections; and an analysis of the most discriminative features in the syntactic model. Although this study focused on the MITI as the coding system and MI as the counseling approach, we believe that the proposed methods could apply to other measures of MI skill fidelity such as Behavior Change Counselor Index (BECCI) (Lane et al., 2005), Independent Tape Rating Scale (ITRS) (Martino et al., 2009), Stimulated Client Interview Rating Scale (SCIRS) (Arthur, 1999), and the One Pass coding system (McMaster and Resnicow, 2015).

stamatatos@aegean.gr

## Abstract

Authorship attribution is associated with important applications in forensics and humanities research. A crucial point in this field is to quantify the personal style of writing, ideally in a way that is not affected by changes in topic or genre. In this paper, we present a novel method that enhances authorship attribution effectiveness by introducing a text distortion step before extracting stylometric measures. The proposed method attempts to mask topic-specific information that is not related to the personal style of authors. Based on experiments on two main tasks in authorship attribution, closed-set attribution and authorship verification, we demonstrate that the proposed approach can enhance existing methods especially under cross-topic conditions, where the training and test corpora do not match in topic.

## 1 Introduction

Authorship attribution is the task of determining the author of a disputed text given a set of candidate authors and samples of their writing (Juola, 2008; Stamatatos, 2009). This task has gained increasing popularity since it is associated with important forensic applications, e.g., identifying the authors of anonymous messages in extremist forums, verifying the author of threatening email messages, etc. (Abbasi and Chen, 2005; Lambers and Veenman, 2009; Coulthard, 2013), as well as humanities and historical research, e.g., unmasking the authors of novels published anonymously or under aliases, verifying the authenticity of literary works by specific authors, etc. (Koppel and Seidman, 2013; Juola, 2013; Stover et al., 2016).

The majority of published works in authorship

attribution focus on *closed-set attribution* where it is assumed that the author of the text under investigation is necessarily a member of a given well-defined set of candidate authors (Stamatatos et al., 2000; Gamon, 2004; Escalante et al., 2011; Schwartz et al., 2013; Savoy, 2013; Seroussi et al., 2014). This setting fits many forensic applications where usually specific individuals have access to certain resources, have knowledge of certain issues, etc. (Coulthard, 2013) A more general framework is *open-set attribution* (Koppel et al., 2011). A special case of the latter is *authorship verification* where the set of candidate authors is singleton (Stamatatos et al., 2000; van Halteren, 2004; Koppel et al., 2007; Jankowska et al., 2014; Koppel and Winter, 2014). This is essentially a one-class classification problem since the negative class (i.e., all texts by all other authors) is huge and extremely heterogeneous. Recently, the verification setting became popular in research community mainly due to the corresponding PAN shared tasks (Stamatatos et al., 2014; Stamatatos et al., 2015).

In authorship attribution it is not always realistic to assume that the texts of known authorship and the texts under investigation belong in the same genre and are in the same thematic area. In most applications, there are certain restrictions that do not allow the construction of a representative training corpus. Unlike other text categorization tasks, a recent trend in authorship attribution research is to build cross-genre and cross-topic models, meaning that the training and test corpora do not share the same properties (Kestemont et al., 2012; Stamatatos, 2013; Sapkota et al., 2014; Stamatatos et al., 2015).

One crucial issue in any authorship attribution approach is to quantify the personal style of authors, a line of research also called stylometry (Stamatatos, 2009). Ideally, stylometric fea-

tures should not be affected by shifts in topic or genre variations and they should only depend on personal style of the authors. However, it is not yet clear how the topic/genre factor can be separated from the personal writing style. Function words (i.e., prepositions, articles, etc.) and lexical richness features are not immune to topic shifts (Mikros and Argiri, 2007). In addition, character  $n$ -grams, the most effective type of features in authorship attribution as demonstrated in multiple studies (Grieve, 2007; Stamatatos, 2007; Luyckx and Daelemans, 2008; Escalante et al., 2011) including cross-topic conditions (Stamatatos, 2013; Sapkota et al., 2015), unavoidably capture information related to theme and genre of texts. Features of higher level of analysis, including measures related to syntactic or semantic analysis of texts, are too noisy and less effective, and can be used as complement to other more powerful low-level features (van Halteren, 2004; Argamon et al., 2007; Hedegaard and Simonsen, 2011).

In this paper, we propose a novel method that is based on text distortion to compress topic-related information. The main idea of our approach is to transform input texts to an appropriate form where the textual structure, related to personal style of authors, is maintained while the occurrences of the least frequent words, corresponding to thematic information, are masked. We show that this distorted view of text when combined with existing authorship attribution methods can significantly improve their effectiveness under cross-topic conditions in both closed-set attribution and authorship verification.

## 2 Related Work

Previous work in authorship attribution focuses mainly on stylometric features that capture aspects of personal writing style (Gamon, 2004; Luyckx and Daelemans, 2008; Escalante et al., 2011; Schwartz et al., 2013; Tschuggnall and Specht, 2014; Sidorov et al., 2014). In addition, beyond the use of typical classification algorithms, several attribution models that are specifically designed for authorship attribution tasks have been proposed (Koppel et al., 2011; Seroussi et al., 2014; Qian et al., 2014). Basic approaches and models are reviewed by Juola (2008) and Stamatatos (2009). In addition, recent studies in authorship verification are surveyed in (Stamatatos et al., 2014; Stamatatos et al., 2015).

An early cross-topic study in authorship attribution using a very small corpus (3 authors and 3 topics) showed that the identification of authors of email messages is not affected too much when the training and test messages are on different topics (de Vel et al., 2001). Based on another small corpus (2 authors and 3 topics) Madigan, *et al.* (2005) demonstrated that POS features are more effective than word unigrams in cross-topic conditions. The *unmasking* method for author verification of long documents based on very frequent word frequencies was successfully tested in cross-topic conditions (Koppel et al., 2007) but Kestemont, *et al.* (2012) found that its reliability was significantly lower in cross-genre conditions. Function words have been found to be effective when topics of the test corpus are excluded from the training corpus (Baayen et al., 2002; Goldstein-Stewart et al., 2009; Menon and Choi, 2011). However, Mikros and Argiri (2007) demonstrated that function word features actually correlate with topic. Other types of features found effective in cross-topic and cross-genre authorship attribution are punctuation mark frequencies (Baayen et al., 2002), LIWC features (Goldstein-Stewart et al., 2009), and character  $n$ -grams (Stamatatos, 2013). To enhance the performance of attribution models based on character  $n$ -gram features, Sapkota et al. (2015) define several  $n$ -gram categories and then they combine  $n$ -grams that correspond to word affixes and punctuation marks. Combining several topics in the training set seems also to enhance the ability to identify the authors of texts on another topic (Sapkota et al., 2014). More recently, Sapkota et al. (2016) proposed a domain adaptation model based on structural correspondence learning and punctuation-based character  $n$ -grams as pivot features.

Text distortion has successfully been used to enhance thematic text clustering by masking the occurrences of frequent words while maintaining the textual structure (Granados et al., 2011; Granados et al., 2012). That way, the clustering model was no longer confused by non relevant information hidden in the produced distorted text (Granados et al., 2014). An important conclusion drawn by these studies was that, in cases the textual structure was not maintained, the performance of clustering decreased despite the fact that the same thematic information was available.

### 3 Text Distortion Views

In this paper we propose a method to transform texts by applying a text distortion process before extracting the stylometric features. The main idea is to provide a new version of texts that is more topic-neutral in comparison to the original texts while maintaining most of the information related with the personal style of the author. Our method is inspired by the text distortion approach introduced by Granados, *et al.* (2011; 2012) but it significantly differs from that since it is more suitable for authorship attribution rather than thematic clustering. In more detail, given the  $k$  most frequent words of the language  $W_k$ , the proposed method transforms the input  $Text$  as described in Algorithm 1.

---

**Algorithm 1** DV-MA

---

**Input:**  $Text, W_k$

**Output:**  $Text$

- 1: Tokenize  $Text$
  - 2: **for** each token  $t$  in  $Text$  **do**
  - 3:   **if** lowercase( $t$ )  $\notin W_k$  **then**
  - 4:     replace each digit in  $t$  with #
  - 5:     replace each letter in  $t$  with \*
  - 6:   **end if**
  - 7: **end for**
- 

We call this method *Distorted View with Multiple Asterisks* (DV-MA). Alternatively, a single symbol can be used to replace sequences of digits/letters meaning that the token length information is lost. This version of the proposed method, called *Distorted View with Single Asterisks* (DV-SA) is illustrated in Algorithm 2.

---

**Algorithm 2** DV-SA

---

**Input:**  $Text, W_k$

**Output:**  $Text$

- 1: Tokenize  $Text$
  - 2: **for** each token  $t$  in  $Text$  **do**
  - 3:   **if** lowercase( $t$ )  $\notin W_k$  **then**
  - 4:     replace any sequence of digits in  $t$  with a single #
  - 5:     replace any sequence of letters in  $t$  with a single \*
  - 6:   **end if**
  - 7: **end for**
- 

Note that DV-MA does not affect the length of input text while DV-SA reduces text-length. The

proposed text transformation is demonstrated in the example of Table 1 where an input text is transformed according to either DV-MA or DV-SA algorithms. In each example,  $W_k$  consists of the  $k$  most frequent words of the BNC corpus<sup>1</sup>. As can be seen, each value of  $k$  provides a distorted view on the text where the textual structure is maintained but some, mainly thematically related, information is masked. In the extreme case where  $k=0$  all words are replaced by asterisks and the only information left concerns word-length, punctuation marks and numbers usage. When  $k=100$ , function words remain visible and it is possible to extract patterns of their usage. Note that capitalization of letters remain unaffected. When  $k$  increases to include thousands of frequent words of BNC more topic-related information is visible. In general, the lower the  $k$ , the more thematic information is masked. By appropriately tuning parameter  $k$ , it is possible to decide how much thematic information is going to be compressed.

The text distortion method described in Granados, *et al.* (2011; 2012) has also been applied to the input text of Table 1 for  $k=1,000$ . In comparison to that method, the proposed approach is different in the following points:

- We replace the occurrences of the least frequent words rather than the most frequent words since it is well known that function word usage provide important stylometric information.
- Punctuation marks and other symbols are maintained since they are important style markers.
- Capitalization of original text is maintained.
- We treat numbers in a special way in order to keep them in the resulting text but in a more neutral way that reflects the stylistic choices of authors. For example, note that in each example of Table 1 both \$15,000 and \$17,000 are transformed to the same pattern. Thus, the proposed methods are able to capture the format used by the author and discard the non-relevant information about the exact numbers. In the case of DV-SA, any similar number (e.g., \$1,000, \$100,000) would have exactly the same transformation.

---

<sup>1</sup><https://www.kilgarriff.co.uk/bnc-readme.html>

- DV-SA: the input texts are distorted using the Algorithm 2.

## 5 Closed-set Attribution

### 5.1 Corpora

First, we examine the case where a given closed-set of candidate authors is given. Multiple corpora are nowadays available for this task. We selected to use the following two corpora:

1. CCAT-10: this is a subset of the *Reuters Corpus v.1* comprising 10 authors and 100 texts per author belonging to the CCAT thematic category (corporate and industrial news). This corpus has been used in several previous studies (Plakias and Stamatatos, 2008; Escalante et al., 2011; Sapkota et al., 2015). Separate training and test corpora of equal size are provided.
2. Guardian: this is a corpus of articles from *The Guardian* UK newspaper. It includes opinion articles by 13 authors on 4 thematic areas (politics, society, UK, and world) as well as book reviews by the same authors. It has been used in previous work that focused on authorship attribution in cross-topic and cross-genre conditions (Stamatatos, 2013; Sapkota et al., 2014). Following the practice of previous studies, we use at most 10 texts per author in each category of this corpus.

It is important to highlight the main difference among the above corpora. CCAT-10 authors tend to write newswire stories on specific subjects and this is consistent in both training and test corpora. On the other hand, in the Guardian corpus the texts by one author cover several thematic areas and two genres (opinion articles and book reviews). Therefore, it is expected that an authorship attribution method that is not robust to topic shifts will be less effective in the Guardian corpus. In CCAT-10, it is the combination of personal style and preferred thematic nuances that define each class (author).

To make this difference among the above corpora more clear, Table 2 shows the top fifteen words of each corpus with respect to their  $\chi^2$  value and a total frequency of at least five. As expected, most of these words correspond to named-entities and other topic-related information. For each word, the total term frequency  $tf$ , document frequency  $df$  (number of different documents where

CCAT-10				Guardian			
Word	$tf$	$df$	$af$	Word	$tf$	$df$	$af$
Prague	133	74	1	dam	14	3	1
crowns	168	43	1	technologies	6	2	1
ING	41	34	2	Congo	12	2	1
PX50	39	29	1	DRC	17	2	1
Wood	27	27	1	Rwandan	25	2	1

derivatives	31	16	1	allusions	6	4	1

Table 2: Top fifteen words with respect to  $\chi^2$  in CCAT-10 and Guardian corpora together with occurrence statistics.

the word appears), and author frequency  $af$  (number of different authors in whose documents the word appears) are also provided. As can be seen, in CCAT-10 there are multiple words that are author-specific and tend to appear in multiple documents by that author (both  $tf$  and  $df$  are high). Thus, these words are useful indicators of authorship for that specific corpus. On the other hand, in the Guardian corpus, it is not easy to find words that appear in multiple documents of the same author and do not appear in documents by other authors (when  $af$  is low,  $df$  is also very low).

### 5.2 Attribution Model

From each text of the corpus (either in its original form or in the proposed distorted view) the stylometric features are extracted (either character  $n$ -grams or token  $n$ -grams) and then a SVM classifier with a linear kernel is built. Such a simple attribution model has been extensively used in previous work and proved to be an effective approach to closed-set authorship attribution (Plakias and Stamatatos, 2008; Stamatatos, 2013; Sapkota et al., 2014; Sapkota et al., 2015).

The BNC corpus is used to estimate the most frequent words of the English language. For each model, the appropriate parameter settings for  $n$ ,  $f_t$ , and  $k$  are estimated based on grid search as described in Section 4.

### 5.3 Results

First, we apply the examined models to the CCAT-10 corpus. Based on 10-fold cross-validation on the training corpus we estimate the best parame-

		Acc.	$n$	$f_t$	$k$	$N$
Character $n$ -grams	Baseline	<b>80.6</b>	6	15		18,859
	DV-MA	78.2	7	35	2,000	5,426
	DV-SA	77.4	7	35	4,000	5,708
Token $n$ -grams	Baseline	80.0	1	20		1,805
	DV-MA	79.2	2	5	4,000	10,199
	DV-SA	79.4	2	10	4,000	4,023

Table 3: Accuracy results of closed-set attribution on the CCAT-10 corpus. For each model, parameter settings ( $n$ ,  $f_t$ ,  $k$ ) and number of features ( $N$ ) are also shown.

ter settings for each model. Then, the best models are applied to the test corpus. Table 3 presents the results of this experiment. As can be seen, the baseline models are the most effective ones using both character and token  $n$ -gram features. However, only the DV-SA model using character  $n$ -grams is statistically significantly worse according to a McNemar’s test with continuity correction ( $p < 0.05$ ) (Dietterich, 1998). For character  $n$ -gram features, both the baseline models and the proposed models are based on long  $n$ -grams ( $n=6$  or  $7$ ), longer than usually examined in authorship attribution studies. This reflects the topic-specificity of classes in that corpus since longer character  $n$ -grams are better able to capture thematic information. Moreover, the proposed distortion-based models were based on high values of  $k$  confirming that thematic information is important in that corpus. As concerns the token  $n$ -gram features, the baseline model was based on unigrams while bigrams were selected for the proposed methods.

Next, we applied the examined models on the opinion articles of the cross-topic Guardian corpus as follows: one thematic category was used as training corpus, another was used as validation corpus (to estimate the best parameter settings) and the remaining two categories were used as test corpus. Since there are four thematic categories in total, all 12 combinations were examined and the results are shown in Table 4. Here the results favour the proposed methods. Note that the average value of  $k$  is low indicating that most thematic information is masked. For character  $n$ -gram features, in almost all cases the distorted view models (both DV-MA and DV-SA) outperform the baseline. In many cases the difference with respect to the baseline is very high, especially for character  $n$ -gram models. According to a McNemar’s test with continuity correction ( $p < 0.05$ ) on the overall performances, DV-MA based on character  $n$ -

grams is significantly better than all other models except the corresponding DV-SA model. The average  $k$  value of this model is very low (150) meaning that essentially only function words remain unmasked. It should be mentioned that the baseline character  $n$ -gram models in most cases are more effective than baseline token  $n$ -gram models. However, in average, they are worse than token  $n$ -grams due to their poor performance when the Society texts are used for training. This thematic category contains the least number of texts (Stamatatos, 2013). All examined models are based on significantly reduced feature sets in comparison to the CCAT-10 corpus indicating that in cross-topic conditions the least frequent features are not so useful.

In another experiment using the Guardian corpus, a cross-genre scenario was followed where the training and evaluation corpora come from different genres. In more detail, the book reviews category of that corpus was used as training corpus, one thematic category of opinion articles was used as validation corpus (to estimate the best parameter settings) and the remaining three thematic categories of opinion articles were used as test corpus. Again, all 4 combinations were examined (each time using a different validation corpus). Note that since the training and validation corpus belong to different genres we expect the attribution models to capture the cross-genre variation. What makes this experiment challenging is again the cross-topic variation since validation and test corpora do not share thematic properties. Table 5 presents the results for all tested models. Again, the proposed distortion-based models perform much better in comparison to the baseline models. In terms of overall performance, a McNemar’s test shows that DV-MA using character  $n$ -grams is significantly better ( $p < 0.05$ ) than the rest of the models. Note also that the feature set size for most models in this experiment is further reduced in comparison to the previous experiment.

Tables 4 and 5 also show the average values of best parameter settings for the experiments related with the Guardian corpus. In comparison to the CCAT-10 corpus (Table 3), we see that shorter character  $n$ -grams are used for the Guardian corpus while parameter  $k$  is much smaller. All these reflect the cross-topic nature of this corpus. Note that the proposed method is able to take advantage of this fact by masking topic-specific information.

#### 5.4 Effect of Parameter $k$

So far, the parameter settings of the proposed models, as well as the baseline methods, were obtained using a validation corpus. To study the effect of the newly introduced parameter  $k$ , we performed an additional experiment this time using character  $n$ -gram features with fixed  $n = 4$  and  $f_t = 5$  and varying  $k$  values ( $k \in \{100, 200, \dots, 1000, 1500, \dots, 5000\}$ ). Similar, for baseline models we used the same fixed  $n$  and  $f_t$  values. Figure 1 shows the performance of DV-MA, DV-SA, and baseline models on the CCAT-10 and Guardian corpora. Note that the results for CCAT-10 are directly comparable to Table 3. On the other hand, for the Guardian corpus we present the average performance of all possible 12 combinations (using one thematic category as training

corpus and another thematic category as test corpus). This is not directly comparable to Table 4 (where the test corpus of each case consists of two thematic categories).

As can be clearly seen in Figure 1 the effect of parameter  $k$  in DV-MA and DV-SA models is crucial. In the case of CCAT-10, performance in general increases with  $k$  reflecting the topic-specific information per author in this corpus. Despite the fact that the baseline approach is better than the proposed models in this corpus, a carefully selected  $k$  value (around 3,500) makes DV-MA equally effective to the baseline. On the other hand, in the Guardian cross-topic corpus, the proposed DV-MA and DV-SA models are better than the baseline for all examined  $k$  values. The best performance is obtained for low  $k$  and the accu-

racy decreases as  $k$  increases. This clearly shows that the use of topic-specific information in this corpus negatively affects the effectiveness of authorship attribution models. It is also notable that, in both corpora, the differences between DV-MA and DV-SA are not significant. However, DV-MA is slightly better than DV-SA in most of the cases.

## 6 Authorship Verification

### 6.1 Corpora

Recently, the PAN evaluation campaigns focused on the authorship verification task and several benchmark corpora were developed for this task (Stamatatos et al., 2014; Stamatatos et al., 2015). Each PAN corpus consists of a number of verification problems and each problem includes a set of known documents by the same author and exactly one document of unknown authorship. The task is to decide whether the known and the unknown documents are by the same author. In this paper, we use the following corpora:

**PAN-2014:** It includes 6 corpora covering 4 languages and several genres: Dutch essays (PAN14-DE), Dutch reviews (PAN14-DR), English essays (PAN14-EE), English novels (PAN14-EN), Greek newspaper articles (PAN14-GR) and Spanish newspaper articles (PAN14-SP). Each corpus is divided into training and test sets. Within each verification problem all documents belong to the same genre and fall into the same thematic area. Details of these corpora are presented in (Stamatatos et al., 2014).

**PAN-2015:** In this collection, within each verification problem the documents can belong to different genres and thematic areas. It includes a cross-genre corpus in Dutch (PAN15-DU), cross-topic corpora in English (PAN15-EN) and Greek (PAN15-GR) and a mixed (partially cross-topic and cross-genre) corpus in Spanish (PAN15-SP). More details of these corpora are provided in (Stamatatos et al., 2015).

### 6.2 Verification model

In this study, we use the authorship verification approach proposed by Potha and Stamatatos (2014). In more detail, this is a *profile-based* approach meaning that first it concatenates all available known documents and then it extracts a single representation from the resulting document (Stamatatos, 2009). The top  $L_k$   $n$ -grams of the known text are then compared to the top  $L_u$   $n$ -grams of

the unknown text and if the similarity is above a predefined threshold the unknown text is attributed to the author of the known texts. Note that parameters  $L_k$  and  $L_u$  essentially replace  $f_t$  that was used in previous experiments. All necessary parameters for this method, including  $n$  and  $k$  for the proposed method are estimated using the training part of each PAN corpus. Moreover, the most frequent words for each language are extracted from the corresponding training corpus.

### 6.3 Results

Table 6 shows the performance of the authorship verification models on the 10 PAN benchmark corpora based on the area under the Receiver-Operating-Characteristic curve (AUC-ROC). This evaluation measure was also used in PAN evaluation campaigns and the presented results can be directly compared to the ones reported by PAN organizers (Stamatatos et al., 2014; Stamatatos et al., 2015). In average, the proposed distortion-based models surpass the performance of the baseline models with both character  $n$ -gram and token  $n$ -gram features. The baseline model is better only in the case of the most challenging cross-genre PAN15-DU corpus. However, its performance essentially resembles random guessing (0.5). DV-SA models seem more competitive than DV-MA in the author verification task.

Table 6 also shows the performance of DV-Opt that corresponds to the best model (either DV-MA or DV-SA using either character or token  $n$ -grams) that can be selected by optimizing the performance (AUC-ROC) on the training corpus, separately for each one of the 10 corpora. The practice of using different models and settings per verification corpus is common in previous work (Seidman, 2013; Jankowska et al., 2014). As can be seen in Table 6, DV-Opt is better than any other single model in average performance and a one-tailed  $t$ -test shows that it is significantly better (at the 5% level) than both baseline models and DV-MA using character  $n$ -grams. The performance of DV-Opt is directly comparable to the results of PAN participants reported in (Stamatatos et al., 2014; Stamatatos et al., 2015) since the best models are selected based on information obtained from the training corpus. The last column of Table 6 compares DV-Opt with the overall winners of PAN-2014 (Khonji and Iraqi, 2014) and PAN-2015 (Bagnall, 2015). DV-Opt achieves better results in comparison to PAN

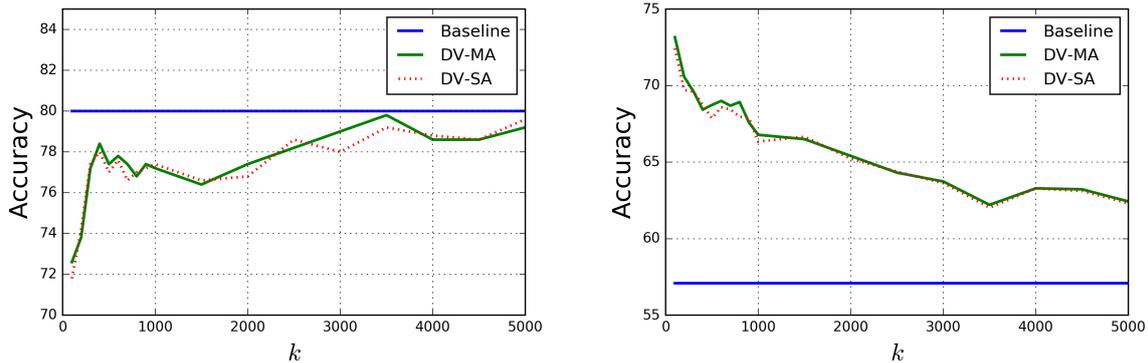

Figure 1: Performance of DV-MA, DV-SA, and baseline models based on character  $n$ -grams for fixed  $n = 4$  and  $f_t = 5$  and varying  $k$  values on CCAT-10 corpus (left) and the Guardian cross-topic corpus (right).

Corpus	Character $n$ -grams			Token $n$ -grams			DV-Opt	Diff. PAN Winner
	Baseline	DV-MA	DV-SA	Baseline	DV-MA	DV-SA

winners in two corpora (PAN14-DE and PAN14-EE) while its performance is notably worse than PAN winners in PAN14-GR, PAN15-DU, and PAN15-GR. It should be underlined that the verification method used in this paper is an *intrinsic* approach while both PAN-2014 and PAN-2015 winners followed an *extrinsic* approach (where additional documents by other authors are considered in order to transform the verification problem to a binary classification task). Extrinsic models tend to perform better (Stamatatos et al., 2015).

## 7 Conclusions

In this paper, we presented techniques of text distortion that can significantly enhance the robustness of authorship attribution methods in challenging cases where the topic of documents by the same author varies. The proposed algorithms transform texts into a form where topic information is compressed while textual structure related to personal style is maintained. These algorithms are language-independent, do not require compli-

cated resources, and can easily be combined with existing authorship attribution methods. Experimental results demonstrated a considerable gain in effectiveness when using the proposed models under the realistic cross-topic conditions in both closed-set attribution and author verification tasks. On the other hand, when the corpora are too topic-specific where the texts by a given author are consistently on certain subjects different than the ones of the other candidate authors, the distortion methods seem not to be helpful. Parameter  $k$  can be carefully adjusted to reflect topic properties of a given corpus.

More experiments are needed in the case of cross-genre conditions to estimate if the proposed method is also able to compress genre information and at the same time maintain properties related to personal style of authors. It would also be interesting to examine whether the distorted views of texts can be useful to other style-based text categorization tasks, including author profiling and genre detection.

# Structured Learning for Temporal Relation Extraction from Clinical Records

Artuur Leeuwenberg and Marie-Francine Moens

Department of Computer Science

KU Leuven, Belgium

{tuur.leeuwenberg, sien.moens}@cs.kuleuven.be

## Abstract

We propose a scalable structured learning model that jointly predicts temporal relations between events and temporal expressions (TLINKS), and the relation between these events and the document creation time (DCTR). We employ a structured perceptron, together with integer linear programming constraints for document-level inference during training and prediction to exploit relational properties of temporality, together with global learning of the relations at the document level. Moreover, this study gives insights in the results of integrating constraints for temporal relation extraction when using structured learning and prediction. Our best system outperforms the state-of-the-art on both the CONTAINS TLINK task, and the DCTR task.

## 1 Introduction

Temporal information is critical in many clinical areas (Combi and Shahar, 1997). A big part of this temporal information is captured in the free text of patient records. The current work aims to improve temporal information extraction from such clinical texts. Extraction of temporal information from clinical text records can be used to construct a time-line of the patient’s condition (such as in Figure 1). The extracted time-line can help clinical researchers to better select and recruit patients with a certain history for clinical trials. Moreover, the time-line is crucial for making a good patient prognosis and clinical decision support (Onisko et al., 2015; Stacey and McGregor, 2007).

Temporal information extraction can be divided into three sub-problems: (1) the detection of events ( $E_e$ ); (2) the detection of temporal expressions ( $E_t$ ); and (3) the detection of temporal rela-

tions between them. In the clinical domain, events include medical procedures, treatments, or symptoms (e.g. *colonoscopy*, *smoking*, *CT-scan*). Temporal expressions include dates, days of the week, months, or relative expressions like *yesterday*, *last week*, or *post-operative*. In this work, we focus on the last sub-problem, extraction of temporal relations (assuming events and temporal expressions are given). As a small example of the task we aim to solve, given the following sentence:

*In 1990 the patient was diagnosed and received surgery directly afterwards.*

in which we assume that the events *diagnosed* and *adenocarcinoma*, and the temporal expression *1990* are given, we wish to extract the following relations:

- CONTAINS(1990, diagnosed)
- CONTAINS(1990, surgery)
- BEFORE(diagnosed, surgery)
- BEFORE(diagnosed,  $d$ )
- BEFORE(surgery,  $d$ )

where  $d$  stands for the document creation time.

Our work leads to the following contributions: First, we propose a scalable structured learning model that jointly predicts temporal relations between events and temporal expressions (TLINKS), and the relation between these events and the document creation time (DCTR). In contrast to existing approaches which detect relation instances separately, our approach employs a structured perceptron (Collins, 2002) for global learning with joint inference of the temporal relations on a document level. Second, we ensure scalability through using integer linear programming (ILP)

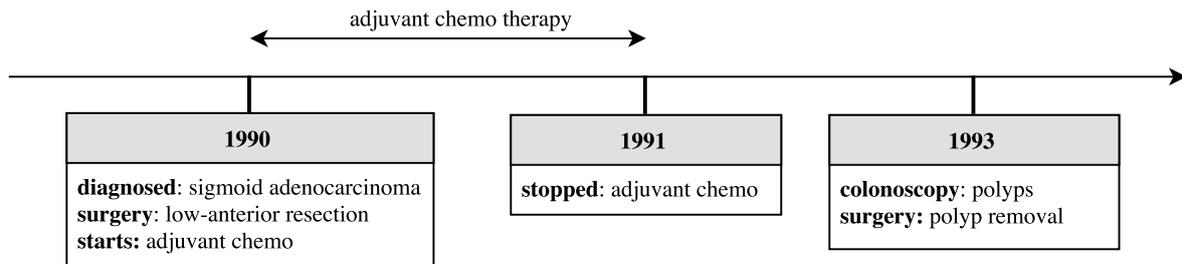

Figure 1: Fragment of a (partial) patient time-line.

constraints with fast solvers, loss augmented sub-sampling, and good initialization. Third, this study leads to valuable insights on when and how to make inferences over the found candidate relations both during training and prediction and gives an in-depth assessment of the use of additional constraints and global features during inference. Finally, our best system outperforms the state-of-the-art of both the CONTAINS TLINK task, and the DCTR task.

## 2 Related Work

There have been two shared tasks on the topic of temporal relation extraction in the clinical domain: the I2B2 Temporal Challenge (Sun et al., 2013), and more recently the Clinical TempEval Shared Task with two iterations, one in 2015 and one in 2016 (Bethard et al., 2014; Bethard et al., 2015; Bethard et al., 2016). In the I2B2 Temporal Challenge eight types of relations were initially annotated. However, due to low inter-annotator agreement these were merged to three types of temporal relations, OVERLAP, BEFORE, and AFTER. Good annotation of temporal relations is difficult, as annotators frequently miss relation mentions. In the Clinical TempEval Shared tasks the THYME corpus is used (Styler IV et al., 2014), with a different annotation scheme that aims at annotating those relations that are most informative w.r.t. the time-line, and gives less priority to relations that can be inferred from the others. This results in two categories of temporal relations: The relation between each event and the document creation time (DCTR), dividing all events in four temporal buckets (BEFORE, BEFORE/OVERLAP, OVERLAP, AFTER). These buckets are called narrative containers (Pustejovsky and Stubbs, 2011). And second, relations between temporal entities that both occur in the text (TLINKS). TLINKS may occur between events ( $E_e \times E_e$ ), and between events

and temporal expressions ( $E_e \times E_t$  and  $E_t \times E_e$ ). The TLINK types (and their relative frequency in the THYME corpus) are CONTAINS (64,42%), OVERLAP (15,19%), BEFORE (12,65%), BEGINS-ON (6.15%), and ENDS-ON (1.59%). The relations AFTER, and DURING are expressed in terms of their inverse, BEFORE, and CONTAINS respectively. In our experiments, we use the THYME corpus for its relatively high inter-annotator agreement (particularly for CONTAINS).

To our knowledge, in all submissions (4 in 2015, and 10 in 2016) of Clinical TempEval the task is approached as a classical entity-relation extraction problem, and the predictions for both categories of relations are made independently from each other, or in a one way dependency, where the containment classifier uses information about the predicted document-time relation. Narrative containment, temporal order, and document-time relation have very strong dependencies. Not modeling these may result in inconsistent output labels, that do not result in a consistent time-line.

An example of inconsistent labeling is given in Figure 2. The example is inconsistent when assigning the AFTER label for the relation between *lesion* and the document-time. It is inconsistent because we can also infer that *lesion* occurs BEFORE the document-time, as the *colonoscopy* event occurs before the document-time, and the *lesion* is contained by the *colonoscopy*.

Temporal inference, in particular *temporal closure*, is frequently used to expand the training data (Mani et al., 2006; Chambers and Jurafsky, 2008; Lee et al., 2016; Lin et al., 2016b), most of the times resulting in an increase in performance, and is also taken into account when evaluating the predicted labels (Bethard et al., 2014; UzZaman and Allen, 2011). Only very limited research regards the modeling of temporal dependencies into the machine learning model. (Chambers and Juraf-

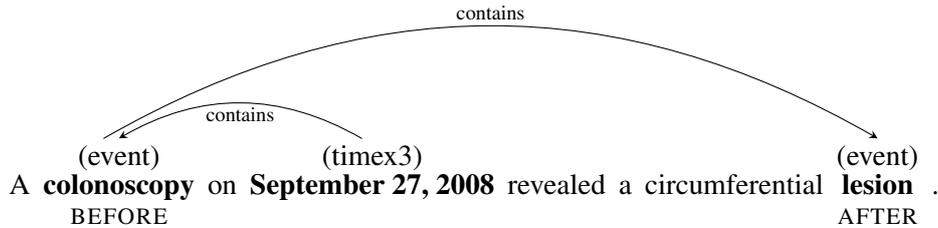

Figure 2: Example of inconsistent output labeling. Containment is indicated by directed edges, and the relation to the document-time by small caps below the events.

sky, 2008) and (Do et al., 2012) modeled label dependencies when predicting TimeBank TLINKS (Pustejovsky et al., 2003). They trained local classifiers and used a set of global temporal label constraints. Integer linear programming was employed to maximize the score from the local classifiers, while satisfying the global label constraints at prediction time. For both, this gave a significant increase in performance, and resulted in consistent output labels.

(Yoshikawa et al., 2009) modeled the label dependencies between TLINKS and DCTR with Markov Logic Networks (MLN), allowing for soft label constraints during training and prediction. However, MLN can sometimes be sub-optimal for text mining tasks w.r.t. time efficiency (Mojica and Ng, 2016). Quite recently, for a similar problem, spatial relation extraction, (Kordjamshidi et al., 2015) used an efficient combination of a structured perceptron or structured support vector machine with integer linear programming. In their experiments, they compare a local learning model (LO), a local learning model with global inference at prediction time (L+I), and a structured learning model with and without inference during training (IBT+I, and IBT-I respectively). In their experiments L+I gave better results than LO, but a more significant improvement was made when using structured learning in contrast to local learning.

In this work, we aim to jointly predict TLINKS and DCTR in a structured learning model with inference during training and prediction, to assess inference with temporal constraints of (Chambers and Jurafsky, 2008; Do et al., 2012) for the THYME relations, and to experiment with both local, and document-level inference for temporal information extraction in the clinical domain.

### 3 The Model

For jointly learning both tasks on a document level, we employ a structured perceptron learning paradigm (Collins, 2002). The structured perceptron model uses a joint feature function  $\Phi(X, Y)$  to represent a full input document  $X$  with a label assignment  $Y$ . During training the model learns a weight vector  $\lambda$  to score how good the label assignment is. Predicting label assignment  $Y$  for a document  $X$  corresponds to finding the  $Y$  with the maximal score. In the following sub-sections we define the joint feature function  $\Phi$ , describe the prediction procedure of the model, and provide how we train the model (i.e. learn a good  $\lambda$ ).

#### 3.1 Joint Features

To compose the joint feature function, we first define two local feature functions:  $\phi_{tl} : (x, y) \rightarrow \mathbb{R}^p$  assigns features for the local classifications regarding TLINKS (with possible labels  $L_{tl} = \{\text{CONTAINS, BEFORE, OVERLAP, BEGINS-ON, ENDS-ON, NO\_LABEL}\}$ ), and a second local feature function  $\phi_{dr} : (x, y) \rightarrow \mathbb{R}^q$ , for local features regarding document-time relation classification (with labels  $L_{dr} = \{\text{BEFORE, BEFORE\_OVERLAP, OVERLAP, AFTER}\}$ ). The features used by these local feature functions are given in Table 1.

From these, we define a joint feature function  $\Phi_{joint} : (X, Y) \rightarrow \mathbb{R}^{p+q}$ , that concatenates ( $\oplus$ ) the summed local feature vectors, creating the feature vector for the global prediction task (predicting all labels in the document for both sub-tasks at once).  $\Phi_{joint}$  is defined in Equation 1, where  $C_{tl}(X)$  and  $C_{dr}(X)$  are candidate generation functions for the TLINK sub-task, and DCTR sub-task respectively (further explained in Section 3.2).

Features	$\phi_{dr}$	$\phi_{tl}$
String features for tokens and POS of each entity	✓	✓
String features for tokens and POS in a window of size $\{3, 5\}$ , left and right of each entity	✓	✓
Boolean features for entity attributes (event polarity, event modality, event degree, and type)	✓	✓
String feature for the token and POS of the closest verb	✓	
String feature for the token and POS of the closest left and right entity	✓	
String features for the token $\{1, 2, 3\}$ -grams and POS $\{1, 2, 3\}$ -grams in-between the two entities		✓
Dependency path between entities (consisting of POS and edge labels)		✓
Boolean feature on if the first argument occurs before the second (w.r.t. word order)		✓

Table 1: Features of the local feature functions of each sub-task,  $\phi_{tl}$  for TLINKS, and  $\phi_{dr}$  for DCTR.

$$\Phi_{joint}(X, Y) = \sum_{x \in C_{dr}(X)} \sum_{l \in L_{dr}} \phi_{dr}(x, l) \oplus \sum_{x \in C_{tl}(X)} \sum_{l \in L_{tl}} \phi_{tl}(x, l) \quad (1)$$

### 3.2 Local Candidate Generation

For each document  $X$ , we create local candidates for both sub-tasks. In this work, we assume that event ( $E_e$ ) and temporal expression ( $E_t$ ) annotations are provided in the input. The DCTR-candidates in document  $X$  are then given by  $C_{dr}(X)$ , which returns all events in the document, i.e.  $E_e(X)$ .  $C_{tl}(X)$  returns all TLINK candidates, i.e.  $E_e(X) \cup E_t(X) \times E_e(X)$ . In our experiments we usually restrict the number of candidates generated by  $C_{tl}$  to gain training and prediction speed (without significant loss in performance). This is explained further in Section 4.3.

### 3.3 Global Features

We also experiment with a set of global features, by which we mean features that are expressed in terms of multiple local labels. The global features are specified in Table 2. Global features are defined by a feature function  $\Phi_{global}(X, Y) \rightarrow \mathbb{R}^r$  and have their corresponding weights in weight vector  $\lambda$ . When using global features  $\Phi_{global}$  is concatenated with the joint feature function  $\Phi_{joint}$  to form the final feature function  $\Phi$ , as shown in Equation 2.

$$\Phi(X, Y) = \Phi_{joint}(X, Y) \oplus \Phi_{global}(X, Y) \quad (2)$$

When not using global features, we use only the joint features, as shown in Equation 3.

$$\Phi(X, Y) = \Phi_{joint}(X, Y) \quad (3)$$

Feature	Description
$\Phi_{sdr}$	Bigram and trigram counts of subsequent DCTR-labels in the document
$\Phi_{drtl}$	Counts of DCTR-label pairs of the entities of each TLINK

Table 2: Global (document-level) features.

### 3.4 Prediction

The model assigns a score to each input document  $X$  together with output labeling  $Y$ . The score for  $(X, Y)$  is defined as the dot product between the learned weight vector  $\lambda$  and the outcome of the joint feature function  $\Phi(X, Y)$ , as shown in Equation 4.

$$S(X, Y) = \lambda \Phi(X, Y) \quad (4)$$

The prediction problem for an input document  $X$  is finding the label assignment  $Y$  that maximizes the score  $S$  based on the weight vector  $\lambda$ , shown in Equation 5.

$$\hat{Y}_k = \arg \max_Y S(X, Y) \quad (5)$$

We use integer linear programming (ILP) to solve the prediction problem in Equation 5. Each possible local decision is modeled with a binary decision variable. For each local relation candidate input  $x_{i,j}$  (for the relation between  $i$  and  $j$ ) a binary decision variable  $w_{i,j}^l$  is used for each potential label  $l$  that could be assigned to  $x_{i,j}$ , depending on the sub-task. The objective of the integer linear program, given in Equation 6, is to maximize the sum of the scores of local decisions. In all equations the constant  $d$  refers to the document-creation time. The objective is maximized under two sets of constraints, given in Equations 7 and 8, that express that each candidate is assigned ex-

actly one label, for each sub-task.

$$O = \arg \max_W \sum_{x_{i,d} \in C_{dr}(X)} \sum_{l \in L_{dr}} w_{i,d}^l \cdot S(x_{i,d}, y_{i,d}^l) + \sum_{x_{i,j} \in C_{tl}(X)} \sum_{l \in L_{tl}} w_{i,j}^l \cdot S(x_{i,j}, y_{i,j}^l) \quad (6)$$

$$\forall_i : \sum_{l \in L_{dr}} w_{i,d}^l = 1 \quad (7)$$

$$\forall_{i,j} : \sum_{l \in L_{tl}} w_{i,j}^l = 1 \quad (8)$$

For solving the integer linear program we use Gurobi (Gurobi Optimization, 2015).

### 3.4.1 Temporal Label Constraints

Because temporal relations are interdependent, we experimented with using additional constraints on the output labeling. The additional temporal constraints we experiment with are shown in Table 3. Constraints are expressed in terms of the binary decision variables used in the integer linear program.

In Table 3, constraints  $\mathcal{C}_{Ctrans}$ , and  $\mathcal{C}_{Btrans}$  model transitivity of CONTAINS, and BEFORE respectively. Constraints  $\mathcal{C}_{CBB}$ , and  $\mathcal{C}_{CAA}$  model the consistency between TLINK relation CONTAINS and DCTR relations BEFORE, and AFTER respectively (resolving the inconsistent example of  $\mathcal{C}_{CBB}$  in section 1, and Figure 2). Similarly,  $\mathcal{C}_{BBB}$ , and  $\mathcal{C}_{BAA}$  model the consistency between TLINK relation BEFORE and DCTR relations BEFORE, and AFTER.

Constraints can be applied during training and prediction, as Equation 5 is to be solved for both. If not mentioned otherwise, we use constraints both during training and prediction.

## 3.5 Training

The training procedure for the averaged structured perceptron is given by Algorithm 1, for  $I$  iterations, on a set of training documents  $T$ . Notice that the prediction problem is also present during training, in line 6 of the algorithm. Weight vector  $\lambda$  is usually initialized with ones, and updated when the predicted label assignment  $\hat{Y}_k$  for input document  $X_k$  is not completely correct. The structured perceptron training may suffer from overfitting. Averaging the weights over the training examples of each iteration is a commonly used way to counteract this handicap (Collins, 2002; Freund

and Schapire, 1999). In Algorithm 1,  $c$  is used to count the number of training updates, and  $\lambda_a$  as a cache for averaging the weights. We also employ local loss-augmented negative sub-sampling, and local pre-learning to address class-imbalance and training time.

---

### Algorithm 1 Averaged Structured Perceptron

---

**Require:**  $\lambda, \lambda_a, c, I, T$   
1:  $c \leftarrow 0$   
2:  $\lambda \leftarrow \langle 1, \dots, 1 \rangle$   
3:  $\lambda_a \leftarrow \langle 1, \dots, 1 \rangle$   
4: **for**  $i$  in  $I$  **do**  
5:   **for**  $k$  in  $T$  **do**  
6:      $\hat{Y}_k \leftarrow \arg \max_Y \lambda \Phi(X_k, Y)$   
7:     **if**  $\hat{Y}_k \neq Y_k$  **then**  
8:        $\lambda \leftarrow \lambda + \Phi(X_k, Y_k) - \Phi(X_k, \hat{Y}_k)$   
9:        $\lambda_a \leftarrow \lambda_a + c \cdot \Phi(X_k, Y_k) - c \cdot \Phi(X_k, \hat{Y}_k)$   
10:      $c \leftarrow c + 1$   
**return**  $\lambda - \lambda_a / c$

---

### 3.5.1 Loss-augmented Negative Sub-sampling

For the TLINK sub-task, we have a very large negative class (NO\_LABEL) and a relatively small positive class (the other TLINK labels) of training examples. To speed up training convergence and address class imbalance at the same time, we sub-sample negative examples during training. Within a document  $X$ , for each positive local training example  $(x_{positive}, y_{positive})$  we take 10 random negative examples and add the negative example  $(x_{negative}, y_{no\_label})$  with the highest score for relation  $y_{positive}$ , i.e.  $S(x_{negative}, y_{positive})$ . This cutting plane optimization gives preference to negative training examples that are more likely to be classified wrongly, and thus can be learned from (in an online manner), and it provides only one negative training example for each positive training example, balancing the TLINK classes.

### 3.5.2 Local Initialization

To reduce training time, we don't initialize  $\lambda$  with ones, but we train a perceptron for both local sub-tasks, based on the same local features mentioned in Table 1, and use the trained weights to initialize  $\lambda$  for those features. A similar approach was used by (Weiss et al., 2015) for dependency parsing. Details on the training parameters of the perceptron are given in Section 4.3.

## 4 Experiments

We use our experiments to look at the effects of four modeling settings.

Abbrev.	Label Dependencies	Constraints
$\mathcal{C}_{Ctrans}$	$\text{CONTAINS}_{i,j} \wedge \text{CONTAINS}_{j,k} \rightarrow \text{CONTAINS}_{i,k}$	$\forall_{i,j,k} : w_{i,k}^{\text{contains}} - w_{i,j}^{\text{contains}} - w_{j,k}^{\text{contains}} \geq -1$
$\mathcal{C}_{Btrans}$	$\text{BEFORE}_{i,j} \wedge \text{BEFORE}_{j,k} \rightarrow \text{BEFORE}_{i,k}$	$\forall_{i,j,k} : w_{i,k}^{\text{before}} - w_{i,j}^{\text{before}} - w_{j,k}^{\text{before}} \geq -1$
$\mathcal{C}_{CBB}$	$\text{CONTAINS}_{i,j} \wedge \text{BEFORE}_{i,d} \rightarrow \text{BEFORE}_{j,d}$	$\forall_{i,j} : w_{j,d}^{\text{before}} - w_{i,j}^{\text{contains}} - w_{i,d}^{\text{before}} \geq -1$
$\mathcal{C}_{CAA}$	$\text{CONTAINS}_{i,j} \wedge \text{AFTER}_{i,d} \rightarrow \text{AFTER}_{j,d}$	$\forall_{i,j} : w_{j,d}^{\text{after}} - w_{i,j}^{\text{contains}} - w_{i,d}^{\text{after}} \geq -1$
$\mathcal{C}_{BBB}$	$\text{BEFORE}_{i,j} \wedge \text{BEFORE}_{j,d} \rightarrow \text{BEFORE}_{i,d}$	$\forall_{i,j} : w_{i,d}^{\text{before}} - w_{i,j}^{\text{before}} - w_{j,d}^{\text{before}} \geq -1$
$\mathcal{C}_{BAA}$	$\text{BEFORE}_{i,j} \wedge \text{AFTER}_{i,d} \rightarrow \text{AFTER}_{j,d}$	$\forall_{i,j} : w_{j,d}^{\text{after}} - w_{i,j}^{\text{before}} - w_{i,d}^{\text{after}} \geq -1$

Table 3: Temporal label dependencies expressed as integer linear programming constraints. The variables  $i, j$  and  $k$  range over the corresponding TLINK arguments, and constant  $d$  refers to the document-creation-time.  $\text{CONTAINS}_{i,j}$  indicates that entity  $i$  contains entity  $j$ .

1. Document-level learning in contrast to pairwise entity-relation learning.
2. Joint learning of DCTR and TLINKS.
3. Integrating temporal label constraints.
4. Using global structured features.

We will discuss our results in Section 4.4. But first, we describe how we evaluate our system, and provide information on our baselines, and the pre-processing and hyper-parameter settings used in the experiments.

#### 4.1 Evaluation

We evaluate our method on the clinical notes test set of the THYME corpus (Styler IV et al., 2014), also used in the Clinical TempEval 2016 Shared Task (Bethard et al., 2016). Some statistics about the dataset can be found in Table 4. F-measure is used as evaluation metric. For this we use the evaluation script from the Clinical TempEval 2016 Shared Task. TLINKS are evaluated under the temporal closure (UzZaman and Allen, 2011).

Section	Documents	TLINKS	EVENTS
Train	440	17.109	38.872
Test	151	8.903	18.989

Table 4: Dataset statistics for the THYME sections we used in our experiments.

#### 4.2 Baselines

Our first baseline is a perceptron algorithm, trained for each local task using the same local features as used to compose the joint feature function  $\Phi_{joint}$  of our structured perceptron. We have

two competitive state-of-the-art baselines, one for the DCTR sub-task, and one for the TLINK sub-task. The first baseline is the best performing system of the Clinical TempEval 2016 on the DCTR task (Khalifa et al., 2016). They experiment with a feature rich SVM and a sequential conditional random field (CRF) for the prediction of DCTR and report the – to our knowledge – highest performance on the DCTR task. The competitive TLINK baseline is the latest version of the cTAKES Temporal system (Lin et al., 2016b; Lin et al., 2016a). They employ two SVMs to predict TLINKS, one for TLINKS between events, and one for TLINKS between events and temporal expressions and recently improved their system by generating extra training data using extracted UMLS concepts. They report the – to our knowledge – highest performance on CONTAINS TLINKS in the THYME corpus.

#### 4.3 Hyper-parameters and Preprocessing

In all experiments, we preprocess the text by using a very simple tokenization procedure considering punctuation<sup>1</sup> or newline tokens as individual tokens, and splitting on spaces. For our part-of-speech (POS) features, and dependency parse path features, we rely on the cTAKES POS tagger and cTAKES dependency parser respectively (Savova et al., 2010). After POS tagging and parsing we lowercase the tokens. As mentioned in Section 3.2, we restrict our TLINK candidate generation in two ways. First, both entities should occur in a token window of 30, selected from  $\{20, 25, 30, 35, 40\}$  based on development set performance. And second, both entities should occur in the same paragraph (paragraphs are separated

<sup>1</sup>,./\ "' =+ - ; : ( ) ! ? < > % & \$ \* [ ] { }

by two consecutive newlines). Our motivation for not using sentence based candidate generation is that the clinical records contain many ungrammatical phrases, bullet point enumerations, and tables that may result in missing cross-sentence relation instances (Leeuwenberg and Moens, 2016). In all experiments, we train the normal perceptron for 8 iterations, and the structured perceptron for 32 iterations, both selected from  $\{1, 2, 4, 8, 16, 32, 64\}$  based on best performance on the development set. The baseline perceptron is also used for the initialization of the structured perceptron. Moreover, we apply the transitive closure of CONTAINS, and BEFORE on the training data.

## 4.4 Results

Our experimental results on the THYME test set are reported in Table 5. In the table, the abbreviation SP refers to the structured perceptron model described in Section 3 but without temporal label constraints or global features, i.e. the joint document-level unconstrained structured perceptron, using local initialization, and loss-augmented negative sub-sampling. We compare this model with a number of modified versions to explore the effect of the modifications.

### 4.4.1 Document-Level Learning

When we compare the local perceptron baseline with any of the document-level models (any SP variation), we can clearly see that learning the relations at a document-level improves our model significantly<sup>2</sup> ( $P < 0.0001$  for both DCTR and TLINKS). Furthermore, when comparing loss-augmented sub-sampling (SP) with random sub-sampling of negative TLINKS (SP<sub>random sub-sampling</sub>) it can be seen that a good selection of negative training instances is very important for learning a good model (again  $P < 0.0001$ ), and resulted in our model to improve the state-of-the-art by 1.4 on the CONTAINS TLINK task<sup>3</sup>.

### 4.4.2 Jointly Learning DCTR and TLINKS

When comparing the disjoint model (SP<sub>disjoint</sub>) with our joint model (SP) it can be noticed that joint prediction gives only a very small improvement ( $P = 0.0768$  for TLINKS, and  $P = 0.0451$  for

DCTR). However, joint learning on a document level provides the flexibility to formulate constraints connecting the labels of both tasks, such as the last four constraints in Table 3, resulting in a more consistent labeling over both tasks. Similarly, in the joint learning setting, we can define global features that connect both tasks (like  $\Phi_{drtl}$ ).

### 4.4.3 Integrating Temporal Constraints

We experimented with integrating label constraints in two ways (1) both during training and prediction (SP<sup>cc</sup> +  $\mathcal{C}_*$ ), or (2) only during prediction (SP<sup>uc</sup> +  $\mathcal{C}_*$ ). In general it can be noticed that in our experiments using the temporal label constraints from Table 3 slightly increases DCTR performance, but slightly decreases TLINK performance. A reason for this can be that the model generally gives better predictions for DCTR, that might result in providing a better alternative to a constraint violating solution. A difference in consistency of the annotation between both tasks could also be a reason. Furthermore, we can see that integrating the constraints both during training and prediction gives slightly lower performance compared only integrating them during prediction.

### 4.4.4 Using Global Structured Features

We have two types of features,  $\Phi_{sdr}$ , which is only based on DCTR labels, and  $\Phi_{drtl}$ , which is based on a combination of DCTR and TLINK labels. When we add  $\Phi_{sdr}$  to our model, the overall F-measure on the DCTR task improves with 1.3 points ( $P < 0.0001$ ), improving the state-of-the-art by 0.3 points. A reason for this can be the sequential dependency of DCTR labels, also exploited by (Khalifa et al., 2016), using the sequential CRF. The second global feature,  $\Phi_{drtl}$ , in fact models the same type of dependencies as the last four constraints in Table 3, relating the TLINK relations with the DCTR labels of each TLINK argument, however as a soft dependency and not as a hard constraint. In our experiments, this feature did not improve either of the two sub-tasks. It appears that training with cross-task constraints, or global cross-task features is not trivial, and further research is needed on how to exploit these cross-task dependencies also during training. We assume that the lower-than-expected scores when modeling cross-task dependencies may be related to sub-sampling the negative TLINK training instances.

<sup>2</sup>Significance is based on a document-level paired t-test.

<sup>3</sup>Only CONTAINS is generally reported for the THYME corpus, as the other TLINKS are less frequent, and the inter-annotator agreement for them is very low. We included them just for completeness in our experiments.

System	$F_{\text{BEFORE}}^{\text{DCTR}}$	$F_{\text{AFTER}}^{\text{DCTR}}$	$F_{\text{OVERLAP}}^{\text{DCTR}}$	$F_{\text{BEFORE/OVERLAP}}^{\text{DCTR}}$	$F_{\text{ALL}}^{\text{DCTR}}$	$F_{\text{CONTAINS}}^{\text{TLINK}}$	$F_{\text{BEFORE}}^{\text{TLINK}}$	$F_{\text{OVERLAP}}^{\text{TLINK}}$	$F_{\text{BEGINS-ON}}^{\text{TLINK}}$	$F_{\text{ENDS-ON}}^{\text{TLINK}}$	$F_{\text{ALL}}^{\text{TLINK}}$

Table 5: Results on the THYME test set. SP refers to our structured perceptron model, without constraints or global features, using local initialization and loss-augmented negative sub-sampling.  $\mathcal{C}_*$  refers to using all constraints. Superscript CC and UC refer to using constraints at training and prediction time, or only at prediction time respectively.

## 5 Conclusions

In this work, we proposed a structured perceptron model for learning temporal relations between events and the document-creation time (DCTR), and between temporal entities in the text (TLINKS) in clinical records. Our model efficiently learns and predicts at a document level, exploiting loss-augmented negative sub-sampling, and uses global features allowing it to exploit relations between local output labels. For construction of a consistent output labeling, needed for time-line construction, we formulated a number of constraints, including those from (Chambers et al., 2007; Do et al., 2012), and assessed them during inference. Our best system outperforms the state-of-the-art of both the CONTAINS TLINK task, and the DCTR task. Our code for this work is available at <https://github.com/tuur/SPTempRels>.

## Acknowledgment

The authors would like to thank the reviewers for their constructive comments which helped us to improve the paper. Also, we would like to thank the Mayo Clinic for permission to use the THYME corpus. This work was funded by the KU Leuven C22/15/16 project "MACHINE READING OF PATIENT RECORDS (MARS)", and by the IWT-SBO 150056 project "ACQUIRING CRUCIAL MEDICAL INFORMATION USING LANGUAGE TECHNOLOGY" (AC-CUMULATE).

## Abstract

Text mining has drawn significant attention in recent past due to the rapid growth in biomedical and clinical records. Entity extraction is one of the fundamental components for biomedical text mining. In this paper, we propose a novel approach of feature selection for entity extraction that exploits the concept of deep learning and Particle Swarm Optimization (PSO). The system utilizes word embedding features along with several other features extracted by studying the properties of the datasets. We obtain an interesting observation that compact word embedding features as determined by PSO are more effective compared to the entire word embedding feature set for entity extraction. The proposed system is evaluated on three benchmark biomedical datasets such as GENIA, GENETAG and AiMed. The effectiveness of the proposed approach is evident with significant performance gains over the baseline models as well as the other existing systems. We observe improvements of 7.86%, 5.27% and 7.25% F-measure points over the baseline models for GENIA, GENETAG, and AiMed dataset respectively.

## 1 Introduction

The tremendous amount of information accumulated in the domains of molecular biology has drawn the attention of biomedical natural language processing (BioNLP) community in order to facilitate the development of various tools for various text processing applications, curation and organization of ever-growing biomedical literature etc. Entity extraction is crucial step for solving

several pipelined applications such as information extraction, automatic summarization, question-answering, word sense disambiguation etc. Biomedical entities mostly refer to the biological sequences of protein & gene such as DNA, RNA, cell\_type, cell\_line etc. (Kim et al., 2004). The way of extracting these information from biomedical and clinical texts refers to as entity extraction. An automatic system which can extract biomedical names such as gene, protein or any disease name from text can substantially reduce the human efforts. However, extracting these entities from text poses several challenges which are presented as follows:

1. Named entities are very generative in nature, i.e. many new names are continuously being generated. Any dictionary can not capture all the various forms of a given name.
2. Similar words convey different meanings, and therefore, a word can have multiple NE types. For example, gene names often contain alphabets, digits, hyphens, and other characters, thus having many variants (e.g., “HIV-1 enhancer” versus “HIV 1 enhancer”). Moreover, many abbreviations (e.g., “IL2” for “Interleukin 2”) constitute integral parts of biomedical named entities (NEs).
3. Biomedical names are usually of long length, and contains different types of symbols, and hence boundary detection becomes problematic.
4. Ambiguity: Same name could be used to represent variety of biological entities which further worsen the problem.

The challenges as of these kinds are the primary causes behind the low accuracies of the systems developed for entity extraction in biomed-

cal text. The research challenges have been addressed in the literature including in some shared-task challenges, such as JNLPBA (Joint Workshop on Natural Language Processing in Biomedicine and its Applications) in 2004 (Kim et al., 2004) and BioCreative (Critical Assessment for Information Extraction in Biology Challenge) II GM (gene mention) subtask in 2007 (Smith et al., 2008). Over the years several benchmark corpora have been created that do not conform to the uniform annotation guidelines. Therefore the system, developed by targeting a specific domain, often fails to show reasonable accuracy when it is evaluated for some other domains. In our work we attempt to build a system for entity extraction that performs well across various biomedical corpora.

Popular existing system mostly rely on rule-based system or supervised machine learning technique to automatically extract entities. They looked upon this problem as in terms of sequence labeling and used algorithm such as hidden markov models (HMM) (Zhao, 2004), support vector machines (SVM) (Kazama et al., 2002; GuoDong and Jian, 2004), maximum entropy Markov model (MEMM) (Finkel et al., 2005) and conditional random fields (CRF) (Ekbal et al., 2013; Settles, 2004; Kim et al., 2005). These supervised learning models is fully dependent on the features that we use for training. Some of the popular features used in the existing studies include linguistic features such as morphological, syntactic and semantic information of words and domain-specific features from biomedical ontologies such as Bio-Thesaurus (Liu et al., 2006) and UMLS (Unified Medical Language System) (Bodenreider, 2004). However, these features heavenly account to the problem of data sparsity.

In the recent past, there has been huge interest in using large unlabeled corpus to generate word representation feature using deep neural network technique. We are motivated by the strength of deep learning concepts to build our model. We use the well-known word embedding model that is a robust framework to incorporate word representation features (Mikolov et al., 2013b). Word representation feature is a mathematical description of the word in vector form. Each position of vector corresponds to a feature with some semantic or grammatical inference which leads to the term word feature. Word representation features contains latent syntactic/semantic informa-

tion of a word. The main objective to use word embedding is to provide more useful information to the model being trained. Vector based word representation has powerful capability that captures the phenomenon that words having the similar meanings should appear together (Mikolov et al., 2013b). In traditional machine learning, data sparsity is a problem that often causes the degradation in performance. This drawback could be overcome by the incorporation of word embedding with the presumption that similar type of word (as to semantics) appear in the similar context (Mikolov et al., 2013b).

The aim is to exploit the usefulness of neural network based word embedding (Bengio et al., 2003) as a feature for entity extraction in biomedical text. In addition we also make use of a very diverse feature set that exploits the properties of data and problem specific knowledge. We restrict ourselves from using much domain-specific information for feature extraction, keeping in view easy adaptability of the system to more than one biomedical corpora.

However, the huge dimensionality of the word representation vector often contributes to the complexity of the system. This motivated us to apply feature selection technique to reduce the dimensionality contributed by word embedding as well as to improve the system performance. Our algorithm for feature selection is based on wrapper based approach, which is formulated as an optimization problem. We use Particle Swarm Optimization(PSO) (Kennedy and Eberhart, 1997) as the underlying optimization strategy. Particle Swarm Optimization is an evolutionary technique, inspired by the social behavior of birds. Some recent studies show that PSO converges faster compared to some other widely used optimization techniques (Bansal et al., 2011). Inspired by this observation we use PSO in our current study.

To analyze the effect of pruned word embedding, we have carried out an experiment with all the handcrafted features and the reduced features as determined by PSO. We perform experiments on three standard datasets, namely GENIA, GENE-TAG and AiMed. Evaluation results show that we achieve significant performance gains with the use of pruned word embedding feature set. The best performance of the system was obtained when we apply PSO based feature selection technique on combination of handcrafted features set and word

embedding features. The key contribution of this paper are, (i) proposal of PSO based feature selection technique in bio-medical entity extraction. (ii) analysis of feature selection on only word representation features. (iii) impact of feature selection on word representation features with hand-craft features.

## 2 Related Works

There has been quite a significant number of existing works available for biomedical named entity recognition (BNER). These approaches can be divided into three major categories: (1) dictionary based, (2) rule based and (3) machine learning based techniques. Among these existing approaches, machine learning based techniques have gained a lot more attention due to the availability of sufficiently good amount of annotated corpus. For example, majority of the systems submitted to the JNLPBA challenge made use of machine learning algorithms which have been observed to significantly outperform the dictionary based methods.

Some of the recent works in BNER includes the unsupervised model as proposed in (Zhang and Elhadad, 2013), and the system based on CRF (Li et al., 2015a). A two-phase approach based on semi-Markov CRF is proposed in (Yang and Zhou, 2014). In the first phase boundaries of entities are identified while in the second phase semantic labeling is performed to label the detected entities. A CRF based system has been proposed by (Tang et al., 2015), where in the first step boundaries of NERs are identified and in the second step appropriate labels are assigned. (Grouin, 2014) performed experiments on the i2b2/VA-2010 challenge dataset to detect bacteria and biotopes names. They developed a model based on CRFs. An unsupervised approach is proposed in (Han et al., 2016) that made use of clustering based active learning. They have used Shared Nearest Neighbor (SNN) clustering technique. The work reported in (Li et al., 2015a), authors have proposed a parallel CRF algorithm (MapReduce CRF) which provides a mechanism to minimise the time taken for CRF learning. They showed that the proposed approach outperforms other traditional models in terms of time and efficiency. While, most of the proposed system used CRF, recently (Patra and Saha, 2013) proposed an entity extraction system based on SVM. Par-

ticularly, they have introduced a tree kernel based function that can efficiently solve the full NER task. The work proposed in (Tohidi et al., 2014) aims to improve the performance of entity extraction using statistical character-based syntax similarity (SCSS) algorithm. This algorithm computes the similarity between the identified candidate entities and a known set of well-known NERs. This set of NERs is created by extracting the most frequently occurring NERs in the GENIA V3.0 corpus. In recent times deep learning based approaches such as Recurrent Neural Network and Bi-directional LSTM have also used for entity extraction (Li et al., 2015b; Limsopatham and Collier, 2016). It is well known that relevant features play an important role for building a high accurate system. In our work, in addition to the standard features we also use the features extracted from the word embedding model.

Bengio et al. (Bengio et al., 2003) have proposed a neural network based model for vector representation of words. Distributed representation (also known as word embedding) of a word has been used to improve the performance of various NLP tasks like Part-of-Speech (POS) tagging, NER in news-wire domain (Collobert et al., 2011), parsing (Socher et al., 2013; Turian et al., 2010) etc. Word cluster has been used by Miller et al. (Miller et al., 2004) to boost the performance of a NER system. Tang et al. (Tang et al., 2012; Tang et al., 2013) have reported that performance of biomedical entity extraction can be improved when word representation is used as a feature to CRF and SVM classifiers.

Here we propose a PSO based feature selection technique that determines the most relevant features from a full word embedding set, and use this subset as feature for classifier's training. Feature selection has been widely used for many tasks such as gene expression (Ding and Peng, 2005), face recognition (Seal et al., 2015) and signal processing (Alamedine et al., 2013). Dealing with biomedical text is, however, more difficult and challenging as the features have non-numeric values and the texts are heavily unstructured. Except the few works such as NER (Ekbal and Saha, 2016), co-reference resolution (Sikdar et al., 2015) and sentiment analysis (Gupta et al., 2015), systematic methods of feature selection using meta-heuristics algorithms are very rare. Nevertheless, the importance of using pruned neural language

model based word representation features with effective feature selection have not been exploited so far in the literature.

## 2.1 A Brief Introduction to Particle Swarm Optimization (PSO)

Particle Swarm Optimization (PSO) is a meta-heuristic intelligent technique inspired by social behavior of the swarm for its survival (Eberhart and Shi, 1998; Kennedy and Eberhart, 1997). This is a population based technique which is perceived in birds and fishes for the search of the best path. In general, PSO consists of the swarm of the particle where each particle has its particular position in the search space with which it moves around the search space by some velocity. The particle selects the best path on each iteration by using its memory and by learning the effective path that was followed previously by the swarm. The new position is chosen on the basis of the knowledge gained previously by its self-best position and the best position of the swarm. PSO, being a meta-heuristic model, makes few or no assumption about the problem being optimized and can search very large spaces of candidate solutions. This makes PSO highly efficient for the optimization purpose (Yan et al., 2013). The algorithm iterates by keeping track of two variables: Global best position represents the most promising vector found so far, and Personal best position denotes the particle's own personal best solution.

### 2.1.1 Algorithm: PSO based Feature Selection

1. Initially, we randomly set the swarm population. Each particle of the swarm is represented by binary-valued features of length  $n$  (total no. of feature) and has its position and velocity with which it moves in search space. Mathematically, particle position and particle velocity are represented as:  $\vec{P}(i)$  and  $\vec{V}(i)$  respectively:

$$\vec{P}(i) = (p(i, 1), p(i, 2), \dots, p(i, n))$$

$$\vec{V}(i) = (v(i, 1), v(i, 2), \dots, v(i, n))$$

where  $p(i, j) \in \{0, 1\}$ ,  $i = 1, 2, \dots, N$  and  $j = 1, 2, \dots, n$  where  $N$  is no. of particle. Particle maintains its best position ( $\vec{B}(i)$ ) that they have achieved so far and also the global best position ( $\vec{G}$ ) i.e., the best position of the particle having the best solution.

2. Particle's position  $\vec{P}(i)$  value is set either  $\{0, 1\}$  on the basis of following expression:

$$p_{(i,j)} = \begin{cases} 1 & \text{if } random \geq 0.5 \\ 0 & \text{otherwise} \end{cases}$$

3. Each particle is evaluated on the basis of fitness function (F-measure value)  $f(\vec{P}(i))$ . The memory is updated by keeping track of the best position and global best position.
4. Initially, the value of best position ( $\vec{B}(i)$ ) of every particle is set to 0. At every epoch(ep) the value of the best position is updated as follows:

$$f(\vec{B}(i))_{ep} = \max(f(\vec{P}(i))_{ep}, f(\vec{B}(i))_{ep-1})$$

5. Update in the global best position value is done when the fitness function  $f(\vec{B}(i))$  in the swarm is superior than the existing  $f(\vec{G})$ .
6. Originally, the velocity vector is generated randomly. At each iteration, velocity of a particle is updated according to the following equation:

$$v_{(i,j)} = \omega * v_{(i,j)} + \phi_1(b_{(i,j)} - p_{(i,j)}) + \phi_2(g_{(j)} - p_{(i,j)}) \quad (1)$$

where  $\omega$  ( $0 < \omega < 1$ ),  $\phi_1$  and  $\phi_2$  are known as inertia weights. These parameters are initialized with an uniformly generated random numbers in the range (0,1). The  $b_{(i,j)}$ ,  $p_{(i,j)}$ , and  $g_{(j)}$  denote the  $j^{th}$  components of  $\vec{B}(i)$ ,  $\vec{P}(i)$  and  $\vec{G}$ , respectively.

7. The position of a particle is updated by the following mathematical expression:

$$p_{(i,j)} = \begin{cases} 1 & \text{if } (random < S(v_{(i,j)})) \\ 0 & \text{otherwise} \end{cases}$$

where  $0 \leq random \leq 1$  is an uniform random number.

$$S(v_{(i,j)}) = \frac{1}{1 + \exp(-v_{(i,j)})}$$

This represents the sigmoid function. Thus, we update the particle position value of 0 or 1 on the basis of the value of velocity.

8. Repeat steps 4-7 until convergence.

## 2.2 Learning Word Representations

Word embedding (also known as distributed word representations) persuade a real-valued latent semantic or syntactic vector for each word from a large unlabeled corpus by using continuous space language models (Tang et al., 2014). Better word representation can be obtained if we have a large amount of training data as the obtained real-valued vectors of words become more representative. We use the popular *word2vec*<sup>1</sup> tool proposed by Mikolov et al. (Mikolov et al., 2013a) to extract the vector representations of words. Owing to its simpler architecture which reduces the computational complexity, this technique can be used for large corpus. Two models have been proposed in (Mikolov et al., 2013a) to learn vector representation known as Continuous Bag-of-Words Model (CBOW) and Skip-gram model. Since skip-gram model is able to capture the semantic information of a word, we adapt this to train the model for vector representation. The Skip-gram architecture tries to maximize the classification of a word based on the other words in the same sentence. More formally, given a sequence of training words  $w_1, w_2, \dots, w_T$ , the objective of the Skip-gram model is to maximize the average log probability

$$\frac{1}{T} \sum_{t=1}^T \sum_{\substack{-c \leq j \leq c \\ j \neq 0}} \log p(w_{t+j}|w_t) \quad (2)$$

where  $c$  is the window size. Here, we show few words that are more nearby to any biomedical entity: ‘antigen’, ‘lymphocytes’ and ‘inhibited’. If we look at the most similar words for the word ‘lymphocytes’, we observe that apart from syntactically similar words like ‘T-lymphocytes’, ‘B-lymphocytes’, it is also able to capture the words which are semantically similar like ‘CD3+’, ‘PBLs’ and ‘T-cells’.

## 3 Features for Entity Extraction

The features being extracted are described as follows:

1. Contextual feature: It is the local contextual feature which refers to the tokens which appear within the window size of 10 words, i.e 5 to the left and 5 to the right w.r.t current token.

<sup>1</sup><https://code.google.com/p/word2vec/>

2. Word prefixes and suffixes: These features refer to the fixed length character sequences stripped either from the left or rightmost positions of the words.
3. Word length: It is observed that short words are rarely the NEs. We define a binary-valued feature that triggers the value 1 if the length of current word is greater than the threshold value specified. The threshold value is set as 5 in this case.
4. Part-of-Speech (PoS) information: PoS provides useful syntactic evidence for detecting named entities (NEs). We use PoS information of the current and/or the surrounding token(s) as the feature. The PoS information was extracted from the GENIA tagger<sup>2</sup> V2.0.2.
5. Chunk information: We use GENIA tagger V2.0.2 corpus to extract the chunk information. We employ the chunk information of the present and neighboring tokens as the features.
6. Word shape: Word shape is defined as the mapping of each word to its equivalent class. In order to implement this feature we normalize the words by converting every capital character by ‘A’, small character to ‘a’ and digit to ‘0’. After this conversion, we squeeze the consecutive characters into a single character. For example, if we consider the token ‘Ly-49’, the normalized word for this token would be ‘Aa-00’.
7. Word class feature : This feature is based on the concept that entities present in the same class are mostly similar. Here, all the capital letters are converted to ‘A’, small letters to ‘a’, numbers to ‘O’ and non-English characters to ‘-’. After this conversion, we squeeze the consecutive characters into a single character. For example, the word class feature for the token ‘IL-2-mediated’ is ‘AA-O-aaaaaaaa’, which is further reduced to ‘A-O-a’.
8. Orthographic features: We use several orthographic features that consider capitalization and digit information. These features are:

<sup>2</sup><http://www.nactem.ac.uk/GENIA/tagger/>

*initial capital, all capital, capital in inner, initial capital then mix, only digits, digit with special character, initial digit then alphabet, digit in inner.* It is observed that some symbols like (‘,’, ‘-’, ‘.’, ‘\_’) are very common in the biomedical text. Some symbols like ‘;’ are also very helpful for the identification of NE boundaries.

## 4 Methodology

We propose a PSO based feature selection technique that determines the most relevant features from a set of features, containing both handcrafted as well as word embedding based features. We use Conditional Random Field (CRF) (Lafferty et al., 2001) as a base learning algorithm. For each token, a feature vector is generated from the training and test dataset using the features as described in the previous section. Basic steps of our algorithm are as follows:

1. Initially, we design 32 features (listed in Section-3) for three datasets, namely GENIA, GENETAG and AiMed. These features are used for the classifier’s training. The models built using these features are termed as the baseline models.
2. We generate the word embedding feature vector of 200 dimensions based on the model trained on a large corpus like Wikipedia and the biomedical corpora such as PubMed<sup>3</sup> and PubMed Central Open Access (PMC OA)<sup>4</sup>.
3. A new feature set is generated by combining both word embedding based features and handcrafted features.
4. PSO based feature selection is performed to determine the most relevant feature set.
5. CRF classifier is trained with the features selected by PSO. The model, thus generated, is evaluated on all the three datasets.

Figure-1 depicts the various steps of our proposed approach.

## 5 Datasets and Experiments

<sup>3</sup><http://www.ncbi.nlm.nih.gov/pubmed>

<sup>4</sup><http://www.ncbi.nlm.nih.gov/pmc/tools/openftlist>

## 5.1 Dataset

Our system is evaluated on three distinguished biomedical datasets, namely GENIA<sup>5</sup>, AiMed<sup>6</sup> and GENETAG<sup>7</sup>. The GENIA corpus is derived from the MEDLINE corpus. It comprises of 500,000 and 100,000 words in training and test dataset, respectively. These datasets are manually annotated with five NE tags, namely *Protein*, *DNA*, *RNA*, *Cell\_line* & *Cell\_type*.

AiMed corpus was created using 20,000 sentences having gene/protein names extracted from the Database of Interacting Protein (DIP). We use 7,500 labeled sentences for training and 2,500 sentences for validation. For evaluation we use a test set consisting of 5,000 sentences.

GENETAG dataset is derived from the ‘Med-Tag’ dataset. Training and test datasets comprise of 118K and 142K words, respectively. In order to properly denote the boundaries of NE, we use the IOB2<sup>8</sup> encoding scheme. We evaluate our system in terms of recall, precision and F-measure values. For evaluation we use the script, which was made available with the JNLPBA 2004 shared task<sup>9</sup>.

## 5.2 Baseline Models and Analysis

We start experiments with the first baseline (i.e. Baseline-1) by developing the model trained with all the features as discussed in Section-3. We evaluate the presence of word embedding features trained on various unlabeled data sets obtained from the different text sources. In order to realize the effect of each trained word representation model, we augment the word vector obtained from the respective model one by one to the baseline feature set. In order to obtain word embedding, we use four different models trained on the unlabeled data extracted from PubMed<sup>10</sup>, PubMed Central Open Access (PMC OA)<sup>11</sup> and the latest English Wikipedia dump<sup>12</sup>. Corpus statistics of PubMed and PMC OA are provided in Table-1. The extracted text upon which four different models are trained are as follows:

<sup>5</sup><http://www.geniaproject.org/shared-tasks/bionlp-jnlpba-shared-task-2004>

<sup>6</sup><ftp://ftp.cs.utexas.edu/pub/mooney/bio-data/>

<sup>7</sup><ftp://ftp.ncbi.nlm.nih.gov/pub/tanabe/GENETAG.tar.gz>

<sup>8</sup>I, O and B represent the intermediate, outside and beginning token of a NE

<sup>9</sup><http://www.nactem.ac.uk/tsujii/GENIA/ERTask/report.html>

<sup>10</sup><http://www.ncbi.nlm.nih.gov/pubmed>

<sup>11</sup><http://www.ncbi.nlm.nih.gov/pmc/tools/openftlist>

<sup>12</sup>[http://en.wikipedia.org/wiki/Main\\_Page](http://en.wikipedia.org/wiki/Main_Page)

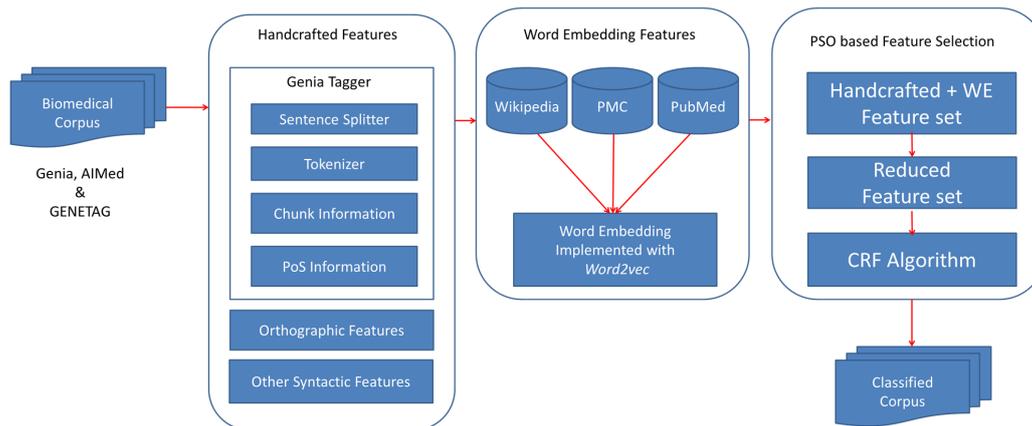

Figure 1: Proposed model architecture for biomedical entity extraction

1. Model developed using extracted data from PubMed biomedical literature: denoted as WE(1).
2. Model built on the extracted text from PMC biomedical literature: denoted as WE(2).
3. Model developed using the combination of extracted text from PubMed and PMC biomedical texts: denoted as WE(3).
4. Model trained using the extracted text from PubMed, PMC and Wikipedia: denoted as WE(4).

We develop the second baseline (i.e. Baseline-2) by executing the best word embedding model in combination with the hand-crafted feature set. We further develop the third baseline, i.e. Baseline-3 by merging word embedding feature set as determined by PSO along with the full handcrafted feature set. We observe that selection of relevant word embedding features helps in improving performance over the whole word embedding feature set.

We generate 200-dimensional word vectors using the parameters<sup>13</sup> as follows: *skip-gram* model with a window size of 5, hierarchical soft-max training, and a frequent word sub-sampling threshold of 0.001. In order to make our proposed system generic, i.e. not biased to any particular domain of data, we use the same parameters of PSO in all our settings. We fine-tune the parameters  $\omega$ ,  $\phi_1$  and  $\phi_2$  by performing 3-fold cross validation experiments. We keep the number of particles

<sup>13</sup>We use same parameters for training of all the four models

Corpus	Documents	Sentences	Tokens
PubMed	22,120,269	124,615,674	2,896,348,481
PMC	672,589	105,194,341	2,591,137,744
PubMed+PMC	22,792,858	229,810,015	5,487,486,225

Table 1: Corpus statistics (Pyysalo et al., 2013) of PubMed and PMC OA openly available biomedical literature; PubMed abstracts for articles that are also present in PMC OA were discarded while creating the data

and the number of iterations as 10 and 100, respectively throughout all the experiments.

Effectiveness of PSO based feature selection is evident with performance improvement as shown in Table-5.

### 5.3 Comparison with Existing Feature Selection Techniques

Here we compare our PSO based feature selection technique with other existing feature selection techniques. We perform experiments with both filter and wrapper based models. For filter based model, we use univariate feature selection based on information theoretical concept like Information Gain. While for multivariate filter model we use correlation based feature selection. Our results indicate that PSO performs better than univariate by 3.03 % and multivariate by 2.60 % F-measure points for the GENIA dataset. We also observe quite similar behaviors for the other two datasets.

In addition, we also explore two popular wrapper based feature selection techniques, Genetic Algorithm (GA) (Holland, 1975) based feature selection (Ekbal et al., 2010) technique and Recursive Feature Elimination (RFE) (Guyon et al., 2002)

Feature Selection	GENIA			GENETAG			AiMed		
	Precision	Recall	F-measure	Precision	Recall	F-measure	Precision	Recall	F-measure
<b>Filter (Information Gain)</b>	69.02	71.28	70.13	88.25	94.47	91.25	87.46	90.47	88.93
<b>Filter (Correlation)</b>	70.19	70.95	70.56	88.89	93.68	91.22	87.18	89.85	88.49
<b>Wrapper (GA)</b>	72.48	71.98	72.22	89.19	95.04	92.02	89.07	91.11	90.07
<b>Wrapper (RFE)</b>	71.28	71.54	71.40	89.25	94.81	91.94	88.67	91.66	90.14
<b>CRF[PSO]</b>	72.48	73.87	73.16	89.33	96.42	92.74	89.77	92.09	90.92

Table 2: Comparison of PSO with other filter (Information Gain & Correlation) and wrapper (G.A & RFE) based feature selection technique

based approach. Genetic algorithm belongs to the class of randomized wrapper model where feature selection is always classifier dependent and is less prone to stuck at local optima. The RFE is categorized under the deterministic type wrapper model which is computationally less complex than randomized type but has the disadvantage to stuck at local optima.

Results show that PSO performs better than RFE for all the datasets and GA for two datasets (GENIA & GENETAG) in terms of F-measure and the number of features selected. Results are depicted in Table-2. On AiMed dataset, GA and RFE based feature selection techniques perform quite comparable to our PSO based method. It is to be noted that PSO based feature selection yields better performance even with a smaller set of features. The pruned and compact feature set incurs less computational complexity.

## 6 Result and Discussion

Table-3 shows the extensive results of our proposed system on all three datasets, namely GENIA, AiMed and GENETAG by augmenting word embedding features. It seems that word embedding features generated from the model which is trained on the combined datasets of PubMed, PMC and Wikipedia [WE(4)] perform better than the other models. The unsupervised word representation features help in detecting unseen entities, i.e. those not appearing in the training data set.

We augment word embedding WE(4) features to the hand-crafted features, and then apply feature selection using PSO on this combined set. Feature selection through PSO not only helps in improving the performance, but at the same time it reduces the feature dimensionality. Evaluation results as reported in Table-4 reveal this fact. Table-3 clearly depicts the effectiveness

of word embedding features in BNER (biomedical NER) system. We observe improvements of 7.86%, 5.27% and 7.25% F-measures over the first baseline (i.e. Baseline-1) for GENIA, AiMed and GENETAG data sets, respectively by using PSO based feature selection on PubMed-PMC-wikipedia trained word embedding and handcrafted features. Evaluation also suggests that performance does not degrade significantly, even when we use word embedding features obtained only from Pubmed & PMC OA. It seems that word embedding features obtained from the combination of Pubmed and PMC are more representatives compared to the individual one.

We also show evaluation of some of the existing approaches that attempt to make use of word representation features. A F-measure of 71.39% is reported in the work (Tang et al., 2014). Word representation feature was also used in (Chang et al., 2015) that reported to have achieved F-measure value of 71.77%.

We perform statistical significance (t-test) test on the results obtained by our proposed model. For different datasets, experiments are executed for 10 independent runs and the t-statistic is adopted to analyze the obtained experimental results. Using the known distribution of the test statistic,  $p$ -value is calculated. It is observed that  $p$  values are less than 0.04 for all the three data sets, which signify that our obtained results are statistically significant.

### 6.1 Error Analysis

Here, we analyze the outputs obtained for each dataset in order to identify the possible errors. We categorize the errors in three ways as follows:

1. Wrong boundary: This error occurs due to the incorrect boundary identification of entities. These types of cases are observed

System	GENIA			AiMed			GENETAG		
	Precision	Recall	F-measure	Precision	Recall	F-measure	Precision	Recall	F-measure
<b>Baseline-1: Handcraft feature</b>	66.78	63.89	65.30	84.11	87.25	85.65	83.88	87.17	85.49
WE1(Handcraft feature + PubMed)	70.72	72.29	71.50	88.42	89.21	88.81	81.92	95.82	88.33
WE2(Handcraft feature + PMC OA)	70.72	72.29	71.50	88.56	89.02	88.78	82.01	95.62	88.29
WE3(Handcraft feature + PubMed + PMC)	70.79	72.47	71.62	89.48	89.01	89.24	82.41	95.89	88.64
WE4(Handcraft feature + PubMed + PMC + Wikipedia)	70.88	72.64	71.75	89.07	90.11	89.59	82.78	95.70	88.77
<b>Baseline-2: Best of WE model</b>	70.88	72.64	71.75	89.07	90.11	89.59	82.78	95.70	88.77
<b>Baseline-3: (PSO with only WE(4)) + Handcraft feature</b>	71.92	72.62	72.26	89.63	90.34	89.98	83.46	95.69	89.15
<b>Proposed: PSO with (handcrafted features + WE)</b>	72.48	73.87	<b>73.16</b>	89.77	92.09	<b>90.92</b>	89.33	96.42	<b>92.74</b>
<b>WE model by Tang et al.(Tang et al., 2014))</b>	70.78	72.00	71.39	-	-	-	-	-	-
<b>WE model by Chang et al.(Chang et al., 2015))</b>	71.36	72.18	71.77	-	-	-	-	-	-

Table 3: Performance evaluation on GENIA, AiMed and GENETAG data sets using various word embedding (WE) features trained on different unlabeled data.

Approach	Dataset		
	GENIA	GENETAG	AiMed
Handcraft Features + W.E Features	232	230	232
PSO based feature selection	129	136	121

Table 4: Comparison of no. of features being used to train the model: Before feature selection and after feature selection

Approach	Dataset		
	GENIA	GENETAG	AiMed
Only W.E features	57.78	55.63	41.22
PSO selected W.E features	58.96	57.41	42.74

Table 5: Comparisons (in terms of F-score) between whole word embedding features using WE(4) and the PSO selected word embedding features excluding handcrafted features. Here, W.E: Word embedding

mostly with the entities having long and compounded wordforms such as ‘T cell activation-specific enhance’. We also observe that our system lacks in correctly classifying the instances which includes brackets.

2. Incorrect entity type: This error is obtained when the entity is properly identified but it belongs to some other entity class. This error is more prominent in case of GENIA and GENETAG datasets. For GENIA dataset, classifier is mostly confused with ‘Protein’ vs. ‘Cell\_line’ or ‘Cell\_type’. In total 126 Protein words are wrongly classified either as the ‘Cell\_line’ or ‘Cell\_type’. While with the use of PSO, the rate of mis-classification was reduced to 97. In GENETAG, majority of classes are predicted as ‘I-NEWGENE’. This may be due to the fact that majority of the instances belongs to the ‘I-NEWGENE’ cat-

egory. While after applying PSO, we observe that mis-classification of ‘I-NEWGENE’ is significantly reduced from 325 to just 129.

3. Missed entity: Our system misses significant number of NE instances. It is found that number of false negatives count to 1357, 155 and 40 for GENIA, AiMed and GENETAG, respectively. All these NEs are mis-classified to belong to the other-than-NE category.

## 7 Conclusions & Future work

In this paper we have investigated the effect of word embedding features in addition to the handcrafted features for entity extraction from three benchmark biomedical data sets, namely GENIA, AiMed & GENETAG. We have evaluated the system using four different word representation schemes trained on extracted texts from PubMed, PMC OA biomedical literature and Wikipedia dump datasets. In addition to this we have performed PSO based feature selection on the whole feature set for the different data sets. We can conclude that instead of using a full word representation feature, if only prominent features are used, it could help in improving the performance of the system. In future work, we would like to perform additional experiments to fine-tune the dimensions of vectors and the parameters of CRF through cross-validation on the training set. The applicability of feature selection on word embedding features need to be explored in other domain also. In addition we want to compare the performance of representation obtained through *word2vec* to the others such as GloVe. We would also like to explore deep learning techniques replacing CRF.

# Distant Supervision for Relation Extraction beyond the Sentence Boundary

Chris Quirk and Hoifung Poon

Microsoft Research

One Microsoft Way

Redmond, WA 98052

{chrisq, hoifung}@microsoft.com

## Abstract

The growing demand for structured knowledge has led to great interest in relation extraction, especially in cases with limited supervision. However, existing distance supervision approaches only extract relations expressed in single sentences. In general, cross-sentence relation extraction is under-explored, even in the supervised-learning setting. In this paper, we propose the first approach for applying distant supervision to cross-sentence relation extraction. At the core of our approach is a graph representation that can incorporate both standard dependencies and discourse relations, thus providing a unifying way to model relations within and across sentences. We extract features from multiple paths in this graph, increasing accuracy and robustness when confronted with linguistic variation and analysis error. Experiments on an important extraction task for precision medicine show that our approach can learn an accurate cross-sentence extractor, using only a small existing knowledge base and unlabeled text from biomedical research articles. Compared to the existing distant supervision paradigm, our approach extracted twice as many relations at similar precision, thus demonstrating the prevalence of cross-sentence relations and the promise of our approach.

## 1 Introduction

The accelerating pace in technological advance and scientific discovery has led to an explosive growth in knowledge. The ensuing information overload creates new urgency in assimilating frag-

mented knowledge for integration and reasoning. A salient case in point is precision medicine (Bahcall, 2015). The cost of sequencing a person's genome has fallen below \$1000<sup>1</sup>, enabling individualized diagnosis and treatment of complex genetic diseases such as cancer. The availability of measurement for 20,000 human genes makes it imperative to integrate all knowledge about them, which grows rapidly and is scattered in millions of articles in PubMed<sup>2</sup>. Traditional extraction approaches require annotated examples, which makes it difficult to scale to the explosion of extraction demands. Consequently, there has been increasing interest in indirect supervision (Banko et al., 2007; Poon and Domingos, 2009; Toutanova et al., 2015), with distant supervision (Craven et al., 1998; Mintz et al., 2009) emerging as a particularly promising paradigm for augmenting existing knowledge bases from unlabeled text (Poon et al., 2015; Parikh et al., 2015).

This progress is exciting, but distant-supervision approaches have so far been limited to single sentences, thus missing out on relations crossing the sentence boundary. Consider the following example: “*The p56Lck inhibitor **Dasatinib** was shown to enhance apoptosis induction by dexamethasone in otherwise GC-resistant CLL cells. This finding concurs with the observation by Sade showing that **Notch**-mediated resistance of a mouse lymphoma cell line could be overcome by inhibiting p56Lck.*” Together, the two sentences convey the fact that the drug *Dasatinib* could overcome resistance conferred by mutations to the *Notch* gene, which can not be inferred from either sentence alone. The impact of missed opportunities is especially pronounced in the long tail of knowledge. Such information is crucial for integrative reasoning as it includes the newest

<sup>1</sup><http://www.illumina.com/systems/hiseq-x-sequencing-system.html>

<sup>2</sup><http://www.ncbi.nlm.nih.gov/pubmed>

findings in specialized domains.

In this paper, we present *DISCREX*, the first approach for distant supervision to relation extraction beyond the sentence boundary. The key idea is to adopt a document-level graph representation that augments conventional intra-sentential dependencies with new dependencies introduced for adjacent sentences and discourse relations. It provides a unifying way to derive features for classifying relations between entity pairs. As we augment this graph with new arcs, the number of possible paths between entities grow. We demonstrate that feature extraction along multiple paths leads to more robust extraction, allowing the learner to find structural patterns even when the language varies or the parser makes an error.

The cross-sentence scenario presents a new challenge in candidate selection. This motivates our concept of *minimal-span candidates* in Section 3.2. Excluding non-minimal candidates substantially improves classification accuracy.

There is a long line of research on discourse phenomena, including coreference (Haghighi and Klein, 2007; Poon and Domingos, 2008; Rahman and Ng, 2009; Raghunathan et al., 2010), narrative structures (Chambers and Jurafsky, 2009; Cheung et al., 2013), and rhetorical relations (Marcu, 2000). For the most part, this work has not been connected to relation extraction. Our proposed extraction framework makes it easy to integrate such discourse relations. Our experiments evaluated the impact of coreference and discourse parsing, a preliminary step toward in-depth integration with discourse research.

We conducted experiments on extracting drug-gene interactions from biomedical literature, an important task for precision medicine. By bootstrapping from a recently curated knowledge base (KB) with about 162 known interactions, our *DISCREX* system learned to extract inter-sentence drug-gene interactions at high precision. Cross-sentence extraction doubled the yield compared to single-sentence extraction. Overall, by applying distant supervision, we extracted about 64,000 distinct interactions from about one million PubMed Central full-text articles, attaining two orders of magnitude increase compared to the original KB.

## 2 Related Work

To the best of our knowledge, distant supervision has not been applied to cross-sentence relation ex-

traction in the past. For example, Mintz et al. (2009), who coined the term “distant supervision”, aggregated features from multiple instances for the same relation triple (relation, entity1, entity2), but each instance is a sentence where the two entities co-occur. Thus their approach cannot extract relations where the two entities reside in different sentences. Similarly, Zheng et al. (2016) aggregated information from multiple sentential instances, but could not extract cross-sentence relations.

Distant supervision has also been applied to completing Wikipedia Infoboxes (Wu and Weld, 2007) or TAC KBP Slot Filling<sup>3</sup>, where the goal is to extract attributes for a given entity, which could be considered a special kind of relation triples (attribute, entity, value). These scenarios are very different from general cross-sentence relation extraction. For example, the entity in consideration is often the protagonist in the document (title entity of the article). Moreover, state-of-the-art methods typically consider extracting from single sentences only (Surdeanu et al., 2012; Surdeanu and Ji, 2014; Koch et al., 2014).

In general, cross-sentence relation extraction has received little attention, even in the supervised-learning setting. Among the limited amount of prior work, Swampillai & Stevenson (2011) is the most relevant to our approach, as it also considered syntactic features and introduced a dependency link between the root nodes of parse trees containing the given pair of entities. However, the differences are substantial. First and foremost, their approach used standard supervised learning rather than distant supervision. Moreover, we introduced the document-level graph representation, which is much more general, capable of incorporating a diverse set of discourse relations and enabling the use of rich syntactic and surface features (Section 3). Finally, Swampillai & Stevenson (2011) evaluated on MUC6<sup>4</sup>, which contains only 318 Wall Street Journal articles. In contrast, we evaluated on large-scale extraction from about one million full-text articles and demonstrated the large impact of cross-sentence extraction for an important real-world application.

The lack of prior work in cross-sentence relation extraction may be partially explained by the domains of focus. Prior extraction work focuses

<sup>3</sup><http://www.nist.gov/tac/2016/KBP/ColdStart/index.html>

<sup>4</sup><https://catalog.ldc.upenn.edu/LDC2003T13>

on newswire text<sup>5</sup> and the Web (Craven et al., 2000). In these domains, the extracted relations often involve popular entities, for which there often exist single sentences expressing the relation (Banko et al., 2007). However, there is much less redundancy in specialized domains such as the frontiers of science and technology, where cross-sentence extraction is more likely to have a significant impact. The long-tailed characteristics of such domains also make distant supervision a natural choice for scaling up learning. This paper represents a first step toward exploring the confluence of these two directions.

Distant supervision has been extended to capture implicit reasoning, via matrix factorization or knowledge base embedding (Riedel et al., 2013; Toutanova et al., 2015; Toutanova et al., 2016). Additionally, various models have been proposed to address the noise in distant supervision labels (Hoffmann et al., 2011; Surdeanu et al., 2012). These directions are orthogonal to cross-sentence extraction, and incorporating them will be interesting future work.

Recently, there has been increasing interest in relation extraction for biomedical applications (Kim et al., 2009; Nédellec et al., 2013). However, past methods are generally limited to single sentences, whether using supervised learning (Björne et al., 2009; Poon and Vanderwende, 2010; Riedel and McCallum, 2011) or distant supervision (Poon et al., 2015; Parikh et al., 2015).

The idea of leveraging graph representations has been explored in many other settings, such as knowledge base completion (Lao et al., 2011; Gardner and Mitchell, 2015), frame-semantic parsing (Das and Smith, 2011), and other NLP tasks (Radev and Mihalcea, 2008; Subramanya et al., 2010). Linear and dependency paths are popular features for relation extraction (Snow et al., 2006; Mintz et al., 2009). However, past extraction focuses on single sentences, and typically considers the shortest path only. In contrast, we allow interleaving edges from dependency and word adjacency, and consider top  $K$  paths rather than just the shortest one. This resulted in substantial accuracy gain (Section 4.5).

There has been prior work on leveraging coreference in relation extraction, often in the standard supervised setting (Hajishirzi et al., 2013; Durrett

and Klein, 2014), but also in distant supervision (Koch et al., 2014; Augenstein et al., 2016). Notably, while Koch et al. (2014) and Augenstein et al. (2016) still learned to extract from single sentences, they augmented mentions with coreferent expressions to include linked entities that might be in a different sentence. We explored the potential of this approach in our experiments, but found that it had little impact in our domain, as it produced few additional candidates beyond single sentences. Recently, discourse parsing has received renewed interest (Ji and Eisenstein, 2014; Feng and Hirst, 2014; Surdeanu et al., 2015), and discourse information has been shown to improve performance in applications such as question answering (Sharp et al., 2015). In this paper, we generated coreference relations using the state-of-the-art Stanford coreference systems (Lee et al., 2011; Recasens et al., 2013; Clark and Manning, 2015), and generated rhetorical relations using the winning approach (Wang and Lan, 2015) in the CoNLL-2015 Shared Task on Discourse Parsing.

### 3 Distant Supervision for Cross-Sentence Relation Extraction

In this section, we present DISCREX, short for *Distant Supervision for Cross-sentence Relation EXtraction*. Similar to conventional approaches, DISCREX learns a classifier to predict the relation between two entities, given text spans where the entities co-occur. Unlike most existing methods, however, DISCREX allows text spans comprising multiple sentences and explores potentially many paths between these entities.

#### 3.1 Distant Supervision

Like prior approaches, DISCREX learns from an existing knowledge base (KB) and unlabeled text. The KB contains known instances for the given relation. In a preprocessing step, relevant entities are annotated within this text using available entity extraction tools. Co-occurring entity pairs known to have the relation in the KB are chosen as positive examples. Under the assumption that related entities are relatively rare, we randomly sample co-occurring entity pairs not known to have the relation as negative examples. To ensure a balanced training set, we always sampled roughly the same number of negative examples as positive ones.

<sup>5</sup>E.g., MUC6, ACE <https://www ldc.upenn.edu/collaborations/past-projects/ace>

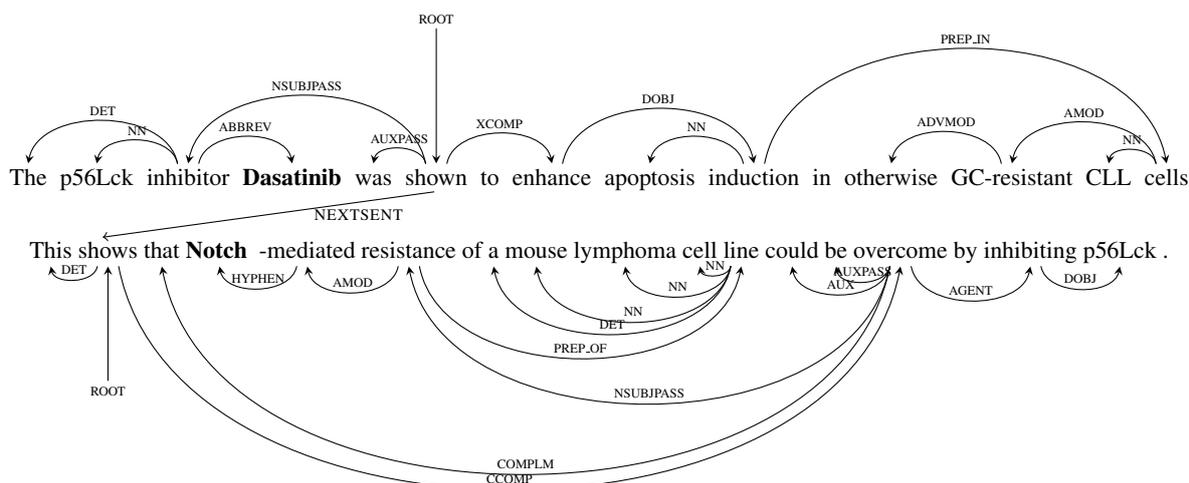

Figure 1: An example document graph for two sentences. Edges represent conventional intra-sentential dependencies, as well as connections between the roots of adjacent sentences (NEXTSENT). For simplicity, we omit edges between adjacent words or representing discourse relations.

### 3.2 Minimal-Span Candidates

In standard distant supervision, co-occurring entity pairs with known relations are enlisted as candidates of positive training examples. This is reasonable when the entity pairs are within single sentences. In the cross-sentence scenario, however, this would risk introducing too many wrong examples. Consider the following two sentences: *Since amuvatinib inhibits **KIT**, we validated **MET** kinase inhibition as the primary cause of cell death. Additionally, **imatinib** is known to inhibit **KIT**.* The mention of drug-gene pair *imatinib* and *KIT* (in bold) span two sentences, but the same pair also co-occur in the second sentence alone. In general, one might find co-occurring entity pairs in a large text span, where the same pairs also co-occur in a smaller text span that overlaps with the larger one. In such cases, if there is a relation between the pair, mostly likely it is expressed in the smaller text span when the entities are closer to each other.

This motivates us to define that an co-occurring entity pair has the *minimal span* if there does not exist another overlapping co-occurrence of the same pair where the distance between the entity mentions is smaller. Here, the distance is measured in the number of consecutive sentences between the two entities. Experimentally, we compared extraction with or without the restriction to minimal-span candidates, and show that the former led to much higher extraction accuracy.

### 3.3 Document Graph

To derive features for entity pairs both within and across sentences, DISCREX introduces a *document graph* with nodes representing words and edges representing intra- and inter-sentential relations such as dependency, adjacency, and discourse relations. Figure 1 shows an example document graph spanning two sentences. Each node is labeled with its lexical item, lemma, and part-of-speech. We used a conventional set of intra-sentential edges: typed, collapsed Stanford dependencies derived from syntactic parses (de Marneffe et al., 2006). To mitigate parser errors, we also add edges between adjacent words.

As for inter-sentential edges, a simple but intuitive approach is to add an edge between the dependency roots of adjacent sentences: if we imagined that each sentence participated as a node in a type of discourse dependency tree, this represents a simple right-branching baseline. To gather a finer grained representation of rhetorical structure, we ran a state-of-the-art discourse parser (Wang and Lan, 2015) to identify discourse relations, which returned a set of labeled binary relations between spans of words. We found the shortest path between any word in the first span and any word in the second span using only dependency and adjacent sentence edges, and added an edge labeled with the discourse relation between these two words. Another source of potentially cross-sentence links comes from coreference. We generated coreference relations using the Stanford Coreference systems (both statistical and deter-

ministic) (Lee et al., 2011; Recasens et al., 2013; Clark and Manning, 2015), and added edges from anaphora to their antecedents.

We also considered a special case of cross-sentence relation extraction by augmenting single-sentence candidates with coreference (Koch et al., 2014; Augenstein et al., 2016). Namely, extraction is still conducted within single sentences, yet entity linking is extended to consider all coreference mentions for a relation argument. However, this did not produce significantly more candidates (2% more for positive examples), most of which were not cross-sentence ones (only 1%).

### 3.4 Features

Dependency paths have been established as a particularly effective source for relation extraction features (Mintz et al., 2009). DISCREX generalizes this idea by defining feature templates over paths in the document graph, which may contain interleaving edges of various types (dependency, word and sentence adjacency, discourse relation). Dependency paths provide interpretable and generalizable features but are subject to parser error. One error mitigation strategy is to add edges between adjacent words, allowing multiple paths between entities.

Feature extraction begins with a pair of entities in the document graph that potentially are connected by a relation. We begin by finding a path between the entities of interest, and extract features from that path.

Over each such path, we explore a number of different features. Below, we assume that each path is a sequence of nodes and edges  $(n_1, e_1, n_2, \dots, e_{L-1}, n_L)$ , with  $n_1$  and  $n_L$  replaced by special entity marker nodes.<sup>6</sup>

**Whole path features** We extract four binary indicator features for each whole path, with nodes  $n_i$  represented by their lexical item, lemma, part-of-speech tag, or nothing. These act as high precision but low recall indicators of useful paths.

**Path n-gram features** A more robust and generalizable approach is to consider a sliding window along each path. For each position  $i$ , we extract  $n$ -gram ( $n = 1-5$ ) features starting at each node ( $n_i$ , then  $n_i \cdot e_i$  and so on until  $n_i \cdot e_i \cdot n_{i+1} \cdot e_{i+1} \cdot n_{i+2}$ ) and each edge ( $e_i$  up to  $e_i \cdot n_{i+1} \cdot e_{i+1} \cdot n_{i+2} \cdot e_{i+2}$ ).

<sup>6</sup> This prevents our method from memorizing the entities in the original knowledge base.

Again, each node could be represented by its lexical item, lemma, or part of speech, leading to 27 feature templates. We add three more feature templates using only edge labels ( $e_i$ ;  $e_i \cdot e_{i+1}$ ; and  $e_i \cdot e_{i+1} \cdot e_{i+2}$ ) for a total of 30 feature templates.

### 3.5 Multiple paths

Most prior work has only looked at the single shortest path between two entities. When authors use consistent lexical and syntactic constructions, and when the parser finds the correct parse, this approach works well. Real data, however, is quite noisy.

One way to mitigate errors and be robust against noise is to consider multiple possible paths. Given a document graph with arcs of multiple types, there are often multiple paths between nodes. For instance, we might navigate from the gene to the drug using only syntactic arcs, or only adjacency arcs, or some combination of the two. Considering such variations gives more opportunities to find commonalities between seemingly disparate language.

We explore varying the number of shortest paths,  $N$ , between the nodes in the document graph corresponding to the relevant entities. By default, all edge types have an equal weight of 1, except edges between adjacent words. Empirically, penalizing adjacency edges led to substantial benefits, though including adjacency arcs was important for benefits from multiple paths. This suggests that the parser produces valuable information, but that we should have a back-off strategy for accommodating parser errors.

### 3.6 Evaluation

There is no gold annotated dataset in distant supervision, so evaluation typically resorts to two strategies. One strategy uses held-out samples from the training dataset, essentially treating the noisy annotation as gold standard. This has the advantage of being automatic, but could produce biased results due to false negatives (i.e., entity pairs not known to have the relation might actually have the relation). Another strategy reports absolute recall (number of extractions from all unlabeled text), as well as estimated precision by manually annotating extraction samples from general text. We conducted both types of evaluation in the experiments.

Disease	Gene	Variant	Description	Effect	Association_1	Therapeutic context_1
ALL	ABL1	T315A	missense mutation	gain-of-function	response	nilotinib, ponatinib
ALL	ABL1	T315I	missense mutation	gain-of-function	response	ponatinib

Figure 2: Sample rows from the Gene Drug Knowledge Database. Our current work focuses on two important columns: gene, and therapeutic context (drug).

## 4 Experiments

We consider the task of extracting drug-gene interactions from biomedical literature. A drug-gene interaction is broadly construed as an association between the drug efficacy and the gene status. The status includes mutations and activity measurements (e.g., overexpression). For simplicity, we only consider the relation at the drug-gene level, without distinguishing among details such as drug dosage or distinct gene status.

### 4.1 Knowledge Base

We used the Gene Drug Knowledge Database (GDKD) (Dienstmann et al., 2015) for distant supervision. Figure 2 shows a snapshot of the dataset. Each row specifies a gene, some drugs, the fine-grained relations (e.g., sensitive), the gene status (e.g., mutation), and some supporting article IDs. In this paper, we only consider the coarse drug-gene association and ignore the other fields.

### 4.2 Unlabeled Text

We obtained biomedical literature from PubMed Central<sup>7</sup>, which as of early 2015 contained about 960,000 full-text articles. We preprocessed the text using SPLAT (Quirk et al., 2012) to conduct tokenization, part-of-speech tagging, and syntactic parsing, and obtained Stanford dependencies (de Marneffe et al., 2006) using Stanford CoreNLP (Manning et al., 2014). We used the entity taggers from Literome (Poon et al., 2014) to identify drug and gene mentions.

### 4.3 Candidate Selection

To avoid unlikely candidates such as entity pairs far apart in the document, we consider entity pairs within  $K$  consecutive sentences.  $K = 1$  corresponds to extraction within single sentences. For cross-sentence extraction, we chose  $K = 3$  as it

<sup>7</sup><http://www.ncbi.nlm.nih.gov/pmc/>

Number of Candidates	$K = 1$	$K = 3$
Unique Pairs	169,168	332,969
Instances	1,724,119	3,913,338
Matching GDKD	58,523	87,773

Table 1: Statistics for drug-gene interaction candidates in PubMed Central articles: unique pairs, instances, instances with known relations in Gene Drug Knowledge Database (GDKD).

doubled the number of overall candidates, while being reasonably small so as not to introduce too many unlikely ones. Table 1 shows the statistics of drug-gene interaction candidates identified in PubMed Central articles. For  $K = 3$ , there are 87,773 instances for which the drug-gene pair has known associations in Gene Drug Knowledge Database (GDKD), which are used as positive training examples. Note that these only include minimal-span candidates (Section 3.2). Without the restriction, there are 225,520 instances matching GDKD, though many are likely false positives.

### 4.4 Classifier

Our classifiers were binary logistic regression models, trained to optimize log-likelihood with an  $\ell_2$  regularizer. We used a weight of 1 for the regularizer; the results were not very sensitive to the specific value. Parameters were optimized using L-BFGS (Nocedal and Wright, 2006). Rather than explicitly mapping each feature to its own dimension, we hashed the feature names and retained 22 bits (Weinberger et al., 2009). Approximately 4 million possible features seemed to suffice for our problem: fewer bits produced degradations, but more bits did not lead to improvements.

### 4.5 Automatic Evaluation

To evaluate the impact of features, we conducted five-fold cross validation, by treating the positive

Features	Single-Sent.	Cross-Sent.
Base	81.3	81.7
3 paths	85.4	85.5
+coref	85.0	84.7
+disc	—	84.6
+coref+disc	—	84.5
10 paths	87.0	86.6
+coref	86.5	85.9
+disc	—	86.5
+coref+disc	—	85.9

Table 2: Average test accuracy in five-fold cross-validation. Cross-sentence extraction was conducted within a sliding window of 3 sentences using minimal-span candidates. `Base` only used the shortest path to construct features. `3 paths` and `10 paths` gathered features from the top three or ten shortest paths, assigning uniform weights to all edges except adjacency, which had a weight of 16. `+coref` adds edges for the relations predicted by Stanford Coreference. `+disc` adds edges for the predicted rhetorical relations by a state-of-the-art discourse parser (Wang and Lan, 2015).

and negative examples from distant supervision as gold annotation. To avoid train-test contamination, all instances from a document are assigned to the same fold. We then evaluated the average test performance across folds. Since our datasets were balanced by design (Section 3.1), we simply reported accuracy. As discussed before, the results could be biased by the noise in annotation, but this automatic evaluation enables an efficient comparison of various design choices.

First, we set out to investigate the impact of edge types and path number. We set the weight for adjacent-word edges to 16, to give higher priority to other edge types (weight 1) that are arguably more semantics-related. Table 2 shows the average test accuracy for single-sentence and cross-sentence extraction with various edge types and path numbers. Compared to extraction within single sentences, cross-sentence extraction attains a similar accuracy, even though the recall for the latter is much higher (Table 1).

Adding more paths other than the shortest one led to a substantial improvement in accuracy. The gain is consistent for both single-sentence and cross-sentence extraction. This is surprising, as prior methods often derive features from the short-

Paths	Adj. Wt.	Single-Sent.	Cross-Sent.
	1	82.2	82.1
3	4	85.0	84.9
	16	85.4	85.5
	64	85.1	85.0
10	1	85.7	83.6
	4	87.2	86.7
	16	87.0	86.6
	64	87.0	86.6
30	1	87.6	85.4
	4	88.0	87.5
	16	87.5	87.2
	64	87.5	87.2

Table 3: Average test accuracy in five-fold cross-validation. Uniform weights are used, except for adjacent-word edges.

est dependency path alone.

Adding discourse relations, on the other hand, consistently led to a small drop in performance, especially when the path number is small. Upon manual inspection, we found that Stanford Coreference made many errors in biomedical text, such as resolving a dummy pronoun with a nearby entity. In hindsight, this is probably not surprising: state-of-the-art coreference systems are optimized for newswire domain and could be ill-suited for scientific literature (Bell et al., 2016). We are less certain about why discourse parsing didn’t seem to help. There are clearly examples where extraction errors could have been avoided given rhetorical relations (e.g., when the sentence containing the second entity starts a new topic). We leave more in-depth investigation to future work.

Next, we further evaluated the impact of path number and adjacency edge weight. Only dependency and adjacency edges were included in these experiments. Table 3 shows the results. Penalizing adjacency produces large gains; a harsh penalty is particularly helpful with fewer paths. These results support the hypothesis that dependency edges are usually more meaningful for relation extraction than word adjacency. Therefore, if adjacency edges get the same weights, they might cause some dependency sub-paths drop out of the top  $K$  paths, thus degrading performance. When the path number increases, there is a consistent and substantial increase in accuracy, which demonstrates the advantage of allowing adjacency edges

<b>Relations</b>	<b>Single-Sent.</b>	<b>Cross-Sent.</b>
Candidates	169,168	332,969
$p \geq 0.5$	32,028	64,828
$p \geq 0.9$	17,349	32,775
<b>GDKD</b>	<b>162</b>	

Table 4: Unique drug-gene interactions extracted from PubMed Central articles, compared to the manually curated Gene Drug Knowledge Database (GDKD) used for distant supervision.  $p$  signifies the output probability. GDKD contains 341 relations, but only 162 have specific drug references usable as distant supervision.

	<b>Gene</b>	<b>Drug</b>
GDKD	140	80
Single-Sent. ( $p \geq 0.9$ )	4036	311
Single-Sent. ( $p \geq 0.5$ )	6189	347
Cross-Sent. ( $p \geq 0.9$ )	5580	338
Cross-Sent. ( $p \geq 0.5$ )	9470	373

Table 5: Numbers of unique genes and drugs in the Gene Drug Knowledge Database (GDKD) vs. DISCREX extractions.

to interleave with dependency ones. This presumably helps address syntactic parsing errors, among other things. The importance of adjacency weights decreases with more paths, but it is still significantly better to penalize adjacency edges.

In the experiments mentioned above, cross-sentence extraction was conducted using minimal-span candidates only. We expected that this would provide a reasonable safeguard to filter out many unlikely candidates. As empirical validation, we also conducted experiments on cross-sentence extraction without the minimal-span restriction, using the base model. Test accuracy dropped sharply from 81.7% to 79.1% (not shown in the table).

#### 4.6 PubMed-Scale Extraction

Our ultimate goal is to extract knowledge from all available text. First, we retrained DISCREX on all available distant-supervision data, not restricting to a subset of the folds as in the automatic evaluation. We used the systems performing best on automatic evaluation, with features derived from 30 shortest paths between each entity pair, and minimal-span candidates within three sentences

for cross-sentence extraction. We then applied the learned extractors to all PubMed Central articles. We grouped the extracted instances into unique drug-gene pairs. The classifier output a probability for each instance. The maximum probability of instances in a group was assigned to the relation as a whole. Table 4 shows the statistics of extracted relations by varying the probability threshold. Cross-sentence extraction obtained far more unique relations compared to single-sentence extraction, improving absolute recall by 89-102%. Table 5 compares the number of unique genes and drugs. DISCREX extractions cover far more genes and drugs compared to GDKD, which bode well for applications in precision medicine.

#### 4.7 Manual Evaluation

Automatic evaluation accuracies can be overly optimistic. To assess the true precision of DISCREX, we also conducted manual evaluation on extracted relations. Based on the automatic evaluation, the accuracy is similar for single-sentence and cross-sentence extraction. So we focused on the latter. We randomly sampled extracted relation instances and asked two researchers knowledgeable in precision medicine to evaluate their correctness. For each instance, the annotators were provided with the provenance sentences where the drug-gene pair were highlighted. The annotators assessed in each case whether some relation was mentioned for the given pair.

A total of 450 instances were judged: 150 were sampled randomly from all candidates (random baseline), 150 from the set of instances with probability no less than 0.5, and 150 with probability no less than 0.9. From each set, we randomly selected 50 relations for review by both annotators. The two annotators agreed on 133 of 150. After review, all disagreements were resolved, and each annotator judged an additional set of 50 relation instances, this time without overlap.

Table 6 showed the sample precision and percentage of errors due to entity linking vs. relation extraction. With either classification threshold, cross-sentence extraction clearly outperformed the random baseline by a wide margin. Not surprisingly, the higher threshold of 0.9 led to higher precision. Interestingly, a significant portion of errors stems from mistakes in entity linking, as has been observed in prior work (Poon et al., 2015). Improved entity linking, either alone or joint with re-

	<b>Prec.</b>	<b>Entity Err.</b>	<b>Relation Err.</b>
<i>Single-sentence extractions</i>			
Random	31	52	17
$p \geq 0.5$	61	25	15
$p \geq 0.9$	<b>71</b>	13	15
<i>Cross-sentence extractions</i>			
Random	23	50	27
$p \geq 0.5$	57	20	23
$p \geq 0.9$	<b>61</b>	13	26

Table 6: Sample precision and error percentage: comparison between the single sentence and cross-sentence extraction models at various thresholds. Single sentence extraction is slightly better at all thresholds, at the expense of substantially lower recall: a reduction of 40% or more in terms of unique interactions.

lation extraction, is an important future direction.

Based on these estimates, DISCREX extracted about 37,000 correct unique interactions at the threshold of 0.5, and about 20,000 at the threshold of 0.9. In both cases, it expanded the Gene Drug Knowledge Base by two orders of magnitude.

We also performed manual evaluation in the single-sentence setting. As in the automatic evaluation, single-sentence precisions are similar though slightly higher at all thresholds. This suggests that the candidate set is cleaner and the resulting predictions are more accurate. However, the resulting recall is substantially lower, dropping by 46% at a threshold of 0.5, and by 40% at a threshold of 0.9.

## 5 Conclusion

We present the first approach for applying distant supervision to cross-sentence relation extraction, by adopting a document-level graph representation that incorporates both intra-sentential dependencies and inter-sentential relations such as adjacency and discourse relations. We conducted both automatic and manual evaluation on extracting drug-gene interactions from biomedical literature. With cross-sentence extraction, our DISCREX system doubled the yield of unique interactions, while maintaining the same accuracy. Using distant supervision, DISCREX improved the coverage of the Gene Drug Knowledge Database (GDKD) by two orders of magnitude, without requiring annotated examples.

Future work includes: further exploration of features; improved integration with coreference and discourse parsing; combining distant supervision with active learning and crowd sourcing; evaluate the impact of extractions to precision medicine; applications to other domains.

## Abstract

In this paper, we address two different types of noise in information extraction models: noise from distant supervision and noise from pipeline input features. Our target tasks are entity typing and relation extraction. For the first noise type, we introduce multi-instance multi-label learning algorithms using neural network models, and apply them to fine-grained entity typing for the first time. Our model outperforms the state-of-the-art supervised approach which uses global embeddings of entities. For the second noise type, we propose ways to improve the integration of noisy entity type predictions into relation extraction. Our experiments show that probabilistic predictions are more robust than discrete predictions and that joint training of the two tasks performs best.

## 1 Introduction

Knowledge bases (KBs) are important resources for natural language processing tasks like question answering and entity linking. However, KBs are far from complete (e.g., Socher et al. (2013)). Therefore, methods for automatic knowledge base completion (KBC) are beneficial. Two subtasks of KBC are *entity typing (ET)* and *relation extraction (RE)*. We address both tasks in this paper.

As in other information extraction tasks, obtaining labeled training data for ET and RE is challenging. The challenge grows as labels become more fine-grained. Therefore, distant supervision (Mintz et al., 2009) is widely used. It reduces the need for manually created resources. Distant supervision assumes that if an entity has a type (resp. two entities have a relationship) in a KB, then all sentences mentioning that entity (resp. those

two entities) express that type (resp. that relationship). However, that assumption is too strong and gives rise to many *noisy* labels. Different techniques to deal with that problem have been investigated. The main technique is multi-instance (MI) learning (Riedel et al., 2010). It relaxes the distant supervision assumption to the assumption that at least one instance of a bag (collection of all sentences containing the given entity/entity pair) expresses the type/relationship given in the KB. Multi-instance multi-label (MIML) learning is a generalization of MI in which one bag can have several labels (Surdeanu et al., 2012).

Most MI and MIML methods are based on hand crafted features. Recently, Zeng et al. (2015) introduced an end-to-end approach to MI learning based on neural networks. Their MI method takes the most confident instance as the prediction of the bag. Lin et al. (2016) further improved that method by taking other instances into account as well; they proposed MI learning based on selective attention as an alternative way of relaxing the impact of noisy labels on RE. In selective attention, a weighted average of instance representations is calculated first and then used to compute the prediction of a bag.

In this paper, we introduce two multi-label versions of MI. (i) *MIML-MAX* takes the maximum instance for each label. (ii) *MIML-ATT* applies, for each label, selective attention to the instances. We apply MIML-MAX and MIML-ATT to fine-grained ET. In contrast to RE, the ET task we consider contains a larger set of labels, with a variety of different granularities and hierarchical relationships. We show that MIML-ATT deals well with noise in corpus-level ET and improves or matches the results of a supervised model based on global embeddings of entities.

The second type of noise we address in this paper influences the integration of ET into RE. It has

been shown that adding entity types as features improves RE models (cf. Ling and Weld (2012), Liu et al. (2014)). However, noisy training data and difficulties of classification often cause wrong predictions of ET and, as a result, noisy inputs to RE. To address this, we propose a joint model of ET and RE and compare it with methods that integrate ET results in a strict pipeline. The joint model performs best. Among the pipeline models, we show that using probabilities instead of binary decisions better deals with noise (i.e., possible ET errors).

To sum up, our contributions are as follows. (i) We introduce new algorithms for MIML using neural networks. (ii) We apply MIML to fine-grained entity typing for the first time and show that it outperforms the state-of-the-art supervised method based on entity embeddings. (iii) We show that a novel way of integrating noisy entity type predictions into a relation extraction model and joint training of the two tasks lead to large improvements of RE performance.

We release code and data for future research.<sup>1</sup>

## 2 Related Work

**Noise mitigation for distant supervision.** Distant supervision can be used to train information extraction systems, e.g., in relation extraction (e.g., Mintz et al. (2009), Riedel et al. (2010), Hoffmann et al. (2011), Zeng et al. (2015)) and entity typing (e.g., Ling and Weld (2012), Yogatama et al. (2015), Dong et al. (2015)). To mitigate the noisy label problem, multi-instance (MI) learning has been introduced and applied in relation extraction (Riedel et al., 2010; Ritter et al., 2013). Surdeanu et al. (2012) introduced multi-instance multi-label (MIML) learning to extend MI learning for multi-label relation extraction. Those models are based on manually designed features. Zeng et al. (2015) and Lin et al. (2016) introduced MI learning methods for neural networks. We introduce MIML algorithms for neural networks. In contrast to most MI/MIML methods, which are applied in relation extraction, we apply MIML to the task of fine-grained entity typing. Ritter et al. (2013) applied MI on a Twitter dataset with ten types. Our dataset has a larger number of classes or types (namely 102) and input examples, compared to that Twitter dataset and also to the most widely used datasets for evaluating MI (cf. Riedel et al. (2010)). This makes our setup more challenging because of dif-

ferent dependencies and the multi-label nature of the problem. Also, there seems to be a difference between how entity relations and entity types are expressed in text. Our experiments support that hypothesis.

**Knowledge base completion (KBC).** Most KBC systems focus on identifying triples  $R(e_1, r, e_2)$  missing from a KB (Nickel et al., 2012; Bordes et al., 2013; Weston et al., 2013; Socher et al., 2013; Jiang et al., 2012; Riedel et al., 2013; Wang et al., 2014). Work on entity typing or unary relations for KBC is more recent (Yao et al., 2013; Neelakantan and Chang, 2015; Yaghoobzadeh and Schütze, 2015; Yaghoobzadeh et al., 2017). In this paper, we build a KBC system for unary and binary relations using contextual information of words and entities.

**Named entity recognition (NER) and typing.** NER systems (e.g., Finkel et al. (2005), Collobert et al. (2011)) used to consider only a small set of entity types. Recent work also addresses fine-grained NER (Yosef et al., 2012; Ling and Weld, 2012; Yogatama et al., 2015; Dong et al., 2015; Del Corro et al., 2015; Ren et al., 2016a; Ren et al., 2016b; Shimaoka et al., 2016). Some of this work (cf. Yogatama et al. (2015), Dong et al. (2015)) treats entity segment boundaries as given and classifies mentions into fine-grained types. We make a similar assumption, but in contrast to NER, we evaluate on the corpus-level entity typing task of Yaghoobzadeh and Schütze (2015); thus, we do not need test sentences annotated with context dependent entity types. This task was also used to evaluate embedding learning methods (Yaghoobzadeh and Schütze, 2016).

**Entity types for relation extraction.** Several studies have integrated entity type information into relation extraction – either coarse-grained (Hoffmann et al., 2011; Zhou et al., 2005) or fine-grained (Liu et al., 2014; Du et al., 2015; Augenstein et al., 2015; Vlachos and Clark, 2014; Yao et al., 2010; Ling and Weld, 2012) entity types. In contrast to most of this work, but similar to Yao et al. (2010), we do not incorporate binary entity type values, but probabilistic outputs. Thus, we allow the relation extraction system to compensate for errors of entity typing. Additionally, we compare this approach to various other possibilities, to investigate which approach performs best. Yao et al. (2010) found that joint training of entity typing and relation extraction is better than a pipeline

<sup>1</sup>cistern.cis.lmu.de

model; we show that this result also holds for neural network models and when the number of entity types is large.

### 3 MIML Learning for Entity Typing

Entity typing (ET) is the task of finding, for each named entity, a set of types or classes that it belongs to, e.g., “author” and “politician” for “Obama”. Our goal is corpus-level prediction of entity types. We use the entity-type information from a KB and annotated contexts of entities in a corpus to estimate  $P(t|e)$ , the probability that entity  $e$  has type  $t$ .

More specifically, consider an entity  $e$  and  $B = \{c_1, c_2, \dots, c_q\}$ , the set of  $q$  contexts of  $e$  in the corpus. Each  $c_i$  is an instance of  $e$  and since  $e$  can have several labels, it is a multi-instance multi-label (MIML) learning problem. We address MIML using neural networks by representing each context as a vector  $\vec{c}_i \in \mathbb{R}^h$ , and learn  $P(t|e)$  from the set of contexts of entity  $e$ . In the following, we first describe our MIML algorithms and then explain how  $\vec{c}_i$  is computed.

**Notations and definitions.** Lowercase letters (e.g.,  $e$ ) refer to variables. Lowercase letters with an upper arrow (e.g.,  $\vec{e}$ ) are vectors. We define BCE, binary cross entropy, as follows where  $y$  is a binary variable and  $\hat{y}$  is a real valued variable between 0 and 1.

$$\text{BCE}(y, \hat{y}) = -\left(y \log(\hat{y}) + (1-y)(1 - \log(\hat{y}))\right)$$

#### 3.1 Algorithms

**Distant supervision.** The basic way to estimate  $P(t|e)$  is based on distant supervision with learning the type probability of each  $c_i$  individually, by making the assumption that each  $c_i$  expresses all labels of  $e$ . Therefore, we define the context-level probability function as:

$$P(t|c_i) = \sigma(\vec{w}_t \vec{c}_i + b_t) \quad (1)$$

where  $\vec{w}_t \in \mathbb{R}^h$  is the output weight vector and  $b_t$  is the bias scalar for type  $t$ . The cost function is defined based on binary cross entropy:

$$L(\theta) = \sum_c \sum_t \text{BCE}(y_t, P(t|c)) \quad (2)$$

where  $y_t$  is 1 if entity  $e$  has type  $t$  otherwise 0. To compute  $P(t|e)$  at prediction time, i.e.,  $P_{\text{pred}}(t|e)$ ,

the context-level probabilities must be aggregated. Average is the usual way of doing that:

$$P_{\text{pred}}(t|e) = \frac{1}{q} \sum_{i=1}^q P(t|c_i) \quad (3)$$

**Multi-instance multi-label.** The distant supervision assumption is that *all* contexts of an entity with type  $t$  are contexts of  $t$ ; e.g., we label all contexts mentioning “Barack Obama” with all of his types. Obviously, the labels are incorrect or *noisy* for some contexts. Multi-instance multi-label (MIML) learning addresses this problem. We apply MIML to fine-grained ET for the first time. Our assumption is: if entity  $e$  has type  $t$ , then there is at least one context of  $e$  in the corpus in which  $e$  occurs as type  $t$ . So, we apply this assumption during training with the following estimation of the type probability of an entity:

$$P(t|e) = \max_{1 \leq i \leq q} P(t|c_i) \quad (4)$$

which means we take the **maximum** probability of type  $t$  over all contexts of entity  $e$  as  $P(t|e)$ . We call this approach **MIML-MAX**.

MIML-MAX picks the most confident context for  $t$ , ignoring the probabilities of all the other contexts. Apart from missing information, this can be especially harmful if the entity annotations in the corpus are the result of an entity linking system. In that case, the most confident context might be wrongly linked to the entity. So, it can be beneficial to leverage all contexts into the final prediction, e.g., by **averaging** the type probabilities of all contexts of entity  $e$ :

$$P(t|e) = \frac{1}{q} \sum_{i=1}^q P(t|c_i) \quad (5)$$

We call this approach **MIML-AVG**. We also propose a combination of the maximum and average, which uses MIML-MAX (Eq. 4) in training and MIML-AVG (Eq. 5) in prediction. We call this approach **MIML-MAX-AVG**.

MIML-AVG treats every context equally which might be problematic since many contexts are irrelevant for a particular type. A better way is to weight the contexts according to their similarity to the types. Therefore, we propose using selective **attention** over contexts as follows and call this approach **MIML-ATT**. MIML-ATT is the multi-label version of the selective attention method proposed in Lin et al. (2016). To compute the type

Model	Train	Prediction
MIML-MAX	MAX	MAX
MIML-AVG	AVG	AVG
MIML-MAX-AVG	MAX	AVG
MIML-ATT	ATT	ATT

Table 1: Different MIML algorithms for entity typing, and the aggregation function they use to get corpus-level probabilities.

probability for  $e$ , we define:

$$P(t|e) = \sigma(\vec{w}_t \vec{a}_t + b_t) \quad (6)$$

where  $\vec{w}_t \in \mathbb{R}^h$  is the output weight vector and  $b_t$  the bias scalar for type  $t$ , and  $\vec{a}_t$  is the aggregated representation of all contexts  $c_i$  of  $e$  for type  $t$ , computed as follows:

$$\vec{a}_t = \sum_i \alpha_{i,t} \vec{c}_i \quad (7)$$

where  $\alpha_{i,t}$  is the attention score of context  $c_i$  for type  $t$  and  $\vec{a}_t \in \mathbb{R}^h$  can be interpreted as the representation of entity  $e$  for type  $t$ .

$\alpha_{i,t}$  is defined as:

$$\alpha_{i,t} = \frac{\exp(\vec{c}_i \mathbf{M} \vec{t})}{\sum_{j=1}^q \exp(\vec{c}_j \mathbf{M} \vec{t})} \quad (8)$$

where  $\mathbf{M} \in \mathbb{R}^{h \times d_t}$  is a weight matrix that measures the similarity of  $\vec{c}$  and  $\vec{t}$ .  $\vec{t} \in \mathbb{R}^{d_t}$  is the representation of type  $t$ .

Table 1 summarizes the differences of our MIML methods with respect to the aggregation function they use to get corpus-level probabilities. For optimization of all MIML methods, we use the binary cross entropy loss function,

$$L(\theta) = \sum_e \sum_t \text{BCE}(y_t, P(t|e)) \quad (9)$$

In contrast to the loss function of distant supervision in Eq. 2, which iterates over all *contexts*, we iterate over all *entities* here.

### 3.2 Context Representation

To produce a high-quality context representation  $\vec{c}$ , we use convolutional neural networks (CNNs).

The first layer of the CNN is a *lookup table* that maps each word in  $c$  to an embedding of size  $d$ . The output of the lookup layer is a matrix  $E \in \mathbb{R}^{d \times s}$  (the embedding layer), where  $s$  is the context size (a fixed number of words).

The CNN uses  $n$  filters of different window widths  $w$  to narrowly convolve  $E$ . For each of the  $n$  filters  $H \in \mathbb{R}^{d \times w}$ , the result of applying  $H$  to matrix  $E$  is a feature map  $\vec{m} \in \mathbb{R}^{s-w+1}$ :

$$m[i] = g(E_{:,i:i+w-1} \odot H) \quad (10)$$

where  $g$  is the *relu* function,  $\odot$  is the Frobenius product,  $E_{:,i:i+w-1}$  are the columns  $i$  to  $i+w-1$  of  $E$  and  $1 \leq w \leq k$  are the window widths we consider. Max pooling then gives us one feature for each filter and the concatenation of those features is the CNN representation of  $c$ .

As it is shown in the entity typing part of Figure 1, we apply the CNN to the left and right context of the entity mention and the concatenation  $\vec{\phi}(c) \in \mathbb{R}^{2n}$  is fed into a multi-layer perceptron (MLP) to get the final context representation  $\vec{c} \in \mathbb{R}^h$ :

$$\vec{c} = \tanh(\mathbf{W}_h \vec{\phi}(c)) \quad (11)$$

## 4 Type-aware Relation Extraction

Relation extraction (RE) is mostly defined as finding relations between pairs of entities, for instance, finding the relation “president-of” between “Obama” and “USA”. Given a set of  $q$  contexts for an entity pair  $z$ ,  $B = \{c_1, c_2, \dots, c_q\}$  in the corpus, we learn  $P(r|z)$ , which is the probability of relation  $r$  for  $z$ . We assume that each  $z$  has one relation  $r(z)$ . Each  $c_i$  is represented by a vector  $\vec{c}_i \in \mathbb{R}^h$ , which is our type-aware representation of context described in Section 4.1.

To learn  $P(r|z)$ , we use the multi-instance (MI) learning method of Zeng et al. (2015):

$$P(r|c_i) = \text{softmax}(\mathbf{W}_{\text{out}} \vec{c}_i), \quad (12)$$

$$P(r|z) = \max_{1 \leq i \leq q} P(r|c_i)$$

where  $P(r|c_i)$  is the probability of relation  $r$  for context  $c_i$ . The cost function we optimize is:

$$L(\theta) = - \sum_z \log P(r(z)|z)$$

### 4.1 Context Representation

Similar to our entity typing system, we apply CNNs to compute the context representation  $\vec{\phi}(c)$ . In particular, we use Adel et al. (2016)’s CNN. It uses an input representation designed for RE. Each sentence is split into three parts: left of the relation arguments, between the relation arguments

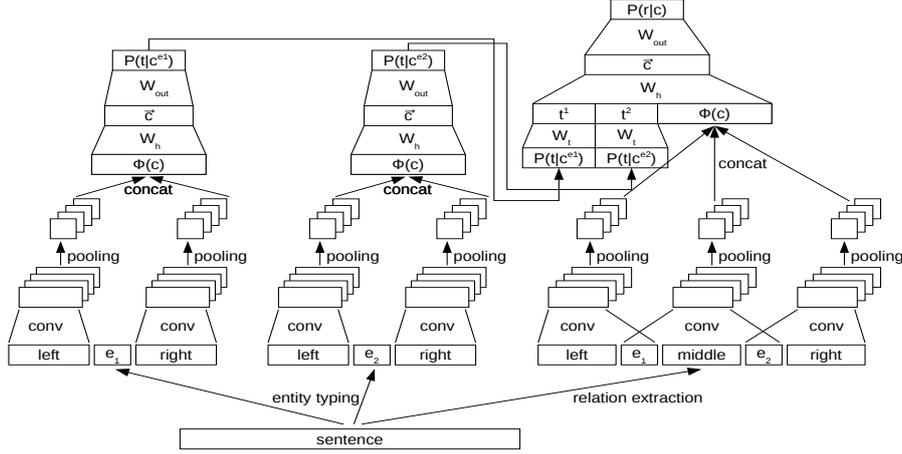

Figure 1: Our architecture for joint entity typing and relation extraction

and right of the relation arguments. The parts “overlap”, i.e., the left (resp. right) argument is included in both left (resp. right) and middle parts. For each of the three parts, convolution and 3-max pooling (Kalchbrenner et al., 2014) is performed. The context representation  $\vec{\phi}(c) \in \mathbb{R}^{3 \cdot 3 \cdot n}$  is the concatenation of the pooling results.

#### 4.1.1 Integration of Entity Types

We concatenate the entity type representations  $t^1 \in \mathbb{R}^\tau$  and  $t^2 \in \mathbb{R}^\tau$  of the relation arguments to the CNN representation of the context,  $\vec{\phi}(c)$ :

$$\vec{\phi}(c)' = [\vec{\phi}(c) : t^1 : t^2] \quad (13)$$

Our context representation  $\vec{c}$  is then:

$$\vec{c} = \tanh(\mathbf{W}_h \vec{\phi}(c)') \quad (14)$$

where  $\mathbf{W}_h \in \mathbb{R}^{h \times (3 \cdot 3 \cdot n + 2\tau)}$  is the weight matrix. This is also depicted in Figure 1, right column, third layer from the top:  $t^1$ ,  $t^2$ ,  $\vec{\Phi}(c)$ . We calculate  $t^1$  and  $t^2$  from the predictions of the entity typing model with the following transformation:

$$t^k = f(\mathbf{W}_t [P(t_1|c^{e_k}) \dots P(t_T|c^{e_k})]) \quad (15)$$

where  $c^{e_k}$  is the context of  $e_k$ ,  $\mathbf{W}_t \in \mathbb{R}^{\tau \times T}$  is a weight matrix (learned from corpus or during training) and  $f$  is a function (identity or tanh). With the transformation  $\mathbf{W}_t$ , the model can combine predictions for different types to learn better internal representations  $t^1$  and  $t^2$ . The choices of  $\mathbf{W}_t$  and  $f$  depend on the different representations we investigate and describe in the following.

**(1) Pipeline:** We integrate entity types into the RE model, using the output of ET in a pipeline

model (see Eq. 15). We test the following representations of  $t^k$ ,  $k \in \{1, 2\}$ . **PREDICTED-HIDDEN:**  $\mathbf{W}_t$  from Eq. 15 is learned during training and  $f$  is tanh. That means that a hidden layer learns representations based on the predictions  $P(t_1|c^{e_k}) \dots P(t_T|c^{e_k})$ . **BINARY-HIDDEN:** This is the binarization of the input of PREDICTED-HIDDEN, i.e., each probability estimate is converted to 0 or 1 (with a threshold of 0.5). **BINARY:**  $t^k$  is the binary vector itself (used by Ling and Weld (2012)). **WEIGHTED:** The columns of matrix  $\mathbf{W}_t$  from Eq. 15 are the distributional embeddings of types trained on the corpus (see Section 5.1).  $f$  is the identity function.

**(2) Joint model:** As an alternative to the pipeline model, we investigate integrating entity typing into RE by jointly training both models. We use the architecture depicted in Figure 1. The key difference to the pipeline model PREDICTED-HIDDEN is that we learn  $P(t|c)$  and  $P(r|c)$  jointly, called **JOINT-TRAIN**. We compare JOINT-TRAIN to other models, including the pipeline models.

During training of JOINT-TRAIN, we compute the cost of the ET model for typing the first entity  $L_1(\theta_T)$ , the cost for typing the second entity  $L_2(\theta_T)$  and the cost of the RE model for assigning a relation to the two entities  $L(\theta_R)$ . Then, we combine those costs with a weight  $\gamma$  which is tuned on the development set:

$$L(\theta) = \sum_z (L_1(\theta_T) + L_2(\theta_T) + \gamma \cdot L(\theta_R)),$$

$$L_i(\theta_T) = \sum_t \text{BCE}(y_t^{e_i}, P(t|c^{e_i})),$$

$$L(\theta_R) = -\log P(r(z)|z)$$

$P(r|z)$  is computed based on Eq. 12.

Note that based on this equation, the ET parameters are optimized on the contexts of the RE examples, which are a subset of all training examples of ET. However in the pipeline models, ET is trained on the whole training set used for typing. Also note that in JOINT-TRAIN we do not use MIML for the ET part but a distant supervised cost function.

## 5 Experimental Data, Setup and Results

For entity typing, we use CF-FIGMENT (URL, 2016b), a dataset published by Yaghoobzadeh and Schütze (2015). CF-FIGMENT is derived from a version of ClueWeb (URL, 2016c) in which Freebase entities are annotated using FACC1 (URL, 2016d; Gabrilovich et al., 2013). CF-FIGMENT contains 200,000 Freebase entities that were mapped to 102 FIGER types (Ling and Weld, 2012), divided into train (50%), dev (20%) and test (30%); and a set of 4,300,000 sentences (contexts) containing those entities.

For relation extraction, we first select the ten most frequent relations (plus NA for no relation according to Freebase) of entity pairs in CF-FIGMENT. We ensure that the entity pairs have at least one context in CF-FIGMENT. This results in 5815, 3054 and 6889 unique entity pairs for train, dev and test.<sup>2</sup> Dev and test set sizes are 124,462 and 556,847 instances. For the train set, we take a subsample of 135,171 sentences. The entity and sentence sets of CF-FIGMENT were constructed to ensure that entities in the entity test set do not occur in the sentence train and dev sets; that is, a sentence was assigned to the train set only if all entities it contains are train entities.<sup>1</sup>

### 5.1 Word, Entity and Type Embeddings

We use 100-dimensional word embeddings to initialize the input layer of ET and RE. Embeddings

<sup>2</sup>We only assign those entity pairs to test (resp. dev, resp. train) for which both constituting entities are in the ET test (resp. dev, resp. train) set.

are kept fixed during training. Since we need embeddings for words, entities and types in the same space, we process ClueWeb+FACC1 (corpus with entity information) as follows. For each sentence  $s$ , we add two copies:  $s$  itself, and a copy in which each entity is replaced with its notable type, the most important type according to Freebase. We process train, dev and test this way, but do not replace test entities with their notable type because the types of test entities are unknown in our application scenario. We run word2vec (Mikolov et al., 2013) on the resulting corpus to learn embeddings for words, entities and types. Note that our application scenario is that we are given an unannotated input corpus and our system then extracts entity types and relations from this input corpus to enhance the KB.

### 5.2 Entity Typing Experiments

**Entity context setup.** We use a window size of 5 on each side of the entity mentions. Following Yaghoobzadeh and Schütze (2015), we replace other entities occurring in the context with their Freebase notable type mapped to FIGER.

**Models.** Yaghoobzadeh and Schütze (2015) applied a multi-layer perceptron (MLP) architecture to create context representations. Therefore, we use an MLP baseline to compute the context representation  $\vec{\phi}(c)$ . The input to the MLP model is a concatenation of context word embeddings. As an alternative to MLP, we also train a CNN (see Section 3.2) to compute context representations. We run experiments with MLP and CNN, each trained with standard distant supervision and with MIML.

**EntEmb and FIGMENT baselines.** Following Yaghoobzadeh and Schütze (2015), we also learn entity embeddings and classify those embeddings to types, i.e., instead of distant supervision, we classify entities based on aggregated information represented in entity embeddings. An MLP with one hidden layer is used as classifier. We call that model EntEmb. We join the results of EntEmb with our best model (line 13 in Table 3), similar to the joint model (FIGMENT) in Yaghoobzadeh and Schütze (2015).

We use the same **evaluation measures** as Ling and Weld (2012), Yaghoobzadeh and Schütze (2015) and Neelakantan and Chang (2015) for entity typing: precision at 1 ( $P@1$ ), which is the accuracy of picking the most confident type for each entity, micro average  $F_1$  of all entity-type

	$P@1$	$F_1$	$F_1$	$F_1$	MAP
	all	all	head	tail	
1 MLP	74.3	69.1	74.8	52.5	42.1

Table 3:  $P@1$ , Micro  $F_1$  for all, head and tail entities and MAP results for entity typing.

assignments and mean average precision (MAP) over types. We could make assignment decisions based on the standard criterion  $p > \theta$ ,  $\theta = 0.5$ , but we found that tuning  $\theta$  improves results. For each probabilistic classifier and each type, we set  $\theta$  to the value that maximizes performance on dev.

**Results.** Table 3 shows results for  $P@1$ , micro  $F_1$  and MAP. For  $F_1$ , we report separate results for all, head (frequency higher than 100) and tail (frequency less than 5) entities.

**Discussion.** The improvement of CNN (6) compared to MLP (1) is not surprising considering the effectiveness of CNNs in finding position independent local features, compared to the flat representation of MLP. Lines 2-5 and 7-10 show the results of different MIML algorithms for MLP and CNN, respectively. Considering micro F1 for all entities as the most importance measure, the trend is similar in both MLP and CNN for MIML methods: ATT > MAX-AVG > AVG > MAX.

MAX is worse than even basic distant supervised models, especially for micro F1. MAX predictions are based on only one context of each entity (for each type), and the results suggest that this is harmful for entity typing. This is in contradiction with the previous results in RE (cf. Zeng et al. (2015)) and suggests that there might be a significant difference between expressing types of entities and relations between them in text. Related to this, MAX-AVG which averages the type probabilities at prediction time improves MAX by a large margin. Averaging the context probabilities seems to be a way to smooth the entity type probabilities. MAX-AVG models are also better than the corresponding models with AVG that train and predict with averaging. This is due to the fact that AVG gives equal weights to all context probabilities both in training and prediction. ATT uses

weighted contexts in both training and prediction and that is probably the reason for its effectiveness over all other MIML algorithms. Overall, using attention (ATT) significantly improves the results of both MLP and CNN models.

CNN+MIML-ATT (10) performs comparable to EntEmb (11), with better micro F1 on all and tail entities and worse MAP and micro F1 on head entities. These two models have different properties, e.g., MIML is also able to type each mention of entities while EntEmb works only for corpus-level typing of entities. (See Yaghoobzadeh and Schütze (2015) for more differences) It is important to note that MIML can also be applied to any entity typing architecture or model that is trained by distant supervision. Due to the lack of large annotated corpora, distant supervision is currently the only viable approach to fine-grained entity typing; thus, our demonstration of the effectiveness of MIML is an important finding for entity typing.

Joining the results of CNN+MIML-ATT with EntEmb (line 13) gives large improvements over each of the single models. It is also consistently better (by more than 3% in all measures) than our baseline FIGMENT (12), which is basically MLP+EntEmb. This improvement is achieved by using CNN instead of MLP for context representation and integrating MIML-ATT. EntEmb is improved by Yaghoobzadeh et al. (2017) by using entity names. We leave the integration of that model to future work.

**Example.** To show the behavior of MIML-MAX and MIML-ATT, we extract the scores that each method assigns to the labels for each context. A comparison for the example entity “Richard Bright” (MID: /m/024g5w) who is a PERSON, DOCTOR and AUTHOR is shown in Figure 2. Note

that the weights from MIML-ATT (Eq. 8) sum to 1 for each label because of the applied softmax function while the scores from MIML-MAX (Eq. 1) do not. For both methods, the scores for the type PERSON are more equally distributed than for the other types which makes sense since the entity has the PERSON characteristics in every sentence. For the other types, both models seem to be influenced by other entities occurring in the context (e.g., an occurrence with another DOCTOR could indicate that the entity is also a DOCTOR) but also by trigger words such as “write” or “book” for the type AUTHOR or “disease” for the type DOCTOR.

### 5.3 Relation Extraction Experiments

**Models.** In our experiments, we compare two state-of-the-art RE architectures: piecewise CNN (Zeng et al., 2015) and contextwise CNN (Adel et al., 2016). We use the publicly available implementation for the piecewise CNN (URL, 2016a) and our own implementation for the contextwise CNN. Both CNNs represent the input words with embeddings and split the contexts based on the positions of the relation arguments. The contextwise CNN splits the input before convolution, the piecewise CNN after convolution. Also, while the piecewise CNN applies a softmax layer directly after pooling, the contextwise CNN feeds the pooling results into a fully-connected hidden layer first. For both models, we use MI learning to mitigate the noise from distant supervision.

**Results.** The precision recall (PR) curves in Figure 3 show that the contextwise CNN outperforms the piecewise CNN on our RE dataset. We also compare them to a baseline model that does not learn context features but uses only the embeddings of the relation arguments as an input and feeds them into an MLP (similar to the EntEmb baseline for ET). The results confirm that the context features which the CNNs extract are very important, not only for ET but also for RE. Note that the PR curves are calculated on the corpus level and not on the sentence-level, i.e., after aggregating the predictions for each entity pair. Following Ritter et al. (2013), we compute the area  $A$  under the PR curves which supports this trend (EntEmb:  $A = 0.34$ , piecewise CNN:  $A = 0.48$ , contextwise CNN:  $A = 0.50$ ).

**Pipeline vs. joint training.** Since the contextwise CNN outperforms the piecewise CNN, we use the contextwise CNN for integrating en-

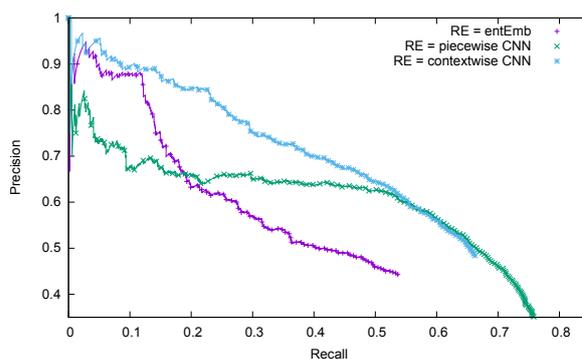

Figure 3: PR curves: relation extraction models

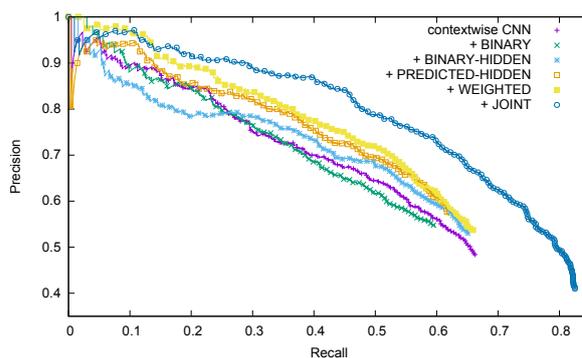

Figure 4: PR curves: type-aware relation extraction models

tity types. Figure 4 shows that the performance on the RE dataset increases when we integrate entity type information into the CNN. The main trend of the PR curves and the areas under them shows the following order of model performances: JOINT-TRAIN > WEIGHTED > PREDICTED-HIDDEN > BINARY-HIDDEN > BINARY.

**Discussion.** The better performance of our approaches of integrating type predictions into the contextwise CNN (PREDICTED-HIDDEN, WEIGHTED) compared to baseline type integrations (BINARY, BINARY-HIDDEN) shows that probabilistic predictions of an entity typing system can be a valuable resource for RE. With binary types, it is not possible to tell whether one of the selected types had a higher probability than another or whether a type whose binary value is 0 just barely missed the threshold. Probabilistic representations preserve this information. Thus, using probabilistic representations, the RE system can compensate for noise in ET predictions.

WEIGHTED with access to the distributional type embeddings learned from the corpus works better than all other pipeline models. This shows

that our type embeddings can be valuable for RE. JOINT-TRAIN performs better than all pipeline models, even though the ET part in the pipelines is trained on more data. The area of JOINT-TRAIN under the PR curve is  $A = 0.66$ . A plausible reason is the mutual dependencies of those two tasks which a joint model can better learn than a pipeline model. We can also relate it to better noise mitigation of jointed ET, compared to isolated models.<sup>3</sup>

**Analysis of joint training.** In this paragraph, we investigate the joint training in more detail. In particular, we evaluate different variants of it by combining relation extraction with other entity typing approaches: EntEmb and FIGMENT. For joint training with ET-EntEmb, we do not use the context for predicting the types of the relation arguments but only their embeddings. Then, we feed those embeddings into an MLP which computes a representation that we use for the type prediction. This corresponds to the EntEmb model presented in Table 3 (line 11). For joint training with ET-FIGMENT, we compute two different cost functions for entity typing: one for typing based on entity embeddings (see ET-EntEmb above) and one for typing based on an MLP context model. This does not correspond exactly to the FIGMENT model from Table 3 (line 12) which combines an entity embedding and MLP context model as a postprocessing step but comes close. In addition to those two baseline ET models, we also train a version in which both entity typing and relation extraction use EntEmb as their only input features. Figure 5 shows the PR curves for those models. The curve for the model that uses only entity embedding features for both entity typing and relation extraction is much worse than the other curves. This emphasizes the importance of our context model for RE (see also Figure 3), also in combination with joint training. Similarly, the curve for the model with EntEmb as entity typing component has more precision variations than the curves for the other models which use context features for ET. Thus, joint training does not help per se but it is important which models are trained together. The areas under the PR curves show the following model trends: joint with ET-FIGMENT  $\approx$  joint as in Figure 1  $>$  joint with ET-EntEmb  $>$  joint with ET-EntEmb and RE-EntEmb.

**Most improved relations.** To identify which

<sup>3</sup>On the joint dataset, joint training improves MAP for entity typing by about 20% compared to the best isolated model.

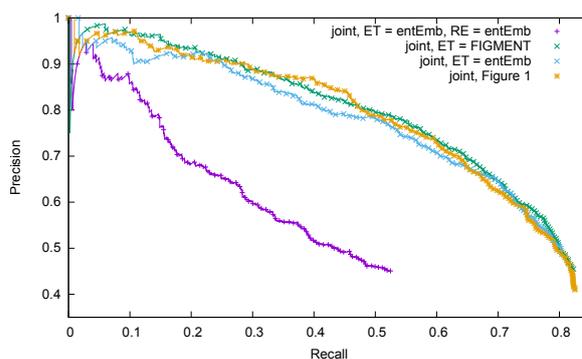

Figure 5: Variants of joint training

relations are improved the most when entity types are integrated, we compare the relation specific  $F_1$  scores of CNN, CNN+WEIGHTED and CNN+JOINT-TRAIN. With WEIGHTED, the relations PPL.deceased\_PER.place\_of\_death and LOC.LOC.containedby are improved the most (from 36.13 to 53.73 and 49.04 to 64.19  $F_1$ , resp.). JOINT-TRAIN has the most positive impact on PPL.deceased\_PER.place\_of\_death, ORG.ORG.place\_founded and GOV.GOV\_agency.jurisdiction (from 36.13 to 67.10, 42.38 to 58.51 and 62.26 to 70.41 resp.).

## 6 Conclusion

In this paper, we addressed different types of noise in two information extraction tasks: entity typing and relation extraction. We presented the first multi-instance multi-label methods for entity typing and showed that it helped to alleviate the noise from distant supervised labels. This is an important contribution because most of the current fine-grained entity typing systems are trained by distant supervision. Our best model sets a new state of the art in corpus-level entity typing. For relation extraction, we mitigated noise from using predicted entity types as features. We compared different pipeline approaches with each other and with our proposed joint type-relation extraction model. We observed that using type probabilities is more robust than binary predictions of types, and joint training gives the best results.

## Abstract

We analyze semantic changes in loanwords from English that are used in Japanese (Japanese loanwords). Specifically, we create word embeddings of English and Japanese and map the Japanese embeddings into the English space so that we can calculate the similarity of each Japanese word and each English word. We then attempt to find loanwords that are semantically different from their original, see if known meaning changes are correctly captured, and show the possibility of using our methodology in language education.

## 1 Introduction

We often come across advertisements that have extravagant images. In Japan, such images are usually accompanied by the following sentence<sup>1</sup>:

この 画像は イメージ です  
kono gazō-wa imēji desu  
this image-TOP image COP  
“This image is an image.”

This sentence sounds like a nonsense tautology, but actually means *this image is only for illustrative purposes and may differ from the actual product*. Both *gazō* and *imēji* are Japanese words, each meaning *image*. However, the latter is a loanword from English, i.e., *image*<sup>2</sup>. In the sentence above, *imēji*, the loanword for image, is closer in meaning to the word *impression*, and it makes the sentence roughly mean *this image is just an impres-*

<sup>1</sup>TOP and COP respectively mean a topic marker and a copula in interlinear glossed text (IGT) representation. The last line is a literal translation of the Japanese sentence.

<sup>2</sup>Note that although *gazō* is also from ancient Chinese, we focus on loanwords from English, which are usually written in *katakana* letters in Japanese.

*sion that you might have on this product*. What happens in this seeming tautology is that the loanword changes meaning; i.e., the sense of the loanword deviates from the sense of its original word.

Loanwords from English occupy an important place in the Japanese language. It is reported that approximately 8% of the vocabulary of contemporary Japanese consists of loanwords from English (Barrs, 2013). One noteworthy characteristics of loanwords in Japanese is that their meanings are often different from their original words, as in the above example. Indeed, the meanings of loanwords in any language are not generally the same as those in the language, but according to Kay (1995), Japanese has particularly a strong tendency of changing the meanings of loanwords; Kay argued that in Japan *there is no deep cultural motivation to protect their original meaning*. Daulton (2009) also argued that Japanese loanwords are malleable in terms of meanings. Thus, Japanese loanwords would be an interesting subject to work on in the study of meaning change.

Japanese loanwords from English are also important in language education (Barrs, 2013). Japanese learners of English often make mistakes in using English words that have corresponding loanwords in Japanese but with very different meanings. By contrast, learners are able to make better use of a loanword in conversation if they know that its meaning is the same as that of the original. It is thus important to know which loanwords are semantically different from their original and which are not.

With this background in mind, we work on Japanese loanwords derived from English. Since the word embedding vectors (or simply, embeddings), which have become very popular recently, are powerful tools for dealing with word meanings, we use them to analyze Japanese loanwords. Specifically, we create word embeddings of En-

glish and Japanese, and map the Japanese embeddings into the English space so that we can calculate the similarity of each Japanese word and each English word. We then attempt to find loanwords that are semantically different from their original, see if known meaning changes are correctly captured, and show the possibility of using our methodology in language education.

In this paper, we use the term *semantic change* or *meaning change* in a broad sense. Some loanwords are semantically different from the original words because the loanwords or the original words semantically changed after they were introduced into Japanese or because only one of the multiple senses of the original words were introduced. Moreover, some loanwords did not come directly from English, but from words in other languages, which later became English words. Thus, in this paper, the terms semantic change or meaning change cover all of these semantic differences.

## 2 Related Work

Japanese loanwords have attracted much interest from researchers. Many interesting aspects of Japanese loanwords are summarized in a book written by Irwin (2011). In the field of natural language processing, there have been a number of efforts to capture the behavior of Japanese loanwords including the phonology (Blair and Ingram, 1998; Mao and Hulden, 2016) and segmentation of multi-word loanwords (Breen et al., 2012). The rest of this section explains the computational approaches to semantic changes or variations of words. In particular, there are mainly two different phenomena, namely diachronic change and geographical variation.

Jatowt and Duh (2014) used conventional distributional representations of words, i.e., bag-of-context-words, calculated from Google Book (Michel et al., 2011)<sup>3</sup> to analyze the diachronic meaning changes of words. They also attempted to capture the change in sentiment of words across time. Kulkarni et al. (2014) used distributed representations of words (or word embeddings), instead of the bag-of-context-words used by Jatowt and Duh, to capture meaning changes of words and in addition used the change point detection technique to find the point on the timeline where the meaning change occurred. Hamil-

<sup>3</sup><https://books.google.com/ngrams/datasets>

ton et al. (2016) also used distributed representations for the same purpose and attempted to reveal the statistical laws of meaning change. They compared the following three methods for creating word embedding: positive pointwise mutual information (PPMI), low-dimensional approximation of PPMI obtained through singular value decomposition, and skip-gram with negative sampling. They suggested that the skip-gram with negative sampling is a reasonable choice for studying meaning changes of words. We decided to follow their work and use the skip-gram with negative sampling to create word embeddings.

Bamman et al. (2014) used a similar technique to study differences in word meanings ascribed to geographical factors. They succeeded in correctly recognizing some dialects of English within the United States. Kulkarni et al. (2016) also worked on geographic variations in languages.

With some modification, the methods used in the literature (Kulkarni et al., 2014; Hamilton et al., 2016) can be applied to loanword analysis.

## 3 Methodology

We use word embeddings to analyze the semantic changes in Japanese loanwords from the corresponding English. Among the methods of analysis, we chose to use the skip-gram with negative sampling for the reason discussed in Section 2 with reference to Hamilton et al.’s work (2016).

First, we create word embeddings for two languages. We then calculate the similarity or dissimilarity between the embedding (or vector) of a word in a language (say, Japanese) and the embedding of a word in another language (say, English). For this purpose, words in the two languages need to be represented in the same vector space with the same coordinates. There are a number of methods for this purpose (Gouws et al., 2015; Zou et al., 2013; Faruqui and Dyer, 2014; Mikolov et al., 2013a). Among them, we choose the simplest and most computationally efficient one proposed by Mikolov et al. (2013a), where it is assumed that embeddings in one language can be mapped into the vector space of another language by means of a linear transformation represented by  $W$ . Suppose we are given trained word embeddings of the two languages and a set of seed pairs of embedding vectors  $\{(x_i, z_i) | 1 \leq i \leq n\}$ , each of which is a pair of a vector in one language and a vector in the other language that are translation equiva-

lents of each other. The transformation matrix  $W$  is obtained by solving the following minimization problem :

$$\min_W \sum_{i=1}^n \|Wx_i - z_i\|^2, \quad (1)$$

where, in our case,  $x_i$  is the embedding of a Japanese seed word and  $z_i$  is the embedding of its English counterpart. Thus, the Japanese word embeddings are mapped into the English vector space so that the embeddings of the words in each seed pair should be as close to each other as possible. Although Hamilton et al. (2016) preserved cosine similarities between embedding vectors by adding the orthogonality constraint (i.e.,  $W^T W = I$ , where  $I$  is the identity matrix) when they aligned English word embeddings of different time periods, we do not adopt this constraint for two reasons. The first reason is that since we need an inter-language mapping instead of across-time mappings of the same language, the orthogonality constraint would degrade the quality of the mapping; the two spaces might be so different that even the best rotation represented by an orthogonal matrix would leave much error between corresponding words. The second reason is that we do not need to preserve cosine similarities between words in mapping embedding vectors, because we do not use the cosine similarities between mapped embedding vectors of Japanese words.

After mapping the Japanese word embeddings to the English vector space, we calculate the cosine similarity between each Japanese loanword and its original English word. If the cosine similarity is low for a pair of words, the meaning of the Japanese loanword is different from that of its original English word.

## 4 Empirical Evaluations

Since it is generally difficult to evaluate methods for capturing semantic changes in words, we conduct a number of quantitative and qualitative evaluations from different viewpoints.

### 4.1 Data and Experimental Settings

The word embeddings of English and Japanese were obtained via the skip-gram with negative sampling (Mikolov et al., 2013b)<sup>4</sup> with different dimensions as shown in the result. The data

<sup>4</sup><https://code.google.com/archive/p/word2vec/> with options “-window 5 -sample 1e-4 -negative 5 -hs 0 -cbow 0 -iter 3”

used for this calculation was taken from Wikipedia dumps<sup>5</sup> as of June 2016 for each language; the text was extracted by using wp2txt (Hasebe, 2006)<sup>6</sup>, non-alphabetical symbols were removed, and noisy lines such as the ones corresponding to the infobox were filtered out<sup>7</sup>. We performed word segmentation on the Japanese Wikipedia data by using the Japanese morphological analyzer MeCab (Kudo et al., 2004)<sup>8</sup> with the neologism dictionary, NEologd<sup>9</sup>, so that named entities would be recognized correctly.

The list of Japanese loanwords was obtained from Wiktionary<sup>10</sup>. Only one-word entries were used and some errors were corrected, resulting in 1,347 loanwords from English<sup>11</sup>.

We extracted seed word pairs from an English-Japanese dictionary, edict (Breen, 2000)<sup>12</sup>; these were used in the minimization problem expressed by Equation (1). Specifically, we extracted one-word English entries that were represented as a single Japanese word. We then excluded the 1,347 loanwords obtained above from the word pairs, which resulted in 41,366 seed word pairs.

### 4.2 Evaluation through Correlation

To see if the differences in word embeddings are related to the meaning changes of loanwords, we calculate an evaluation measure indicating the global trend. We first extracted one-to-one translation sentence pairs from Japanese-English News Article Alignment Data (JENAAD) (Utiyama and Isahara, 2003). We then use this set of sentence pairs to calculate the Dice coefficient for each pair of a loanword  $w_{\text{jpn}}$  and its original English word  $w_{\text{eng}}$ , which is defined as

$$\frac{2 \times P(w_{\text{jpn}}, w_{\text{eng}})}{P(w_{\text{jpn}}) + P(w_{\text{eng}})}, \quad (2)$$

<sup>6</sup><https://github.com/yohasebe/wp2txt>

<sup>7</sup><https://en.wikipedia.org/wiki/Help:Infobox>

<sup>8</sup><http://taku910.github.io/mecab/>

<sup>9</sup><https://github.com/neologd/mecab-ipadic-neologd>

<sup>10</sup><https://ja.wiktionary.org/wiki/%E3%82%AB%E3%83%86%E3%82%B4%E3%83%AA%3A%E6%97%A5%E6%9C%AC%E8%AA%9E.%E5%A4%96%E6%9D%A5%E8%AA%9E>

<sup>11</sup>Some of these loanwords may have been introduced into Japanese via other languages. However, in this paper, we regard them as from English as long as they are also used in English.

<sup>12</sup><http://www.edrdg.org/jmdict/edict.html>

dimension		correlation coefficient	
dim <sub>jpn</sub>	dim <sub>eng</sub>	Pearson	Spearman
100	100	0.363	0.443
200	100	0.386	0.471
200	200	0.402	0.474
400	200	0.404	0.487
300	300	0.422	0.492
600	300	0.432	0.506

Table 1: Correlation coefficients between the Dice coefficient and the cosine similarity.  $\text{dim}_{\text{jpn}}$  and  $\text{dim}_{\text{eng}}$  are respectively the dimensions of the Japanese and English word embeddings; i.e., the  $\text{dim}_{\text{jpn}}$ -dimensional space is mapped to the  $\text{dim}_{\text{eng}}$ -dimensional space. All the coefficients are statistically significant (significance level 0.01).

where  $P(w_{\text{jpn}}, w_{\text{eng}})$  is the probability that this word pair appears in the same sentence pair, and  $P(w_{\text{jpn}})$  and  $P(w_{\text{eng}})$  are the generative probabilities of  $w_{\text{jpn}}$  and  $w_{\text{eng}}$ . All the probabilities were obtained using the maximum likelihood estimation. The Dice coefficient is a measure of co-occurrence and can be used to extract translate equivalents (Smadja et al., 1996). If the Dice coefficient of a word pair is low, the words in the pair are unlikely to be translation equivalents of each other. Therefore, if the meaning of a loanword has changed from the original English word, its Dice coefficient should be low. In other words, the cosine similarity should be correlated to the Dice coefficient if the cosine similarity is a good indicator of meaning change. We thus calculate the Pearson’s correlation coefficient between the two. In addition, we calculate the Spearman’s rank-order correlation coefficient to examine the relation of the orders given by the Dice coefficient and the cosine similarity.

Note that although we use a parallel corpus for evaluation, it does not mean that we can simply use a parallel corpus for finding meaning changes in loanwords. Parallel corpora are usually much smaller than monolingual corpora and can cover only a small portion of the entire set of loanwords. With the model described in Section 3, we will be able to find meaning changes in loanwords that do not appear in a parallel corpus.

The results for different Japanese and English dimensions,  $\text{dim}_{\text{jpn}}$  and  $\text{dim}_{\text{eng}}$ , are shown in Table 1. Pearson’s correlation coefficients suggest that the cosine similarity is moderately cor-

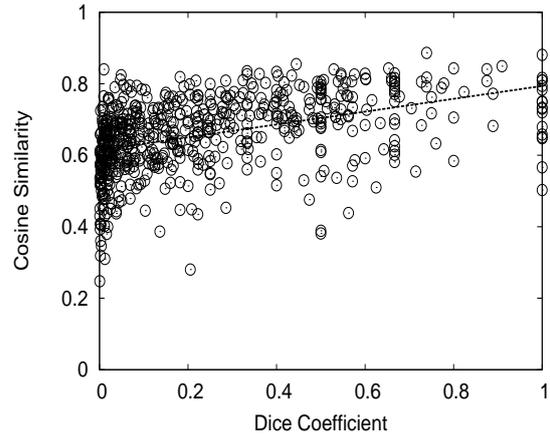

Figure 1: Dice coefficient vs. cosine similarity. Dice coefficients are extracted from a parallel corpus. Cosine similarities are for the embedding vectors of the Japanese loanwords and their English counterparts. The line in the figure is obtained by linear regression.

related with the Dice coefficient except for the case  $\text{dim}_{\text{eng}}=100$ , which shows weak correlation. Spearman’s rank-order correlation coefficients also suggest that these two are moderately correlated with each other. The result depends on the dimensions of the word embeddings. Basically, larger dimensions tend to have higher correlation coefficients. In addition, when the dimension is decreased (e.g.,  $\text{dim}_{\text{jpn}} = 600$  to  $\text{dim}_{\text{eng}} = 300$ ), the correlation coefficients tend to be higher, compared with the case where the dimension remains the same (e.g.,  $\text{dim}_{\text{jpn}} = 300$  to  $\text{dim}_{\text{eng}} = 300$ ). This result is consistent with the report by Mikolov et al. (2013a) that *the word vectors trained on the source language should be several times (around 2x-4x) larger than the word vectors trained on the target language*.

To examine the relation between the Dice coefficient and the cosine similarity in more detail, we plot these values for the bottom row in Table 1, i.e., where the dimensions for Japanese number 600 and the dimensions for English number 300. The scatter plot that we obtained is shown in Figure 1. The line obtained by linear regression is also drawn in the figure.

### 4.3 Detailed Evaluation on Known Change

Here, we conduct a detailed evaluation on meaning changes that are already known. We selected the ten Japanese loanwords shown in Ta-

$w_{\text{eng}}$	$w_{\text{jpn}}$	$w_a$	$w_b$	$\cos(w_{\text{eng}}, w_a) - \cos(w_{\text{jpn}}, w_a)$	$\cos(w_{\text{jpn}}, w_b) - \cos(w_{\text{eng}}, w_b)$
image	imēji	photo	impression	0.097	0.274
corner	cōnā	crossroad	section	0.099	0.115
digest	daijesuto	dissolve	summary	0.047	0.291
bug	bagu	insect	glitch	0.092	0.200
idol	aidoru	deity	popstar	0.127	0.086
icon	aikon	deity	illustration	-0.035	0.145
cunning	kanningu	shrewd	cheating	0.259	0.273
pension	penshon	annuity	hotel	0.368	0.445
nature	neichā	characteristics	magazine	0.106	0.202
driver	doraibā	chauffeur	screwdriver	-0.063	0.158

Table 2: Differences in cosine similarity. The Japanese loanword from *corner* can mean a small section in a larger building or space. The Japanese loanword from *bug* usually means a bug in a computer program. The Japanese loanword from *cunning* usually means cheating on an exam. The Japanese loanword from *nature* is often used to indicate the scientific journal *Nature*. The Japanese loanword from *driver* can mean both a vehicle driver and a screwdriver (the latter meaning was not one of the original word).

ble 2 that are supposed to have different meanings compared with the original English words. Some of these words were taken from a book about loanwords written by Kojima (1988). The others were collected by the authors. We also added two *pivot* words  $w_a$  and  $w_b$  for each word<sup>13</sup>. For the first nine words, the meaning of pivot word  $w_a$  is supposed to be closer to the English word  $w_{\text{eng}}$  than to the Japanese loanword  $w_{\text{jpn}}$ , and the meaning of the pivot word  $w_b$  is supposed to be closer to the Japanese loanword  $w_{\text{jpn}}$  than to the English word  $w_{\text{eng}}$ . It is thus expected that  $\cos(w_{\text{eng}}, w_a) - \cos(w_{\text{jpn}}, w_a) > 0$  and  $\cos(w_{\text{jpn}}, w_b) - \cos(w_{\text{eng}}, w_b) > 0$  hold true. The last Japanese loanword in Table 2 is used as both pivot words  $w_a$  and  $w_b$ , but the original English word is not used as  $w_b$ . It is thus expected that  $\cos(w_{\text{jpn}}, w_b) - \cos(w_{\text{eng}}, w_b) > 0$  holds true, but  $\cos(w_{\text{eng}}, w_a) - \cos(w_{\text{jpn}}, w_a) > 0$  might not be necessarily true. The differences in cosine similarities are shown in Table 2. As expected, almost all the differences are positive, which suggests that the difference of the word embeddings captures the meaning change. However, there was one exception:

$$\cos(\text{icon}, \text{deity}) - \cos(\text{icon}_{\text{jpn}}, \text{deity}) = -0.035.$$

<sup>13</sup>Pivot words are not necessarily synonyms of the corresponding English words. They are the words that we think are useful for capturing how the meanings of the loanwords and the original English are different. We also made sure that pivot words themselves are unambiguous.

The cosine similarity between *icon* and *deity* was 0.266, which is smaller than expected. We randomly sampled 100 lines containing *icon* from English Wikipedia text, which we used for calculating word embeddings, and found that the dominant sense of *icon* in Wikipedia is not *a religious painting or figure*, but *a representative person or thing*’ as in the Wikipedia page of a football superstar David Beckham<sup>14</sup>:

*Beckham became known as a fashion icon, and together with Victoria, the couple became . . .*

Thus, the reason of *icon*’s anomalous behavior is that the distribution over senses in Wikipedia was a lot different from the expected one.

#### 4.4 Nearest Neighbors

We show in Table 3 the English nearest neighbors of the English word  $w_{\text{eng}}$  and the Japanese loanword  $w_{\text{jpn}}$  in the 300-dimensional space of English. Japanese loanwords are mapped from the 600-dimensional space of Japanese into the 300-dimensional space of English. The English word *image* is close in meaning to the word *picture*, as suggested by *jpeg* and *close-up*, while its loanword seems to have a more abstract meaning such as *idealizing*. The nearest neighbors of the English word *digest* are influenced by an American fam-

<sup>14</sup>[https://en.wikipedia.org/wiki/David\\_Beckham](https://en.wikipedia.org/wiki/David_Beckham)

Table 3: English words that are nearest  $w_{\text{eng}}$  and  $w_{\text{jpn}}$ .  $w_{\text{jpn}}$  is a Japanese loanword and  $w_{\text{eng}}$  is the original English word.  $w_{\text{jpn}}$  is mapped into the English vector space. Only words that appear more than 100 times in the Wikipedia corpus are considered as candidates of the nearest neighbors. The value next to each word is the cosine similarity between the nearest neighbor word and  $w_{\text{eng}}$  or  $w_{\text{jpn}}$ .

ily magazine *Reader’s Digest*<sup>15</sup> by Wallaces, but the terms related to *summary* do not appear in the top-5 list, except for *digest* itself. In contrast, its loanword seems to mean *wrap-up*. We now return to the English word *icon* that was mentioned as an exception in Section 4.3. Besides *icons*, the nearest neighbors of *icon* are *iverskaya*, *nicopeia*, *eleusa*, and *derzhavnaya*. These four words are all related to religious paintings or figures, but they have low cosine similarities. The other parts of the table are also mostly interpretable. The nearest neighbors of  $w_{\text{eng}}$  *nature* look uninterpretable at a first glance, but they are influenced by the Sørøst-Svalbard Nature Reserve in Norway, and *Natura naturans*, which is a term associated with the philosophy of Baruch Spinoza.

#### 4.5 Ranking of Word Pairs According to Similarity

Here, we investigate the possibility of whether the similarity calculated in the mapped space can be used to detect the loanwords that are very different from or close to the original English words. We show the 20 words with the lowest cosine similarities and the 20 words with highest cosine similarities in Table 4. First, let us take a look at the words on the right, which have high similarities. Most of them are technical terms (e.g., *hexadecane* and *propylene*), and domain-specific terms such as musical instruments (e.g., *piano* and *violin*) and computer-related terms (*computer* and *software*). This result is consistent with the fact that the meanings of technical terms tend not to change, at least for Japanese (Nishiyama, 1995). Next, let us take a look at the words on the left, which have low similarities. Many of them are actually ambiguous, and this ambiguity is often due to the Japanese phonetic system. For example, *lighter* and *writer* are assigned to the same loanword in Japanese, because the Japanese language does not distinguish the consonants *l* and *r*. The words *clause*, *close* and *clothe* are also assigned to the same loanword also because of the Japanese phonetic system. Other words are used as parts of named entities, also resulting in low similarity. For example, the Japanese loanword for *refer* is more often used as *Rifaa*, the name of a city in Bahrain, but hardly as *refer*. The loanword for *irregular* is often used as part of a video game title *Irregular Hunter*. However, we can also find words with sig-

<sup>15</sup><http://rd.com>

dissimilar pair		similar pair	
$w_{\text{eng}}$	cosine	$w_{\text{eng}}$	cosine
lac	0.225	piano	0.886
refer	0.245	violin	0.881
police	0.247	cello	0.881
spread	0.251	hexadecane	0.864
mof	0.261	propylene	0.857
pond	0.270	keyboard	0.855
inn	0.274	clarinet	0.851
ism	0.279	cheese	0.849
lighter	0.280	mayonnaise	0.848
root	0.281	software	0.847
tabu	0.284	methanol	0.843
gnu	0.293	hotel	0.843
thyme	0.296	chocolate	0.841
clause	0.310	computer	0.840
board	0.315	engine	0.840
present	0.319	globalization	0.835
coordinate	0.337	tomato	0.833
expanded	0.341	trombone	0.832
irregular	0.342	recipe	0.831
measure	0.346	antimony	0.829

Table 4: Twenty words with the lowest similarities and twenty words with the highest similarities.

nificant changes in meaning, such as *present*<sup>16</sup> and *coordinate*<sup>17</sup>. Therefore, the result suggests that the similarity calculated by our method has the capability of detecting changes in the meanings of loanwords, but we need to filter out the words that are ambiguous in the Japanese phonetic system.

We manually evaluated the 100 words that have the lowest similarities to the corresponding loanwords including the 20 words shown in Table 4. Among the 100 words, 21 words are influenced by ambiguity, and 19 are influenced by named entities. Among the remaining 60 words, 57 are judged to be semantically different from their loanwords. For the other three words, the embeddings would not be quite accurate probably due to their infrequency in either the English or the Japanese corpora used for training.

#### 4.6 Evaluation for Educational Use

To see if the obtained word embeddings of English and Japanese can assist in language learn-

<sup>16</sup>In Japanese, *present* usually means a gift, or to give a gift, but hardly to show or introduce.

<sup>17</sup>In Japanese, this word usually means to match one’s clothes attractively.

ing, for purposes such as lexical-choice error correction, we evaluate their usefulness by using the writings of Japanese learners of English. Specifically, we use the Lang-8 English data set (Mizumoto et al., 2011)<sup>18</sup> to calculate the Dice coefficient instead of JENAAD. This dataset consists of sentences originally written by learners, some of which have been corrected by (presumably) native speakers of English. Because we target embeddings of English and Japanese, we only use English sentences written by Japanese among other learners of English. Of those, approximately one million sentences have corresponding corrections. With these sentence pairs, we calculate the Dice coefficient just as in Section 4.2. The coefficient measures how often a word co-occurs in the original sentences and corresponding corrections. If a word is often corrected to another, it tends to appear only in the original sentences and not in the corresponding corrections, and thus, its Dice coefficient becomes small, and vice versa. In other words, the Dice coefficient roughly measures how often a word is corrected in the Lang-8 English data. Considering this, we compare the cosine similarity based on the proposed method with the Dice coefficient by means of the Pearson's correlation to evaluate how effective the cosine similarity is in predicting words in which lexical-choice errors likely occur<sup>19</sup>; the higher the correlation is, the better the cosine similarity is as an indicator of lexical-choice errors. Note that we apply lemmatization to all words both in the original sentences and in the corresponding corrections when calculating the Dice coefficient in order to focus only on lexical-choice errors<sup>20</sup>.

It turns out that the value of the Pearson's correlation coefficient shows a milder correlation ( $\rho=0.302$ ; significant at the significance level  $\alpha=0.01$ ) in this dataset than in JENAAD. Some loanwords having the almost equivalent senses in English have high values both for the cosine similarity and the Dice coefficient; examples are musical instruments

such as *piano* (cos=0.886, Dice=0.951) and *violin* (cos=0.881, Dice=0.914); computer terms *computer* (cos=0.840, Dice=0.865) and *software* (cos=0.847, Dice=0.880) as has discussed in Section 4.5. Moreover, some that do not have equivalent senses show mild correspondences (e.g., *sentence* (cos=0.493, Dice=0.346); *note* (cos=0.470, Dice=0.352)).

By contrast, most of the others show less correspondence. One possible reason is that in the Lang-8 English data, corrections are applied to grammatical errors other than lexical choices, which undesirably decreases the Dice coefficient. Typical examples are errors in number (singular countable nouns are often corrected as corresponding plural nouns; e.g., *book*  $\rightarrow$  *books*) and in inflection (e.g., *book*  $\rightarrow$  *booked*). Therefore, loanwords whose corresponding English words undergo word-form changes less often tend to show strong correspondences as can be seen in the above examples (i.e., *software* and *piano*). This can be regarded as noise in the use of the Lang-8 data set. As mentioned above, we applied lemmatization to reduce the influences by noise. More sophisticated methods such as word alignment might improve the accuracy of the evaluation.

## 5 Conclusions

We computationally analyzed semantic changes of Japanese loanwords. We used the word embeddings of Japanese and English, and mapped the Japanese embeddings to the space of English, where we calculated the cosine similarity of a Japanese loanword and its original English word. We regarded this value as an indicator of semantic change. We evaluated our methodology in a number of ways.

To detect semantic changes accurately, we have to filter out the words that are ambiguous in the Japanese phonetic system. Such words tend to have low cosine similarities. One direction for future work is application of the technique to similar tasks. For example, we can use our method to analyze semantic changes of cognates. There are also a number of ways to investigate semantic changes of loanwords in more detail. For example, we can examine the relation between the semantic change of a loanword and the time at which the word was introduced in the target language. Hamilton et al. (2016) reported that they

<sup>18</sup><http://cl.naist.jp/nldata/lang-8/>

<sup>19</sup>Some of the words in the loanword list are too infrequent to calculate the Dice coefficient in the Lang-8 data set. Accordingly, we excluded those appearing fewer than 30 times in it when calculating the Pearson's correlation.

<sup>20</sup>Other grammatical errors including errors in number and inflection often appear in the Lang-8 English data, which are mistakenly included in lexical-choice errors in the calculation of the Dice coefficient. Lemmatization reduces their influences to some extent.

used word embeddings to show the relation between semantic changes and polysemy. It would be interesting to see if similar results are obtained for loanwords.

## Abstract

Most current approaches in phylogenetic linguistics require as input multilingual word lists partitioned into sets of etymologically related words (cognates). Cognate identification is so far done manually by experts, which is time consuming and as of yet only available for a small number of well-studied language families. Automatizing this step will greatly expand the empirical scope of phylogenetic methods in linguistics, as raw wordlists (in phonetic transcription) are much easier to obtain than wordlists in which cognate words have been fully identified and annotated, even for under-studied languages. A couple of different methods have been proposed in the past, but they are either disappointing regarding their performance or not applicable to larger datasets. Here we present a new approach that uses support vector machines to unify different state-of-the-art methods for phonetic alignment and cognate detection within a single framework. Training and evaluating these method on a typologically broad collection of gold-standard data shows it to be superior to the existing state of the art.

## 1 Introduction

Computational historical linguistics is a relatively young sub-discipline of computational linguistics which uses computational methods to uncover how the world's 7 000 human languages have developed into their current shape. The discipline has made great strides in recent years. Exciting progress has been made with regard to automated language classification (Bowerman and Atkin-

son, 2012; Jäger, 2015), inference regarding the time depth and geographic location of ancestral language stages (Bouckaert et al., 2012), or the identification of sound shifts and the reconstruction of ancestral word forms (Bouchard-Côté et al., 2013), to mention just a few. Most of the mentioned and related work relies on multilingual word lists manually annotated for *cognacy*. Unlike the classical NLP conception, cognate words are here understood as words in different languages which are *etymologically related*, that means, they have regularly developed from a common ancestral form, such as both English *tooth* and German *Zahn* 'tooth' that go back to an earlier Proto-Germanic word *tanθ-* with the same meaning. Manual cognate classification is a slow and labor intensive task requiring expertise in historical linguistics and intimate knowledge of the language family under investigation. From a methodological perspective, it can further be problematic to build phylogenetic inference on expert judgments, as the expert annotators necessarily base their judgments on certain hypotheses regarding the internal structure of the language family in question. In this way, the human-annotated cognate sets bear the danger of circularity. Deploying automatically inferred cognate classes thus has two advantages: it avoids the bias inherent in manually collected expert judgments and it is applicable to both well-studied and under-studied language families.

In the typical scenario, the researcher has obtained a collection of multilingual word lists in phonetic transcription (e.g. from field research or from dictionaries) and wants to classify them according to cognacy. Such datasets usually cover many languages and/or dialects (from scores to hundreds or even thousands) but only a small number of concepts (often the 200-item or 100-item Swadesh list or subsets thereof). The machine

learning task is to perform cross-linguistic clustering. There exists a growing body of gold standard data, i.e. multilingual word lists covering between 40 and 210 concepts which are manually annotated for cognacy (see Methods section for details). This suggests a supervised learning approach. The challenge here is quite different from most machine learning problems in NLP though since the goal is not to identify and deploy language-specific features based on a large amount of mono- or bi-lingual resources. Rather, the gold standard data have to be used to find cross-linguistically informative features that generalize across arbitrary language families. In the remainder of this paper we will propose such an approach, drawing on and expanding related work such as List (2014b) and Jäger and Sofroniev (2016).

## 2 Previous Work

Cognate detection is a *partitioning task*: a *clustering task* which does not necessarily assume a hierarchy. An early approach (Dolgopolsky, 1964) is based on the idea of *sound classes*: In order to reduce the phonetic space and to guarantee comparability across languages, sounds are clustered into classes which frequently occur in correspondence relation in genetically related languages. Dolgopolsky proposed a very rough sound class system, proposing to group all consonants into ten classes ignoring vowels. When converting all transcriptions in the data to their respective sound classes, one can use different criteria to assign words resembling each other in their sound classes to the same set of cognate words. Turchin et al. (2010) further formalized this approach and employed a modified sound class schema of 9 vowel classes to test the Altaic hypothesis. Their *Consonant Class Matching* (CCM) approach was reported to produce a low rate of false positives. Unfortunately, the rate of false negatives is also very high (List, 2014b). This is especially due to the lack of flexibility of the procedure, which hard-codes sounds to classes, ignoring that sound change is usually based on fine-grained transitions.

An alternative family of approaches to cognate detection circumvents this problem by first calculating distances or similarities between pairs of words in the data, and then feeding those scores to a flat clustering algorithm which partitions the words into cognate sets. This workflow

is very common in evolutionary biology, where it is used to detect homologous genes and proteins (Bernardes et al., 2015). Two basic families of partitioning algorithms can be distinguished: hierarchical cluster algorithms and graph-based algorithms. Hierarchical cluster algorithms are based on classical agglomerative cluster algorithms (Sokal and Michener, 1958), but terminate when a user-defined threshold of average similarities among clusters is reached. In graph-based partitioning algorithms (Andreopoulos et al., 2009), words are represented as nodes in a network and links between nodes represent similarities. When clustering, links are added and removed until the nodes are partitioned into homogeneous groups (van Dongen, 2000).

More important than the clustering algorithm one uses is the computation of pairwise similarity scores between words. Here, different measures have been tested, ranging from simple string distance metrics (Bergsma and Kondrak, 2007), via enhanced sound-class-based alignment algorithms (SCA, List 2014a), to iterative frameworks in which segmental similarities between sounds are either iteratively inferred from the data (Steiner et al., 2011), or aggregated using machine learning techniques (Hauer and Kondrak, 2011). Frameworks may differ greatly regarding their underlying workflow. While the LexStat algorithm by List (2014b) uses a permutation method to compute individual segmental similarities between individual language pairs which are then fed to an alignment algorithm, the *PMI similarity approach* by Jäger (2013) infers general segmental similarities between sounds from an exhaustive parameter training procedure.

## 3 Materials

Benchmark data for training and testing was assembled from different previous studies and considerably enhanced by unifying semantic and phonetic representations and correcting numerous errors in the datasets. Our collection was taken from six major sources (Greenhill et al., 2008; Dunn, 2012; Wichmann and Holman, 2013; List, 2014b; List et al., 2016b; Menecier et al., 2016)<sup>1</sup> and

<sup>1</sup>The Indo-European data from `ielex.mpi.nl` were accessed on 4-26-2016. The Austronesian data from the *Austronesian Basic Vocabulary Database* (ABVD, `language.psy.auckland.ac.nz/austronesian/`) were accessed on 12-2-2015. Among the 395 languages covered by ABVD, we only used a randomly selected subset of 100 lan-

Table 1: Benchmark data used for the study. Items on red background were used for testing, and the rest for training. Items on white are available in ASJP transcription; all others are available in IPA transcription. The last column lists the diversity of each dataset by dividing the number of actual cognates by the number of potentially different cognates (List 2014:188).

covers datasets ranging between 100 and 210 concepts translated into 5 to 100 languages from 13 different language families.

Modifications introduced in the process of preparing the datasets included (a) the correction of errata (e.g. orthographic forms in place of phonetic representations), (b) the replacement of non-IPA symbols with their IPA counterparts (e.g.  $\text{t} \rightarrow \text{t}$  or  $' \rightarrow ?$ ), (c) the removal of non-IPA symbols used to convey meta-information (e.g.  $\%$ ), (d) removal of extraneous phonetic representation variants, and (e) the removal of morphological markers. In addition, all concept labels in the different datasets were linked to the Concepticon (<http://concepticon.clld.org>, List et al. 2016a), a resource which links concept labels

language since the computational effort would have been impractical otherwise. For all data sets, only entries containing both a phonetic transcription and the cognate classification were used.

to standardized concept sets in order to ease the exchange and standardization of cross-linguistic datasets. A small sample of the entries extracted from the IELex data is shown in Table 2 for illustration.

## 4 Methods

Unlike many other supervised or semi-supervised clustering tasks, the set of cluster labels to be inferred is disjoint from the gold standard labels. Therefore we chose a two-step procedure: (1) A similarity score for each pair of synonymous words from the same dataset is inferred using supervised learning, and (2) these inferred similarities are used as input for unsupervised clustering.

As for subtask (1), the relevant gold standard information are the labels “cognate” and “not cognate” for pairs of synonymous words. The sub-goal is to predict a probability distribution over these labels for unseen pairs of synonymous words. This is achieved by training a Support Vector Machine (SVM), followed by Platt scaling (Platt, 1999). The SVM primarily operates on two string similarity measure from the literature, *PMI similarity* Jäger (2013) and *LexStat similarity* (List, 2014b), which are both known to generalize well across languages and language families. We also used some auxiliary features from (Jäger and Sofroniev, 2016), which are derived from string similarities. For the clustering subtask (2), we followed List et al. (2016b) and List et al. (2017) in using the Infomap algorithm (Rosvall and Bergstrom, 2008).

The gold standard data were split into a training set and a test set. Feature selection for subtask (1) and parameter training for subtask (2) were achieved via cross-validation over the train-

ing data. For evaluation, we trained an SVM on all training data and used it to perform automatic clustering on the test data.

The remainder of this section spells out these steps in detail.

#### 4.1 String Similarity Measures

Our strategy is to first calculate string similarities and distances between pairs of words denoting the same concept and then inferring a partition of the corresponding words from those similarities or distances via a partitioning algorithm. For word comparison we utilize two recently proposed string similarity measures.

The first string similarity measure is the one underlying the above-mentioned LexStat algorithm for automatic cognate detection (List, 2014b). The core features of the string similarity produced by the LexStat algorithm include (a) an enhanced sound-class model of 28 symbols, including tone symbols for the handling of South-East Asian tone languages, (b) a linguistically informed scoring function derived from frequently recurring directional sound change processes, and (c) a prosodic tier which automatically defines a prosodic context for each sound in a word and thus allows for a rough handling of context. The LexStat algorithm for determining string similarities can be roughly divided into four stages. In a first stage, words for the same concept in each language pair are aligned, using the SCA algorithm for phonetic alignment (List, 2014b), both globally and locally, and correspondences in the word pairs with a promising score are retained. At the same time, a randomized distribution of expected sound correspondences is calculated, using a permutation method (Kessler, 2001) in which the wordlist are shuffled, so that words denoting different concepts, which are much more likely to be not cognate, are aligned instead. In a second step, both distributions are compared, and log-odds scores (Durbin et al., 2002) for each segment pair  $s_{x,y}$  are calculated (List, 2014b, 181). In a third step, the new scoring function is used to re-align the words, using a semi-global alignment algorithm which ignores prefixes or suffixes occurring in one of two strings (Durbin et al., 2002), and the similarity scores produced by classical alignment algorithms are normalized to similarity scores using the formula by Downey et al. (2008)

$$D = \frac{2 \cdot S_{AB}}{S_A + S_B} \quad (1)$$

where  $S_{AB}$  is the similarity score of an alignment of two words  $A$  and  $B$  produced by the SCA method, and  $S_A$  and  $S_B$  are the similarity scores produced by the alignment of  $A$  and  $B$  with themselves.<sup>2</sup>

In Jäger (2013) a data-driven method for determining string similarities is proposed which we will refer to as *PMI similarity*, as it is based on the notion of *Pointwise Mutual Information* between phonetic segments. It has successfully been used for phylogenetic inference in Jäger (2015). The method operates on phonetic strings in ASJP transcription (Brown et al., 2013) without diacritics, i.e., each segment is assigned one out of only 41 sound classes.

The PMI score of two sound classes  $a, b$  is defined as

$$\text{PMI}(a, b) \doteq \log \frac{s(a, b)}{q(a)q(b)}, \quad (2)$$

where  $s(a, b)$  is the probability of  $a$  and  $b$  being aligned to each other in a pair of cognate words, and  $q(a), q(b)$  are the probabilities of occurrence of  $a$  and  $b$  respectively. Sound pairs with positive PMI score provide evidence for cognacy, and vice versa.

To estimate the likelihood of sound class alignments, a corpus of *probable cognate pairs* was compiled from the ASJP data base<sup>3</sup> using two heuristics. First, a crude similarity measure between wordlists, based on Levenshtein distance, was defined and the 1% of all ASJP doculect<sup>4</sup> pairs with highest similarity were kept as *probably related*. Second, the normalized *Levenshtein distance* was computed for all translation pairs from probably related doculects. Those with a distance below a certain threshold were considered as *probably cognate*. These probable cognate pairs were used to estimate PMI scores. Subsequently, all translation pairs were aligned via the Needleman-Wunsch algorithm Needleman and Wunsch (1970) using the PMI scores from the previous step as weights. This resulted in a measure of string similarity, and all pairs above a certain similarity

<sup>2</sup>The original LexStat algorithm uses distance scores by subtracting the similarity score from 1.

<sup>3</sup>The ASJP database Wichmann et al. (2013), available from <http://asjp.cild.org/>, is a collection of 40-item Swadesh lists from more than 6,000 languages and dialects covering all regions of the globe.

<sup>4</sup>*Doculect* is a neutral term for a linguistic variety which is documented in some coherent way, leaving the issue of distinguishing between languages and dialects aside.

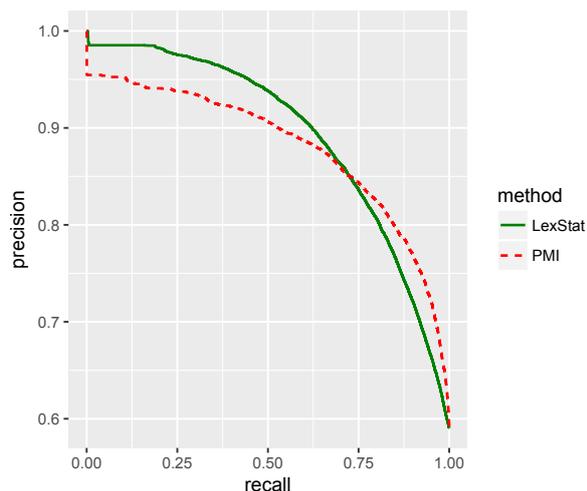

Figure 2: Precision-Recall curves for LexStat and PMI string similarities, based on the evaluation of the word pairs from the data by List (2014a).

tion of auxiliary predictors pertaining to the similarity of the doculects compared and the differential diachronic stability of lexical meanings, to infer cognate classifications. We chose a supervised learning approach using a Support Vector Machine (SVM) for this purpose. The overall workflow is shown in Figure 3. It consists of two major parts. During the first phase (the upper part in the figure shown in red), a SVM is trained on a set of training data and then used to predict the *probability of cognacy* between pairs of words from a set of test data. During the second phase (lower part in the figure, shown in green), those probabilities are used to cluster the words from the test set into *inferred cognacy classes*. The system is evaluated by comparing the inferred classification with the expert classification. We used the three largest data sets at our disposal (cf. the datasets colored in red in Table 1), *ABVD*, *Central Asian*, and *IELex*, for testing and all other datasets for training.

### 4.3 Support Vector Machine Training

Each data point during the first phase is a pair of words  $w_1, w_2$  (i.e., a pair of phonetic strings) from doculects  $L_1, L_2$  from data set  $S$ , both denoting the same concept  $c$ . It is mapped to a vector of values for the following features:<sup>6</sup>

1. LexStat string similarity between  $w_1$  and  $w_2$  (computed with LingPy, List and Forkel,

<sup>6</sup>Features 2–5 are taken from (Jäger and Sofroniev, 2016). The other features used there (calibrated PMI distances and their logarithms, and the logarithm of doculect similarity) did not improve results under cross-validation over the training data.

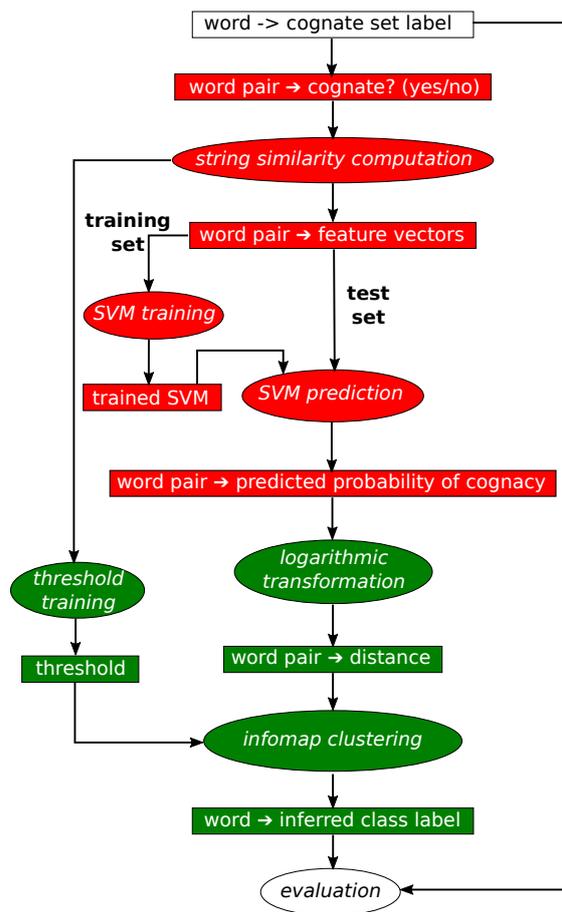

Figure 3: Workflow for supervised learning and prediction. Boxes and ellipses represent data and computations respectively.

2016),

2. PMI string similarity between  $w_1$  and  $w_2$ ,
3. doculect similarity between  $L_1$  and  $L_2$  as defined in Jäger (2013),<sup>7</sup>
4. mean word length (measured in number of segments) of words for concepts  $c$  within  $S$ .
5. correlation coefficient between PMI string similarity and doculect similarity across all word pairs denoting concept  $c$  within  $S$ .<sup>8</sup>

The marginal distributions for cognate and non-cognate pairs of those features (for the data from List (2014b) and List et al. (2016b)) is displayed in Figure 4. It can be discerned from these plots that word length is a negative predictor and the other four features are positive predictors for cognacy.

<sup>7</sup>We refrain from recapitulating the full definition here for reasons of space. Essentially this amounts to the average PMI similarity between synonymous word pairs from  $L_1$  and  $L_2$ .

<sup>8</sup>The last two features represent measures of the diachronic stability of concepts, based on Dellert and Buch (2016).

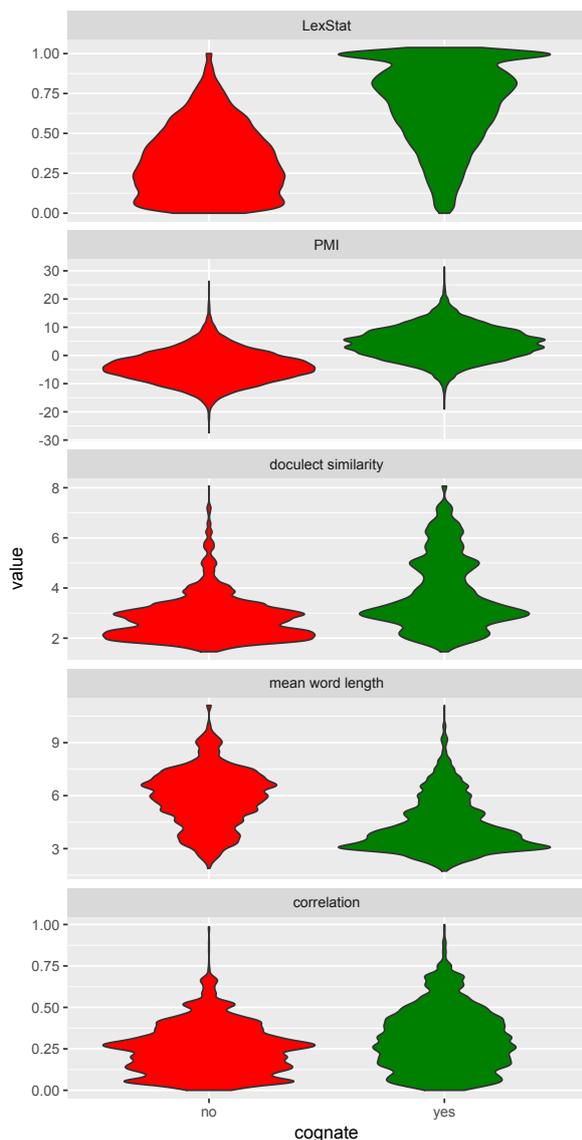

Figure 4: Distribution of features values for cognate and non-cognate word pairs

The fact that word length is a negative predictor of cognacy arguably results from the interplay of two known regularities. (1) Pagel et al. (2007) present evidence that diachronic stability of concepts is positively correlated with their usage frequency in modern corpora. (2) According to *Zipf’s Law of Abbreviation* (Zipf, 1935), there is a negative correlation between the corpus frequency of words and their lengths. Taken together, this means that concepts usually being expressed by short words tend to have a high usage frequency and therefore tend to be diachronically stable. Therefore we expect a higher proportion of cognate pairs among concepts expressed by short words than among those expressed by long words.

As the data points within the training set are mutually non-independent, we randomly chose one word pair per concept and data set for training the SVM. During the training phase, we used cross-validation over the data sets within the training set (i.e., using one training data set for validation and the other training data sets for SVM training) to identify the optimal kernel and its optimal parameters. This was carried out by completing both phases of the work flow and optimizing the *Adjusted Rand Index* (see Subsection 4.5) of the resulting classification. Training and prediction was carried out using the `svm` module from the Python package `sklearn` (<http://scikit-learn.org/stable/modules/svm.html>), which is based on the LIBSVM library (Fan et al., 2005). Predicting class membership probabilities from a trained SVM was carried out using Platt scaling (Platt, 1999) as implemented in `sklearn` (<http://scikit-learn.org>). This results in a *predicted probability of cognacy*  $p(w_1, w_2|c, S)$  for each data point. The best cross-validation performance was achieved with a linear kernel with a penalty value of  $C = 0.82$ . Polynomial and RBF-kernels performed slightly worse. Also, we found that leaving out any subset of the features decreases performance.

#### 4.4 Cognate Set Partitioning

In order to cluster the words into sets of potentially cognate words, we follow recent approaches by List et al. (2016b) and List et al. (2017) in using Infomap (Rosvall and Bergstrom, 2008), an algorithm which was originally designed for the detection of communities in large social networks, to detect “communities” of related words. Infomap uses random walks in undirected networks to identify the best way to assign the nodes in the network, that is, in our case, the words, to distinct groups which form a homogeneous class.

For each data set  $D$  and each concept  $c$  covered in  $D$ , a network was constructed. The vertices are all words from  $D$  denoting  $c$ . Two vertices are connected if and only if the corresponding words are predicted to be cognate with a probability  $\geq \theta$  according to SVM prediction + Platt scaling. The optimal value for  $\theta$  was determined as 0.66 via cross-validation over the training data. Infomap was then applied to this network, resulting in an assignment of class labels to vertices/words.

data set	Adjusted Rand Index		B-Cubed Precision		B-Cubed Recall		B-Cubed F-Score	
	LexStat	SVM	LexStat	SVM	LexStat	SVM	LexStat	SVM
aggregated	0.676	0.683	0.868	0.847	0.838	0.869	0.850	0.855
Austronesian	0.545	0.588	0.791	0.781	0.801	0.855	0.796	0.817
Central Asian	0.866	0.843	0.916	0.883	0.962	0.981	0.938	0.929
Indo-European	0.618	0.619	0.896	0.877	0.750	0.770	0.817	0.820

Table 3: Evaluation results on the test data for the benchmark method (LexStat) and our method (SVM) according to Adjusted Rand Index and B-Cubed precision, recall, and F-score

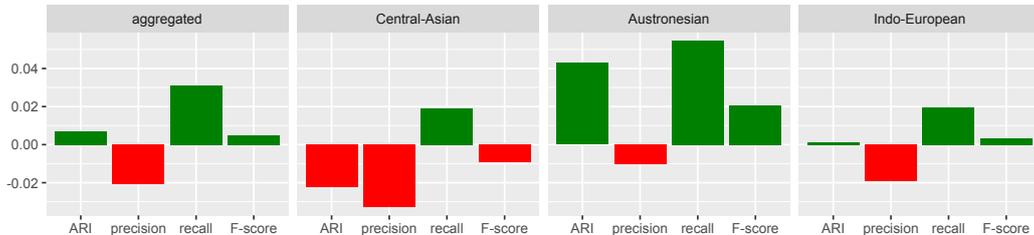

Figure 5: Evaluation results (difference between performance of our method and baseline). Green bars indicate positive values (our method outperforms baseline) and red bars indicate negative values.

#### 4.5 Evaluation

We used two evaluation measures to compare inferred with expert classifications on the test data. The *Adjusted Rand Index* (ARI, Hubert 1985) assesses how much the equivalence relations induced by two partitions coincide. It assumes real values  $\leq 1$ , where 1 means “perfect agreement” and 0 means “degree of agreement expected by chance”. Negative values may result when from an agreement smaller than expected by chance.

B-Cubed scores (Bagga and Baldwin, 1998) measure precision and recall of a partition analysis compared against a gold standard by computing an individual accuracy score for the cluster decisions on each item in the data and then averaging the results. Hauer and Kondrak (2011) were the first to introduce this measure to test the accuracy of multilingual cognate detection algorithms. In contrast to pair scores such as ARI, B-Cubed scores have the advantage of being independent of the evaluation data itself. While pair-scores tend vary greatly depending on dataset size and cognate density, B-Cubed scores do not show this effect. They are reported as precision and recall. A low B-Cubed precision almost directly translates to the classical notion of a high amount of false positive cognate judgments made by an algorithm, while low B-Cubed recall points to a large amount of cognate sets which were missed by an algorithm.

We took the original LexStat algorithm as a baseline with which we compare our results.

LexStat provides a good baseline, since it was shown to outperform alternative approaches like the above-mentioned CCM approach (Turchin et al., 2010), or clustering based on alternative string similarity measures, like the normalized edit distance, or the normalized scores of the above-mentioned SCA algorithm (List, 2014b). The LexStat implementation in LingPy offers different methods for cognate clustering. Since we employed Infomap for our SVM approach, and since Infomap clustering was shown to work well with LexStat similarities (List et al., 2017), we also used Infomap as the cluster algorithm for the LexStat approach. Since Infomap requires a threshold, we trained the threshold on our training data, excluding short wordlists. Optimal results on the training data was obtained with  $\theta^* = 0.57$ .

## 5 Results and Outlook

The evaluation results are given in Table 3, and the differences to the baseline are visualized in Figure 5. On average, the SVM-based classification shows a superior performance when compared to the baseline (an improvement of 0.7% ARI and 0.5% B-cubed F-score). This is mostly due to a substantial improvement for the Austronesian data (4.3% ARI/2.1% B-cubed F-score). Our method slightly outperforms the baseline for Indo-European but is minimally inferior when applied to the Central Asian data. While this might seem a minor improvement only, it is worth exploring on

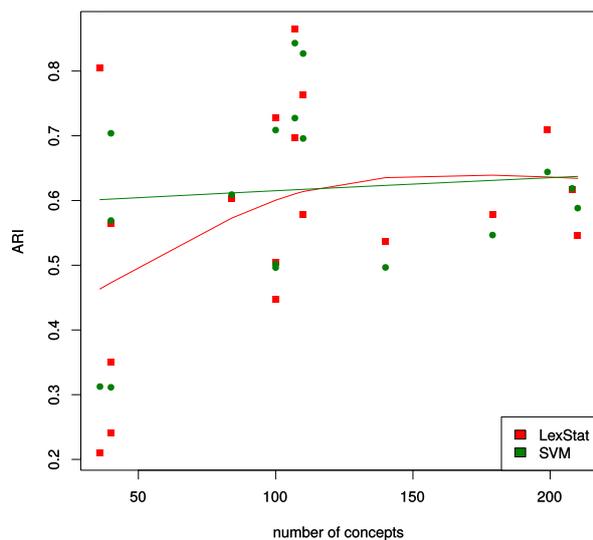

Figure 6: Performance of our method and the benchmark, depending on length of wordlists. Each dot represents one dataset/method pair. The  $x$ -axis shows the number of concepts covered in this dataset and the  $y$ -axis the Adjusted Rand Index. Solid lines represent smoothed interpolations using Generalized Additive Models.

what type of data our method makes progress.

The plot in Figure 6 shows the dependency of performance (ARI) on the number concepts per data base for the training data. While this result has to be taken with a grain of salt as it involves the data used for model fitting, the pattern is both plausible and striking. It shows that our method clearly outperforms LexStat if the number of concepts is smaller than 100. This finding is unsurprising since LexStat depends on regular sound correspondences. If those cannot be reliably inferred due to data sparseness, its performance drops. Our method is more robust here as it makes use of the PMI string similarity which does not rely on language-specific information. This may also explain the performance on the Austronesian data: although it covers 210 concepts across 100 languages, the languages contain many gaps, and many languages have only 100 words if not even less.

In order to get a clearer impression on where our algorithm failed, we compared false positives and negatives in the Indo-European data (Dunn, 2012), which has been investigated in deep detail during the last 200 years. While a quantitative comparison of part of speech and word length did not reveal any strong correlations with the

accuracy of our approach, a qualitative analysis showed that false positives produced by our approach are usually due to *language-specific factors*. Among the factors triggering false negatives, there are specific *morphological processes* involving complex paradigms, such as Proto-Indo-European *\*séh<sub>2</sub>wel-* ‘sun’, which shows many suffixes in its descendant forms, and specific instances of sound change, involving words that were drastically changed (cf. English *four* vs. French *quatre*). False positives are not only due to chance similarities (compare English *much* with Spanish *mucho*), but also due to words which share morphological elements but are marked as non-cognate in our gold standard (cf. Dutch *man* vs. German *Ehemann* ‘husband’), and errors in the gold standard (cf. Upper Sorbian *powjaz* vs. Lower Sorbian *powrjuz* ‘rope’, wrongly marked as non-cognate in the gold standard).

The classical methods for the identification of cognate words in genetically related languages are based on the general idea that relatedness can be rigorously proven. This requires that the languages under investigation have retained enough similarity to identify regular sound correspondences. The further we go back in time, however, the less similarities we find. The fact that an algorithm like LexStat, which closely mimics the classical comparative method in historical linguistics, needs at least 100 (if not more) concepts in order to yield a satisfying performance reflects this problem of data sparseness in historical linguistics. One could argue that a serious analysis in historical linguistics should never be carried out if data are too sparse. As an alternative to this agnostic attitude, however, one could also try to work on methods that go beyond the classical framework, adding a probabilistic component, where data are too sparse to yield undisputable proof. In this paper, we have tried to make a first step into this direction by testing the power of machine learning approaches with state-of-the-art measures for string similarity in quantitative historical linguistics. The fact that our approach outperforms existing automatic approaches shows that this direction could prove fruitful in future research.

## Abstract

We investigate the value of feature engineering and neural network models for predicting successful writing. Similar to previous work, we treat this as a binary classification task and explore new strategies to automatically learn representations from book contents. We evaluate our feature set on two different corpora created from Project Gutenberg books. The first presents a novel approach for generating the gold standard labels for the task and the other is based on prior research. Using a combination of hand-crafted and recurrent neural network learned representations in a dual learning setting, we obtain the best performance of 73.50% weighted F1-score.

## 1 Introduction

Every year millions of new books are published, but only a few of them turn into commercial successes, and even fewer achieve critical praise in the form of prestigious awards or meaningful sales. Editors have the difficult task of making the go/no-go decision for all manuscripts they receive, and the revenue for their publishing house depends on the accuracy of that judgment. The website [www.litrejections.com](http://www.litrejections.com) documents some of the biggest mistakes in the history of the publishing industry, including Agatha Christie, J.K. Rowling, and Dr. Seuss, all of whom received many rejection letters before landing their first publishing deal.

Many factors contribute to the eventual success of a given book. Internal factors such as plot, story line, and character development all have a role in the likability of a book. External factors such as author reputation and marketing strategy are arguably equally relevant. Some factors might even be out of the control of an author or publishing house, such as the current trends, the competition from books released simultaneously, and the historical and contextual factors inherent to society.

Previous work by Ganjigunte Ashok et al. (2013) demonstrated relevant results using stylistic features to predict the success of books. Their definition of success was a function of the number of downloads from Project Gutenberg. However downloading a book is not by itself an indicator of a highly liked or a commercially successful book. We instead propose to use the rating from reviewers collected from Goodreads as a measure of success. We also propose features and deep learning techniques that have not been used before on this problem, and validate their usefulness in two different tasks: success prediction and genre classification. Our key contributions are the following:

- We provide a new benchmark dataset for predicting successful books in a more realistic class distribution. This data set is available to the community from this link<sup>1</sup>.
- We show that sentiment analysis using SenticNet sentics is an accurate way to model emotion in books.

<sup>1</sup>The data can be downloaded from <http://ritual.uh.edu/resources/page>.

- We provide the first results on using recurrent neural networks (RNN) to discover book content representations that are useful for classification tasks such as success prediction and genre detection.
- We show that the multitask approach, simultaneously evaluating success and genre prediction, benefits from its constituent tasks to obtain better performance than the single success prediction task approach.

## 2 Previous work

Predicting the success of books is a difficult task, even for an experienced editor. Researchers have studied related tasks, for example predicting the quality of text from lexical features, syntactic features and different measures of density. Pitler and Nenkova (2008) found a strong correlation between user-perceived text quality and the likelihood measures of the vocabulary as computed by a language model, as well as the likelihood measures of discourse relations, as determined by a language model trained on discourse relations. Louis and Nenkova (2013) proposed a combination of genre-specific and readability features with topic-interest metrics for the prediction of great writing in science articles. While some of the features in this prior work were relevant to our task, our goal is different and more aligned to Ganjigunte Ashok et al. (2013), since we aim to model success in books of different genres.

Ganjigunte Ashok et al. (2013) investigated the correlation between writing style and number of downloads. The authors analyzed lexical features, production rules, constituents, and sentiment features of books downloaded from Project Gutenberg<sup>2</sup>. They obtained an average accuracy of 70.38% using only unigram features with Support Vector Machines (SVM) as the classifier.

Deep learning representations have seen their share of successes in Natural Language Processing (NLP) tasks (Bahdanau et al., 2014; Zheng et al., 2013; Gao et al., 2014; Glorot et al., 2011; Samih et al., 2016). In particular, RNN models have been successfully applied in several scenarios where temporal dependencies provide relevant information (Ian Goodfellow and Courville, 2016; LeCun et al., 2015). Kiros et al. (2015) used RNN models to learn language

models from books using an unsupervised approach. Also, word embedding (Mikolov et al., 2013) and Paragraph Vector (Le and Mikolov, 2014) have been shown to achieve state-of-the-art performance in several text classification and sentiment classification tasks. These techniques are able to learn distributed vector representations that capture semantic and syntactic relationships between words. Collobert and Weston (2008) trained jointly a single Convolutional Neural Network (CNN) architecture on different NLP tasks and showed that multitask learning increases the generalization of the shared tasks. Other researchers (Ian Goodfellow and Courville, 2016; Søggaard and Goldberg, 2016; Attia et al., 2016) have also reached to similar conclusions.

## 3 Dataset

We experimented with two book collections: one prepared by Ganjigunte Ashok et al. (2013)<sup>3</sup> and the other constructed by us to evaluate a new definition of success. We refer to the first dataset as EMNLP13 and the second dataset as Goodreads.

The EMNLP13 collection contained Project Gutenberg books from eight different genres. The authors created a balanced dataset containing 100 books per genre, resulting in a total of 800 books. We manually reviewed the dataset and found missing or irrelevant content in 58 books: a total of 53 books contained Project Gutenberg license information repeated verbatim, and five books contained only the audio recording certificate in place of the actual book content. We removed the license-related text, since lexical features might be erroneously biased, and replaced the five files with the actual content of the books. Except for these corrections, the data we used is the same as that presented in Ganjigunte Ashok et al. (2013).

We also identified some odd adjudications. For example, ‘The Prince And The Pauper’ is a popular book by Mark Twain that was adapted into various films and stage plays. Also, ‘The Adventures of Captain Horn’ was the third best selling book of 1895 (Hackett, 1967). Both these books are labeled as unsuccessful due to their low download counts. We suspect as well that some of the counts are inflated by college students doing English or Literature assignments that may not be directly related to the potential commercial success

of a book.

To address these concerns, we propose a new approach to creating gold labels for successful books based on public reviews rather than download counts. We collected a new set of Project Gutenberg books for this benchmarking. We mapped the books to their review pages on Goodreads<sup>4</sup>, a website where book lovers can search, review, and rate books. We consider only those books that have been rated by at least 10 people. We use the average star rating and total number of reviews for labeling each book. We then set an average rating of 3.5 as the threshold for success, such that books with average rating  $< 3.5$  are classified as *Unsuccessful*. Table 1 shows the data distribution of our books. To our knowledge, we have one of the largest collection of books, as researchers generally work with a low number of books (Coll Ardanuy and Sporleder, 2014; Goyal et al., 2010; van Cranenburgh and Koolen, 2015).

**Success Definitions Comparison:** After compiling and labeling both the datasets, we drew a comparison between the two definitions of success. To do this, we downloaded the Project Gutenberg download counts for the books in Goodreads dataset and labeled them using the Ganjigunte Ashok et al. (2013) definition of success. Since they only considered books in the extremes of download counts, we could only label 399 books in the Goodreads dataset using their definition. We found that 142 books had different labels according to the two definitions. 19.7% of these mismatched books were labeled as unsuccessful

despite having ratings  $\geq 3.5$  and being reviewed by more than 100 reviewers. Table 2 details the discrepancies between the two definitions.

## 4 Methodology

We investigated a wide range of textual features in an attempt to capture the topic, sentiment, writing style, and readability for each book. This set included both new and previously used features. We also explored techniques for automatically learning representations from text using neural networks, which have been shown to be successful in various text classification tasks (Kiros et al., 2015; LeCun et al., 2015). These techniques include word embeddings, document embeddings, and recurrent neural networks.

### 4.1 Hand-crafted text features

**Lexical:** We used skip-grams, char  $n$ -grams, and typed char  $n$ -grams (Sapkota et al., 2015) with term frequency-inverse document frequency (TF-IDF) as the weighting scheme. Sapkota et al. (2015) showed that classical character  $n$ -grams lose some information in merging instances of  $n$ -grams like *the* which could be a prefix (*thesis*), a suffix (*breathe*), or a standalone word (*the*). They separated character  $n$ -grams into ten categories representing grammatical classes, like affixes, and stylistic classes, like beg-punct and mid-punct which reflect the position of punctuation marks in the  $n$ -gram. The purpose of these features is to correlate success with an author’s word choice.

**Constituents:** We computed the normalized counts of ‘*SBAR*’, ‘*SQ*’, ‘*SBARQ*’, ‘*SINV*’, and ‘*S*’ syntactic tag sets from the parse tree of each sentence in each book, following the method of Ganjigunte Ashok et al. (2013) to determine the syntactic style of the authors.

**Sentiment:** We computed sentence neutrality, positive and negative, using SentiWordNet (Baccianella et al., 2010) along with the counts of nouns, verbs, adverbs, and adjectives. We averaged these scores for every 50 consecutive sentences in order to evaluate change in sentiment throughout the course of each book, because we anticipate emotions, like suspense, anger, and happiness to contribute to the success of the book.

**SenticNet Concepts:** We extracted sentiment concepts from the books using the Sentic Concept

<sup>4</sup><https://www.goodreads.com/>

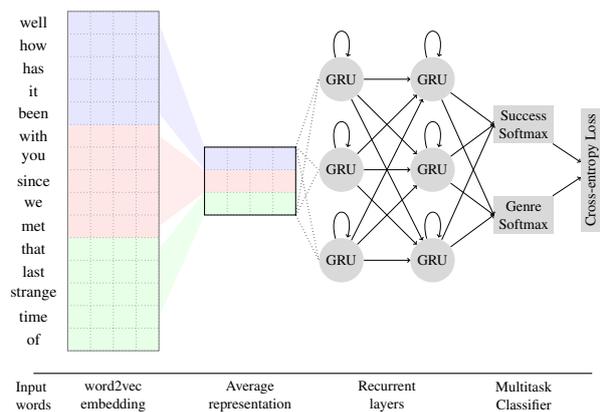

Figure 1: Multitask method. Words are represented in the Word2Vec space. Such representations are averaged per window. Sequences are feed to GRU network. Finally, the features are feed to two softmax components to predict genre and success simultaneously.

Parser<sup>5</sup>. The parser chunks a sentence into noun and verb clauses, and extracts concepts from them using Part Of Speech (POS) bigram rules. We modeled these as binary bag-of-concepts (BoC) features. We also extracted average polarity, sensitivity, attention, pleasantness, and aptitude scores for the concepts defined in the SenticNet-3.0 knowledgebase, which contains semantics and sentsics associated with 30,000 common-sense concepts (Cambria and Hussain, 2015).

**Writing density:** We computed the number of words, characters, uppercase words, exclamations, question marks, as well as the average word length, sentence length, words per sentence, and lexical diversity of each book, with the expectation that successful and unsuccessful writings will have dissimilar distributions of these density metrics.

**Readability:** We computed multiple readability measures including Gunning Fog Index (Gunning, 1952), Flesch Reading Ease (Flesch, 1948), Flesch Kincaid Grade Level (Kincaid et al., 1975), RIX, LIX (Anderson, 1983), ARI (Senter and Smith, 1967), and Smog Index (Mc Laughlin, 1969) and used their mean normalized values for training. Intuitively, the use of simple language will resonate with a larger audience and contribute to book success.

## 4.2 Neural network learned representations

Representation learning techniques are able to learn a set of features automatically from the raw data. Our hypothesis is that the learned representation can capture the complex factors that influence the success of a book.

**Word embeddings with Book2Vec:** In contrast with Word2Vec, which learns a representation for individual words, Doc2Vec learns a representation for text fragments or even for full documents. We trained the Doc2Vec module of the Gensim (Řehůřek and Sojka, 2010) Python library, on all the books in the Goodreads dataset to obtain a 500 dimensional dense vector representation for each book. Using Doc2Vec, we first trained a distributional memory (DM) model with two approaches: concatenation of context vectors (DMC) and sum of context word vectors (DMM). Then we trained a distributional bag of words (DBoW) model and combined it with the DMC and the DMM for a total of five different models. We set the number of iterations to 50 epochs and shuffled the training data in each pass. We called these book vectors *Book2Vec*. Furthermore, we created two 300 dimensional vector representations for each book by averaging the vectors of each word in the book using pre-trained Word2Vec vectors from the Google News dataset<sup>6</sup> and our own Word2Vec trained with  $\sim 350M$  words from 5,000 random books crawled from Project Gutenberg.

**Multitask RNN method:** When dealing with variable length data such as time series or plain text, traditional approaches like feed-forward neural networks are not easily adapted since they expect fixed-size input to model sequential data. One limitation of RNNs is that it has problems dealing with long sequences (Pascanu et al., 2013). We propose a strategy to represent large documents, such as books, with an aggregated representation. Figure 1 depicts the proposed multitask method. The overall strategy uses a RNN to learn a model of sequences of sentences. Each sentence is represented by the average of the Word2Vec representation of its constituent words. The RNN is composed of 2 hidden layers with 32 hidden gated recurrent units (GRU) (Cho et al., 2014) each, and the output is a softmax layer. We train the RNN

<sup>5</sup><https://github.com/pbhuss/Sentimental/blob/master/parser/SenticParser.py>

<sup>6</sup>The pre-trained Word2Vec was downloaded from <https://code.google.com/p/word2vec/>

in a supervised fashion using the success categorization and the book genre as labels. The RNN serves a feature extractor and the last hidden states for each sequence acts as its representation. At training time, all sentences from one book are extracted and divided in chunks of 128 sentences. The book’s success/genre labels are assigned to each sequence. A sentence is then represented as the average of its constituent word vectors. To make the book label assignment at testing time, we average the predictions of all sequences extracted from each book. Using 128 sentences has three-fold a motivation: (1) mitigate vanishing gradient problem (Pascanu et al., 2013), (2) obtain more examples from one book, and (c) be a power of 2 to efficiently use the GPU.

An interesting property of neural networks is that the same learning approach, i.e stochastic gradient descent, still holds for more complex architectures as long as the objective cost function is differentiable. We take advantage of this property to build a unified neural network that addresses both genre and success prediction using a single model. These kinds of multitask architectures are also useful as regularizers (Ian Goodfellow and Courville, 2016). In particular, our cost function  $J(X, Y)$  is defined as follows:

$$\begin{aligned}
 h_i &= rnn(x_i) \\
 \hat{y}_i^{succ} &= \frac{e^{z_i^{succ}}}{\sum_k e^{z_k^{succ}}} \\
 \hat{y}_i^{gen} &= \frac{e^{z_i^{gen}}}{\sum_l e^{z_l^{gen}}} \\
 J(X, Y) &= - \sum_i (y_i^{succ} \ln \hat{y}_i^{succ} + y_i^{gen} \ln \hat{y}_i^{gen})
 \end{aligned}$$

where  $x_i$  represents the  $i$ -th sample and  $y^{succ}$  and  $y^{gen}$  are success and genre labels respectively. The  $rnn(\cdot)$  function represents the forward propagation over the recurrent neural network and  $h$  represents the last hidden state.  $\hat{y}^{succ}$  and  $\hat{y}^{gen}$  represent predictions for the two labels. Notice that both of them are computed using the same unified representation  $h$ .  $z^{succ}$  and  $z^{gen}$  represent two different linear transformations over  $h$  that map to the number of classes.

## 5 Experiments and Results

### 5.1 Experiments on Goodreads dataset

We merged books from different genres, and then randomly divided the data into a 70:30 train-

ing/test ratio, while maintaining the distribution of *Successful* and *Unsuccessful* classes per genre. As a preprocessing step we converted all words to lowercase and removed infrequent tokens having document frequency  $\leq 2$ . For our tagging and parsing needs, we used the Stanford parser (Socher et al., 2013). We then trained a LibLinear Support Vector Machine (SVM)<sup>7</sup> classifier with L2 regularization using the hand-crafted features described in Section 4. We tuned the C parameter in the training set with 3-fold grid search cross-validation over different values of  $1e\{-4, \dots, 4\}$ .

With the features used by Ganjigunte Ashok et al. (2013), we obtained the highest weighted F1-score of 0.659 with word bigram features. We set this value as our baseline. In order to study the effect of the multitask approach, we devised analogous experiments to our proposed multitask RNN method and predicted both genre and success together for the features described in Section 4. Hence we have two settings for the classification experiments, Single task (ST) and Multitask (MT).

Since we had average rating information, we also modeled the problem as a regression problem and predicted the average rating using only the content of the books. Our work differs from other researchers in this aspect, as most of them (Lei et al., 2016; Li et al., 2011; Mudambi et al., 2014) use review content instead of the actual book content to predict the average rating. We used the Elastic Net regression algorithm with *l1\_ratio* tuned over range  $\{0.01, 0.05, 0.25, 0.5, 0.75, 0.95, 0.99\}$  with 3-fold grid search cross-validation of the training data.

**Parameter tuning for RNN:** We trained 25 models with random hyper-parameter initialization for learning rate, weights initialization ranges and regularization parameters. We chose the best validation performance model. This is preferable over grid search when training deep models (Bergstra and Bengio, 2012). We used the ADAM algorithm (Kingma and Ba, 2014) to update the gradients. Since these models are prone to overfitting because of the high number of parameters, we applied clip gradient, max-norm weights, early stopping and dropout regularization strategies.

<sup>7</sup>We use LibLinear SVM wrapper from <http://scikit-learn.org/stable/>

Table 3: Results for classification (ST = Single task setting, MT = Multi-task setting) and regression tasks on Goodreads dataset. MSE = Mean Square Error, F1 score is weighted F1 scores across *Successful* and *Unsuccessful* classes.

## 5.2 Results on Goodreads dataset

Table 3 shows the results with our new proposed feature sets for the classification and regression tasks. In the ST setting, except for the character  $n$ -gram features, all proposed hand-crafted features individually had a weighted F1-score less than the word bigram baseline. On the other hand, the neural network methods obtained better results than the baseline. We obtained the highest weighted F1-score of 0.695 and 0.731 with the *Book2Vec* method in the ST and MT settings, respectively. The results show that the MT approach is better than the ST approach. The genre prediction task must have acted as a regularizer for the success prediction task. Also, we found that modeling the entire book as a vector, rather than modeling it as the average of word vectors, gave better performance. Although the ST *Book2Vec* performs better than the MT RNN method, the difference is very small. We performed McNemar’s test on these methods and found that the results were not statistically significant, with  $p=0.5$ . The MT RNN method had the lowest mean square error (MSE) for the regression task, at 0.125.

The character  $n$ gram proved to be one of the most important hand-crafted features, whereas clausal feature was the least important one. In-

Features	ST (F1)	MT (F1)	MSE

Table 4: Feature Combination Results for Goodreads dataset. (ST = Single Task, MT =Multi-task, SCS = Sentic concept+average scores of sensitivity, attention, pleasantness, aptitude, polarity, WR = Writing Density, R = Readability)

dividually, writing density and readability features seemed to be weak features. We assumed that the sentiment changes in books would be an important characteristic for the task. However, the results in Table 3 show an unimpressive F1-score of 0.610 for sentiment features. On the other hand, the bag of sentic concepts model with average scores for sensitivity, attention, pleasantness, aptitude, and polarity gave a more impressive F1-score of 0.670, much higher than the baseline. This result points to the relevance of performing a more nuanced sentiment analysis beyond lexical statistics for this task.

Our next set of experiments included the combinations of hand-crafted and neural network representations. Some of the best combination results are shown in Table 4. Out of the different possible feature combinations, we obtained the highest weighted F1 score of 0.735 by combining hand-crafted and learned representations in the MT setting. We observed that combining low performing hand-crafted features like readability, syntactic clauses, and skip grams with neural representation boosted their performance. Likewise for the regression task, the MT RNN representation proved to be a better choice, as its combination with other features generally lowered the MSE. The best combinations for the regression task lowered the MSE to 0.123. Deep learning and hand-crafted methods may capture complementary sources of information, which upon combination boost performance.

### 5.3 Results on EMNLP13 dataset

We tried to reproduce the results reported in Ganjigunte Ashok et al. (2013) by re-implementing their system. Unlike our setup, they performed experiments on individual genres and reported average accuracy across all genres. We obtained similar results, but not as close as we expected, even after extensive experimentation, and extending the search for parameter optimization. For most of their features we obtained a lower accuracy<sup>8</sup>. The differences may be due to a combination of the curating process we described in Section 3 that corrected content in the books used, as well as the different set of parameter values we explored for tuning the classifier. As pointed out by Fokkens et al. (2013), even seemingly small differences in preprocessing can prevent reproducibility. *Hence, we consider our best accuracy so far (71.25%) to be the state-of-the-art performance on this data set.*

Table 5 shows the results from some of our best feature sets. The features that worked best for the Goodreads data also worked best for the EMNLP13 data. Significantly, with the combination of the sentic concepts and scores, typed *n*grams, and writing density, we obtained an average accuracy of 73.00%, much higher than the baseline score of 71.25% for this dataset.

The RNN performance was very low in comparison with the handcrafted features. We relate this behavior to the small size of this particular training dataset and evaluation setup. Notice that Ganjigunte Ashok et al. (2013) experimented per genre, i.e. trained a single classifier per genre. Thus, in a 5-fold approach we only have 80 samples to train and 20 to test. Additionally, we must take out some samples from the training data for validation. It has been empirically shown that one of the key elements in the success of representation learning strategies is a large amount of data, on the order of tens of thousands of samples at least. Moreover, in the EMNLP13 dataset, it is not possible to take advantage of the multitask approach because there is only one target genre in each experiment.

## 6 Discriminative features

Table 6 lists some of the features that were highly-weighted by the classifier. For the sentic concepts, salient features included important adjectives, verbs and relations; all objects that might

<sup>8</sup>There was a maximum 4% difference for some features.

Features	Avg Accuracy(%)

Table 6: Discriminative Features

trigger a crucial event. Similarly, for the character *n*-gram features, honorific titles, stop words, common word endings, and especially *n*-grams with quotation marks were highly weighted. Quotation marks indicate the exchange of dialogues between characters. This suggests that dialogue is an important aspect of novels. Word *n*-gram features also support this suggestion. Features like *s/he said*, *said Person.Name* were also highly weighted. Moreover, pronouns and titles related to male gender also had high weights. Features like *i was*, *i*, *i am* also had high weights. This might be an indication that books with first person narration tend to be more successful. Another interesting observation was that the number of question marks in a book was also consistently positively correlated with success. This might suggest that readers enjoy books consisting of dialogue or interaction between the characters. We also calculated the maximal information criterion (MIC) and correlation coefficient (CC) for the writing density as well as the readability features against the average rating. Generally, readers prefer books with high writing density (0.19 MIC, 0.25 CC) and somewhat complex writing (0.17 MIC, 0.21 CC).

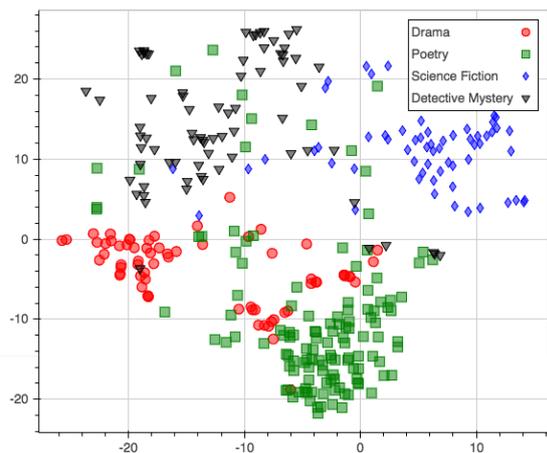

Figure 2: Projection of Book2Vec from four different genres into 2D space for the Goodreads dataset.

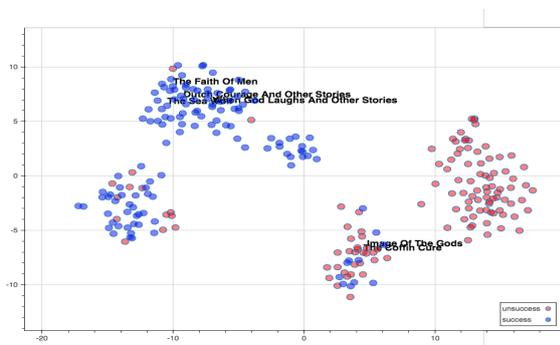

Figure 3: Projection of successful and unsuccessful books using representation learned with the RNN model.

## 7 Analysis of learned representations

In order to investigate deep vectors, we projected them onto 2-dimensional space using t-SNE. Figure 2 suggests that the vectors successfully capture genre-related concepts, as books from the same genre are close to each other in the 2D space. We then performed 8-way genre classification experiment using random stratified division of the data into 70:30 training/test ratio. We obtained an accuracy of 62.50% and F1 score of 69.30% for the EMNLP13 and Goodreads datasets, respectively. These scores were well above the random baseline of 12.50% accuracy and 15.23% F1-score for the EMNLP13 and Goodreads datasets, respectively. We further found that Poetry and Drama were the most accurately classified genres, whereas Fiction was the most difficult to classify.

In order to further investigate the representations learned by RNN for successful and unsuccessful books, we plotted the 2D t-SNE projection of the book representations. Figure 3 shows the

projection of vectors for the Short stories genre. The visualization shows that the RNN is able to cluster the book vectors into two separate regions. Furthermore, to investigate what else the RNN might be learning, we plotted some books by the same authors. Figure 3 also shows books from authors Jack London and Alan E. Nourse. The four books by Jack London and the two books by Alan E. Nourse are very close to each other. We thus infer that along with learning peculiarities of successful and unsuccessful classes, the RNN was able to capture features related to the style of authors.

## 8 How much content is needed for success prediction?

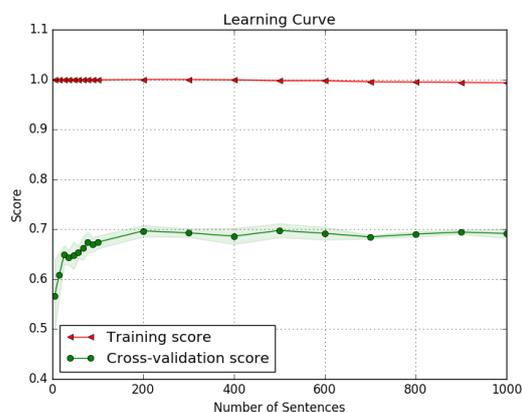

Figure 4: Weighted F1 score for training and validation data for varying number of sentences with char 3 gram feature.

Humans are good at detecting poor writing after reading just a few pages. We wanted to investigate if it is the same for machines. We devised stratified 3-fold cross-validation exploratory experiments on training data by gradually increasing the content of the books in the training fold. The results are shown in Figure 4. We see that the cross-validation score gradually increases until we reach 200 sentences. After this point, it plateaued out. Hence, we conclude that 200 sentences is the minimum threshold for the classifier.

## 9 Conclusions

In this paper we propose new features for predicting the success of books. We used two main feature categories: hand-crafted and RNN-learned features. Hand-crafted features included typed character  $n$ -grams and sentic concepts. For the

learned features we proposed two different strategies based on neural networks. The first extends Word2Vec-type representations to work in large documents such as books, and the second one uses an RNN to capture sequential patterns in large texts. We evaluated our methods on our Goodreads dataset, whose classes are not based on download counts, but rather are a function of average star ratings and number of reviewers. Our results outperform state-of-the-art methods. We conclude that instead of having either deep-learning or hand-crafted features outperform the other, both methods capture complementary information, which upon combination gives better performance. Also, the multitask setting is preferable to the single task setting, as the multitask approach helps the classifier better generalize during learning by letting constituent tasks act as regularizers. As our next steps, we plan to investigate features that capture plot-related aspects, such as character profiles and interaction through social network analysis, historical setting, and other feature-learning strategies.

## Acknowledgments

We would like to thank the National Science Foundation for partially funding this work under awards 1462141 and 1549549. We also thank Simon Tice and the three anonymous reviewers for reviewing the paper and providing helpful comments and suggestions.

## Abstract

We consider the task of predicting how literary a text is, with a gold standard from human ratings. Aside from a standard bigram baseline, we apply rich syntactic tree fragments, mined from the training set, and a series of hand-picked features. Our model is the first to distinguish degrees of highly and less literary novels using a variety of lexical and syntactic features, and explains 76.0 % of the variation in literary ratings.

## 1 Introduction

What makes a literary novel *literary*? This seems first of all to be a value judgment; but to what extent is this judgment arbitrary, determined by social factors, or predictable as a function of the text? The last explanation is associated with the concept of *literariness*, the hypothesized linguistic and formal properties that distinguish literary language from other language (Baldick, 2008). Although the definition and demarcation of literature is fundamental to the field of literary studies, it has received surprisingly little empirical study. Common wisdom has it that literary distinction is attributed in social communication about novels and that it lies mostly outside of the text itself (Bourdieu, 1996), but an increasing number of studies argue that in addition to social and historical explanations, textual features of various complexity may also contribute to the perception of literature by readers (cf. Harris, 1995; McDonald, 2007). The current paper shows that not only lexical features but also hierarchical syntactic features and other textual characteristics contribute to explaining judgments of literature.

Our main goal in this project is to answer the following question: are there particular textual conventions in literary novels that contribute to readers judging them to be literary? We address this ques-

tion by building a model of literary evaluation to estimate the contribution of textual factors. This task has been considered before with a smaller set of novels (restricted to thrillers and literary novels), using bigrams (van Cranenburgh and Koolen, 2015). We extend this work by testing on a larger, more diverse corpus, and by applying rich syntactic features and several hand-picked features to the task. This task is first of all relevant to literary studies—to reveal to what extent literature is empirically associated with textual characteristics. However, practical applications are also possible; e.g., an automated model could help a literary publisher decide whether the work of a new author fits its audience; or it could be used as part of a recommender system for readers.

Literary language is arguably a subjective notion. A gold standard could be based on the expert opinions of critics and literary prizes, but we can also consider the reader directly, which, in the form of a crowdsourced survey, more easily provides a statistically adequate number of responses. We therefore base our gold standard on a large online survey of readers with ratings of novels.

Literature comprises some of the most rich and sophisticated language, yet stylometry typically does not exploit linguistic information beyond part-of-speech (POS) tags or grammar productions, when syntax is involved at all (cf. e.g., Stamatos et al., 2009; Ashok et al., 2013). While our results confirm that simple features are highly effective, we also employ full syntactic analyses and argue for their usefulness. We consider tree fragments: arbitrarily-sized connected subgraphs of parse trees (Swanson and Charniak, 2012; Bergsma et al., 2012; van Cranenburgh, 2012). Such features are central to the Data-Oriented Parsing framework (Scha, 1990; Bod, 1992), which postulates that language use derives from arbitrary chunks (e.g., syntactic tree fragments) of previous lan-

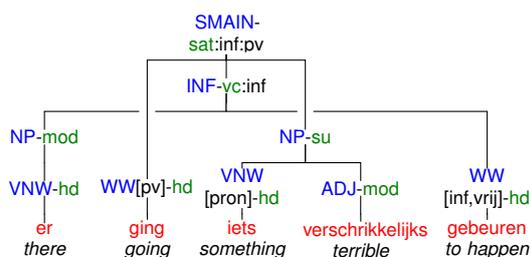

Figure 1: A parse tree fragment from Franzen, *The Corrections*. Original sentence: something terrible was going to happen.

guage experience. In our case, this suggests the following hypothesis.

**HYPOTHESIS 1:** Literary authors employ a distinctive inventory of lexico-syntactic constructions (e.g., a register) that marks literary language.

Next we provide an analysis of these constructions which supports our second hypothesis.

**HYPOTHESIS 2:** Literary language invokes a larger set of syntactic constructions when compared to the language of non-literary novels, and therefore more variety is observed in the parse tree fragments whose occurrence frequencies are correlated with literary ratings.

The support provided for these hypotheses suggests that the notion of literature can be explained, to a substantial extent, from textual factors, which contradicts the belief that external, social factors are more dominant than internal, textual factors.

## 2 Task, experimental setup

We consider a regression problem of a set of novels and their literary ratings. These ratings have been obtained in a large reader survey (about 14k participants),<sup>1</sup> in which 401 recent, bestselling Dutch novels (as well as works translated into Dutch) were rated on a 7-point Likert scale from *definitely not* to *highly literary*. The participants were presented with the author and title of each novel, and provided ratings for novels they had read. The ratings may have been influenced by well known authors or titles, but this does not affect the results of this paper because the machine learning models are not given such information. The task we consider is to predict the mean<sup>2</sup> rating for each novel. We ex-

<sup>1</sup>The survey was part of The Riddle of Literary Quality, cf. <http://literaryquality.huygens.knaw.nl>

<sup>2</sup>Strictly speaking the Likert scale is ordinal and calls for the median, but the symmetric 7-point scale and the number of ratings arguably makes using the mean permissible; the latter provides more granularity and sensitivity to minority ratings.

clude 16 novels that have been rated by less than 50 participants. 91 % of the remaining novels have a *t*-distributed 95 % confidence interval  $< 0.5$ ; e.g., given a mean of 3, the confidence interval typically ranges from 2.75 to 3.25. Therefore for our purposes the ratings form a reliable consensus. Novels rated as highly literary have smaller confidence intervals, i.e., show a stronger consensus. Where a binary distinction is needed, we call a rating of 5 or higher ‘literary.’

Since we aim to extract relevant features from the texts themselves and the number of novels is relatively small, we apply cross-validation, so as to exploit the data to the fullest extent while maintaining an out-of-sample approach. We divide the corpus in 5 folds of roughly equal size, with the following constraints: (a) novels by the same author must be in the same fold, since we want to rule out any influence of author style on feature selection or model validation; (b) the distribution of literary ratings in each fold should be similar to the overall distribution (stratification).

We control for length and potential particularities of the start of novels by considering sentences 1000–2000 of each novel. 18 novels with fewer than 2000 sentences are excluded. Together with the constraint of at least 50 ratings, this brings the total number of novels we consider to 369.

We evaluate the effectiveness of the features using a ridge regression model, with 5-fold cross-validation; we do not tune the regularization. The results are presented incrementally, to illustrate the contribution of each feature relative to the features before it. This makes it possible to gauge the effective contribution of each feature while taking any overlap into account.

We use  $R^2$  as the evaluation metric, expressing the percentage of variance explained (perfect score 100); this shows the improvement of the predictions over a baseline model that always predicts the mean value (4.2, in this dataset). A mean baseline model is therefore defined to have an  $R^2$  of 0. Other baseline models, e.g., always predicting 3.5 or 7, attain negative  $R^2$  scores, since they perform worse than the mean baseline. Similarly, a random baseline will yield a negative expected  $R^2$ .

## 3 Basic features

Sentence length, direct speech, vocabulary richness, and compressibility are simple yet effective stylistic features. We count direct speech sentences

by matching on specific punctuation; this provides a measure of the amount of dialogue versus narrative text in the novel. Vocabulary richness is defined as the proportion of words in a text that appear in the top 3000 most common words of a large reference corpus (Sonar 500; Oostdijk et al., 2013); this shows the proportion of difficult or unusual words. Compressibility is defined as the `bzip2` compression ratio of the texts; the intuition is that a repetitive and predictable text will be highly compressible. CLICHES is the number of cliché expressions in the texts based on an external dataset of 6641 clichés (van Wingerden and Hendriks, 2015); clichés, being marked as informal and unoriginal, are expected to be more prevalent in non-literary texts. Table 1 shows the results of these features. Several other features were also evaluated but were either not effective or did not achieve appreciable improvements when these basic features are taken into account; notably Flesch readability (Flesch, 1948), average dependency length (Gibson, 2000), and D-level (Covington et al., 2006).

## 4 Automatically induced features

In this section we consider extracting syntactic features, as well as three (sub)lexical baselines.

TOPICS is a set of 50 topic weights induced with Latent Dirichlet Allocation (LDA; Blei et al., 2003) from the corpus (for details, cf. Jautze et al., 2016).

Furthermore, we use character and word  $n$ -gram features. For words, bigrams present a good trade off in terms of informativeness (a bigram frequency is more specific than the frequency of an individual word) and sparsity (three or more consecutive words results in a large number of  $n$ -gram types with low frequencies). For character  $n$ -grams,  $n = 4$  achieved good performance in previous work (e.g., Stamatatos, 2006).

We note three limitations of  $n$ -grams. First, the fixed  $n$ : larger or discontinuous chunks are not extracted. Combining  $n$ -grams does not help since a linear model cannot capture feature interactions, nor is the consecutive occurrence of two features

captured in the bag-of-words representation. Second, larger  $n$  imply a combinatorial explosion of possible features, which makes it desirable to select the most relevant features. Finally, word and character  $n$ -grams are surface features without linguistic abstraction. One way to overcome these limitations is to turn to syntactic parse trees and mine them for relevant features unrestricted in size.

Specifically, we consider tree fragments as features, which are arbitrarily-sized fragments of parse trees. If a parse tree is seen as consisting of a sequence of grammar productions, a tree fragment is a connected subsequence thereof. Compared to bag-of-word representations, tree fragments can capture both syntactic and lexical elements; and these combine to represent constructions with open slots (e.g., to take NP into account), or sentence templates (e.g., “Yes, but . . .”, he said). Tree fragments are thus a very rich source of features, and larger or more abstract features may prove to be more linguistically interpretable.

We present a data-driven method for extracting and selecting tree fragments. Due to combinatorics, there are an exponential number of possible fragments given a parse tree. For this reason it is not feasible to extract all fragments and select the relevant ones later; we therefore use a strategy to directly select fragments for which there is evidence of re-use by considering commonalities in pairs of trees. This is done by extracting the largest common syntactic fragments from pairs of trees (Sangati et al., 2010; van Cranenburgh, 2014). This method is related to tree-kernel methods (Collins and Duffy, 2002; Moschitti, 2006), with the difference that it extracts an explicit set of fragments. The feature selection approach is based on relevance and redundancy (Yu and Liu, 2004), similar to Swanson and Charniak (2013). Kim et al. (2011) also use tree fragments, for authorship attribution, but with a frequent tree mining approach; the difference with our approach is that we extract the largest fragments attested in each tree pair, which are not necessarily the most frequent.

### 4.1 Preprocessing

We parse the 369 novels with Alpino (Bouma et al., 2001). The parse trees include discontinuous constituents, non-terminal labels consist of both syntactic categories and function tags, selected morphological features,<sup>3</sup> and constituents are bina-

<sup>3</sup>The DCOI tag set (van Eynde, 2005) is fine grained; we restrict the set to distinguish the 7 coarse POS tags, as well

alized head-outward with a markovization of  $h=1$ ,  $v=1$  (Klein and Manning, 2003).

For a fragment to be attested in a pair of parse trees, its labels need to match exactly, including the aforementioned categories, tags, and features. The  $h = 1$  binarization implies that fragments may contain partial constituents; i.e., a contiguous sequence of children from an  $n$ -ary constituent.

Figure 1 shows an example parse tree; for brevity, this tree is rendered without binarization. The non-terminal labels consist of a syntactic category (shown in red), followed by a function tag (green). The part-of-speech tags additionally have morphological features (black) in square brackets. Some labels contain percolated morphological features, prefixed by a colon.

## 4.2 Mining syntactic tree fragments

The procedure is divided in two parts. The first part concerns fragment extraction:

1. Given texts divided in folds  $F_1 \dots F_n$ , each  $C_i$  is the set of parse trees obtained from parsing all texts in  $F_i$ . Extract the largest common fragments of the parse trees in all pairs of folds  $\langle C_i, C_j \rangle$  with  $i < j$ . A common fragment  $f$  of parse trees  $t_1, t_2$  is a connected subgraph of  $t_1$  and  $t_2$ . The result is a set of initial candidates that occur in at least two different texts, stored separately for each pair of folds  $\langle C_i, C_j \rangle$ .
2. Count occurrences of all fragments in all texts.

Fragment selection is done separately w.r.t. each test fold. Given test fold  $i$ , we consider the fragments found in training folds  $\{1..n\} \setminus i$ ; e.g., given  $n = 5$ , for test fold 1 we select only from the fragments and their counts as observed in training folds 2–5. Given a set of fragments from training folds, selection proceeds as follows:

1. Zero count threshold: remove fragments that occur in less than 5 % of texts (too specific to particular novels); frequency threshold: remove fragments that occur less than 50 times across the corpus (too rare to reliably detect a correlation with the ratings).
2. Relevance threshold: select fragments by considering the correlation of their counts with the literary ratings of the novels in the training folds. Apply a simple linear regression

as infinite verbs, auxiliary verbs, proper nouns, subordinating conjunctions, personal pronouns, and postpositions.

based on the Pearson correlation coefficient, and use an F-test to filter out fragments whose  $p$ -value<sup>4</sup>  $> 0.05$ . The F-test determines significance based on the number of datapoints  $N$ , and the correlation  $r$ ; the effective threshold is approximately  $|r| > 0.11$ .

3. Redundancy removal: greedily select the most relevant fragment and remove other fragments that are too similar to it. Similarity is measured by computing the correlation coefficient between the feature vectors of two fragments, with a cutoff of  $|r| > 0.5$ . Experiments where this step was not applied indicated that it improves performance.

Note that there is some risk of overfitting since fragments are both extracted and selected from the training set. However, this is mitigated by the fact that fragments are extracted from pairs of folds, while selection is constrained to fragments that are attested and significantly correlated across the whole training set.

The values for the thresholds were chosen manually and not tuned, since the limited number of novels is not enough to provide a proper tuning set. Table 2 lists the number of fragments extracted from folds 2–5 after each of these steps.

recurring fragments	3,193,952
occurs in $> 5\%$ of texts	375,514
total freq. $> 50$ across corpus	98,286
relevance: correlated s.t. $p < 0.05$	30,044
redundancy: $ r  < 0.5$	7,642

Table 2: The number of fragments in folds 2–5 after each filtering step.

## 4.3 Evaluation

Due to the large number of induced features, Support Vector Regression (SVR) is more effective than ridge regression. We therefore train a linear SVR model with the same cross-validation setup, and feed its predictions to the ridge regression model (i.e., stacking). Feature counts are turned into relative frequencies. The model has two hyperparameters:  $C$  determines the regularization, and  $\epsilon$  is a threshold beyond which predictions are considered good enough during training. Instead of

<sup>4</sup>If we were actually testing hypotheses we would need to apply Bonferroni correction to avoid the Family-Wise Error due to multiple comparisons; however, since the regression here is only a means to an end, we leave the  $p$ -values uncorrected.

	1	2	3	4	5	Mean
Word Bigrams	59.8	47.0	58.0	63.6	50.7	55.8
Char. 4-grams	58.6	50.4	54.2	65.0	<b>56.2</b>	56.9
Fragments	<b>61.6</b>	<b>53.4</b>	<b>58.7</b>	<b>65.8</b>	46.5	<b>57.2</b>

+ CHAR. 4-GRAMS	59.9
+ FRAGMENTS	61.2

Table 4: Automatically induced features; incremental scores.

tuning these parameters we pick fixed values of  $C=100$  and  $\epsilon=0$ , reducing regularization compared to the default of  $C=1$  and disabling the threshold.

Cf. Table 3 for the scores. The syntactic fragments perform best, followed by char. 4-grams and word bigrams. We report scores for each of the 5 folds separately because the variance between folds is high. However, the differences between the feature types are relatively consistent. The variance is not caused by the distribution of ratings, since the folds were stratified on this. Nor can it be explained by the agreement in ratings per novel, since the 95 % confidence intervals of the individual ratings for each novel were of comparable width across the folds. Lastly, author gender, genre, and whether the novel was translated do not differ markedly across the folds. It seems most likely that the novels simply differ in how predictable their ratings are from textual features.

In order to gauge to what extent these automatically induced features are complementary, we combine them in a single model together with the basic features; cf. the scores in Table 4. Both character 4-grams and syntactic fragments still provide a relatively large improvement over the previous features, taking into account the inherent diminishing returns of adding more features.

Figure 2 shows a bar plot of the ten novels with the largest prediction error with the fragment and word bigram models. Of these novels, 9 are highly literary and underestimated by the model. For the other novel (Smeets, *Afrekening*) the literary rating is overestimated by the model. Since this top 10 is based on the mean prediction from both models, the error is large for both models. This does not

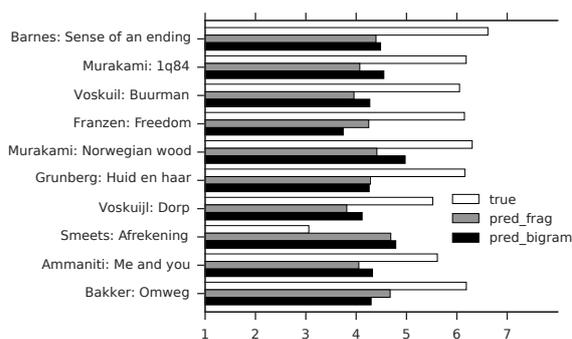

Figure 2: The ten novels with the largest prediction error (using both fragments and bigrams).

Novel	residual (true - pred.)	mean sent. len.	% direct speech	% Top 3000 vocab.	bzip2 ratio

Table 5: Comparison of baseline features for novels with good (1–4) and bad (5–8) predictions.

change when the top 10 errors using only fragments or bigrams is inspected; i.e., the hardest novels to predict are hard with both feature types.

What could explain these errors? At first sight, there is no obvious commonality between the literary novels that are predicted well, or between the ones with a large error; e.g., whether the novels have been translated or not does not explain the error. A possible explanation is that the successfully predicted literary novels share a particular (e.g., rich) writing style that sets them apart from other novels, while the literary novels that are underestimated by the model are not marked by such a writing style. It is difficult to confirm this directly by inspecting the model, since each prediction is the sum of several thousand features, and the contributions of these features form a long tail. If we define the contribution of a feature as the absolute value of its weight times its relative frequency in the document, then in case of Barnes, *The sense of an ending*, the top 100 features contribute only 34 % of the total prediction.

Table 5 gives the basic features for the top 4 literary novels with the largest error and contrasts them with 4 literary novels which are well predicted. The most striking difference is sentence length: the underestimated literary novels have

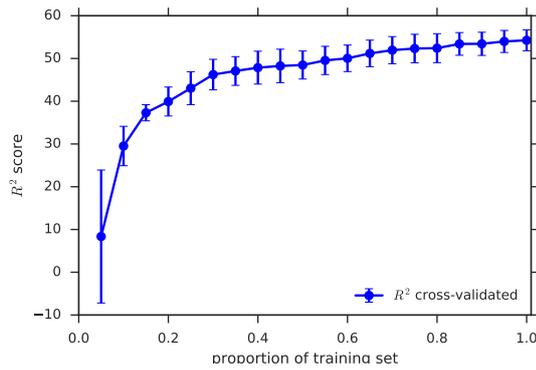

Figure 3: Learning curve when varying training set size. The error bars show the standard error.

markedly shorter sentences. Voskuil and Franzen have a higher proportion of direct speech (they are in fact the only literary novels in the top 10 novels with the most direct speech). Lastly, the underestimated novels have a higher proportion of common words (lower vocabulary richness). These observations are compatible with the explanation suggested above, that a subset of the literary novels share a simple, readable writing style with non-literary novels. Such a style may be more difficult to detect than a literary style with long and complex sentences, or rich vocabulary and phraseology, because a simple, well-crafted sentence may not offer overt surface markers of stylization. Book reviews appear to support this notion for *The sense of an ending*: “A slow burn, measured but suspenseful, this compact novel makes every slyly crafted sentence count” (Tonkin, 2011); and “polished phrasings, elegant verbal exactness and epigrammatic perceptions” (Kemp, 2011).

In order to test whether the amount of data is sufficient to learn to predict the ratings, we construct a learning curve for different training set sizes; cf. Figure 3. The set of novels is shuffled once, so that initial segments of different size represent random samples. The novels are sampled in 5 % increments (i.e., 20 models are trained). The graphs show the cross-validated scores.

The graphs show that increasing the number of novels has a large effect on performance. The curve is steep up to 30 % of the training set, and the performance keeps improving steadily but more slowly up to the last data point. Since the performance is relatively flat starting from 85 %, we can conclude that the  $k$ -fold cross-validation with  $k = 5$  provides an adequate estimate of the model’s performance if

	$R^2$
BASIC FEATURES (TABLE 1)	30.0
+ AUTO. INDUCED FEAT. (TABLE 4)	61.2
+ GENRE	74.3
+ TRANSLATED	74.0
+ AUTHOR GENDER	76.0

Table 6: Metadata features; incremental scores.

it were trained on the full dataset; if the model was still gaining performance significantly with more training data, the cross-validation score would underestimate the true prediction performance.

A similar experiment was performed varying the number of features. Here the performance plateaus quickly and reaches an  $R^2$  of 53.0 % at 40 %, and grows only slightly from that point.

## 5 Metadata features

In addition to textual features, we also include three (categorical) metadata features not extracted from the text, but still an inherent feature of the novel in question: GENRE, TRANSLATED, and AUTHOR GENDER; cf. Table 6 for the results. Figure 4 shows a visualization of the predictions in a scatter plot.

GENRE is the coarse genre classification Fiction, Suspense, Romantic, Other, derived from the publisher’s categorization. Genre alone is already a strong predictor, with an  $R^2$  of 58.3 on its own. However, this score is arguably misleading, because the predictions are very coarse due to the discrete nature of the feature.

A striking result is that the variables AUTHOR GENDER and TRANSLATED increase the score, but only when they are both present. Inspecting the mean ratings shows that translated novels by female authors have an average rating of 3.8, while originally Dutch male authors are rated 5.0 on average; the ratings of the other combinations lie in between these extremes. This explains why the combination works better than either feature on its own, but due to possible biases inherent in the makeup of the corpus, such as which female or translated authors are published and selected for the corpus, no conclusions on the influence of gender or translation should be drawn from these datapoints.

## 6 Previous work

Table 7 shows an overview of previous work on the task of predicting the (literary) quality of novels. Note that the datasets and targets differ, therefore none of the results are directly comparable. For

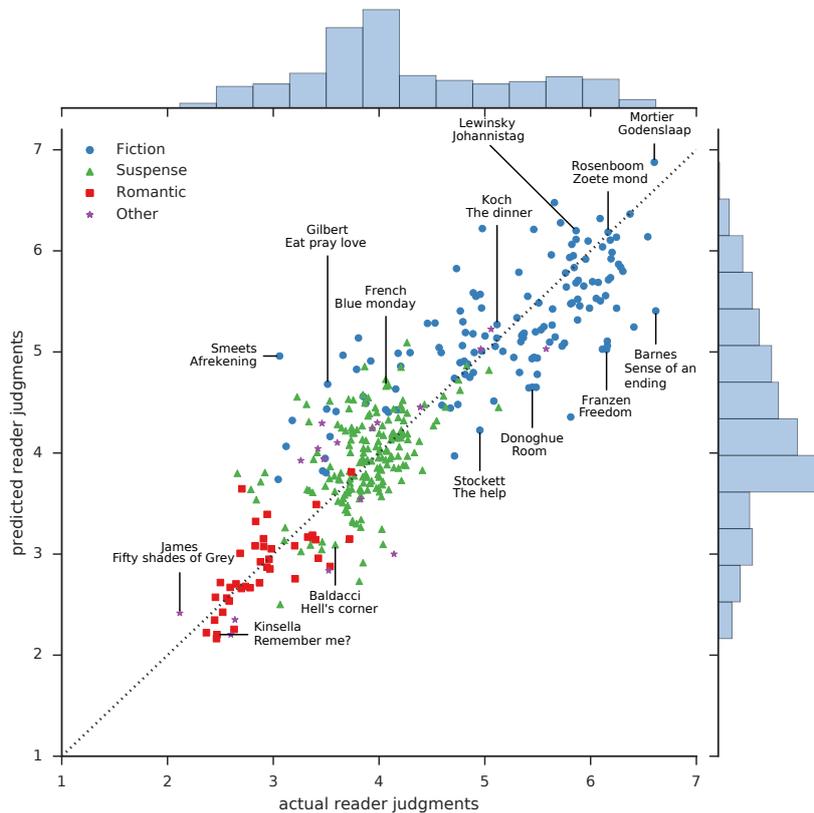

Figure 4: A scatter plot of regression predictions and actual literary ratings. Original/translated titles. Note the histograms beside the axes showing the distribution of ratings (top) and predictions (right).

example, regression is a more difficult task than binary classification, and recognizing the difference between an average and highly literary novel is more difficult than distinguishing either from a different domain or genre (e.g., newswire).

Louwerse et al. (2008) discriminate literature from other texts using Latent Semantic Analysis. Ashok et al. (2013) use bigrams, POS tags, and grammar productions to predict the popularity of Gutenberg texts. van Cranenburgh and Koolen (2015) predict the literary ratings of texts, as in the present paper, but only using bigrams, and on a smaller, less diverse corpus. Compared to previous work, this paper gives a more precise estimate of how well shades of literariness can be predicted from a diverse range of features, including larger and more abstract syntactic constructions.

## 7 Analysis of selected tree fragments

An advantage of parse tree fragments is that they offer opportunities for interpretation in terms of linguistic aspects as well as basic distributional aspects such as shape and size.

Figure 5 shows three fragments ranked highly

Binary classification	Dataset, task	Acc.
Louwerse et al. (2008)	119 all-time literary classics and 55 other texts, literary novels vs. non-fiction/sci-fi	87.4
Ashok et al. (2013)	800 19th century novels, low vs. high download count	75.7
van Cranenburgh and Koolen (2015)	146 recent novels, low vs. high survey ratings	90.4
Regression result	Dataset, task	$R^2$
van Cranenburgh and Koolen (2015)	146 recent novels, survey ratings	61.3
This work	401 recent novels, survey ratings	76.0

Table 7: Overview of previous work on modeling (literary) quality of novels.

by the correlation metric, as extracted from the first fold. The first fragment shows an incomplete constituent, indicated by the ellipses as first and last leaves. Such incomplete fragments are made possible by the binarization scheme (cf. Sec. 4.1).

Table 8 shows a breakdown of fragment types in the first fold. In contrast with  $n$ -grams, we also see

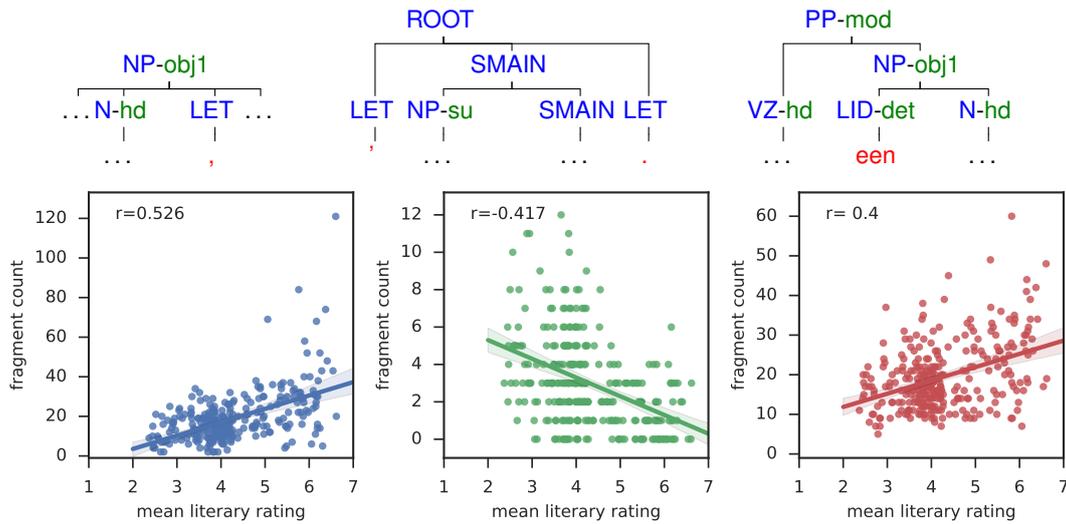

Figure 5: Three fragments whose frequencies in the first fold have a high correlation with the literary ratings. Note the different scales on the  $y$ -axis. From left to right; Blue: complex NP with comma; Green: quoted speech; Red: Adjunct PP with indefinite article.

fully lexicalized	1,321
syntactic (no lexical items)	2,283
mixed	4,038
<hr/>	
discontinuous	684
discontinuous substitution site	396
<hr/>	
total	7,642

Table 8: Breakdown of fragment types selected in the first fold.

a large proportion of purely syntactic fragments, and fragments mixing both lexical elements and substitution sites. In the case of discontinuous fragments, it turns out that the majority has a positive correlation; this might be due to being associated with more complex constructions.

Figure 6 shows a breakdown by fragment size (defined as number of non-terminals), distinguishing fragments that are positively versus negatively correlated with the literary ratings.

Note that 1 and 3 are special cases corresponding to lexical (e.g., DT  $\rightarrow$  the) and binary grammar productions (e.g., NP  $\rightarrow$  DT N), respectively. The fragments with 2, 4, and 6 non-terminals are not as common because an even number implies the presence of unary nodes. Except for fragments of size 1, the frontier of fragments can consist of either substitution sites or terminals (since we distinguish only the number of non-terminals). On the one hand smaller fragments corresponding to one or two grammar productions are most common, and are predominantly positively correlated with the

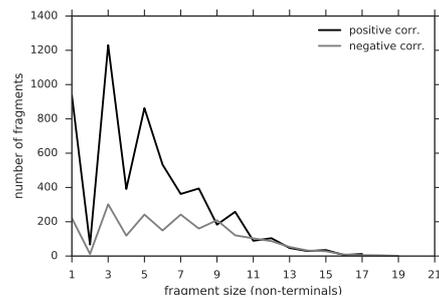

Figure 6: Breakdown by fragment size (number of non-terminals).

literary ratings. On the other hand there is a significant negative correlation between fragment size and literary ratings ( $r = -0.2, p < 0.001$ ); i.e., smaller fragments tend to be positively correlated with the literary ratings.

It is striking that there are more positively than negatively correlated fragments, while literary novels are a minority in the corpus (88 out of 369 novels are rated 5 or higher). Additionally, the breakdown by size shows that the larger number of positively correlated fragments is due to a large number of small fragments of size 3 and 5; however, combinatorially, the number of possible fragment types grows exponentially with size (as reflected in the initial set of recurring fragments), so larger fragment types would be expected to be more numerous. In effect, the selected negatively correlated fragments ignore this distribution by being relatively uniform with respect to size, while the

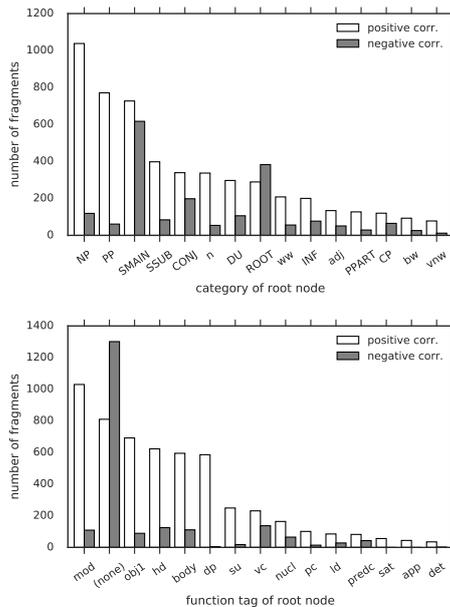

Figure 7: Breakdown by category (above) and function tag (below) of fragment root (top 15 labels).

literary fragments actually show the opposite distribution.

What could explain the peak of positively correlated, small fragments? In order to investigate the peak of small fragments, we inspect the 40 fragments of size 3 with the highest correlations. These fragments contain indicators of unusual or more complex sentence structure:

- DU, dp: discourse phenomena for which no specific relation can be assigned (e.g., discourse relations beyond the sentence level).
- appositive NPs, e.g., ‘John the artist.’
- a complex NP, e.g., containing punctuation, nested NPs, or PPs.
- an NP containing an adjective used nominally or an infinitive verb.

On the other hand, most non-literary fragments are top-level productions containing ROOT or clause-level labels, for example to introduce direct speech.

Another way of analyzing the selected fragments is by frequency. When we consider the total frequencies of selected fragments across the corpus, there is a range of 50 to 107,270. The bulk of fragments have a low frequency (before fragment selection 2 is by far the most dominant frequency), but the tail is very long. Except for the fact that there is a larger number of positively correlated fragments, the histograms have a very similar shape.

Lastly, Figure 7 shows a breakdown by the syn-

tactic categories and function tags of the root node of the fragments. The positively correlated fragments are spread over a larger variety of both syntactic categories and function tags. This means that for most labels, the number of positively correlated fragments is higher; the exceptions are ROOT, SV1 (a verb-initial phrase, not part of the top 15), and the absence of a function tag (indicative of a non-terminal directly under the root node). All of these exceptions point to a tendency for negatively correlated fragments to represent templates of complete sentences.

## 8 Conclusion

The answer to the main research question is that literary judgments are non-arbitrary and can be explained to a large extent from the text itself: there is an intrinsic *literariness* to literary texts. Our model employs an ensemble of textual features that show a cumulative improvement on predictions, achieving a total score of 76.0 % variation explained. This result is remarkably robust: not just broad genre distinctions, but also finer distinctions in the ratings are predicted.

The experiments showed one clear pattern: literary language tends to use a larger set of syntactic constructions than the language of non-literary novels. This also provides evidence for the hypothesis that literature employs a specific inventory of constructions. All evidence points to a notion of literature which to a substantial extent can be explained purely from internal, textual factors, rather than being determined by external, social factors.

Code and details of the experimental setup are available at <https://github.com/andreasvc/literariness>

### Abstract

Political surveys have indicated a relationship between a sense of Scottish identity and voting decisions in the 2014 Scottish Independence Referendum. Identity is often reflected in language use, suggesting the intuitive hypothesis that individuals who support Scottish independence are more likely to use distinctively Scottish words than those who oppose it. In the first large-scale study of sociolinguistic variation on social media in the UK, we identify distinctively Scottish terms in a data-driven way, and find that these terms are indeed used at a higher rate by users of pro-independence hashtags than by users of anti-independence hashtags. However, we also find that in general people are *less* likely to use distinctively Scottish words in tweets with referendum-related hashtags than in their general Twitter activity. We attribute this difference to style-shifting relative to audience, aligning with previous work showing that Twitter users tend to use fewer local variants when addressing a broader audience.

### 1 Introduction

A central idea from sociolinguistics is that people's social identity is reflected in their use of language, and that people modulate their use of language in order to present particular identities in different situations. The recent availability of social media data has raised interest in confirming and extending these results using large scale datasets. For example, Twitter data has been used to examine patterns

of regional variation in general US English (Doyle, 2014; Huang et al., 2015), African American English (Jones, 2015), and global Spanish (Gonçalves and Sánchez, 2014), and to study variation associated with factors such as race/ethnicity (Jones, 2015; Blodgett et al., 2016; Jørgensen et al., 2015) and gender (Bamman et al., 2014). These studies have shown that tweets mirror spoken language in many ways, such as displaying dialect variation not only in the use of distinct lexical items, but also in the use of non-standard spellings to indicate non-standard pronunciation—in fact, these spellings even reflect the phonological processes found in spoken language (Eisenstein, 2015). There is also evidence that, as in spoken language, individuals may shift their style of language in response to the audience. In particular, studies have found that when the expected audience of a tweet is larger, Americans use fewer non-standard and local words (Pavalanathan and Eisenstein, 2015) and Dutch bilingual speakers of a minority language are more likely to use Dutch rather than their other language (Nguyen et al., 2015). A small-scale case study of a single Scottish Twitter user also provides preliminary evidence that users may modulate their production of regional variants according to the topic of the tweet (Tatman, 2015).

Here we present the first large-scale sociolinguistic study of British tweets, and the first to examine the relationship between sociolinguistic variation and political views using social media data. We use a large corpus of tweets to examine the relationship between users' linguistic choices and their views about the 2014 Scottish independence referendum. The referendum (on whether Scotland should leave the UK) generated considerable political discussion and an unprecedented turnout of 84.6% of the

electorate, with the ‘No’ (anti-independence) side taking 55.3% of the vote. The 2013 Scottish Social Attitudes Survey (ScotCen, 2013) showed a clear correlation between national identity and voting intentions (53% of those who identified as ‘Scottish not British’ said they intended to vote ‘Yes’ to independence, vs. just 5% of those who identified as ‘British not Scottish’), and there was much discussion in the popular press about the relationship between a sense of Scottish identity and support for Scottish sovereignty.

Although this recent discussion was not centered on language, there is a long history of scholarly discourse connecting the use of the Scots language<sup>1</sup> and sociolinguistic and political identity (Grant, 1931; McAfee, 1985; Corbett et al., 2003). If this connection still holds today, then we might expect to find that those on the ‘Yes’ side of the debate use more identifiably Scottish language than those on the ‘No’ side. We might also expect to find some modulation of Scottish language use depending on whether users are discussing the referendum or not.

To examine these questions, we used a data-driven approach to identify linguistic terms that are used more in Scotland than in the rest of the UK. The identified terms include uniquely Scots words that are attested in Scots literature dating back to the 1600s and earlier, contemporary regional colloquialisms, spelling variants of Standard English words which reflect Scottish pronunciations, and acronyms used as shorthand for distinctive Scottish phrases. From these, we selected variables for which users can produce either a Standard English or Scottish variant (e.g., DO vs. DAE). We then classified users as pro- or anti-independence based on the referendum-related hashtags they used and asked whether these two groups use Scottish variants at different rates. We found that the pro-independence group did use Scottish variants significantly more than the anti-independence group, although the overall rate of Scottish variants is very low amongst all users.

Next, we compared the use of Scottish variants in tweets containing referendum-related hashtags to their use in other tweets. If users are aiming to project their Scottish identity as part of politi-

cal discourse, then we might expect greater use of Scottish variants in referendum tweets than in non-referendum tweets. However, previous studies have suggested that non-standard and local variants are used *less* frequently in tweets containing hashtags, which typically have a larger audience than other tweets (Pavalanathan and Eisenstein, 2015). This effect would predict the opposite result—a lower use of Scottish variants in tweets with referendum hashtags—and indeed this is the result we found. So it appears that although pro-independence users do make greater use of Scottish variants overall, they do not increase their Scottish usage when engaging in broad-audience political discourse.

To summarize, the contributions of our paper are: (1) The first large-scale study of dialect variation on twitter in the UK. We show that in addition to using Scots in speech and some literary genres such as poetry, people are using Scots in informal public writing. The data-driven approach enables us to identify Scotland-specific lexical items without relying on pre-conceived notions of which variables to look for (cf. Tatman, 2015), and reveals that in addition to using attested Scots vocabulary, Twitter users appear to be creatively adapting to the medium with their use of acronyms for distinctly Scottish turns of phrase. (2) The first study connecting sociolinguistic variables to political stance using social media data, showing that pro-independence users have a higher rate of Scottish usage. (3) Further evidence of Pavalanathan and Eisenstein’s (2015) claim that Twitter users modulate their language according to the audience, with local variants being less likely in tweets directed to larger audiences.

## 2 Context

‘Scots’ refers to the group of dialects historically spoken in the Lowlands of Scotland. While Scots has Anglo-Scandinavian origins in common with English, by the 16th century its pronunciation, vocabulary, and literary norms had considerably diverged from those of English, and Scots had become established as the prestige language in Scotland (Kay, 1988).<sup>2</sup> However, following the Union of Crowns in 1603, when King James VI of Scotland acceded to the thrones of England and Ireland,

<sup>1</sup>Historically, Scots has been considered a different language than English (see §2), though with many cognates and overlapping vocabulary. Most native Scottish people today speak some variety of Scottish English, which retains a few uniquely Scots words but is mainly distinguished from other varieties of English by its pronunciation.

<sup>2</sup>Previously, Gaelic had been the dominant spoken and literary language in Scotland. Note that while in medieval times non-Gaelic speakers referred to the Gaels as ‘Scots’, what we now refer to as ‘Scots’ is the Anglo-Scandinavian language which spread at the expense of Scottish Gaelic (a Celtic language) in the 15th & 16th centuries.

he and his court began to adopt English norms in their writing. After the Union of Parliaments in 1707, English firmly replaced Scots as the language of serious or elevated discourse in Scotland (Grant, 1931). While some people still use distinctive elements of Scots in their speech, until recently the average Scottish person’s exposure to written Scots would have been largely confined to a select few literary domains such as poetry and comic narrative (Corbett et al., 2003). However, social media has given rise to a new genre of casual, communicative writing that is potentially visible to large and diverse audiences, providing both a platform and an impetus to express one’s identity through the use of written language. Below, we provide three example tweets (each from a different user) which contain orthographic representations of Scots vocabulary and/or Scottish English pronunciation. Standard English variants of Scottish terms are provided in italics.

- (1) No matter how shite [*shit*] a day you’ve had just remember there’s always good biscuits in yer [*your*] grannies hoose [*house*]
- (2) “Absolute carnage” at polling station earlier. Bairns [*kids*] playing, polite grannies, Yessers and Nos blethering [*blathering*] to each other. #VoteYesScotland
- (3) #fuckoffscotland hud on we will fuck off but afore we dae eh challenge ye tae a square go ya queen loving DIDDY doughnut Sasijs YUP-TAE  
*#fuckoffscotland hold on we will fuck off but before we do I challenge you to a fair fight you queen loving fools. What are you doing!?*

### 3 Data

Our data was drawn from the Sample endpoint of Twitter’s Streaming API (a.k.a. the ‘Spritzer’), which provides a random 1% sample of all public tweets in near real-time. We started with all tweets streamed from the Spritzer between 1st September 2013 and 30th September 2014. These dates cover a year of activity leading up to the referendum, as well as the day the vote took place (18 September 2014), and immediate reactions. We used a language classifier (Lui and Baldwin, 2012) to filter out non-English tweets, yielding an initial dataset of 629,431,509 tweets.<sup>3</sup> Because we are interested

<sup>3</sup>One might be concerned that an automatic language filter could remove some of the heavily Scottish tweets. However,

in the linguistic choices that individuals make in various contexts, we took steps to remove tweets which were not originally authored by the individual who posted them. Retweets (tweets which are verbatim copies of other tweets) were identified by a case-insensitive search for the token ‘RT’, and discarded. Quote tweets (tweets which contain verbatim copies of other tweets, but are augmented with original comments) were dealt with by discarding any text between double quotation marks, but retaining the remainder of the tweet.

From this initial dataset we extracted three overlapping subsets:

**The Geotagged-UK (GU) dataset** contains all tweets geotagged to a location in the United Kingdom (1,654,204 tweets by 446,923 distinct users).

**The Geotagged-Scotland (GS) dataset** contains all tweets geotagged to a location in Scotland (166,992 tweets by 40,861 distinct users).

**The Indyref Tweets (IT) dataset** consists of tweets containing hashtags relating to the 2014 Scottish Independence Referendum.

To construct the IT dataset, we first created a list of relevant hashtags, starting with the following five seed hashtags: #IndyRef, #VoteYes, #VoteNo, #YesScotland, #BetterTogether.<sup>4</sup> For each of these five seeds, we extracted from our initial filtered dataset a list of *all* tweets by any user who used the seed hashtag. We identified the 100 most frequent hashtags in each of these five lists of tweets, and manually discarded all hashtags which were unrelated to the referendum, as well as those which were highly ambiguous (e.g., #Indy, which sometimes refers to the referendum, but also commonly refers to a genre of music). The resulting list of referendum-related hashtags is given in Table 1.

Next, we extracted all tweets from our initial dataset which contain at least one of the hashtags on this list, yielding 77,708 tweets by 26,019 distinct users. We then applied a heuristic to filter out tweets produced by bots and spammers: for

even tweets such as example (3) in §2 are assigned a very high probability of being English by the filter. Perhaps other tweets with many Scottish terms were filtered out, in which case we will underestimate the probability that users choose Scottish variants. However this issue should not cause us to find differences in use between different groups where there are none.

<sup>4</sup>‘Yes Scotland’ and ‘Better Together’ are the names of the principal organisations representing the Yes and No vote campaigns, respectively.

each user in the IT dataset for whom we had at least 5 tweets in the initial dataset, we computed the proportion of their tweets that contain URLs, and discarded users for whom this proportion was in the 90th percentile. This step filtered out 11,443 tweets by 1389 users.

Note that seven of the hashtags in Table 1 (*#voteyes*, *#bettertogether*, *#nothanks*, *#voteno*, *#yes2014*, *#letsstaytogether*, and *#yesvote*) are occasionally used in contexts unrelated to the Scottish Independence Referendum (e.g. *#bettertogether* can also refer to interpersonal relationships). However, they are distinctive enough that if a user has also used hashtags which are unambiguously related to the referendum, then it seems reasonable to assume that their usage of these potentially-ambiguous hashtags relates to the referendum too. Therefore, in order for a tweet containing one of these seven hashtags to be retained in the Indyref dataset, we required that its author had also used at least one other hashtag from Table 1. This criterion filtered out a further 6601 tweets by 6041 distinct users, such that the final IT dataset contains 59,664 tweets by 18,589 distinct users.

#### 4 Identifying distinctively Scottish vocabulary on Twitter

We wish to identify terms that are more likely to be used by Twitter users in Scotland than in the rest of the UK. We follow the method of Pavalanathan and Eisenstein (2015), who used the Sparse Additive Generative Model of Text (SAGE) framework (Eisenstein et al., 2011) to identify tweet terms associated with metropolitan areas in the United States. SAGE models deviations in the log-frequencies of terms in a corpus of interest (here, the GS dataset) with respect to their log-frequencies in some “background” corpus (here, the GU dataset). The estimated deviations are regularized to avoid overstating the importance of deviations in the frequencies of rare words. Here, we use a publicly available implementation of SAGE<sup>5</sup> to obtain log-frequency deviation estimates for all terms which occur at least fifty times in the GU dataset, excluding hashtags, mentions, URLs, and stopwords. The terms with the highest estimates are those which are most distinctive to tweets geo-located in Scotland.

<sup>5</sup><https://github.com/jacobeisenstein/jos-gender-2014/>

#### 4.1 Scotland-specific terms

Unsurprisingly, many of the Scotland-specific terms are proper nouns which are topically associated with Scotland, such as Scottish placenames, political figures, and sports personalities. There are also several common nouns (e.g. ‘devolution’, ‘bagpipes’) and verbs (e.g. ‘canvass’, ‘invade’) which are strongly associated with the political or cultural climate in Scotland. These terms occur with greater relative frequency in the GS dataset simply because their referents are discussed with greater relative frequency; not because they are distinct from the terms that people in the rest of the UK use to index those referents. However, there are also many terms with high log-frequency deviations that *are* linguistically distinctive. To isolate such terms, we began with the 400 terms with the highest estimated deviations, and then manually filtered this list, discarding Standard English words, proper nouns, numerals, and non-standard terms which had clear topical associations (e.g. ‘devo’: an abbreviation for ‘devolution’; ‘hh’: an acronym for ‘Hail Hail’, a football chant used by supporters of Celtic F.C.). The remaining 113 distinctively Scottish terms are listed in Table 2.

Almost three fourths of these terms are attested in the Scottish National Dictionary (SND) (Grant and Murison, 1931) or its online supplement (Scottish Language Dictionaries, 2004), which catalogue words that are distinctive to Scots (i.e. those which are not used, or are used differently, in Standard English), covering the period from the 1700s up to the present day. Many are also attested in the Dictionary of the Older Scottish Tongue (Aitken et al., 1990), which catalogues the entire vocabulary of Scots from the 1100s to the late 1600s. Of the attested Scots words, some are unique to Scots, e.g. BAIRNS (‘sons/daughters’), GREETIN (‘weeping’); some are cognates with English words that have fallen out of common usage, e.g. CRABBIT (‘crabbed’; ‘ill-tempered’), FEART (‘feared’; ‘frightened/timid’); some are cognates with English words but have a wider range of senses, e.g. HUNNERS is cognate with ‘hundreds’, but used more generally to mean ‘lots’ as in “love you hunners”, “there was hunners to do”; and many differ only in form from their English cognates, e.g. AFF (‘off’) and BAW (‘ball’).

Of the 29 terms that are not attested in SND, 9 are spelling variants or derived forms of attested

Table 1: Hashtags related to the Scottish Independence Referendum and their frequencies in the IT dataset

Scots words, e.g. CANA, CANNY, and CANI are alternative spellings of the attested CANNAE, and WANTY is a contracted form of ‘want to’, analogous to the attested GONNAE and GONY. A further 5 are orthographic representations of distinctively Scottish pronunciations, e.g. ANO (‘I know’), HING (‘thing’); and 2 are acronyms for distinctively Scottish turns of phrase: GTF (‘Get Tae Fuck’) and MWI (‘Mad Wae It’). The final 13 could be described as contemporary Scottish slang, and include abbreviations: BEVY (‘beverage’)<sup>6</sup>, DEFOS (‘definitely’); drug-related lexis: WHITEY, ECCIES; profanities: BOABY, FANNYS; and everyday affective and descriptive words: DYNNO (‘amazing’), ROASTER (‘idiot’).

## 4.2 Lexical variables

Our goal is to measure the rate at which people index their Scottishness (either consciously or subconsciously) through the use of distinctively Scottish words, and to find out whether this rate varies across different groups of users (Yes hashtag users vs. No hashtag users), or across different contexts (tweets which contain referendum-related hashtags vs. tweets that don’t).

Were we to directly compare the frequencies of our Scottish terms across different sets of tweets, it would be difficult to untangle differences in the rate at which users are indexing the *referents* of those terms from differences in the rate at which they are indexing their Scottishness. For example, if people use the term MASEL (‘myself’) with a lower frequency in one context than in another, this could be because they are modulating their use of distinctively Scottish terms in response to the context, but it could also be because they are modulating the

<sup>6</sup>While ‘bevy’ is also used colloquially for ‘beverage’ in other parts of the UK, in Scotland it is more frequent and can additionally be used as a mass noun (“I had so much bevy I couldn’t even carry it”), and as a verb (“I’d bevy with him every weekend”).

rate at which they talk about themselves. To avoid this confound, we instead compare the *conditional* probabilities with which Scottish terms are used, given that their referents are being indexed at all.

We therefore consider only those Scottish terms for which we can identify semantically equivalent Standard English variants. We require that each variant of a given variable indexes the same set of senses and can occur in the same set of contexts, so for example we do not include YOUS as a variant of YOU, since while Scottish YI and Standard English YOU can index both the singular and plural second person pronouns, YOUS is only used for the plural. We also did not include variants of YES and NO since their use could be influenced by campaign slogans (e.g., the hashtags #VoteAye and #JustSayNaw). Our variables are listed in Table 3.

## 5 Study 1: Scotland-specific vocabulary usage on either side of the debate

Do tweeters who use Yes hashtags use Scottish variants at a higher rate than tweeters who use No hashtags, either when using these hashtags, or in general?

### 5.1 Method

We assign users in the IT dataset to two groups, **Yes** and **No**, based on the quantity  $\frac{n_{u,yes}}{n_{u,yes}+n_{u,no}}$ , where  $n_{u,yes}$  is the number of tweets in which user  $u$  has used at least one of the Yes hashtags and none of the No hashtags in Table 1; and  $n_{u,no}$  is the number of tweets in which  $u$  has used at least one No hashtag and none of the Yes hashtags. The **Yes** group consists of all users for whom this quantity is greater than or equal to 0.75, while the **No** group consists of all users for whom it is less than or equal to 0.25. Users for whom the value lies between 0.25 and 0.75 (as well as those for whom our dataset does not contain any tweets with Yes or No hashtags), are not assigned to either group. The **Yes** group

**Acronyms:** GTF MWI

**Closed Class Words:** ABOUT AE AFF ATS DAE FAE HAE MASEL MASELF OAN OOR OOT TAE WAE WAN WI WIS YERSEL YI YIN YOUS

**Contractions** CANNAE CANNI CANY CANA DEH DINI DINNY DIDNY DOESNY GONNAE GONY ISNY WANTY YER YIR

**Discourse Markers:** ACH ANAW ANO AWRIGHT AWRITE AWRYT AYE EH NAE NAW OOFT YASS YASSS YASSSS YASSSSS YIP

**Open Class Words:** AULD AWFY BAIRNS BAW BAWs BELTER BELTERS BEVY BOABY BOKE BRAW BURD BURDS CRABBIT DAFTY DAIN DEFOS DOON DUGS DYNO ECCIES FANNYS FEART FITBA FUD GAD GAWN GEES GID GRANDA GREETIN HAME HAW HING HINK HOOSE HOWLIN HUNNERS JIST LADDIE LASSIE LASSIES MANKY MAW MAWS MORRA MONGO PISH PISHED PISHING RAGIN ROASTER SARE SHITE SHITEY STEAMIN SUHIN WEANS WHITEY

Table 2: Scotland-specific vocabulary. Standard English equivalents of many words are shown in Table 3.

contains 4,513 users, while the *No* group contains 1,356 users, which is consistent with the general perception at the time that the Yes campaign was much more vocal than the No campaign. To test our hypothesis that the probability of choosing Scottish variants is, on average, greater for users in the *Yes* group than for users in the *No* group, we estimate the difference between the two groups in the average probability of choosing Scottish variants, and conduct a permutation test to approximate the distribution of this difference under the null hypothesis. We first test whether the *Yes* group are more likely than the *No* group to use Scottish variants in tweets which contain hashtags that indicate a stance on the referendum. Subsequently, we test whether the *Yes* group are more likely than the *No* group to use Scottish variants in general across all of their tweets.

### 5.1.1 Test statistic

Let  $U_g$  be the set of all users in group  $g \in \{yes, no\}$  who have used at least one of the variables in Table 3. For a given user  $u \in U_g$ , let  $V$  be the set of all variables that  $u$  has used in at least one tweet. We estimate the probability of user  $u$  choosing a Scottish variant of variable  $v \in V$  as  $\hat{p}_{u,v} = \frac{n_{u,vscot}}{n_{u,v}}$ , where  $n_{u,vscot}$  is the token count of Scottish variants of  $v$  in user  $u$ 's tweets, and  $n_{u,v}$  is the token count of all variants of  $v$  in user  $u$ 's tweets. Averaging across variables, we obtain  $\hat{p}_u = \frac{1}{|V|} \sum_{v \in V} \hat{p}_{u,v}$ . We then average across users to obtain the group mean,  $\hat{p}_g = \frac{1}{|U_g|} \sum_{u \in U_g} \hat{p}_u$ . Our test statistic is the difference between the two group means,  $d = \hat{p}_{yes} - \hat{p}_{no}$ .

### 5.1.2 Permutation test

We randomly shuffle users between the two groups (maintaining each group's original number of users), and re-compute the value of  $d$  using these permuted groups. We repeat this procedure 100,000 times in order to approximate the distri-

Group	Tweets w/ Yes or No hashtags		All tweets	
	Yes	No	Yes	No
# Users	3776	1121	4352	1322
# Tweets	10,436	2411	173,171	80,736

Table 4: Number of users and tweets included per group in the two analyses in Study 1

bution of differences in group means that would be observable were the difference independent of the assignment of users to groups. The proportion of permuted differences which are greater than or equal to the observed difference between the original group means provides an approximate p-value.

## 5.2 Results

For a tweet to be included in the analysis, it must contain at least one of the variables in Table 3. Hence not all users contribute data to the test statistic, as some have not used any of the variables in their tweets. The number of tweets and users included in each analysis are shown in Table 4.

The results for the first analysis are shown in the left column of Table 5. The difference between the two groups in their average probability of choosing Scottish variants in tweets that contain polarised referendum hashtags is statistically significant ( $p < 0.002$ ). Results for the second analysis are shown in the right column of Table 5. Once again, the difference between the two groups is statistically significant ( $p < 0.001$ ).

## 5.3 Discussion

The results show that the *Yes* group do use Scottish variants at a significantly higher rate than the *No* group, both when using Yes or No hashtags, and in general. The stronger significance level for the 'All tweets' dataset is partly due to its larger size (see Table 4), which enables better estimates of the

$\hat{p}_{no}$	0.00211	0.00734
$d$	0.00555	0.00709
$p$ -value	0.00103	0.00001

Table 5: Results of the two analyses in Study 1

usage rates. While the rates are very low overall, the relative differences are large: the **Yes** group rate is more than three times the **No** group rate when we include only tweets with Yes or No hashtags, and approximately twice as big when we include all tweets. The higher rates in the ‘All Tweets’ dataset suggest that both groups of users chose Scottish variants less often when discussing the referendum than in their other tweets. However, the test we used does not provide a significance value for the difference in usage rates across the two datasets. To establish whether users do modulate their usage of Scottish variants when discussing the referendum, we will need a more careful paired design.

## 6 Study 2: Effects of topic and audience on Scotland-specific vocabulary usage

Do tweeters choose Scottish variants at a different rate when using referendum-related hashtags than in their other tweets?

### 6.1 Method

We need a statistic that corrects for the fact that some variables might have higher rates of Scottish variants than others. For example if users tend to produce Scottish variants of variable  $v_1$  at a higher rate than for  $v_2$ , and use  $v_1$  more in tweets that don’t contain referendum-related hashtags, then it could appear that users are suppressing their Scottish usage in referendum-related tweets when in fact this is a lexical effect.

Let  $U$  be the set of all users who have used at least one of the variables in Table 3 in both a tweet that contains a referendum-related hashtag (i.e. a tweet that belongs to the IT dataset, referred to hereafter as an Indyref tweet) and in a tweet that does not contain a referendum-related hashtag (referred to hereafter as a Control tweet). For a given user  $u \in U$ , let  $V$  be the set of all variables that  $u$  has used in at least one Indyref tweet, and in at least one Control tweet. Let  $\hat{p}_{I,v}$  for user  $u$  be the

estimated probability that  $u$  chooses a Scottish variant of variable  $v \in V$ , conditioned on the fact that she is using variable  $v$  in an Indyref tweet. Analogously, let  $\hat{p}_{C,v}$  be the estimated probability that  $u$  chooses a Scottish variant of variable  $v$ , conditioned on the fact that she is using variable  $v$  in a Control tweet. The difference in user  $u$ ’s probability of choosing a Scottish variant of variable  $v$  in an Indyref tweet and in a Control tweet is then  $d_v = \hat{p}_{I,v} - \hat{p}_{C,v}$ . Averaging across all variables, we define  $d_u = \frac{1}{|V|} \sum_{v \in V} d_v$ .

The null hypothesis is that on average, users are no more or less likely to choose Scottish variants in Indyref tweets than in Control tweets. Therefore, under the null hypothesis, the mean value of  $d_u$  across all users,  $\bar{d}_u = \frac{1}{|U|} \sum_{u \in U} d_u$ , would be zero. We perform a one-sample t-test to determine whether  $\bar{d}_u$  is significantly different than zero.

We use this method to conduct two separate analyses. In the first analysis, our pool of Control tweets is the set of *all* tweets from the original filtered dataset that do not contain any of the hashtags in Table 1. In the second analysis, we limit our pool of Control tweets to those which do not contain any of the hashtags from Table 1, but *do* contain at least one other hashtag. This second analysis is designed to test whether the recent finding that US Twitter users are less likely to use regionally-specific words in tweets which contain hashtags (Pavalanathan and Eisenstein, 2015) applies to Scottish users as well.

### 6.2 Results

The number of tweets and users that were included in each analysis are shown in Table 6.

Results for the first analysis are shown in the left column of Table 7. The difference is statistically significant ( $p < 0.01$ ), indicating that on average, individuals are less likely to choose Scottish variants when using referendum-related hashtags than in their other tweets. Results for the second analysis are shown in the right column of Table 7. In this case, the difference is not statistically significant.

### 6.3 Discussion

In light of (a) the apparent relationship between national identity and constitutional preference, (b) the history of Scots as the prestige language of a previously-independent Scotland, supplanted by English in large part due to the birth of the United Kingdom, and (c) the results of Study 1, which indicate that pro-independence users choose Scottish variants at a significantly higher rate than anti-

	All Controls	Controls w/ Hashtags
# Users	11,011	7429
# Indyref Tweets	41,924	35,241
# Control Tweets	693,815	195,145

Table 6: Number of users and tweets included in the two analyses in Study 2

	All Controls	Controls w/ Hashtags
$\bar{d}_u$	-0.0015	-0.0010
std error	0.0005	0.0006
<i>t</i> -statistic	-2.996	-1.758
<i>p</i> -value	0.0027	0.0788

Table 7: Results of the two analyses in Study 2

independence users—it may at first appear surprising that people are *less* likely to choose Scottish variants in tweets containing referendum-related hashtags than in their other tweets.

It is conceivable that *Yes* users increase their rate of Scottish variants in Indyref tweets whilst *No* users decrease it, such that their effects cancel out; but since *Yes* users are more prolific in the IT dataset, if anything we would expect this imbalance to make the effect even more positive. The fact that we see a significant negative effect in spite of the greater number of *Yes* tweets means we can be reasonably confident that even if *Yes* users aren't significantly reducing their usage of Scottish variants in Indyref tweets, they certainly aren't increasing it.

It is also worth noting that we did not exhaustively identify every hashtag that has been used in relation to the referendum, so inevitably there will be some tweets with referendum-related hashtags in the Control set (such as example tweet (3) in §2), and there may also be some non-referendum tweets in the Indyref set. However, if anything this would dilute any differences between the two lists, yet we still find an effect.

The fact that this effect does not reach significance when we remove Control tweets without hashtags suggests that the primary reason users are reducing their rate of Scottish variants in Indyref tweets is not because of the *topic* under discussion, but because the use of hashtags broadens the potential audience. This explanation accords with Pavalanathan and Eisenstein's (2015) finding that

amongst Twitter users in the US, non-standard and regional variants are less likely to be used in tweets that target larger audiences. Of course, it is possible that topic has an effect as well, but the present study does not provide evidence for that conclusion.

## 7 Conclusion

We presented the first large-scale study of distinctively Scottish language use on social media, showing that this use includes a mixture of traditional Scots vocabulary, newer Scottish slang, and alternative spellings that reflect Scottish pronunciation. We also studied how users' language might reflect their political views and discourse. We showed that *Yes* users use Scottish variants at a higher rate than *No* users, whether discussing the independence referendum or not. But overall, users tend to decrease their use of Scottish variants when discussing the referendum. This result suggests that although *Yes* users generally express a stronger Scottish linguistic identity than *No* users, they are not choosing to express this identity strongly in political discourse aimed at a broad audience. Due to the very low rates of Scottish variants overall, our data set is too small to study differences between individual variables or even conclusively say whether there may be effects of both topic and audience size on the use of Scottish language. However, we hope to be able to answer these questions in future by collecting a more complete set of data for the particular users studied here.

## Abstract

Recurrent neural network grammars (RNNG) are a recently proposed probabilistic generative modeling family for natural language. They show state-of-the-art language modeling and parsing performance. We investigate what information they learn, from a linguistic perspective, through various ablations to the model and the data, and by augmenting the model with an attention mechanism (GA-RNNG) to enable closer inspection. We find that explicit modeling of composition is crucial for achieving the best performance. Through the attention mechanism, we find that headedness plays a central role in phrasal representation (with the model’s latent attention largely agreeing with predictions made by hand-crafted head rules, albeit with some important differences). By training grammars without nonterminal labels, we find that phrasal representations depend minimally on nonterminals, providing support for the endocentricity hypothesis.

## 1 Introduction

In this paper, we focus on a recently proposed class of probability distributions, recurrent neural network grammars (RNNGs; Dyer et al., 2016), designed to model syntactic derivations of sentences. We focus on RNNGs as generative probabilistic models over trees, as summarized in §2.

Fitting a probabilistic model to data has often been understood as a way to test or confirm some aspect of a theory. We talk about a model’s assumptions and sometimes explore its parameters or posteriors over its latent variables in order to gain understanding of what it “discovers” from the

data. In some sense, such models can be thought of as mini-scientists.

Neural networks, including RNNGs, are capable of representing larger classes of hypotheses than traditional probabilistic models, giving them more freedom to explore. Unfortunately, they tend to be bad mini-scientists, because their parameters are difficult for human scientists to interpret.

RNNGs are striking because they obtain state-of-the-art parsing and language modeling performance. Their relative lack of independence assumptions, while still incorporating a degree of linguistically-motivated prior knowledge, affords the model considerable freedom to derive its own insights about syntax. If they are mini-scientists, the discoveries they make should be of particular interest as propositions about syntax (at least for the particular genre and dialect of the data).

This paper manipulates the inductive bias of RNNGs to test linguistic hypotheses.<sup>1</sup> We begin with an ablation study to discover the importance of the composition function in §3. Based on the findings, we augment the RNNG composition function with a novel **gated attention** mechanism (leading to the GA-RNNG) to incorporate more interpretability into the model in §4. Using the GA-RNNG, we proceed by investigating the role that individual heads play in phrasal representation (§5) and the role that nonterminal category labels play (§6). Our key findings are that lexical heads play an important role in representing most phrase types (although compositions of multiple salient heads are not infrequent, especially

<sup>1</sup>RNNGs have less inductive bias relative to traditional unlexicalized probabilistic context-free grammars, but more than models that parse by transducing word sequences to linearized parse trees represented as strings (Vinyals et al., 2015). Inductive bias is necessary for learning (Mitchell, 1980); we believe the important question is not “how little can a model get away with?” but rather the benefit of different forms of inductive bias as data vary.

for conjunctions) and that nonterminal labels provide little additional information. As a by-product of our investigation, a variant of the RNNG without ensembling achieved the best reported supervised phrase-structure parsing (93.6  $F_1$ ; English PTB) and, through conversion, dependency parsing (95.8 UAS, 94.6 LAS; PTB SD). The code and pretrained models to replicate our results are publicly available<sup>2</sup>.

## 2 Recurrent Neural Network Grammars

An RNNG defines a *joint* probability distribution over string terminals and phrase-structure nonterminals.<sup>3</sup> Formally, the RNNG is defined by a triple  $\langle N, \Sigma, \Theta \rangle$ , where  $N$  denotes the set of nonterminal symbols (NP, VP, etc.),  $\Sigma$  the set of all terminal symbols (we assume that  $N \cap \Sigma = \emptyset$ ), and  $\Theta$  the set of all model parameters. Unlike previous works that rely on hand-crafted rules to compose more fine-grained phrase representations (Collins, 1997; Klein and Manning, 2003), the RNNG implicitly parameterizes the information passed through compositions of phrases (in  $\Theta$  and the neural network architecture), hence weakening the strong independence assumptions in classical probabilistic context-free grammars.

The RNNG is based on an abstract state machine like those used in transition-based parsing, with its algorithmic state consisting of a stack of partially completed constituents, a buffer of already-generated terminal symbols, and a list of past actions. To generate a sentence  $x$  and its phrase-structure tree  $y$ , the RNNG samples a sequence of actions to construct  $y$  top-down. Given  $y$ , there is one such sequence (easily identified), which we call the oracle,  $\mathbf{a} = \langle a_1, \dots, a_n \rangle$  used during supervised training.

The RNNG uses three different actions:

- $\text{NT}(X)$ , where  $X \in N$ , introduces an open nonterminal symbol onto the stack, e.g., “(NP”;
- $\text{GEN}(x)$ , where  $x \in \Sigma$ , generates a terminal symbol and places it on the stack and buffer; and
- $\text{REDUCE}$  indicates a constituent is now complete. The elements of the stack that comprise the current constituent (going back to the last

<sup>2</sup><https://github.com/clab/rnng/tree/master/interpreting-rnng>

<sup>3</sup>Dyer et al. (2016) also defined a conditional version of the RNNG that can be used only for parsing; here we focus on the generative version since it is more flexible and (rather surprisingly) even learns better estimates of  $p(\mathbf{y} | \mathbf{x})$ .

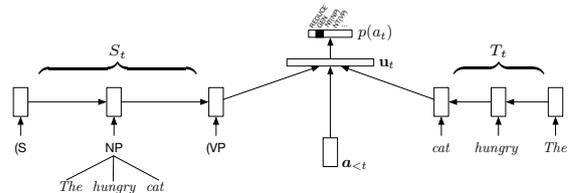

Figure 1: The RNNG consists of a stack, buffer of generated words, and list of past actions that lead to the current configuration. Each component is embedded with LSTMs, and the parser state summary  $\mathbf{u}_t$  is used as top-layer features to predict a softmax over all feasible actions. This figure is due to Dyer et al. (2016).

open nonterminal) are popped, a **composition function** is executed, yielding a composed representation that is pushed onto the stack.

At each timestep, the model encodes the stack, buffer, and past actions, with a separate LSTM (Hochreiter and Schmidhuber, 1997) for each component as features to define a distribution over the next action to take (conditioned on the full algorithmic state). The overall architecture is illustrated in Figure 1; examples of full action sequences can be found in Dyer et al. (2016).

A key element of the RNNG is the composition function, which reduces a completed constituent into a single element on the stack. This function computes a vector representation of the new constituent; it also uses an LSTM (here a bidirectional one). This composition function, which we consider in greater depth in §3, is illustrated in Fig. 2.

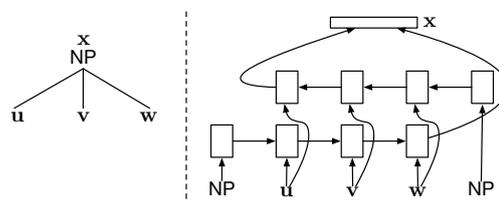

Figure 2: RNNG composition function on each REDUCE operation; the network on the right models the structure on the left (Dyer et al., 2016).

Since the RNNG is a generative model, it attempts to maximize  $p(\mathbf{x}, \mathbf{y})$ , the *joint* distribution

of strings and trees, defined as

$$p(\mathbf{x}, \mathbf{y}) = p(\mathbf{a}) = \prod_{t=1}^n p(a_t \mid a_1, \dots, a_{t-1}).$$

In other words,  $p(\mathbf{x}, \mathbf{y})$  is defined as a product of local probabilities, conditioned on all past actions. The joint probability estimate  $p(\mathbf{x}, \mathbf{y})$  can be used for both phrase-structure parsing (finding  $\arg \max_{\mathbf{y}} p(\mathbf{y} \mid \mathbf{x})$ ) and language modeling (finding  $p(\mathbf{x})$  by marginalizing over the set of possible parses for  $\mathbf{x}$ ). Both inference problems can be solved using an importance sampling procedure.<sup>4</sup> We report all RNNG performance based on the corrigendum to Dyer et al. (2016).

### 3 Composition is Key

Given the same data, under both the discriminative and generative settings RNNGs were found to parse with significantly higher accuracy than (respectively) the models of Vinyals et al. (2015) and Choe and Charniak (2016) that represent  $\mathbf{y}$  as a “linearized” sequence of symbols and parentheses without explicitly capturing the tree structure, or even constraining the  $\mathbf{y}$  to be a well-formed tree (see Table 1). Vinyals et al. (2015) directly predict the sequence of nonterminals, “shifts” (which consume a terminal symbol), and parentheses from left to right, conditional on the input terminal sequence  $\mathbf{x}$ , while Choe and Charniak (2016) used a sequential LSTM language model on the same linearized trees to create a generative variant of the Vinyals et al. (2015) model. The generative model is used to re-rank parse candidates.

Model	$F_1$
Vinyals et al. (2015) – PTB only	88.3
Discriminative RNNG	<b>91.2</b>
Choe and Charniak (2016) – PTB only	92.6
Generative RNNG	<b>93.3</b>

Table 1: Phrase-structure parsing performance on PTB §23. All results are reported using single-model performance and without any additional data.

The results in Table 1 suggest that the RNNG’s explicit composition function (Fig. 2), which

<sup>4</sup>Importance sampling works by using a proposal distribution  $q(\mathbf{y} \mid \mathbf{x})$  that is easy to sample from. In Dyer et al. (2016) and this paper, the proposal distribution is the discriminative variant of the RNNG; see Dyer et al. (2016).

Vinyals et al. (2015) and Choe and Charniak (2016) must learn implicitly, plays a crucial role in the RNNG’s generalization success. Beyond this, Choe and Charniak’s generative variant of Vinyals et al. (2015) is another instance where generative models trained on the PTB outperform discriminative models.

### 3.1 Ablated RNNGs

On close inspection, it is clear that the RNNG’s three data structures—stack, buffer, and action history—are redundant. For example, the action history and buffer contents completely determine the structure of the stack at every timestep. Every generated word goes onto the stack, too; and some past words will be composed into larger structures, but through the composition function, they are all still “available” to the network that predicts the next action. Similarly, the past actions are redundant with the stack. Despite this redundancy, only the stack incorporates the composition function. Since each of the ablated models is sufficient to encode all necessary partial tree information, the primary difference is that ablations with the stack use explicit composition, to which we can therefore attribute most of the performance difference.

We conjecture that the stack—the component that makes use of the composition function—is critical to the RNNG’s performance, and that the buffer and action history are not. In transition-based parsers built on expert-crafted features, the most recent words and actions are useful if they are salient, although neural representation learners can automatically learn what information should be salient.

To test this conjecture, we train **ablated RNNGs** that lack each of the three data structures (action history, buffer, stack), as well as one that lacks both the action history and buffer.<sup>5</sup> If our conjecture is correct, performance should degrade most without the stack, and the stack alone should perform competitively.

**Experimental settings.** We perform our experiments on the English PTB corpus, with §02–21 for training, §24 for validation, and §23 for test; no additional data were used for training. We fol-

<sup>5</sup>Note that the ablated RNNG without a stack is quite similar to Vinyals et al. (2015), who encoded a (partial) phrase-structure tree as a sequence of open and close parentheses, terminals, and nonterminal symbols; our action history is quite close to this, with each NT(X) capturing a left parenthesis and X nonterminal, and each REDUCE capturing a right parenthesis.

low the same hyperparameters as the generative model proposed in Dyer et al. (2016).<sup>6</sup> The generative model did not use any pretrained word embeddings or POS tags; a discriminative variant of the standard RNNG was used to obtain tree samples for the generative model. All further experiments use the same settings and hyperparameters unless otherwise noted.

**Experimental results.** We trained each ablation from scratch, and compared these models on three tasks: English phrase-structure parsing (labeled  $F_1$ ), Table 2; dependency parsing, Table 3, by converting parse output to Stanford dependencies (De Marneffe et al., 2006) using the tool by Kong and Smith (2014); and language modeling, Table 4. The last row of each table reports the performance of a novel variant of the (stack-only) RNNG with attention, to be presented in §4.

Model	$F_1$
Vinyals et al. (2015) <sup>†</sup>	92.1
Choe and Charniak (2016)	92.6
Choe and Charniak (2016) <sup>†</sup>	<b>93.8</b>
Baseline RNNG	93.3
<hr/>	
Ablated RNNG (no history)	93.2
Ablated RNNG (no buffer)	93.3
Ablated RNNG (no stack)	92.5
Stack-only RNNG	<b>93.6</b>
<hr/>	
GA-RNNG	93.5

Table 2: Phrase-structure parsing performance on PTB §23. <sup>†</sup> indicates systems that use additional unparsed data (semisupervised). The GA-RNNG results will be discussed in §4.

**Discussion.** The RNNG with only a stack is the strongest of the ablations, and it even outperforms the “full” RNNG with all three data structures. Ablating the stack gives the worst among the new results. This strongly supports the importance of the composition function: a proper REDUCE operation that transforms a constituent’s parts and non-terminal label into a single explicit (vector) representation is helpful to performance.

It is noteworthy that the stack alone is stronger than the original RNNG, which—in principle—can learn to disregard the buffer and action his-

<sup>6</sup>The model is trained using stochastic gradient descent, with a learning rate of 0.1 and a per-epoch decay of 0.08. All experiments with the generative RNNG used 100 tree samples for each sentence, obtained by sampling from the local softmax distribution of the discriminative RNNG.

Model	UAS	LAS
Kiperwasser and Goldberg (2016)	93.9	91.9

tory. Since the stack maintains syntactically “recent” information near its top, we conjecture that the learner is overfitting to spurious predictors in the buffer and action history that explain the training data but do not generalize well.

A similar performance degradation is seen in language modeling (Table 4): the stack-only RNNG achieves the best performance, and ablating the stack is most harmful. Indeed, modeling syntax without explicit composition (the stack-ablated RNNG) provides little benefit over a sequential LSTM language model.

Model	Test ppl. (PTB)
IKN 5-gram	169.3
LSTM LM	113.4
RNNG	105.2
<hr/>	
Ablated RNNG (no history)	105.7
Ablated RNNG (no buffer)	106.1
Ablated RNNG (no stack)	113.1
Stack-only RNNG	<b>101.2</b>
<hr/>	
GA-RNNG	<b>100.9</b>

Table 4: Language modeling: perplexity. IKN refers to Kneser-Ney 5-gram LM.

We remark that the stack-only results are the best published PTB results for both phrase-structure and dependency parsing among supervised models.

## 4 Gated Attention RNNG

Having established that the composition function is key to RNNG performance (§3), we now seek to understand the nature of the composed phrasal representations that are learned. Like most neural networks, interpreting the composition function’s

behavior is challenging. Fortunately, linguistic theories offer a number of hypotheses about the nature of representations of phrases that can provide a conceptual scaffolding to understand them.

#### 4.1 Linguistic Hypotheses

We consider two theories about phrasal representation. The first is that phrasal representations are strongly determined by a privileged lexical head. Augmenting grammars with lexical head information has a long history in parsing, starting with the models of Collins (1997), and theories of syntax such as the “bare phrase structure” hypothesis of the Minimalist Program (Chomsky, 1993) posit that phrases are represented purely by single lexical heads. Proposals for multiple headed phrases (to deal with tricky cases like conjunction) likewise exist (Jackendoff, 1977; Keenan, 1987). Do the phrasal representations learned by RNNGs depend on individual lexical heads or multiple heads? Or do the representations combine all children without any salient head?

Related to the question about the role of heads in phrasal representation is the question of whether phrase-internal material wholly determines the representation of a phrase (an endocentric representation) or whether nonterminal relabeling of a constituent introduces new information (exocentric representations). To illustrate the contrast, an endocentric representation is representing a noun phrase with a noun category, whereas  $S \rightarrow NP VP$  exocentrically introduces a new syntactic category that is neither NP nor VP (Chomsky, 1970).

#### 4.2 Gated Attention Composition

To investigate what the stack-only RNNG learns about headedness (and later endocentricity), we propose a variant of the composition function that makes use of an explicit attention mechanism (Bahdanau et al., 2015) and a sigmoid gate with multiplicative interactions, henceforth called **GA-RNNG**.

At every REDUCE operation, the GA-RNNG assigns an “attention weight” to each of its children (between 0 and 1 such that the total weight off all children sums to 1), and the parent phrase is represented by the combination of a sum of each child’s representation scaled by its attention weight and its nonterminal type. Our weighted sum is more expressive than traditional head rules, however, because it allows attention to be divided among multiple constituents. Head rules, con-

versely, are analogous to giving all attention to one constituent, the one containing the lexical head.

We now formally define the GA-RNNG’s composition function. Recall that  $\mathbf{u}_t$  is the concatenation of the vector representations of the RNNG’s data structures, used to assign probabilities to each of the actions available at timestep  $t$  (see Fig. 1, the layer before the softmax at the top). For simplicity, we drop the timestep index here. Let  $\mathbf{o}_{nt}$  denote the vector embedding (learned) of the nonterminal being constructed, for the purpose of computing attention weights.

Now let  $\mathbf{c}_1, \mathbf{c}_2, \dots$  denote the sequence of vector embeddings for the constituents of the new phrase. The length of these vectors is defined by the dimensionality of the bidirectional LSTM used in the original composition function (Fig. 2). We use semicolon (;) to denote vector concatenation operations.

The attention vector is given by:

$$\mathbf{a} = \text{softmax} \left( [\mathbf{c}_1 \ \mathbf{c}_2 \ \dots]^\top \mathbf{V} [\mathbf{u}; \mathbf{o}_{nt}] \right) \quad (1)$$

Note that the length of  $\mathbf{a}$  is the same as the number of constituents, and that this vector sums to one due to the softmax. It divides a single unit of attention among the constituents.

Next, note that the *constituent source vector*  $\mathbf{m} = [\mathbf{c}_1; \mathbf{c}_2; \dots] \mathbf{a}$  is a convex combination of the child-constituents, weighted by attention. We will combine this with another embedding of the nonterminal denoted as  $\mathbf{t}_{nt}$  (separate from  $\mathbf{o}_{nt}$ ) using a sigmoid gating mechanism:

$$\mathbf{g} = \sigma (\mathbf{W}_1 \mathbf{t}_{nt} + \mathbf{W}_2 \mathbf{m} + \mathbf{b}) \quad (2)$$

Note that the value of the gate is bounded between  $[0, 1]$  in each dimension.

The new phrase’s final representation uses element-wise multiplication ( $\odot$ ) with respect to both  $\mathbf{t}_{nt}$  and  $\mathbf{m}$ , a process reminiscent of the LSTM “forget” gate:

$$\mathbf{c} = \mathbf{g} \odot \mathbf{t}_{nt} + (1 - \mathbf{g}) \odot \mathbf{m}. \quad (3)$$

The intuition is that the composed representation should incorporate both nonterminal information and information about the constituents (through weighted sum and attention mechanism). The gate  $\mathbf{g}$  modulates the interaction between them to account for varying importance between the two in different contexts.

**Experimental results.** We include this model’s performance in Tables 2–4 (last row in all tables). It is clear that the model outperforms the baseline RNNG with all three structures present and achieves competitive performance with the strongest, stack-only, RNNG variant.

## 5 Headedness in Phrases

We now exploit the attention mechanism to probe what the RNNG learns about headedness on the WSJ §23 test set (unseen before by the model).

### 5.1 The Heads that GA-RNNG Learns

The attention weight vectors tell us which constituents are most important to a phrase’s vector representation in the stack. Here, we inspect the attention vectors to investigate whether the model learns to center its attention around a single, or by extension a few, salient elements, which would confirm the presence of headedness in GA-RNNG.

First, we consider several major nonterminal categories, and estimate the average *perplexity* of the attention vectors. The average perplexity can be interpreted as the average number of “choices” for each nonterminal category; this value is only computed for the cases where the number of components in the composed phrase is at least two (otherwise the attention weight would be trivially 1). The minimum possible value for the perplexity is 1, indicating a full attention weight around one component and zero everywhere else.

Figure 3 (in blue) shows much less than 2 average “choices” across nonterminal categories, which also holds true for all other categories not shown. For comparison we also report the average perplexity of the uniform distribution for the same nonterminal categories (Fig. 3 in red); this represents the highest entropy cases where there is no headedness at all by assigning the same attention weight to each constituent (e.g. attention weights of 0.25 each for phrases with four constituents). It is clear that the learned attention weights have much lower perplexity than the uniform distribution baseline, indicating that the learned attention weights are quite peaked around certain components. This implies that phrases’ vectors tend to resemble the vector of one salient constituent, but not exclusively, as the perplexity for most categories is still not close to one.

Next, we consider the how attention is distributed for the major nonterminal categories in

Table 5, where the first five rows of each category represent compositions with highest entropy, and the next five rows are qualitatively analyzed. The high-entropy cases where the attention is most divided represent more complex phrases with conjunctions or more than one plausible head.

**NPs.** In most simple noun phrases (representative samples in rows 6–7 of Table 5), the model pays the most attention to the *rightmost noun* and assigns near-zero attention on determiners and possessive determiners, while also paying nontrivial attention weights to the adjectives. This finding matches existing head rules and our intuition that nouns head noun phrases, and that adjectives are more important than determiners.

We analyze the case where the noun phrase contains a conjunction in the last three rows of Table 5. The syntax of conjunction is a long-standing source of controversy in syntactic analysis (Johannessen, 1998, *inter alia*). Our model suggests that several representational strategies are used, when coordinating single nouns, both the first noun (8) and the last noun (9) may be selected. However, in the case of conjunctions of multiple noun *phrases* (as opposed to multiple single-word nouns), the model consistently picks the conjunction as the head. All of these representational strategies have been argued for individually on linguistic grounds, and since we see all of them present, RNNGs face the same confusion that linguists do.

**VPs.** The attention weights on simple verb phrases (e.g., “VP → V NP”, 9) are peaked around the noun phrase instead of the verb. This implies that the verb phrase would look most similar to the noun under it and contradicts existing head rules that unanimously put the verb as the head of the verb phrase. Another interesting finding is that the model pays attention to *polarity* information, where negations are almost always assigned nontrivial attention weights.<sup>7</sup> Furthermore, we find that the model attends to the conjunction terminal in conjunctions of verb phrases (e.g., “VP → VP and VP”, 10), reinforcing the similar finding for conjunction of noun phrases.

**PPs.** In almost all cases, the model attends to the preposition terminal instead of the noun phrases or complete clauses under it, regardless of the type of preposition. Even when the preposi-

<sup>7</sup>Cf. Li et al. (2016), where sequential LSTMs discover polarity information in sentiment analysis, although perhaps more surprising as polarity information is less intuitively central to syntax and language modeling.

tional phrase is only used to make a connection between two noun phrases (e.g., “PP → NP after NP”, 10), the prepositional connector is still considered the most salient element. This is less consistent with the Collins and Stanford head rules, where prepositions are assigned a lower priority when composing PPs, although more consistent with the Johansson head rule (Johansson and Nugues, 2007).

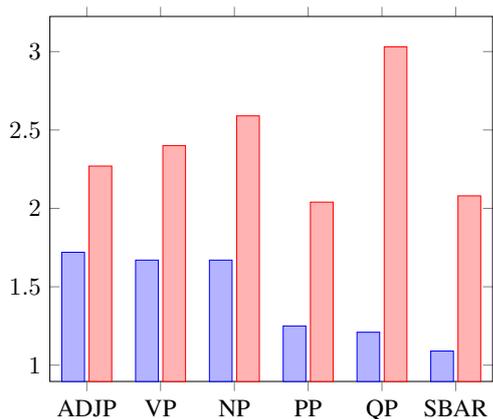

Figure 3: Average perplexity of the learned attention vectors on the test set (blue), as opposed to the average perplexity of the uniform distribution (red), computed for each major phrase type.

## 5.2 Comparison to Existing Head Rules

To better measure the overlap between the attention vectors and existing head rules, we converted the trees in PTB §23 into a dependency representation using the attention weights. In this case, the attention weight functions as a “dynamic” head rule, where all other constituents within the same composed phrase are considered to modify the constituent with the highest attention weight, repeated recursively. The head of the composed representation for “S” at the top of the tree is attached to a special root symbol and functions as the head of the sentence.

We measure the overlap between the resulting tree and conversion results of the same trees using the Collins (1997) and Stanford dependencies (De Marneffe et al., 2006) head rules. Results are evaluated using the standard evaluation script (excluding punctuation) in terms of UAS, since the attention weights do not provide labels.

**Results.** The model has a higher overlap with the conversion using Collins head rules (49.8

UAS) rather than the Stanford head rules (40.4 UAS). We attribute this large gap to the fact that the Stanford head rules incorporate more semantic considerations, while the RNNG is a purely syntactic model. In general, the attention-based tree output has a high error rate ( $\approx 90\%$ ) when the dependent is a verb, since the constituent with the highest attention weight in a verb phrase is often the noun phrase instead of the verb, as discussed above. The conversion accuracy is better for nouns ( $\approx 50\%$  error), and much better for determiners (30%) and particles (6%) with respect to the Collins head rules.

**Discussion.** GA-RNNG has the power to infer head rules, and to a large extent, it does. It follows some conventions that are established in one or more previous head rule sets (e.g., prepositions head prepositional phrases, nouns head noun phrases), but attends more to a verb phrase’s nominal constituents than the verb. It is important to note that this is not the by-product of learning a specific model for parsing; the training objective is *joint* likelihood, which is not a proxy loss for parsing performance. These decisions were selected because they make the data maximally likely (though admittedly only locally maximally likely). We leave deeper consideration of this noun-centered verb phrase hypothesis to future work.

## 6 The Role of Nonterminal Labels

Emboldened by our finding that GA-RNNGs learn a notion of headedness, we next explore whether heads are sufficient to create representations of phrases (in line with an endocentric theory of phrasal representation) or whether extra nonterminal information is necessary. If the endocentric hypothesis is true (that is, the representation of a phrase is built from *within* depending on its components but independent of explicit category labels), then the nonterminal types should be easily inferred given the endocentrically-composed representation, and that ablating the nonterminal information would not make much difference in performance. Specifically, we train a GA-RNNG on unlabeled trees (only bracketings without nonterminal types), denoted U-GA-RNNG.

This idea has been explored in research on methods for learning syntax with less complete annotation (Pereira and Schabes, 1992). A key finding from Klein and Manning (2002) was that,

	Noun phrases	Verb phrases	Prepositional phrases

Table 5: Attention weight vectors for some representative samples for NPs, VPs, and PPs.

given bracketing structure, simple dimensionality reduction techniques could reveal conventional nonterminal categories with high accuracy; Petrov et al. (2006) also showed that latent variables can be used to recover fine-grained nonterminal categories. We therefore expect that the vector embeddings of the constituents that the U-GA-RNNG correctly recovers (on test data) will capture categories similar to those in the Penn Treebank.

**Experiments.** Using the same hyperparameters and the PTB dataset, we first consider *unlabeled*  $F_1$  parsing accuracy. On test data (with the usual split), the GA-RNNG achieves 94.2%, while the U-GA-RNNG achieves 93.5%. This result suggests that nonterminal category labels add a relatively small amount of information compared to purely endocentric representations.

**Visualization.** If endocentricity is largely sufficient to account for the behavior of phrases, where do our robust intuitions for syntactic category types come from? We use t-SNE (van der Maaten and Hinton, 2008) to visualize composed phrase vectors from the U-GA-RNNG model applied to the unseen test data. Fig. 4 shows that the U-GA-RNNG tends to recover nonterminal categories as encoded in the PTB, even when trained without them.<sup>8</sup> These results suggest nonterminal types can be inferred from the purely endocentric compositional process to a certain extent, and that the phrase clusters found by the U-GA-RNNG largely overlap with nonterminal categories.

**Analysis of PP and SBAR.** Figure 4 indicates a certain degree of overlap between SBAR (red) and PP (yellow). As both categories are interesting from the linguistic perspective and quite similar, we visualize the learned phrase vectors of 40 randomly selected SBARs and PPs from the test set (using U-GA-RNNG), illustrated in Figure 5. First, we can see that phrase representations for PPs and SBARs depend less on the nonterminal

<sup>8</sup>We see a similar result for the non-ablated GA-RNNG model, not shown for brevity.

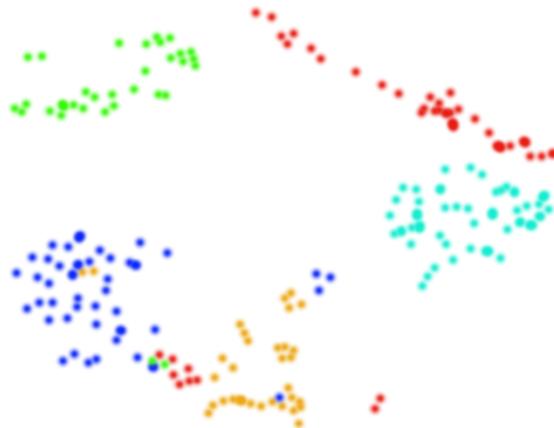

Figure 4: t-SNE on composed vectors when training without nonterminal categories. Vectors in dark blue are VPs, red are SBARs, yellow are PPs, light blue are NPs, and green are Ss.

categories<sup>9</sup> and more on the connector. For instance, the model learns to cluster phrases that start with words that can be either prepositions or complementizers (e.g., *for*, *at*, *to*, *under*, *by*), regardless of whether the true nonterminal labels are PPs or SBARs. This suggests that SBARs that start with “prepositional” words are similar to PPs from the model’s perspective.

Second, the model learns to disregard the word *that*, as “SBAR  $\rightarrow$  *that* S” and “SBAR  $\rightarrow$  S” are close together. This finding is intuitive, as complementizer *that* is often optional (Jaeger, 2010), unlike prepositional words that might describe relative time and location. Third, certain categories of PPs and SBARs form their own separate clusters, such as those that involve the words *because* and *of*. We attribute these distinctions to the fact that these words convey different meanings than many prepositional words; the word *of* indicates possession while *because* indicates cause-and-effect relationship. These examples show that, to a certain extent, the GA-RNNG is able to learn non-

<sup>9</sup>Recall that U-GA-RNNG is trained without access to the nonterminal labels; training the model with nonterminal information would likely change the findings.

trivial semantic information, even when trained on a fairly small amount of syntactic data.

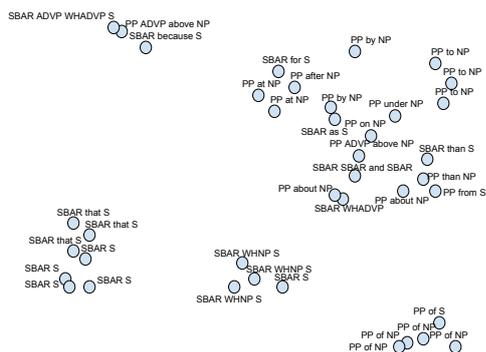

Figure 5: Sample of PP and SBAR phrase representations.

## 7 Related Work

The problem of understanding neural network models in NLP has been previously studied for sequential RNNs (Karpathy et al., 2015; Li et al., 2016). Shi et al. (2016) showed that sequence-to-sequence neural translation models capture a certain degree of syntactic knowledge of the source language, such as voice (active or passive) and tense information, as a by-product of the translation objective. Our experiment on the importance of composition function was motivated by Vinyals et al. (2015) and Wiseman and Rush (2016), who achieved competitive parsing accuracy without explicit composition. In another work, Li et al. (2015) investigated the importance of recursive tree structures (as opposed to linear recurrent models) in four different tasks, including sentiment and semantic relation classification. Their findings suggest that recursive tree structures are beneficial for tasks that require identifying long-range relations, such as semantic relationship classification, with no conclusive advantage for sentiment classification and discourse parsing. Through the stack-only ablation we demonstrate that the RNNG composition function is crucial to obtaining state-of-the-art parsing performance.

Extensive prior work on phrase-structure parsing typically employs the probabilistic context-free grammar formalism, with lexicalized (Collins, 1997) and nonterminal (Johnson, 1998; Klein and Manning, 2003) augmentations. The conjecture that fine-grained nonterminal rules and labels can be discovered given weaker bracketing structures was based on several studies (Chiang

and Bikel, 2002; Klein and Manning, 2002; Petrov et al., 2006).

In a similar work, Sangati and Zuidema (2009) proposed entropy minimization and greedy familiarity maximization techniques to obtain lexical heads from labeled phrase-structure trees in an unsupervised manner. In contrast, we used neural attention to obtain the “head rules” in the GARNNG; the whole model is trained end-to-end to maximize the log probability of the correct action given the history. Unlike prior work, GARNNG allows the attention weight to be divided among phrase constituents, essentially propagating (weighted) headedness information from multiple components.

## 8 Conclusion

We probe what recurrent neural network grammars learn about syntax, through ablation scenarios and a novel variant with a gated attention mechanism on the composition function. The composition function, a key differentiator between the RNNG and other neural models of syntax, is crucial for good performance. Using the attention vectors we discover that the model is learning something similar to heads, although the attention vectors are not completely peaked around a single component. We show some cases where the attention vector is divided and measure the relationship with existing head rules. RNNGs without access to nonterminal information during training are used to support the hypothesis that phrasal representations are largely endocentric, and a visualization of representations shows that traditional nonterminal categories fall out naturally from the composed phrase vectors. This confirms previous conjectures that bracketing annotation does most of the work of syntax, with nonterminal categories easily discoverable given bracketing.

## Abstract

This article introduces a novel transition system for discontinuous lexicalized constituent parsing called SR-GAP. It is an extension of the shift-reduce algorithm with an additional gap transition. Evaluation on two German treebanks shows that SR-GAP outperforms the previous best transition-based discontinuous parser (Maier, 2015) by a large margin (it is notably twice as accurate on the prediction of discontinuous constituents), and is competitive with the state of the art (Fernández-González and Martins, 2015). As a side contribution, we adapt span features (Hall et al., 2014) to discontinuous parsing.

## 1 Introduction

Discontinuous constituent trees can be used to model directly certain specific linguistic phenomena, such as extraposition, or more broadly to describe languages with some degree of word-order freedom. Although these phenomena are sometimes annotated with indexed traces in CFG treebanks, other constituent treebanks are natively annotated with discontinuous constituents, e.g. the Tiger corpus (Brants, 1998).

From a parsing point of view, discontinuities pose a challenge. Mildly context-sensitive formalisms, that are expressive enough to model discontinuities have high parsing complexity. For example, the CKY algorithm for a binary probabilistic LCFRS is in  $\mathcal{O}(n^{3k})$ , where  $k$  is the fan-out of the grammar (Kallmeyer, 2010).

Recently, there have been several proposals for direct discontinuous parsing. They correspond roughly to three different parsing paradigms. (i) Chart parsers are based on probabilistic LCFRS (Kallmeyer and Maier, 2013; Maier, 2010; Evang

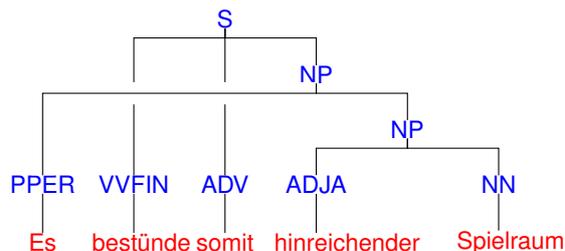

Figure 1: Discontinuous tree extracted from the Tiger corpus (punctuation removed).

and Kallmeyer, 2011), or on the Data-Oriented Parsing (DOP) framework (van Cranenburgh, 2012; van Cranenburgh and Bod, 2013; van Cranenburgh et al., 2016). However, the complexity of inference in this paradigm requires to design elaborate search strategies and heuristics to make parsing run-times reasonable. (ii) Several approaches are based on modified non-projective dependency parsers, for example Hall and Nivre (2008), or more recently Fernández-González and Martins (2015) who provided a surprisingly accurate parsing method that can profit from efficient dependency parsers with rich features. (iii) Transition-based discontinuous parsers are based on the easy-first framework (Versley, 2014a) or the shift-reduce algorithm augmented with a swap action (Maier, 2015). In the latter system, which we will refer to as SR-SWAP, a SWAP action pushes the second element of the stack back onto the buffer.

Although SR-SWAP is fast and obtained good results, it underperforms Fernández-González and Martins (2015)'s parser by a large margin. We believe this result does not indicate a fatal problem for the transition-based framework for discontinuous parsing, but emphasizes several limitations inherent to SR-SWAP, in particular the length of derivations (Section 3.5).

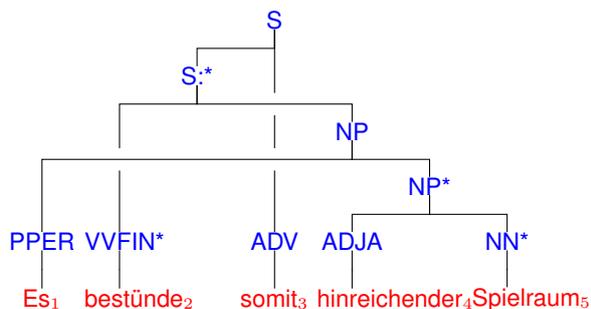

Figure 2: Lexicalized binarized tree. The symbol ‘\*’ encodes head information. Symbols suffixed by ‘:’ are temporary symbols introduced by the binarization.

**Contributions** We introduce a novel transition system for discontinuous parsing we call SR-GAP. We evaluate this algorithm on two German treebanks annotated with discontinuous constituents, and show that, in the same experimental settings, it outperforms the previous best transition-based parser of Maier (2015), and matches the best published results on these datasets (Fernández-González and Martins, 2015). We provide a theoretical and empirical comparison between SR-GAP and SR-SWAP. Finally we adapt span-based features to discontinuous parsing.

The code and preprocessing scripts to reproduce experiments are available for download at <https://github.com/mcoavoux/mtg>.

## 2 Discontinuous Shift-Reduce Parsing

In this section we present SR-GAP, a transition system for discontinuous constituent parsing. SR-GAP is an extension of the shift-reduce system. In what follows, we assume that part-of-speech tags for the words of a sentence are given. A *terminal* refers to a tag-word couple.

### 2.1 Standard Shift-Reduce Constituent Parsing

The shift-reduce system is based on two data structures. The stack ( $S$ ) contains tree fragments representing partial hypotheses and the buffer ( $B$ ) contains the remaining terminals. A parsing configuration is a couple  $\langle S, B \rangle$ . Initially,  $B$  contains the sentence as a list of terminals and  $S$  is empty.

The three types of actions are defined as follows.

- $\text{SHIFT}(\langle S, w|B \rangle) = \langle S|w, B \rangle$
- $\text{REDUCE-X}(\langle S|A_1|A_2, B \rangle) = \langle S|X, B \rangle$

- $\text{REDUCEUNARY-X}(\langle S|A, B \rangle) = \langle S|X, B \rangle$

where  $X$  is any non-terminal in the grammar. The analysis terminates when the buffer is empty and the only symbol in the stack is an axiom of the grammar. This transition system can predict any labelled constituent tree over a set of non-terminal symbols  $N$ .

These three action types can only produce binary trees. In practice, shift-reduce parsers often assume that their data are binary. In this article, we assume that trees are binary, that each node  $X$  is annotated with a head  $h$  (notation:  $X[h]$ ), and that the only unary nodes are parents to a terminal. Therefore, we only need unary reductions immediately after a SHIFT. We refer the reader to Section 3.1 for the description of the preprocessing operations.

### 2.2 SR-GAP Transition System

In order to handle discontinuous constituents, we need an algorithm expressive enough to predict non-projective trees.

Compared to the standard shift-reduce algorithm, the main intuition behind SR-GAP is that reductions do not always apply to the two top-most elements in the stack. Instead, the left element of a reduction can be any element in the stack and must be chosen dynamically.

To control the choice of the symbols to which a reduction applies, the usual stack is split into two data structures. A deque  $D$  represents its top and a stack  $S$  represents its bottom. Alternatively, we could see these two data structures as a single stack with two pointers indicating its top and a split point. The respective top-most element of  $D$  and  $S$  are those available for a reduction.

The transition system is given as a deductive system in Figure 3. A REDUCE-X action pops the top element of  $S$  and the top element of  $D$ , flushes the content of  $D$  to  $S$  and finally pushes a new non-terminal  $X$  on  $D$ . As feature extraction (Section 3.1) relies on the lexical elements, we use two types of binary reductions, left and right, to assign heads to new constituents. Unary reductions replace the top of  $D$  by a new non-terminal.

The SHIFT action flushes  $D$  to  $S$ , pops the next token from  $B$  and pushes it onto  $D$ .

Finally, the GAP action pops the first element of  $S$  and appends it at the bottom of  $D$ . This action enables elements below the top of  $S$  to be also available for a reduction with the top of  $D$ .

Input	$t_1[w_1]t_2[w_2] \dots t_n[w_n]$
Axiom	$\langle \epsilon, \epsilon, t_1[w_1]t_2[w_2] \dots t_n[w_n] \rangle$
Goal	$\langle \epsilon, S[w], \epsilon \rangle$
SH	$\frac{\langle S, D, t[w]   B \rangle}{\langle S   D, t[w], B \rangle}$
RU(X)	$\frac{\langle S, d_0[h], B \rangle}{\langle S, X[h], B \rangle}$
RR(X)	$\frac{\langle S   s_0[h], D   d_0[h'], B \rangle}{\langle S   D, X[h'], B \rangle}$
RL(X)	$\frac{\langle S   s_0[h], D   d_0[h'], B \rangle}{\langle S   D, X[h], B \rangle}$
GAP	$\frac{\langle S   s_0[h], D, B \rangle}{\langle S, s_0[h]   D, B \rangle}$

Figure 3: SR-GAP transition system for discontinuous phrase structure parsing.  $X[h]$  denotes a non-terminal  $X$  and its head  $h$ .  $s_0$  and  $d_0$  denote the top-most elements of respectively  $S$  and  $D$ .

**Constraints** In principle, a tree can be derived by several distinct sequences of actions. If a SHIFT follows a sequence of GAPS, the GAPS will have no effect, because SHIFT flushes  $D$  to  $S$  before pushing a new terminal to  $D$ . In order to avoid useless GAPS, we do not allow a SHIFT to follow a GAP. A GAP must be followed by either another GAP or a binary reduction.

Moreover, as we assume that preprocessed trees do not contain unary nodes, except possibly above the terminal level, unary reductions are only allowed immediately after a SHIFT. Other constraints on the transition system are straightforward, we refer the reader to Table 7 of Appendix A for the complete list.

### 2.3 Oracle and Properties

**Preliminary Definitions** Following Maier and Lichte (2016), we define a discontinuous tree as a rooted connected directed acyclic graph  $T = (V, E, r)$  where

- $V$  is a set of nodes;
- $r \in V$  is the root node;
- $E : V \times V$  is a set of (directed) edges and  $E^*$  is the reflexive transitive closure of  $E$ .

If  $(u, v) \in E$ , then  $u$  is the parent of  $v$ . Each node has a unique parent (except the root that has none). Nodes without children are *terminals*.

The *right index* (resp. *left index*) of a node is the index of the rightmost (resp. leftmost) terminal dominated by this node. For example, the left index of the node labelled  $S$ : in Figure 2 is 1 and its right index is 5.

**Oracle** We extract derivations from trees by following a simple tree traversal. We start with an initial configuration. While the configuration is not final, we derive a new configuration by performing the gold action, which is chosen as follows:

- if the nodes at the top of  $S$  and at the top of  $D$  have the same parent node in the gold tree, perform a reduction with the parent node label;
- if the node at the top of  $D$  and the  $i^{\text{th}}$  node in  $S$  have the same parent node, perform  $i - 1$  GAP;
- otherwise, perform a SHIFT, optionally followed by a unary reduction in the case where the parent node of the top of  $D$  has only one child.

For instance, the gold sequence of actions for the tree in Figure 2 is the sequence SH, SH, SH, SH, SH, RR(NP), GAP, GAP, RR(NP), GAP, RL(S:), RR(S). Table 1 details the sequence of configurations obtained when deriving this tree.

Given the constraints defined in Section 2.2, and if we ignore lexicalisation, there is a bijection between binary trees and derivations.<sup>1</sup> To see why, we define a total order  $<$  on the nodes of a tree. Let  $n$  and  $n'$  be two nodes and let  $n < n'$  iff either  $rindex(n) < rindex(n')$  or  $(n', n) \in E^*$ .

It is immediate that if  $(n', n) \in E^*$ , then  $n$  must be reduced before  $n'$  in a derivation. An invariant of the GAP transition system is that the right index of the first element of  $D$  is equal to the index of the last shifted element. Therefore, after having shifted the terminal  $j$ , it is impossible to create nodes whose right-index is strictly smaller to  $j$ . We conclude that during a derivation, the nodes must be created according to the strict total order  $<$  defined above. In other words, for a given tree, there is a unique possible derivation which enforces the constraints described above. Recip-

<sup>1</sup>But several binarized trees can correspond to the same  $n$ -ary tree.

Table 1: Example derivation for the sentence in Figure 2, part-of-speech tags are omitted.

roccally, a well-formed derivation corresponds to a unique tree.

**Completeness and Soundness** The GAP transition system is sound and complete for the set of discontinuous binary trees labelled with a set of non-terminal symbols. When augmented with certain constraints to make sure that predicted trees are unbinarizable (see Table 7 of Appendix A), this result also holds for the set of discontinuous  $n$ -ary trees (modulo binarization and unbinarization).

Completeness follows immediately from the correctness of the oracle, which corresponds to a tree traversal in the order specified by  $<$ .

To prove soundness, we need to show that any valid derivation sequence produces a discontinuous binary tree. It holds from the transition system that no node can have several parents, as parent assignment via REDUCE actions pops the children nodes and makes them unavailable to other reductions. This implies that at any moment, the content of the stack is a forest of discontinuous trees. Moreover, at each step, at least one action is possible (thanks to the constraints on actions). As there can be no cycles, the number of actions in a derivation is upper-bounded by  $\frac{1}{2}(n^2 + n)$  for a sentence of length  $n$  (see Appendix A.1). Therefore, the algorithm can always reach a final configuration, where the forest only contains one discontinuous tree.

The correctness of SR-GAP system holds only for the robust case: that is the full set of labeled discontinuous trees, and not, say, for the set of trees derived by a true LCFRS grammar also able to reject agrammatical sentences. From an empirical point of view, a transition system that over-

generates is necessary for robustness, and is desirable for fast approximate linear-time inference. However, from a formal point of view, the relationship of the SR-GAP transition system with automata explicitly designed for LCFRS parsing (Villemonte de La Clergerie, 2002; Kallmeyer and Maier, 2015) requires further investigations.

## 2.4 Length of Derivations

Any derivation produced by SR-GAP for a sentence of length  $n$  will contain exactly  $n$  SHIFTS and  $n - 1$  binary reductions. In contrast, the number of unary reductions and GAP actions can vary. Therefore several possible derivations for the same sentence may have different lengths.

This is a recurring problem for transition-based parsing because it undermines the comparability of derivation scores. In particular, Crabbé (2014) observed that the score of a parse item is approximately linear in the number of previous transitions, which creates a bias towards long derivations.

Different strategies have been proposed to ensure that all derivations have the same length (Zhu et al., 2013; Crabbé, 2014; Mi and Huang, 2015). Following Zhu et al. (2013), we use an additional IDLE action that can only be performed when a parsing item is final. Thus, short derivations are padded until the last parse item in the beam is final. IDLE actions are scored exactly like any other action.

**SR-CGAP** As an alternative strategy to the problem of comparability of hypotheses, we also present a variant of SR-GAP, called SR-CGAP, in which the length of any derivation only depends on the length of the sentence. In SR-CGAP, each

SHIFT action must be followed by either a unary reduction or a ghost reduction (Crabbé, 2015), and each binary reduction must be preceded by exactly one compound  $GAP_i$  action ( $i \in \{0, \dots, m\}$ ) specifying the number  $i$  of consecutive standard GAPS. For example,  $GAP_0$  will have no effect, and  $GAP_2$  counts as a single action equivalent to two consecutive GAPS. We call these actions COMPOUNDGAP, following the COMPOUNDSWAP actions of Maier (2015).

With this set of actions, any derivation will have exactly  $4n - 2$  actions, consisting of  $n$  shifts,  $n$  unary reductions or ghost reductions,  $n - 1$  compound gaps, and  $n - 1$  reductions.

The parameter  $m$  (maximum index of a compound gap) is determined by the maximum number of consecutive gaps observed in the training set. Contrary to SR-GAP, SR-CGAP is not complete, as some discontinuous trees whose derivation should contain more than  $m$  consecutive GAPS cannot be predicted.

## 2.5 Beam Search with a Tree-structured Stack

A naive beam implementation of SR-GAP will copy the whole parsing configuration at each step and for each item in the beam. This causes the parser algorithm to have a practical  $\mathcal{O}(k \cdot n^2)$  complexity, where  $k$  is the size of the beam and  $n$  the length of a derivation. To overcome this, one can use a tree-structured stack (TSS) to factorize the representations of common prefixes in the stack as described by (Goldberg et al., 2013) for projective dependency parsing. However the discontinuities entail that a limited amount of copying cannot be entirely avoided. When a reduction follows  $n$  GAP actions, we need to grow a new branch of size  $n + 1$  in the tree-structured stack to account for reordering. The complexity of the inference becomes  $\mathcal{O}(k \cdot (n + g))$  where  $g$  is the number of gaps in the derivation. As there are very few gap actions (in proportion) in the dataset, the practical runtime is linear in the length of the derivation.

## 2.6 Relationship to Dependency Parsing Algorithms

The transition system presented in this article uses two distinct data structures to represent the stack. In this respect, it belongs to the family of algorithms presented by Covington (2001) for dependency parsing. Covington’s algorithm iterates over every possible pair of words in a sentence

and decides for each pair whether to attach them – with a left or right arc – or not. This algorithm can be formulated as a transition system with a split stack (Gómez-Rodríguez and Fernández-González, 2015).

## 3 Experiments

### 3.1 Datasets

We evaluated our model on two corpora, namely the Negra corpus (Skut et al., 1997) and the Tiger corpus (Brants, 1998). To ensure comparability with previous work, we carried out experiments on several instantiations of these corpora.

We present results on two instantiations of Negra. NEGRA-30 consists of sentences whose length is smaller than, or equal to, 30 words. We used the same split as Maier (2015). A second instantiation, NEGRA-ALL, contains all the sentences of the corpus, and uses the standard split (Dubey and Keller, 2003).

For the Tiger corpus, we also use two instantiations. TIGERHN08 is the split used by Hall and Nivre (2008). TIGERM15 is the split of Maier (2015), which corresponds to the SPMRL split (Seddah et al., 2013).<sup>2</sup> We refer the reader to Table 8 in Appendix A for further details on the splits used.

For both corpora, the first step of preprocessing consists in removing function labels and reattaching the nodes attached to the ROOT and causing artificial discontinuities (these are mainly punctuation terminals).<sup>3</sup>

Then, corpora are head-annotated using the headrules included in the DISCO-DOP package, and binarized by an order-0 head-Markovization (Klein and Manning, 2003). There is a rich literature on binarizing LCFRS (Gómez-Rodríguez et al., 2009; Gildea, 2010), because both the gap-degree and the rank of the resulting trees need to be minimized in order to achieve a reasonable complexity when using chart-based parsers (Kallmeyer and Maier, 2013). However, this seems not to be a problem for transition-based parsing, and the gains of using optimized binarization algorithms do not seem to be worth the

<sup>2</sup>As in previous work (Maier, 2015), two sentences (number 46234 and 50224) are excluded from the test set because they contain annotation errors.

<sup>3</sup>We used extensively the publicly available software TREETOOLS and DISCO-DOP for these preprocessing steps. The preprocessing scripts will be released with the parser source code for full replicability.

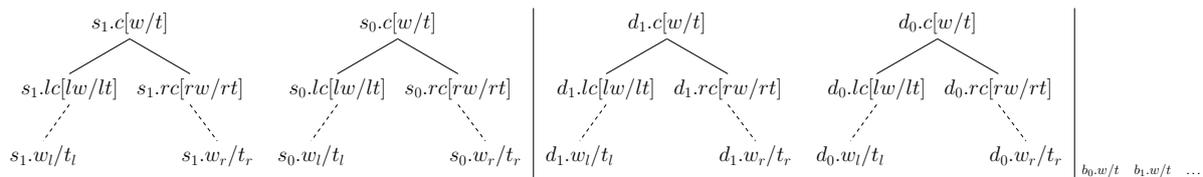

Figure 4: Schematic representation of the top-most elements of  $S$ ,  $D$  and  $B$ , using the notations introduced in Table 2. Due to discontinuities, it is possible that both the left- and right- index of  $s_i$  are generated by the same child of  $s_i$ .

Table 2: Feature templates.  $s$ ,  $d$  and  $b$  refer respectively to the data structures ( $S$ ,  $D$ ,  $B$ ) presented in Section 2.2. The integers are indices on these data structures. *left* and *right* refer to the children of nodes. We use  $c$ ,  $w$  and  $t$  to denote a node’s label, its head and the part-of-speech tag of its head. When used as a subscript,  $l$  ( $r$ ) refers to the left (right) index of a node. Finally  $lo$  ( $ro$ ) denotes the token immediately left to the left index (right to the right index). See Figure 4 for a representation of a configuration with these notations.

complexity of these algorithms (van Cranenburgh et al., 2016).

Unless otherwise indicated, we did experiments with gold part-of-speech tags, following a common practice for discontinuous parsing.

### 3.2 Classifier

We used an averaged structured perceptron (Collins, 2002) with early-update training (Collins and Roark, 2004). We use the hash trick (Shi et al., 2009) to speed up feature hashing. This has no noticeable effect on accuracy and this improves training and parsing speed. The only hyperparameter of the perceptron is the number of training epochs.

We fixed it at 30 for every experiment, and shuffled the training set before each epoch.

**Features** We tested three feature sets described in Table 2 and Figure 4. The BASELINE feature set is the transposition of Maier (2015)’s baseline features to the GAP transition system. It is based on  $B$ , on  $S$ , and on the top element of  $D$ , but does not use information from the rest of  $D$  (i.e. the gapped elements). This feature set was designed in order to obtain an experimental setting as close as possible to that of Maier (2015).

In contrast, the EXTENDED feature set includes information from further in  $D$ , as well as additional context in  $S$  and  $n$ -grams of categories from both  $S$  and  $D$ .

The third feature set SPANS is based on the idea that constituent boundaries contain critical information (Hall et al., 2014) for phrase structure parsing. This intuition is also confirmed in the context of lexicalized transition-based constituent parsing (Crabbé, 2015). To adapt this type of features to discontinuous parsing, we only rely on the right and left index of nodes, and on the tokens preceding the left index or following the right index.<sup>4</sup>

**Unknown Words** In order to learn parameters for unknown words and limit feature sparsity, we replace hapaxes in the training set by an UNKNOWN pseudo-word. This accounts for an improvement of around 0.5 F1.

### 3.3 Results

We report results on test sets in Table 3. All the metrics were computed by DISCO-DOP with the parameters included in this package (`proper.prm`). The metrics are labelled F1, ignoring roots and punctuation. We also present metrics which consider only the discontinuous constituents (Disc. F1 in Tables 3 and 4), as these

<sup>4</sup>For discontinuous constituents, internal boundaries (for gaps) might prove useful too.

can give some qualitative insight into the strengths and weaknesses of our model.

For experiments on TIGERM15, we additionally report evaluation scores computed with the SPMRL shared task parameters<sup>5</sup> for comparability with previous work.

**SR-GAP vs SR-CGAP** In most experimental settings, SR-CGAP slightly underperformed SR-GAP. This result came as a surprise, as both compound actions for discontinuities (Maier, 2015) and ghost reductions (Crabbé, 2014) were reported to improve parsing.

We hypothesize that this result is due to the rarity of unary constituents in the datasets and to the difficulty to predict COMPOUNDGAPS with a bounded look at  $D$  and  $S$  caused by our practical definition of feature templates (Table 2). In contrast, predicting gaps separately involves feature extraction at each step, which crucially helps.

**Feature Sets** The EXTENDED feature set outperforms the baseline by up to one point of F1. This emphasizes that information about gapped non-terminal is important. The SPANS feature set gives another 1 point improvement. This demonstrates clearly the usefulness of span features for discontinuous parsing. A direct extension of this feature set would include information about the

<sup>5</sup>These are included in [http://pauillac.inria.fr/~seddah/evalb\\_spmrl2013.tar.gz](http://pauillac.inria.fr/~seddah/evalb_spmrl2013.tar.gz). In this setting, we reattach punctuation to the root node before evaluation.

boundaries of gaps in a discontinuous constituent. A difficulty of this extension is that the number of gaps in a constituent can vary.

### 3.4 Comparisons with Previous Works

There are three main approaches to direct discontinuous parsing.<sup>6</sup> One such approach is based on unprojective or pseudo-projective dependency parsing (Hall and Nivre, 2008; Fernández-González and Martins, 2015), and aims at enriching dependency labels in such a way that constituents can be retrieved from the dependency tree. The advantage of such systems is that they can use off-the-shelf dependency parsers with rich features and efficient inference.

<sup>6</sup>As opposed to non-direct strategies, based for example on PCFG parsing and post-processing.

The second approach is chart-based parsing, as exemplified by the DOP (Data Oriented Parsing) models of van Cranenburgh (2012) and van Cranenburgh et al. (2016) and Probabilistic LCFRS (Kallmeyer and Maier, 2013; Evang and Kallmeyer, 2011).

The last paradigm is transition-based parsing. Versley (2014a) and Versley (2014b) use an easy-first strategy with a swap transition. Maier (2015) and Maier and Lichte (2016) use a shift-reduce algorithm augmented with a swap transition.

Table 3 includes recent results from these various parsers. The most successful approach so far is that of Fernández-González and Martins (2015), which outperforms by a large margin transition-based parsers (Maier, 2015; Maier and Lichte, 2016).

**SR-GAP vs SR-SWAP** In the same settings (baseline features and beam size of 4), SR-GAP outperforms SR-SWAP by a large margin on all datasets. It is also twice as accurate when we only consider discontinuous constituents.

In Section 3.5, we analyse the properties of both transition systems and give hypotheses for the performance difference.

**Absolute Scores** On all datasets, our model reaches or outperforms the state of the art (Fernández-González and Martins, 2015). This is still the case in a more realistic experimental setup with predicted tags, as reported in Table 5.<sup>7</sup>

As pointed out by Maier and Lichte (2016), a limitation of shift-reduce based parsing is the locality of the feature scope when performing the search. The parser could be in states where the necessary information to take the right parsing decision is not accessible with the current scoring model.

To get more insight into this hypothesis, we tested large beam sizes. If the parser maintains a much larger number of hypotheses, we hope that it could compensate for the lack of information by delaying certain decisions. In Table 4, we present additional results on development sets of both instantiations of the TIGER corpus, with different beam sizes. As was expected, a larger beam size

<sup>7</sup>Like Fernández-González and Martins (2015), we used the predicted tags provided by the SPMRL shared task organizers.

TIGERM15	F1 (spmrl.prm)	
	≤ 70	All
Versley (2014b)	73.90	-
Fernández-González and Martins (2015)	77.72	77.32
SR-GAP, beam=32, +SPANS	<b>79.44</b>	<b>79.26</b>

Table 5: Results on the Tiger corpus in the SPMRL predicted tag scenario.

gives better results. The beam size controls the tradeoff between speed and accuracy.<sup>8</sup>

Interestingly, the improvement from a larger beam size is greater on discontinuous constituents than overall. For example, from 16 to 32, F1 improves by 0.5 on TIGERHN8 and F1 on discontinuous constituents improves by 1.4.

This suggests that further improvements could be obtained by augmenting the lookahead on the buffer and using features further on  $S$  and  $D$ . We plan in the future to switch to a neural model such as a bi-LSTM in order to obtain more global representations of the whole data structures ( $S$ ,  $D$ ,  $B$ ).

### 3.5 Discussion: Comparing SR-SWAP and SR-GAP

This section investigates some differences between SR-SWAP and SR-GAP. We think that characterizing properties of transition systems helps to gain better intuitions into the problems inherent to discontinuous parsing.

**Derivation Length** Assuming that GAP or SWAP are the hardest actions to predict and are responsible for the variability of the lengths of derivation, we hypothesize that the number of these actions, hence the length of a derivation, is an important factor. Shorter derivations are less prone to error propagation.

In both cases, the shortest possible derivation for a sentence of length  $n$  corresponds to a projective tree, as the derivation will not contain any SWAP or GAP.

In the worst case, i.e. the tree that requires the longest derivation to be produced by a transition system, SR-GAP is asymptotically twice as more economical than SR-SWAP (Table 6). In Figure 5 of Appendix A, we present the trees corresponding to the longest possible derivations in both cases.

<sup>8</sup>Training with the full-feature model took approximately 1h30 on TIGERM15 with a beam size of 4. Parsing speed, in the same setting, is approximately 4,700 tokens per second (corresponding to 260 sentences per second) on a single Xeon 2.30 GHz CPU.

	SR-GAP	SR-SWAP	SR-CSWAP
Theoretical longest derivation	$\frac{n^2+n}{2}$	$n^2 - n + 1$	
Longest derivation	276	2187	1276
Total number of gaps/swaps	64096	411970	
Max consecutive gaps/swaps	10	69	
Avg. deriv. length wrt $n$	$2.03n$	$3.09n$	$2.66n$

Table 6: Statistics on Tiger train corpus.  $n$  is the length of a sentence. SR-CSWAP is a variant of SR-SWAP proposed by Maier (2015).

These trees maximise the number of GAP and SWAP actions.

The fact that derivations are shorter with SR-GAP is confirmed empirically. In Table 6, we present several metrics computed on the train section of TIGERM15. In average, SR-SWAP derivations are empirically 50% longer than SR-GAP derivations. Despite handling discontinuities, SR-GAP derivations are not noticeably longer than those we would get with a standard shift-reduce transition system ( $n$  shifts and  $n - 1$  binary reductions).

Intuitively, the difference in length of derivations comes from two facts. First, swapped terminals are pushed on the buffer and must be shifted once more, whereas with SR-GAP, each token is shifted exactly once. Second, transition systems for discontinuous parsing implicitly predict an order on terminals (discontinuous trees can be transformed to continuous trees by changing the precedence order on terminals). With SR-SWAP, reordering is done by swapping two terminals. In contrast, SR-GAP can swap complex non-terminals (already ordered chunks of terminals), making the reordering more efficient in terms of number of operations.

It would be interesting to see if SR-SWAP is improved when swapping non-terminals is allowed. However, it would make feature extraction more complex, because it would no longer be assumed that the buffer contains only tokens.

The effect of the derivation length is confirmed by Maier and Lichte (2016) who explored different oracles for SR-SWAP and found that oracles producing shorter derivations gave better results.

**Feature Locality** A second property which explains the performance of SR-GAP is the access to three data structures (vs two for SR-SWAP) for extracting features; SR-GAP has access to an extended domain of locality. Moreover, with SR-SWAP, the semantics of features from the queue

does not make a distinction between swapped tokens and tokens that have not been shifted yet. When the parser needs to predict a long sequence of consecutive swaps, it is hardly in a position to have access to the relevant information. The use of three data structures, along with shorter sequences of GAP actions, seems to alleviate this problem.

## 4 Conclusion

We have introduced a novel transition system for lexicalized discontinuous parsing. The SR-GAP transition system produces short derivations, compared to SR-SWAP, while being able to derive any discontinuous tree.

Our experiments show that it outperforms the best previous transition system (Maier, 2015) in similar settings and different datasets. Combined with a span-based feature set, we obtained a very efficient parser with state-of-the-art results.

We also provide an efficient C++ implementation of our parser, based on a tree-structured stack.

Direct follow-ups to this work consist in switching to a neural scoring model to improve the representations of  $D$  and  $S$  and alleviate the locality issues in feature extraction (Kiperwasser and Goldberg, 2016; Cross and Huang, 2016).

## Acknowledgments

We thank three anonymous reviewers, as well as Héctor Martínez Alonso, Olga Seminck and Chloé Braud for comments and suggestions to improve prior versions of this article. We also thank Djamel Seddah for help with the SPMRL dataset.

## A Supplemental Material

Action	Conditions
SHIFT	$B$ is not empty. The last action is not GAP.
GAP	$S$ has at least 2 elements. If $d_0$ is a temporary symbol, there must be at least one non temporary symbol in $S_1$ .
RU(X)	The last action is SHIFT. X is an axiom iff this is a one-word sentence.
R(R L)(X)	$S$ is not empty. X is an axiom iff $B$ is empty, and $S$ and $D$ both have exactly one element. If X is a temporary symbol and if $B$ is empty, there must be a non-temporary symbol in either $S_1$ . or $D_1$ .
RR(X)	$s_0$ is not a temporary symbol.
RL(X)	$d_0$ is not a temporary symbol.
IDLE	The configuration must be final, i.e. $S$ and $B$ are empty and the only element of $S$ is the axiom.

Table 7: List of all constraints on actions for the SR-GAP transition system. The notation  $S_1$  is used to denote the elements of  $S$  without the first one.

### A.1 Longest Derivation Computation

This section details the computation of the longest possible derivations for a sentence of length  $n$ . For the sake of simplicity, we ignore unary constituents.

		Number or index of sentences
NEGRA-30	train/dev/test	14669/1833/1833
NEGRA-ALL	train/test/dev	18602/1000/1000
TIGERM15	train/dev/test	40468/5000/5000
TIGERHN08	train/dev	$i \pmod{10} > 1/i \equiv 1 \pmod{10}$
TIGERHN08	train/test	$i \not\equiv 0 \pmod{10}/i \equiv 0 \pmod{10}$

Table 8: Details on the standard splits.

**SR-GAP** There are  $n$  shifts and  $n - 1$  binary reductions in a derivation. The longest derivation maximises the number of gap actions, by performing as many gap actions as possible before each binary reductions. When  $S$  contains  $k$  elements, there are  $k - 1$  possible consecutive gap actions. So the longest derivation starts by  $n$  shifts, followed by  $n - 2$  gap actions, one binary reduction,  $n - 3$  gap actions, one binary reduction, and so on.

$$\begin{aligned}
L_{gap}(n) &= n + ((n - 2) + 1) + \dots + 1 \\
&= 1 + 2 + \dots + n \\
&= \frac{n(n - 1)}{2}
\end{aligned}$$

This corresponds to the tree on the left-hand side of Figure 5.

**SR-SWAP** Using the oracle or Maier (2015), the longest derivation for a sentence of length  $n$  consists in maximising the number of swaps before each reduction.<sup>9</sup>

After the first shift, the derivation performs repeatedly  $n - i$  shifts,  $n - i - 1$  swaps and one reduction,  $i$  being the number of shifted terminals before each iteration.

$$\begin{aligned}
L_{swap}(n) &= 1 + \sum_{i=1}^{n-1} ((n - i) + (n - i - 1) + 1) \\
&= 1 + 2 \sum_{i=1}^{n-1} (n - i) \\
&= 1 + 2 \frac{n(n - 1)}{2} \\
&= n^2 - n + 1
\end{aligned}$$

This corresponds to the tree on the right-hand side of Figure 5.

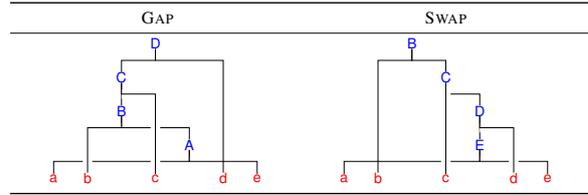

Figure 5: Example tree corresponding to the longest derivation for a sentence of length 5 with GAP and SWAP.

<sup>9</sup>Other possible oracles (Maier and Lichte, 2016) are more efficient on this example and could have different (and better) worst cases.

# Neural Architectures for Fine-grained Entity Type Classification

## Abstract

In this work, we investigate several neural network architectures for fine-grained entity type classification and make three key contributions. Despite being a natural comparison and addition, previous work on attentive neural architectures have not considered hand-crafted features and we combine these with learnt features and establish that they complement each other. Additionally, through quantitative analysis we establish that the attention mechanism learns to attend over syntactic heads and the phrase containing the mention, both of which are known to be strong hand-crafted features for our task. We introduce parameter sharing between labels through a hierarchical encoding method, that in low-dimensional projections show clear clusters for each type hierarchy. Lastly, despite using the same evaluation dataset, the literature frequently compare models trained using different data. We demonstrate that the choice of training data has a drastic impact on performance, which decreases by as much as 9.85% loose micro F1 score for a previously proposed method. Despite this discrepancy, our best model achieves state-of-the-art results with 75.36% loose micro F1 score on the well-established FIGER (GOLD) dataset and we report the best results for models trained using publicly available data for the OntoNotes dataset with 64.93% loose micro F1 score.

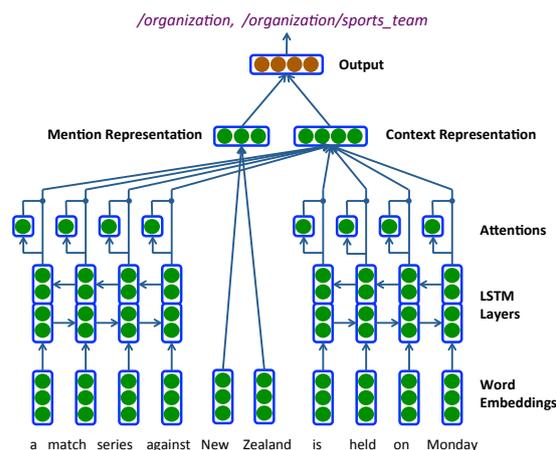

Figure 1: An illustration of the attentive encoder neural model predicting fine-grained semantic types for the mention “New Zealand” in the expression “a match series against New Zealand is held on Monday”.

## 1 Introduction

Entity type classification aims to label entity mentions in their context with their respective semantic types. Information regarding entity type mentions has proven to be valuable for several natural language processing tasks; such as question answering (Lee et al., 2006), knowledge base population (Carlson et al., 2010), and co-reference resolution (Recasens et al., 2013). A natural extension to traditional entity type classification has been to divide the set of types – which may be too *coarse-grained* for some applications (Sekine, 2008) – into a larger set of *fine-grained* entity types (Lee et al., 2006; Ling and Weld, 2012; Yosef et al., 2012; Gillick et al., 2014; Del Corro et al., 2015); for example *person* into *actor*, *artist*, etc.

Given the recent successes of attentive neural

\*This work was conducted during a research visit to University College London.

models for information extraction (Globerson et al., 2016; Shimaoka et al., 2016; Yang et al., 2016), we investigate several variants of an attentive neural model for the task of fine-grained entity classification (e.g. Figure 1). This model category uses a neural attention mechanism – which can be likened to a soft alignment – that enables the model to focus on informative words and phrases. We build upon this line of research and our contributions are three-fold:

1. Despite being a natural comparison and addition, previous work on attentive neural architectures do not consider hand-crafted features. We combine learnt and hand-crafted features and observe that they complement each other. Additionally, we perform extensive analysis of the attention mechanism of our model and establish that the attention mechanism learns to attend over syntactic heads and the tokens prior to and after a mention, both which are known to be highly relevant to successfully classifying a mention.
2. We introduce label parameter sharing using a hierarchical encoding that improves performance on one of our datasets and the low-dimensional projections of the embedded labels form clear coherent clusters.
3. While research on fine-grained entity type classification has settled on using two evaluation datasets, a wide variety of training datasets have been used – the impact of which has not been established. We demonstrate that the choice of training data has a drastic impact on performance, observing performance decreases by as much as 9.85% loose Micro F1 score for a previously proposed method. However, even when comparing to models trained using different datasets we report state-of-the-art results of 75.36% loose micro F1 score on the FIGER (GOLD) dataset.

## 2 Related Work

Our work primarily draws upon two strains of research, fine-grained entity classification and attention mechanisms for neural models. In this section we introduce both of these research directions.

By expanding a set of coarse-grained types into a set of 147 fine-grained types, Lee et al. (2006)

were the first to address the task of fine-grained entity classification. Their end goal was to use the resulting types in a question answering system and they developed a conditional random field model that they trained and evaluated on a manually annotated Korean dataset to detect and classify entity mentions. Other early work include Sekine (2008), that emphasised the need for having access to a large set of entity types for several NLP applications. The work primarily discussed design issues for fine-grained set of entity types and served as a basis for much of the future work on fine-grained entity classification.

The first work to use distant supervision (Mintz et al., 2009) to induce a large – but noisy – training set and manually label a significantly smaller dataset to evaluate their fine-grained entity classification system, was Ling and Weld (2012) who introduced both a training and evaluation dataset FIGER (GOLD). Arguing that fine-grained sets of types must be organised in a very fine-grained hierarchical taxonomy, Yosef et al. (2012) introduced such a taxonomy covering 505 distinct types. This new set of types lead to improvements on FIGER (GOLD), and they also demonstrated that the fine-grained labels could be used as features to improve coarse-grained entity type classification performance. More recently, continuing this very fine-grained strategy, Del Corro et al. (2015) introduced the most fine-grained entity type classification system to date, covering the more than 16,000 types contained in the WordNet hierarchy.

While initial work largely assumed that mention assignments could be done independently of the mention context, Gillick et al. (2014) introduced the concept of context-dependent fine-grained entity type classification where the types of a mention is constrained to what can be deduced from its context and introduced a new OntoNotes-derived manually annotated evaluation dataset. In addition, they addressed the problem of label noise induced by distant supervision and proposed three label cleaning heuristics. Building upon the noise reduction aspects of this work, Ren et al. (2016) introduced a method to reduce label noise even further, leading to significant performance gains on both the evaluation dataset of Ling and Weld (2012) and Gillick et al. (2014).

Yogatama et al. (2015) proposed to map hand-crafted features and labels to embeddings in or-

der to facilitate information sharing between both related types and features. A pure feature learning approach was proposed by Dong et al. (2015). They defined 22 types and used a two-part neural classifier that used a recurrent neural network to obtain a vector representation of each entity mention and in its second part used a fixed-size window to capture the context of a mention. A recent workshop paper (Shimaoka et al., 2016) introduced an attentive neural model that unlike previous work obtained vector representations for each mention context by composing it using a recurrent neural network and employed an attention mechanism to allow the model to focus on relevant expressions in the mention context. Although not pointed in Shimaoka et al. (2016), the attention mechanism used differs from previous work in that it does not condition the attention. Rather, they used global weights optimised to provide attention for every fine-grained entity type classification decision.

To the best of our knowledge, the first work that utilised an attention architecture within the context of NLP was Bahdanau et al. (2014), that allowed a machine translation decoder to attend over the source sentence. Doing so, they showed that adding the attention mechanism significantly improved their machine translation results as the model was capable of learning to align the source and target sentences. Moreover, in their qualitative analysis, they concluded that the model can correctly align mutually related words and phrases. For the set of neural models proposed by Hermann et al. (2015), attention mechanisms are used to focus on the aspects of a document that help the model answer a question, as well as providing a way to qualitatively analyse the inference process. Rocktäschel et al. (2015) demonstrated that by applying an attention mechanism to a textual entailment model, they could attain state-of-the-art results, as well as analyse how the entailing sentence would align to the entailed sentence.

Our work differs from previous work on fine-grained entity classification in that we use the *same publicly available training data* when comparing models. We also believe that we are the first to consider the *direct combination of hand-crafted features and an attentive neural model*.

Feature	Description	Example
Head	Syntactic head of the mention	Obama
Non-head	Non-head words of the mention	Barack, H.
Cluster	Brown cluster for the head token	1110, ...
Characters	Character trigrams for the mention head	:ob, oba, ...
Shape	Word shape of the mention phrase	Aa A. Aa
Role	Dependency label on the mention head	subj
Context	Words before and after the mention	B:who, A:first
Parent	The head's lexical parent	picked
Topic	The LDA topic of the document	LDA:13

Table 1: Hand-crafted features, based on those of Gillick et al. (2014), used by the sparse feature and hybrid model variants in our experiments. The features are extracted for each entity mention and the example mention used to extract the example features in this table is "... who [Barack H. Obama] first picked ...".

### 3 Models

In this section we describe the neural model variants used in this paper as well as a strong feature-based baseline from the literature. We pose fine-grained entity classification as a multi-class, multi-label classification problem. Given a mention in a sentence, the classifier predicts the types  $t \in \{1, 0\}^K$  where  $K$  is the size of the set of types. Across all the models, we compute a probability  $y_k \in \mathbb{R}$  for each of the  $K$  types using logistic regression. Variations of the models stem from the ways of computing the input to the logistic regression.

At inference time, we enforce the assumption that at least one type is assigned to each mention by first assigning the type with the largest probability. We then assign any additional types based on the condition that their corresponding probabilities must be greater than a threshold of 0.5, which was determined by tuning it using development data.

#### 3.1 Sparse Feature Model

For each entity mention  $m$ , we create a binary feature indicator vector  $f(m) \in \{0, 1\}^{D_f}$  and feed it to the logistic regression layer. The features used are described in Table 1, which are comparable to those used by Gillick et al. (2014) and Yogatama et al. (2015). It is worth noting that we aimed for this model to resemble the independent classifier model in Gillick et al. (2014) so that it constitutes as a meaningful well-established baseline; however, there are two noteworthy differences. Firstly, we use the more commonly used clustering method of Brown et al. (1992), as opposed to Uszkoreit and Brants (2008), as Gillick

et al. (2014) did not make the data used for their clusters publicly available. Secondly, we learned a set of 15 topics from the OntoNotes dataset using the LDA (Blei et al., 2003) implementation from the popular gensim software package,<sup>1</sup> in contrast to Gillick et al. (2014) that used a supervised topic model trained using an unspecified dataset. Despite these differences, we argue that our set of features is comparable and enables a fair comparison given that the original implementation and some of the data used is not publicly available.

### 3.2 Neural Models

The neural models from Shimaoka et al. (2016) processes embeddings of the words of the mention and its context; and we adopt the same formalism when introducing these models and our variants. First, the mention representation  $v_m \in \mathbb{R}^{D_m \times 1}$  and context representation  $v_c \in \mathbb{R}^{D_c \times 1}$  are computed separately. Then, the concatenation of these representations is used to compute the prediction:

$$y = \frac{1}{1 + \exp\left(-W_y \begin{bmatrix} v_m \\ v_c \end{bmatrix}\right)} \quad (1)$$

Where  $W_y \in \mathbb{R}^{K \times (D_m + D_c)}$  is the weight matrix.

Let the words in the mention be  $m_1, m_2, \dots, m_{|m|}$ . Then the representation of the mention is computed as follows:

$$v_m = \frac{1}{|m|} \sum_{i=1}^{|m|} u(m_i) \quad (2)$$

Where  $u$  is a mapping from a word to an embedding. This relatively simple method for composing the mention representation is motivated by it being less prone to overfitting.

Next, we describe the three methods from Shimaoka et al. (2016) for computing the context representations; namely, Averaging, LSTM, and Attentive Encoder.

#### 3.2.1 Averaging Encoder

Similarly to the method of computing the mention representation, the Averaging encoder computes the averages of the words in the left and right context. Formally, let  $l_1, \dots, l_C$  and  $r_1, \dots, r_C$  be the words in the left and right contexts respectively, where  $C$  is the window size. Then, for each sequence of words, we compute the average of the

corresponding word embeddings. Those two vectors are then concatenated to form the representation of the context  $v_c$ .

#### 3.2.2 LSTM Encoder

For the LSTM Encoder, the left and right contexts are encoded by an LSTM (Hochreiter and Schmidhuber, 1997). The high-level formulation of an LSTM can be written as:

$$h_i, s_i = lstm(u_i, h_{i-1}, s_{i-1}) \quad (3)$$

Where  $u_i \in \mathbb{R}^{D_m \times 1}$  is an input embedding,  $h_{i-1} \in \mathbb{R}^{D_h \times 1}$  is the previous output, and  $s_{i-1} \in \mathbb{R}^{D_h \times 1}$  is the previous cell state.

For the left context, the LSTM is applied to the sequence  $l_1, \dots, l_C$  from left to right and produces the outputs  $\vec{h}_1^l, \dots, \vec{h}_C^l$ . For the right context, the sequence  $r_C, \dots, r_1$  is processed from right to left to produce the outputs  $\vec{h}_1^r, \dots, \vec{h}_C^r$ . The concatenation of  $\vec{h}_C^l$  and  $\vec{h}_1^r$  then serves as the context representation  $v_c$ .

#### 3.2.3 Attentive Encoder

An attention mechanism aims to encourage the model to focus on salient local information that is relevant for the classification decision. The attention mechanism variant used in this work is defined as follows. First, bi-directional LSTMs (Graves, 2012) are applied for both the right and left context. We denote the output layers of the bi-directional LSTMs as  $\vec{h}_1^l, \vec{h}_1^r, \dots, \vec{h}_C^l, \vec{h}_C^r$  and  $\overleftarrow{h}_1^l, \overleftarrow{h}_1^r, \dots, \overleftarrow{h}_C^l, \overleftarrow{h}_C^r$ .

For each output layer, a scalar value  $\tilde{a}_i \in \mathbb{R}$  is computed using a feed forward neural network with the hidden layer  $e_i \in \mathbb{R}^{D_a \times 1}$  and weight matrices  $W_e \in \mathbb{R}^{D_a \times 2D_h}$  and  $W_a \in \mathbb{R}^{1 \times D_a}$ :

$$e_i^l = \tanh\left(W_e \begin{bmatrix} \vec{h}_i^l \\ \overleftarrow{h}_i^l \end{bmatrix}\right) \quad (4)$$

$$\tilde{a}_i^l = \exp(W_a e_i^l) \quad (5)$$

Next, the scalar values are normalised such that they sum to 1:

$$a_i^l = \frac{\tilde{a}_i^l}{\sum_{i=1}^C \tilde{a}_i^l + \tilde{a}_i^r} \quad (6)$$

These normalised scalar values  $a_i \in \mathbb{R}$  are referred to as attentions. Finally, we compute the sum of the output layers of the bidirectional

<sup>1</sup><http://radimrehurek.com/gensim/>

LSTMs, weighted by the attentions  $a_i$  as the representation of the context:

$$v_c = \sum_{i=1}^C a_i^l \begin{bmatrix} \overrightarrow{h_i} \\ \overleftarrow{h_i} \\ \overleftarrow{h_i} \end{bmatrix} + a_i^r \begin{bmatrix} \overrightarrow{h_i} \\ \overleftarrow{h_i} \end{bmatrix} \quad (7)$$

An illustration of the attentive encoder model variant can be found in Figure 1.

### 3.3 Hybrid Models

To allow model variants to use both human background knowledge through hand-crafted features as well as features learnt from data, we extended the neural models to create new hybrid model variants as follows. Let  $v_f \in \mathbb{R}^{D_l \times 1}$  be a low-dimensional projection of the sparse feature  $f(m)$ :

$$v_f = W_f f(m) \quad (8)$$

Where  $W_f \in \mathbb{R}^{D_l \times D_f}$  is a projection matrix. The hybrid model variants are then defined as follows:

$$y = \frac{1}{1 + \exp \left( -W_y \begin{bmatrix} v_m \\ v_c \\ v_f \end{bmatrix} \right)} \quad (9)$$

These models can thus draw upon learnt features through  $v_m$  and  $v_c$  as well as hand-crafted features using  $v_f$  when making classification decisions. While existing work on fine-grained entity type classification have used either sparse, manually designed features or dense, automatically learnt embedding vectors, our work is the first to propose and evaluate a model using the combination of both features.

### 3.4 Hierarchical Label Encoding

Since the fine-grained types tend to form a forest of type hierarchies (e.g. musician is a subtype of artist, which in turn is a subtype of person), we investigated whether the encoding of each label could utilise this structure to enable parameter sharing. Concretely, we compose the weight matrix  $W_y$  for the logistic regression layer as the product of a learnt weight matrix  $V_y$  and a constant sparse binary matrix  $S$ :

$$W_y^T = V_y S \quad (10)$$

We encode the type hierarchy formed by the set of types in the binary matrix  $S$  as follows. Each type is mapped to a unique column in  $S$ , where membership at each level of

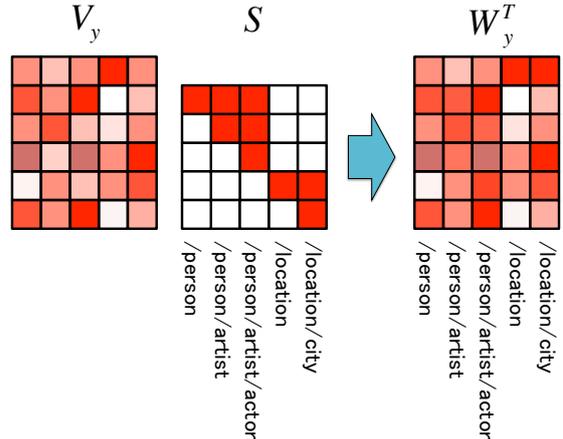

Figure 2: Hierarchical label encoding illustration.

Work	W2M	W2M+D	W2.6M	GN1	GN2

its type hierarchy is marked by a 1. For example, if we use the set of types defined by Gillick et al. (2014), the column for /person could be encoded as  $[1, 0, \dots]$ , /person/artist as  $[1, 1, 0, \dots]$ , and /person/artist/actor as  $[1, 1, 1, 0, \dots]$ . This encoding scheme is illustrated in Figure 2.

This enables us to share parameters between labels in the same hierarchy, potentially making learning easier for infrequent types that can now draw upon annotations of other types in the same hierarchy.

## 4 Experiments

### 4.1 Datasets

Despite the research community having largely settled on using the manually annotated datasets FIGER (GOLD) (Ling and Weld, 2012) and OntoNotes (Gillick et al., 2014) for evaluation, there is still a remarkable difference in the data used to train models (Table 2) that are then evaluated on the same manually annotated datasets. Also worth noting is that some data is not even publicly available, making a

fair comparison between methods even more difficult. For evaluation, in our experiments we use the two well-established manually annotated datasets FIGER (GOLD) and OntoNotes, where like Gillick et al. (2014), we discarded pronominal mentions, resulting in a total of 8,963 mentions. For training, we use the automatically induced publicly available datasets provided by Ren et al. (2016). Ren et al. (2016) aimed to eliminate label noise generated in the process of distant supervision and we use the “raw” noisy data<sup>2</sup> provided by them for training our models.

## 4.2 Pre-trained Word Embeddings

We use pre-trained word embeddings that were not updated during training to help the model generalise to words not appearing in the training set (Rocktäschel et al., 2015). For this purpose, we used the freely available 300-dimensional cased word embeddings trained on 840 billion tokens from the Common Crawl supplied by Pennington et al. (2014). For words not present in the pre-trained word embeddings, we use the embedding of the “unk” token.

## 4.3 Evaluation Criteria

We adopt the same criteria as Ling and Weld (2012), that is, we evaluate the model performance by strict accuracy, loose macro, and loose micro scores.

## 4.4 Hyperparameter Settings

Values for the hyperparameters were obtained from preliminary experiments by evaluating the model performance on the development sets. Concretely, all neural and hybrid models used the same  $D_m = 300$ -dimensional word embeddings, the hidden-size of the LSTM was set to  $D_h = 100$ , the hidden-layer size of the attention module was set to  $D_a = 100$ , and the size of the low-dimensional projection of the sparse features was set to  $D_l = 50$ . We used Adam (Kingma and Ba, 2014) as our optimisation method with a learning rate of 0.001, a mini-batch size of 1,000, and iterated over the training data for five epochs. As a regularizer we

<sup>2</sup> Although Ren et al. (2016) provided both “raw” data and code to “denoise” the data, we were unable to replicate the performance benefits reported in their work after running their pipeline. We have contacted them regarding this as we would be interested in comparing the benefit of their denoising algorithm for each model, but at the time of writing we have not yet received a response.

used dropout (Hinton et al., 2012) with probability 0.5 applied to the mention representation and sparse feature representation. The context window size was set to  $C = 10$  and if the length of a context extends beyond the sentence length, we used a padding symbol in-place of a word. After training, we picked the best model on the development set as our final model and report their performance on the test sets. Our model implementation was done in Python using the TensorFlow (Abadi et al., 2015) machine learning library.

## 4.5 Results

When presenting our results, it should be noted that we aim to make a clear separation between results from models trained using different datasets.

### 4.5.1 FIGER (GOLD)

We first analyse the results on FIGER (GOLD) (Tables 3 and 4). The performance of the baseline model that uses the sparse hand-crafted features is relatively close to that of the FIGER system of Ling and Weld (2012). This is consistent with the fact that both systems use linear classifiers, similar sets of features, and training data of the same size and domain.

Looking at the results of neural models, we observe a consistent pattern that adding hand-crafted features boost performance significantly, indicating that the learnt and hand-crafted features complement each other. The effects of adding the hier-

Model	Acc.	Macro	Micro

FIGER (Ren et al., 2016)	36.90	57.80	51.60

Table 5: Performance on OntoNotes for models using the *same* W2M training data.

archical label encoding were inconsistent, sometimes increasing, sometimes decreasing performance. We thus opted not to include them in the results table due to space constraints and hypothesise that given the size of the training data, parameter sharing may not yield any large performance benefits. Among the neural models, we see that the averaging encoder perform considerably worse than the others. Both the LSTM and attentive encoder show strong results and the attentive encoder with hand-crafted features achieves the best performance among all the models we investigated.

When comparing our best model to previously introduced models trained using different training data, we find that we achieve state-of-the-art results both in terms of loose macro and micro scores. The closest competitor, FIGER + PLE (Ren et al., 2016), achieves higher accuracy at the expense of lower F1 scores, we suspect that this is due to an accuracy focus in their label pruning strategy. It is worth noting that we achieve state-of-the-art results without the need for any noise reduction strategies. Also, even with 600,000 fewer training examples, our variant with hand-crafted features of the attentive model from Shimaoka et al. (2016) outperforms its feature-learning variant.

In regards to the impact of the choice of training set, we observe that the model introduced in Shimaoka et al. (2016) drops as much as 3.36 points of loose micro score when using a smaller dataset. Thus casting doubts upon the comparability of results of fine-grained entity classification models using different training data.

#### 4.5.2 OntoNotes

Secondly, we discuss the results on OntoNotes (Tables 5, and 6). Again, we see consistent per-

Model	Data	Acc.	Macro	Micro
Averaging + Hand-crafted + Hier	W2M	51.74	70.98	64.91
Attentive + Hand-crafted + Hier	W2M	50.89	70.80	64.93
FIGER + PLE (Ren et al., 2016)	W2M+D	<b>57.2</b>	<b>71.5</b>	66.1
HYENA + PLE (Ren et al., 2016)	W2M+D	54.6	69.2	62.5
Hand-crafted (Gillick et al., 2014)	GN1	n/a	n/a	70.01
K-WASABIE (Yogatama et al., 2015)	GN2	n/a	n/a	<b>72.98</b>

Table 6: Performance on OntoNotes for models using *different* training data.

formance improvements when the sparse hand-crafted features are added to the neural models. In the absence of hand-crafted features, the averaging encoder suffer relatively poor performance and the attentive encoder achieves the best performance. However, when the hand-crafted features are added, a significant improvement occurs for the averaging encoder, making the performance of the three neural models much alike. We speculate that some of the hand-crafted features such as the dependency role and parent word of the head noun, provide crucial information for the task that cannot be captured by the plain averaging model, but can be learnt if an attention mechanism is present. Another speculative reason is that because the training dataset is noisy compared to FIGER (GOLD) (since FIGER (GOLD) uses anchors to detect entities whereas OntoNotes uses an external tool), and the size of the dataset is small, the robustness of the simpler averaging model becomes clearer when combined with the hand-crafted features.

Another interesting observation can be seen for models with the hierarchical label encoding, where it is clear that consistent performance increases occur. This can be explained by the fact that the type ontology used in OntoNotes is more well-formed than its FIGER counterpart. While we do not obtain state-of-the-art performance when considering models using different training data, we do note that in terms of F1-score we perform within 1 point of the state of the art. This being achieved despite having trained our models on different non-proprietary noisy data.

Once again we have an opportunity to study the impact of the choice of training data by comparing the results of the hand-crafted features of Gillick et al. (2014) to our own comparable set of features. What we find is that the performance drop is very dramatic, 9.85 points of loose micro score. Given that the training data for the previously introduced model is not publicly available, we hesi-

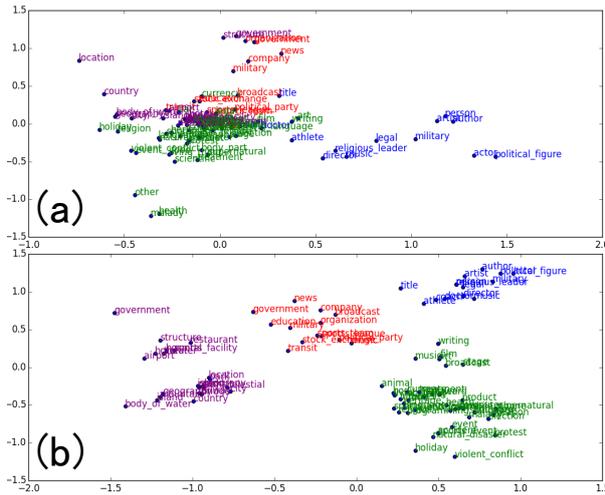

Figure 3: PCA projections of the label embeddings learnt from the OntoNotes dataset where subtypes share the same color as their parent type. Sub-figure (a) uses the non-hierarchical encoding, while sub-figure (b) uses the hierarchical encoding.

tate to speculate as to exactly why this drop is so dramatic, but similar observations have been made for entity linking (Ling et al., 2015). This clearly underlines how essential it is to compare models on an equal footing using the same training data.

#### 4.6 PCA visualisation of label embeddings

By visualising the learnt label embeddings (Figure 3) and comparing the non-hierarchical and hierarchical label encodings, we can observe that the hierarchical encoding forms clear distinct clusters.

#### 4.7 Attention Analysis

While visualising the attention weights for specific examples have become commonplace, it is still not clear exactly what syntactic and semantic patterns that are learnt by the attention mechanism. To better understand this, we first qualitatively analysed a large set of attention visualisations and observed that head words and the words contained in the phrase forming the mention tended to receive the highest level of attention. In order to quantify this notion, we calculated how frequently the word strongest attended over for all mentions of a specific type was the syntactic head or the words before and after the mention in its phrase. What we found through our analysis (Table 7) was that our attentive model without hand-crafted features does indeed learn that head words and the phrase surrounding the mention are highly indica-

Type	Parent	Before	After	Frequent Words
/location	0.319	0.228	0.070	in, at, born
/organization	0.324	0.178	0.119	at, the, by
/art/film	0.207	0.429	0.021	film, films, in
/music	0.259	0.116	0.018	album, song, single
/award	0.583	0.292	0.083	won, a, received
/event	0.310	0.188	0.089	in, during, at

Table 7: Quantitative attention analysis.

tive of the mention type, without any explicit supervision. Furthermore, we believe that this in part might explain why the performance benefit of adding hand-crafted features was smaller for the attentive model compared to our other two neural variants.

## 5 Conclusions and Future Work

In this paper, we investigated several model variants for the task of fine-grained entity type classification. The experiments clearly demonstrated that the choice of training data – which until now been ignored for our task – has a significant impact on performance. Our best model achieved state-of-the-art results with 75.36% loose micro F1 score on FIGER (GOLD) despite being compared to models trained using larger datasets and we were able to report the best results for any model trained using publicly available data for OntoNotes with 64.93% loose micro F1 score. The analysis of the behaviour of the attention mechanism demonstrated that it can successfully learn to attend over expressions that are important for the classification of fine-grained types. It is our hope that our observations can inspire further research into the limitations of what linguistic phenomena attentive models can learn and how they can be improved.

As future work, we see the re-implementation of more methods from the literature as a desirable target, so that they can be evaluated after utilising the same training data. Additionally, we would like to explore alternative hierarchical label encodings that may lead to more consistent performance benefits.

To ease the reproducibility of our work, we make our code used for the experiments available at <https://github.com/shimaokasonse/NFGEC>.

## Acknowledgments

This work was supported by CREST-JST, JSPS KAKENHI Grant Number 15H01702, a Marie

Curie Career Integration Award, and an Allen Distinguished Investigator Award. We would like to thank Dan Gillick for answering several questions related to his 2014 paper.
