## Preface: General Chair

Welcome to the EACL 2017, the 15th Conference of the European Chapter of the Association for Computational Linguistics! This is the largest ever EACL in terms of the number of papers being presented. We have a strong scientific program, including 14 workshops, six tutorials, a demos session, and a student research workshop. EACL received a record number of submissions this year, approximately 1,000 long and short papers combined, which reflects how broad and active our field is. We are also fortunate to have three excellent invited speakers: David Blei (University of Columbia), Devi Parikh (Virginia Tech), and Hinrich Schütze (LMU Munich). I hope that you will enjoy both the conference and Valencia.

I am deeply indebted to the Program Committee Chairs, Alexander Koller and Phil Blunsom, for their hard work. They put together a team of 27 area chairs who in turned assembled many reviewers and handled a large number of papers. The Workshop Chairs, Laura Rimmell and Richard Johansson, coordinated with the workshop chairs for ACL 2017 and EMNLP 2017 and succeeded in putting together an exciting and broad programme including 14 workshops. The student research workshop was organised by the student members of the EACL board — John Camilleri, Mariona Coll Ardanuy Uxoá Iñourrieta, and Florian Kunneman. With the help of Barbara Plank (Faculty advisor), they issued the call, organised a team of reviewers, assigned papers, coordinated and mediated among reviewers, and finally constructed a schedule consisting of 12 papers.

The Tutorial Chairs, Lucia Specia and Alexandre Klementiev, put together a very strong programme of six tutorials, which I hope many of us will attend. The publication chairs, Maria Liakata and Chris Biemann, have been short of amazing. They undertook the complex task of producing the conference proceedings and managed to make it seem easy, while being extremely thorough and paying attention to every detail. Chris Biemann deserves a double thank you for being Sponsorship Chair. Our demo chairs, Anselmo Peñas and André Martins, did a fantastic job selecting 30 demos for our demo session which I encourage you all to attend. I would also like to thank David Weir our publicity chair and the ACL business manager Priscilla Rassmussen, who knows more about our conferences than anyone else. Sincere thanks are due to the various sponsors for their generous contribution. I am grateful to all members of the EACL board for their advice and guidance, in particular to Lluís Márques and Walter Daelemans.

Last, but not least, this conference could not have taken place without the local organising committee who have worked tremendously hard to make EACL 2017 a success. The Local Chair, Paolo and Andrea Aldea from Grupo Pacifico, have brought together a fantastic local team and have dealt with many of the day-to-day tasks arising in organizing such a large conference expertly and efficiently.

I am always amazed by the dedication of our colleagues and their willingness to share knowledge and invest precious time in order to make our conferences a success. On that note, I would like to thank the authors who submitted their work to EACL and everyone else involved: area chairs, workshop organizers, tutorial presenters, reviewers, demo presenters, and participants of the conference.

Welcome to EACL 2017!

Mirella Lapata  
General Chair

## Preface: Programme Chairs

Welcome to the 15<sup>th</sup> Conference of the European Chapter of the Association for Computational Linguistics! In these proceedings you will find all the papers accepted for presentation at the conference in Valencia from the 3<sup>rd</sup> to the 7<sup>th</sup> of April 2017. The main conference program consists of both oral and poster presentations and also includes additional presentations of papers from the Transaction of the Association for Computational Linguistics (TACL), posters from the Student Research Workshop, and two demonstration sessions.

We received considerably more paper submissions than previous meetings of the EACL: 441 Long Papers and 502 Short Papers (excluding papers withdrawn or rejected for incorrect formatting). The Short Paper deadline was set after that for Long Papers and it is notable that we received more submissions of Short than Long papers. After the commendable reviewing efforts of our Program Committee we accepted 119 Long Papers, 78 as oral presentations and 41 posters, and 120 Short Papers, 47 orals and 73 posters. Overall the acceptance rates were 27% and 24% for the Long and Short Paper tracks respectively. The EACL 2017 programme also contained the oral presentations of four papers published in TACL.

It would not have been possible to produce such a high quality programme without the amazing effort and dedication of our Program Committee. We would like to thank all of those who served on the committee, which consisted of 27 Area Chairs and 612 Reviewers, drawn from a diverse range of fields and from both Europe and further afield. Each paper received at least three reviews. We selected the final programme based on the recommendations of the Area Chairs and reviewers, while aiming to ensure the representation of a wide variety of research areas. The Area Chairs were each asked to nominate candidate papers for the Outstanding Papers sessions, of which the Programme Chairs and General Chair selected three Long Papers and one Short Paper. These were allocated extra time in the programme for their oral presentations.

Following the precedent set at ACL 2016, we decided to allocate Long Paper and Short Paper oral presentations 20 minute and 15 minute slots respectively, including time for questions and changing speakers. While this shorter scheduling requires presenters to be more concise in their presentation, it allowed us to accommodate a larger program of talks in the space available at the venue.

In addition to the main conference programme, a Student Research Workshop was held which selected 12 papers for presentation as posters, and two demonstration sessions were held during the evening poster sessions. We are particularly grateful to our three distinguished invited speakers, Devi Parikh (Georgia Tech), David Blei (Columbia University), and Hinrich Schütze (LMU Munich). They represent the amazing diversity of contemporary research being conducted across Computational Linguistics, Artificial Intelligence, and Machine Learning.

In total the programme contains 126 talks and 126 posters, making this the largest EACL conference by a considerable margin. Firstly this would not be possible without the authors who chose to submit their research papers for publication at EACL, and we thank them for choosing our conference. Obviously coordinating such a programme requires contributions from many people beyond the Programme Chairs. We would like to thank our Area Chairs who ensured the smooth running of the two reviewing cycles. We are also thankful for the support we received from the rest of the organising committee, including the Publication Chairs, Local Organisers, Workshop Chairs, Tutorial Chairs, Demo Chairs, the Handbook Chair, and the Student Research Workshop Chair, all listed in full later in the proceedings. We are also grateful for the technical support received from the START team. We would like to thank the Programme Chairs for ACL 2016, Katrin Erk and Noah Smith, who generously provided many insights and tips from their own experience to help us avoid pitfalls and ensure the smooth running of the reviewing process. Finally, we are thankful to have been blessed with an exceptionally calm and organised General Chair in Mirella Lapata, who ensured the smooth running of the organising process and the ultimate success of

this conference.

We hope you enjoy EACL 2017 in Valencia!

Phil Blunsom and Alexander Koller  
EACL 2017 Programme Chairs

# Organisers

## General Chair:

Mirella Lapata, University of Edinburgh

## Program Chairs:

Phil Blunsom, University of Oxford

Alexander Koller, University of Saarbrücken

## Local Organising Committee:

Paolo Rosso (Chair), PRHLT, Universitat Politècnica de València

Francisco Casacuberta (Co-chair), PRHLT, Universitat Politècnica de València

Jon Ander Gómez (Co-chair), PRHLT, Politècnica de València

## Publication Chairs:

Maria Liakata, University of Warwick

Chris Biemann, University of Hamburg

## Workshop Chairs:

Laura Rimell, University of Cambridge

Richard Johansson, University of Gothenburg

## Tutorial Chairs:

Alex Klementiev, Amazon Berlin

Lucia Specia, University of Sheffield

## Demo Chairs:

Anselmo Peñas, UNED, Madrid

André Martins, Unbabel Lda, Portugal

## Student Research Workshop Chairs:

John J. Camilleri, University of Gothenburg

Mariona Coll Ardanuy, University of Göttingen

Uxo Iñurrieta, University of the Basque Country

Florian Kunneman, Radboud University

## Student Research Workshop Faculty Advisor:

Barbara Plank, University of Groningen

## Sponsorship Chairs:

Chris Biemann, University of Hamburg

Suzan Verberne, Leiden Institute of Advanced Computer Science

**Publicity Chair:**

David Weir, University of Sussex

**Conference Handbook Chair:**

Andreas Vlachos, University of Sheffield

**Area Chairs:**

Enrique Alfonseca, Nicholas Asher, Jason Baldridge, Alexandra Birch, Stephen Clark, Shay B. Cohen, Marcello Federico, Stefan L. Frank, Yoav Goldberg, Emiel Krahmer, Tom Kwiatkowski, Marie-Francine Moens, Malvina Nissim, Stephan Open, Miles Osborne, Rebecca J. Passonneau, Sebastian Riedel, Marcus Rohrbach, Andrew Rosenberg, Tatjana Scheffler, Hinrich Schütze, Gabriel Skantze, Mark Stevenson, Stephanie Strassel, Andreas Vlachos, Feiyu Xu, François Yvon

**Reviewers:**

Stergos Afantenos, Željko Agić, Alan Akbik, Nikolaos Aletras, Jan Alexandersson, Afra Alishahi, Tamer Alkhouli, Miltiadis Allamanis, Alexandre Allauzen, Carlos Alzate, Hadi Amiri, Waleed Ammar, Nicholas Andrews, Ion Androutsopoulos, Yoav Artzi, Isabelle Augenstein, Harald Baayen, Dzmitry Bahdanau, JinYeong Bak, Alexandra Balahur, Timothy Baldwin, Borja Balle, Miguel Ballesteros, David Bamman, Mohit Bansal, Daniel Bauer, Timo Baumann, Beata Beigman Klebanov, Núria Bel, Islam Beltagy, Anja Belz, Emily M. Bender, Andrew Bennett, Adrian Benton, Anton Benz, Jonathan Berant, Christina Bergmann, Laurent Besacier, Archana Bhatia, Yonatan Bisk, Johannes Bjerva, Frédéric Blain, Roi Blanco, Eduardo Blanco, Nate Blaylock, Nikolay Bogoychev, Bernd Bohnet, Gemma Boleda, Danushka Bollegala, Claire Bonial, Kalina Bontcheva, Johan Bos, Matko Bosnjak, Johan Boye, Chris Brew, Julian Brooke, Harm Brouwer, Elia Bruni, Christian Buck, Paul Buitelaar, José G. C. de Souza, Elena Cabrio, Deng Cai, Nicoletta Calzolari, Nick Campbell, Fabienne Cap, Xavier Carreras, Francisco Casacuberta, Daniel Cer, Mauro Cettolo, Nathanael Chambers, Kai-Wei Chang, Angel Chang, Rajen Chatterjee, Wanxiang Che, Danqi Chen, Yun-Nung Chen, Chen Chen, Boxing Chen, Hsin-Hsi Chen, Colin Cherry, Jackie Chi Kit Cheung, David Chiang, Christian Chiarcos, Do Kook Choe, Eunsol Choi, Monojit Choudhury, Christos Christodoulopoulos, Grzegorz Chrupała, Jennifer Chu-Carroll, Tagyoung Chung, Stephane Clinchant, Trevor Cohn, Nigel Collier, Michael Collins, John Conroy, Bonaventura Coppola, Ryan Cotterell, Danilo Croce, Heriberto Cuayahuitl, Walter Daelemans, Marina Danilevsky, Pradipto Das, Adrià de Gispert, Daniël de Kok, Gerard de Melo, Thierry Declerck, Marco Del Tredici, Estelle Delpesch, Vera Demberg, Thomas Demeester, Pascal Denis, Michael Denkowski, Tejaswini Deoskar, Leon Derczynski, Nina Dethlefs, Ann Devitt, Giuseppe Di Fabrizio, Mona Diab, Georgiana Dinu, Simon Dobnik, A. Seza Doğruöz, Markus Dreyer, Lan Du, Jason Duncan, Jesse Dunietz, Nadir Durrani, Jens Edlund, Koji Eguchi, Kathrin Eichler, Vladimir Eidelman, Michael Elhadad, Desmond Elliott, Micha Elsner, Ramy Eskander, Allyson Ettinger, Federico Fancellu, M. Amin Farajian, Geli Fei, Anna Feldman, Yansong Feng, Raquel Fernandez, Olivier Ferret, Katja Filippova, Andrew Finch, Nicholas FitzGerald, Antske Fokkens, José A. R. Fonolosa, Mikel Forcada, Martin Forst, George Foster, Jennifer Foster, Stella Frank, Anette Frank, Michael Franke, Dayne Freitag, Daniel Fried, Annemarie Friedrich, Hagen Fuerstenau, Alona Fyshe, Michel Galley, Michael Gamon, Kuzman Ganchev, Miguel A. García-Cumbreras, Claire Gardent, Matt Gardner, Milica Gasic, Albert Gatt, Eric Gaussier, Kallirroi Georgila, Kripabandhu Ghosh, Dafydd Gibbon, Daniel Gildea, Kevin Gimpel, Filip Ginter, Jonathan Ginzburg, Roxana Girju, Dimitra Gkatzia, Goran Glavaš, Yoav Goldberg, Dan Goldwasser, Juan Carlos Gomez, Kyle Gorman, Parantapa Goswami, Amit Goyal, Joao Graca, Yvette Graham, Mark Granroth-

Wilding, Ralph Grishman, Liane Guillou, Weiwei Guo, Joakim Gustafson, Nizar Habash, Ben Hachey, Barry Haddow, Gholamreza Haffari, Masato Hagiwara, Udo Hahn, Dilek Hakkani-Tur, John Hale, Bo Han, Sanda Harabagiu, Kazuma Hashimoto, Helen Hastie, Claudia Hauff, Daqing He, Yifan He, Luheng He, Kenneth Heafield, Sebastian Hellmann, Oliver Hellwig, Matthew Henderson, James Henderson, Lisa Anne Hendricks, Leonhard Hennig, Aurélie Herbelot, Jack Hessel, Dirk Hovy, Christine Howes, Ruihong Huang, Fei Huang, Matthias Huck, Mans Hulden, Muhammad Humayoun, Jena D. Hwang, Nancy Ide, Iustina Ilisei, Kentaro Inui, Hitoshi Isahara, Mohit Iyyer, Shahab Jalalvand, Srinivasan Janarthanam, Yacine Jernite, Yangfeng Ji, Wenbin Jiang, Richard Johansson, Kenneth Joseph, Patrick Juola, Dan Jurafsky, Gerhard Jäger, Nobuhiro Kaji, Jaap Kamps, Katharina Kann, Simon Keizer, Frank Keller, Casey Kennington, Douwe Kiela, Yubin Kim, Svetlana Kiritchenko, Julia Kiseleva, Dietrich Klakow, Manfred Klenner, Alistair Knott, Philipp Koehn, Rik Koncel-Kedziorski, Grzegorz Kondrak, Ioannis Konstas, Stefan Kopp, Moshe Koppel, Selcuk Kopru, Parisa Kordjamshidi, Valia Kordoni, Bhushan Kotnis, Mikhail Kozhevnikov, Sebastian Krause, Jayant Krishnamurthy, Canasai Kruengkrai, Lun-Wei Ku, Marco Kuhlmann, Roland Kuhn, Jonathan K. Kummerfeld, Polina Kuznetsova, Vasileios Lampos, Gerassimos Lampouras, Shalom Lappin, Birger Larsen, Staffan Larsson, Jey Han Lau, Alon Lavie, Angeliki Lazaridou, Joseph Le Roux, Moontae Lee, Sungjin Lee, Kenton Lee, Els Lefever, Alessandro Lenci, Gregor Leusch, Roger Levy, Mike Lewis, Chen Li, Junyi Jessy Li, Fangtao Li, Qi Li, Yunyao Li, Jing Li, Xiao Ling, Tal Linzen, Christina Lioma, Pierre Lison, Fei Liu, Kang Liu, Yang Liu, Shujie Liu, Jing Liu, Qun Liu, Varvara Logacheva, Aurelio Lopez-Lopez, Bin Lu, Wei Lu, Andy Luecking, Michal Lukasik, Zhunchen Luo, Minh-Thang Luong, Pranava Swaroop Madhyastha, Walid Magdy, Mateusz Malinowski, Shervin Malmasi, Gideon Mann, Diego Marcheggiani, Daniel Marcu, Scott Martin, Patricio Martinez-Barco, Héctor Martínez Alonso, Prashant Mathur, Takuya Matsuzaki, Austin Matthews, Evgeny Matusov, Arne Mauser, Diana McCarthy, David McClosky, Ryan McDonald, Florian Metzger, Adam Meyers, Haitao Mi, Timothy Miller, Tristan Miller, Seyed Abolghasem Mirroshandel, Teruko Mitamura, Daichi Mochihashi, Saif Mohammad, Karo Moilanen, Manuel Montes, Taesun Moon, Roser Morante, Mathieu Morey, Alessandro Moschitti, Philippe Muller, Maria Nadejde, Masaaki Nagata, Preslav Nakov, Courtney Napoles, Jason Naradowsky, Shashi Narayan, Tahira Naseem, Alexis Nasr, Borja Navarro, Roberto Navigli, Matteo Negri, Yael Netzer, Graham Neubig, Guenter Neumann, Mariana Neves, Hwee Tou Ng, Vincent Ng, Dong Nguyen, Vlad Niculae, Joakim Nivre, Pierre Nugues, Brendan O'Connor, Timothy O'Donnell, Kemal Oflazer, Jong-Hoon Oh, Alice Oh, Naoaki Okazaki, Tsuyoshi Okita, Constantin Orasan, Katja Ovchinnikova, Ulrike Pado, Muntsa Padró, Sebastian Padró, Alexis Palmer, Sinno Jialin Pan, Denis Paperno, Antonio Pareja Lora, Devi Parikh, Siddharth Patwardhan, Michael J. Devi Parikh, Virginia Tech  
Hinrich Schütze, LMU Munich

## Invited Talk: David Blei

### **Title: Probabilistic Topic Models and User Behavior**

Topic modeling algorithms analyze a document collection to estimate its latent thematic structure. However, many collections contain an additional type of data: how people use the documents. For example, readers click on articles in a newspaper website, scientists place articles in their personal libraries, and lawmakers vote on a collection of bills. Behavior data is essential both for making predictions about users (such as for a recommendation system) and for understanding how a collection and its users are organized.

I will review the basics of topic modeling and describe our recent research on collaborative topic models, models that simultaneously analyze a collection of texts and its corresponding user behavior. We studied collaborative topic models on 80,000 scientists' libraries from Mendeley and 100,000 users' click data from the arXiv. Collaborative topic models enable interpretable recommendation systems, capturing scientists' preferences and pointing them to articles of interest. Further, these models can organize the articles according to the discovered patterns of readership. For example, we can identify articles that are important within a field and articles that transcend disciplinary boundaries.

### **Biography:**

David Blei is a Professor of Statistics and Computer Science at Columbia University, and a member of the Columbia Data Science Institute. His research is in statistical machine learning, involving probabilistic topic models, Bayesian nonparametric methods, and approximate posterior inference algorithms for massive data. He works on a variety of applications, including text, images, music, social networks, user behavior, and scientific data. David has received several awards for his research, including a Sloan Fellowship (2010), Office of Naval Research Young Investigator Award (2011), Presidential Early Career Award for Scientists and Engineers (2011), Blavatnik Faculty Award (2013), and ACM-Infosys Foundation Award (2013). He is a fellow of the ACM.

## Invited Talk: Devi Parikh

### Title: Words, Pictures, and Common Sense

Wouldn't it be nice if machines could understand content in images and communicate this understanding as effectively as humans? Such technology would be immensely powerful, be it for aiding a visually-impaired user navigate a world built by the sighted, assisting an analyst in extracting relevant information from a surveillance feed, educating a child playing a game on a touch screen, providing information to a spectator at an art gallery, or interacting with a robot. As computer vision and natural language processing techniques are maturing, we are closer to achieving this dream than we have ever been.

Visual Question Answering (VQA) is one step in this direction. Given an image and a natural language question about the image (e.g., "What kind of store is this?", "How many people are waiting in the queue?", "Is it safe to cross the street?"), the machine's task is to automatically produce an accurate natural language answer ("bakery", "5", "Yes"). In this talk, I will present our dataset, some neural models, and open research questions in free-form and open-ended Visual Question Answering (VQA). I will also show a teaser about the next step moving forward: Visual Dialog. Instead of answering individual questions about an image in isolation, can we build machines that can hold a sequential natural language conversation with humans about visual content?

While machines are getting better at superficially connecting words to pictures, interacting with them quickly reveals that they lack a certain common sense about the world we live in. Common sense is a key ingredient in building intelligent machines that make "human-like" decisions when performing tasks – be it automatically answering natural language questions, or understanding images and videos. How can machines learn this common sense? While some of this knowledge is explicitly stated in human-generated text (books, articles, blogs, etc.), much of this knowledge is unwritten. While unwritten, it is not unseen! The visual world around us is full of structure bound by commonsense laws. But machines today cannot learn common sense directly by observing our visual world because they cannot accurately perform detailed visual recognition in images and videos. We argue that one solution is to give up on photorealism. We propose to leverage abstract scenes – cartoon scenes made from clip art by crowd sourced humans – to teach our machines common sense. I will demonstrate how knowledge learnt from this abstract world can be used to solve commonsense textual tasks.

### Biography:

Devi Parikh is an Assistant Professor in the School of Interactive Computing at Georgia Tech, and a Visiting Researcher at Facebook AI Research (FAIR). From 2013 to 2016, she was an Assistant Professor in the Bradley Department of Electrical and Computer Engineering at Virginia Tech. From 2009 to 2012, she was a Research Assistant Professor at Toyota Technological Institute at Chicago (TTIC), an academic computer science institute affiliated with University of Chicago. She has held visiting positions at Cornell University, University of Texas at Austin, Microsoft Research, MIT, and Carnegie Mellon University. She received her M.S. and Ph.D. degrees from the Electrical and Computer Engineering department at Carnegie Mellon University in 2007 and 2009 respectively. She received her B.S. in Electrical and Computer Engineering from Rowan University in 2005. Her research interests include computer vision and AI in general and visual recognition problems in particular. Her recent work involves exploring problems at the intersection of vision and language, and leveraging human-machine collaboration for building smarter machines. She has also worked on other topics such as ensemble of classifiers, data fusion, inference in probabilistic models, 3D reassembly, barcode segmentation, computational photography, interactive computer vision, contextual reasoning, hierarchical representations of images, and human-debugging. She is a recipient of an NSF CAREER award, a Sloan Research Fellowship, an Office of Naval Research (ONR) Young Investigator Program (YIP) award, an Army Research Office (ARO) Young Investigator Program (YIP) award, an Allen Distinguished Investigator Award in Artificial Intelligence from the Paul G. Allen Family Foundation, four Google Faculty Research Awards,

an Amazon Academic Research Award, an Outstanding New Assistant Professor award from the College of Engineering at Virginia Tech, a Rowan University Medal of Excellence for Alumni Achievement, Rowan University's 40 under 40 recognition, and a Marr Best Paper Prize awarded at the International Conference on Computer Vision (ICCV).

## Invited Talk: Hinrich Schütze

**Title: Don't cram two completely different meanings into a single !&??@#^\$% vector! Or should you?**

It is tempting to interpret a high-dimensional embedding space cartographically, i.e., as a map each point of which represents a distinct identifiable meaning – just as cities and mountains on a real map represent distinct identifiable geographic locations. On this interpretation, ambiguous words pose a problem: how can two completely different meanings be in the same location? Instead of learning a single embedding for an ambiguous word, should we rather learn a different embedding for each of its senses (as has often been proposed)? In this talk, I will take a fresh look at this question, drawing on simulations with pseudowords, sentiment analysis experiments, psycholinguistics and – if time permits – lexicography.

### **Biography:**

Hinrich Schütze is professor of computational linguistics and director of the Center for Information and Language Processing at LMU Munich. He received his PhD from Stanford University's Department of Linguistics in 1995 and worked on natural language processing and information retrieval technology at Xerox PARC, at several Silicon Valley startups and at Google 1995-2004 and 2008/9. He coauthored *Foundations of Statistical Natural Language Processing* (with Chris Manning) and *Introduction to Information Retrieval* (with Chris Manning and Prabhakar Raghavan). His research is motivated by a fundamental question that computational linguists face today: Is domain knowledge about language dispensable (as many in deep learning seem to believe) or can linguistics and statistical NLP learn and benefit from each other?

<i>Computational Argumentation Quality Assessment in Natural Language</i> Henning Wachsmuth, Nona Naderi, Yufang Hou, Yonatan Bilu, Vinodkumar Prabhakaran, Tim Alberdingk Thijm, Graeme Hirst and Benno Stein . . . . .	176
<i>A method for in-depth comparative evaluation: How (dis)similar are outputs of pos taggers, dependency parsers and coreference resolvers really?</i> Don Tugener . . . . .	188
<i>Re-evaluating Automatic Metrics for Image Captioning</i> Mert Kilickaya, Aykut Erdem, Nazli Ikizler-Cinbis and Erkut Erdem . . . . .	199
<i>Integrating Meaning into Quality Evaluation of Machine Translation</i> Osman Baskaya, Eray Yildiz, Doruk Tunaoglu, Mustafa Tolga Eren and A. Seza Dogruoz . . . . .	210
<i>Cross-Lingual Dependency Parsing with Late Decoding for Truly Low-Resource Languages</i> Michael Schlichtkrull and Anders Søgaard . . . . .	219
<i>Parsing Universal Dependencies without training</i> Héctor Martínez Alonso, Željko Agić, Barbara Plank and Anders Søgaard . . . . .	229
<i>Delexicalized Word Embeddings for Cross-lingual Dependency Parsing</i> Mathieu Dehouck and Pascal Denis . . . . .	240
<i>Stance Classification of Context-Dependent Claims</i> Roy Bar-Haim, Indrajit Bhattacharya, Francesco Dinuzzo, Amrita Saha and Noam Slonim . . . . .	250
<i>Exploring the Impact of Pragmatic Phenomena on Irony Detection in Tweets: A Multilingual Corpus Study</i> Jihen Karoui, Benamara Farah, Véronique Moriceau, Viviana Patti, Cristina Bosco and Nathalie Aussenac-Gilles . . . . .	261
<i>A Multi-View Sentiment Corpus</i> Debora Nozza, Elisabetta Fersini and Enza Messina . . . . .	272
<i>A Systematic Study of Neural Discourse Models for Implicit Discourse Relation</i> Attapol Rutherford, Vera Demberg and Nianwen Xue . . . . .	280
<i>Cross-lingual RST Discourse Parsing</i> Chloé Braud, Maximin Coavoux and Anders Søgaard . . . . .	291
<i>Dialog state tracking, a machine reading approach using Memory Network</i> Julien Perez and Fei Liu . . . . .	304
<i>Sentence Segmentation in Narrative Transcripts from Neuropsychological Tests using Recurrent Convolutional Neural Networks</i> Marcos Treviso, Christopher Shulby and Sandra Aluísio . . . . .	314
<i>Joint, Incremental Disfluency Detection and Utterance Segmentation from Speech</i> Julian Hough and David Schlangen . . . . .	325
<i>From Segmentation to Analyses: a Probabilistic Model for Unsupervised Morphology Induction</i> Toms Bergmanis and Sharon Goldwater . . . . .	336
<i>Creating POS Tagging and Dependency Parsing Experts via Topic Modeling</i> Atreyee Mukherjee, Sandra Kübler and Matthias Scheutz . . . . .	346

<i>Universal Dependencies and Morphology for Hungarian - and on the Price of Universality</i> Veronika Vincze, Katalin Simkó, Zsolt Szántó and Richárd Farkas .....	355
<i>Addressing the Data Sparsity Issue in Neural AMR Parsing</i> Xiaochang Peng, Chuan Wang, Daniel Gildea and Nianwen Xue .....	365
<i>Generating Natural Language Question-Answer Pairs from a Knowledge Graph Using a RNN Based Question Generation Model</i> Sathish Reddy, Dinesh Raghu, Mitesh M. Khapra and Sachindra Joshi .....	375
<i>Enumeration of Extractive Oracle Summaries</i> Tsutomu Hirao, Masaaki Nishino, Jun Suzuki and Masaaki Nagata .....	385
<i>Neural Semantic Encoders</i> Tsendsuren Munkhdalai and Hong Yu .....	396
<i>Efficient Benchmarking of NLP APIs using Multi-armed Bandits</i> Gholamreza Haffari, Tuan Dung Tran and Mark Carman .....	407
<i>Character-Word LSTM Language Models</i> Lyan Verwimp, Joris Pelemans, Hugo Van hamme and Patrick Wambacq .....	416
<i>A Hierarchical Neural Model for Learning Sequences of Dialogue Acts</i> Quan Hung Tran, Ingrid Zukerman and Gholamreza Haffari .....	427
<i>A Network-based End-to-End Trainable Task-oriented Dialogue System</i> Tsung-Hsien Wen, David Vandyke, Nikola Mrkšić, Milica Gasic, Lina M. Rojas Barahona, Pei-Hao Su, Stefan Ultes and Steve Young .....	437
<i>May I take your order? A Neural Model for Extracting Structured Information from Conversations</i> Baolin Peng, Michael Seltzer, Y.C. Ju, Geoffrey Zweig and Kam-Fai Wong .....	449
<i>A Two-stage Sieve Approach for Quote Attribution</i> Grace Muzny, Michael Fang, Angel Chang and Dan Jurafsky .....	459
<i>Out-of-domain FrameNet Semantic Role Labeling</i> Silvana Hartmann, Ilia Kuznetsov, Teresa Martin and Iryna Gurevych .....	470
<i>TDParse: Multi-target-specific sentiment recognition on Twitter</i> Bo Wang, Maria Liakata, Arkaitz Zubiaga and Rob Procter .....	482
<i>Annotating Derivations: A New Evaluation Strategy and Dataset for Algebra Word Problems</i> Shyam Upadhyay and Ming-Wei Chang .....	493
<i>An Extensive Empirical Evaluation of Character-Based Morphological Tagging for 14 Languages</i> Georg Heigold, Guenter Neumann and Josef van Genabith .....	504
<i>Neural Multi-Source Morphological Reinflection</i> Katharina Kann, Ryan Cotterell and Hinrich Schütze .....	513
<i>Online Automatic Post-editing for MT in a Multi-Domain Translation Environment</i> Rajen Chatterjee, Gebremedhen Gebremelak, Matteo Negri and Marco Turchi .....	524
<i>An Incremental Parser for Abstract Meaning Representation</i> Marco Damonte, Shay B. Cohen and Giorgio Satta .....	535

<i>Integrated Learning of Dialog Strategies and Semantic Parsing</i>	
Aishwarya Padmakumar, Jesse Thomason and Raymond J. Mooney .....	546
<i>Unsupervised AMR-Dependency Parse Alignment</i>	
Wei-Te Chen and Martha Palmer .....	557
<i>Improving Chinese Semantic Role Labeling using High-quality Surface and Deep Case Frames</i>	
Gongye Jin, Daisuke Kawahara and Sadao Kurohashi .....	567
<i>Multi-level Representations for Fine-Grained Typing of Knowledge Base Entities</i>	
Yadollah Yaghoobzadeh and Hinrich Schütze .....	577
<i>The ContrastMedium Algorithm: Taxonomy Induction From Noisy Knowledge Graphs With Just A Few Links</i>	
Stefano Faralli, Alexander Panchenko, Chris Biemann and Simone Paolo Ponzetto .....	589
<i>Probabilistic Inference for Cold Start Knowledge Base Population with Prior World Knowledge</i>	
Bonan Min, Marjorie Freedman and Talya Meltzer .....	600
<i>Generalizing to Unseen Entities and Entity Pairs with Row-less Universal Schema</i>	
Patrick Verga, Arvind Neelakantan and Andrew McCallum .....	612
<i>Learning to Generate Product Reviews from Attributes</i>	
Li Dong, Shaohan Huang, Furu Wei, Mirella Lapata, Ming Zhou and Ke Xu .....	622
<i>Learning to generate one-sentence biographies from Wikidata</i>	
Andrew Chisholm, Will Radford and Ben Hachey .....	632
<i>Transition-Based Deep Input Linearization</i>	
Ratish Puduppully, Yue Zhang and Manish Shrivastava .....	642
<i>Generating flexible proper name references in text: Data, models and evaluation</i>	
Thiago Castro Ferreira, Emiel Krahmer and Sander Wubben .....	654
<i>Dependency Parsing as Head Selection</i>	
Xingxing Zhang, Jianpeng Cheng and Mirella Lapata .....	664
<i>Tackling Error Propagation through Reinforcement Learning: A Case of Greedy Dependency Parsing</i>	
Minh Le and Antske Fokkens .....	676
<i>Noisy-context surprisal as a human sentence processing cost model</i>	
Richard Futrell and Roger Levy .....	687
<i>Task-Specific Attentive Pooling of Phrase Alignments Contributes to Sentence Matching</i>	
Wenpeng Yin and Hinrich Schütze .....	698
<i>On-demand Injection of Lexical Knowledge for Recognising Textual Entailment</i>	
Pascual Martínez-Gómez, Koji Mineshima, Yusuke Miyao and Daisuke Bekki .....	709
<i>Learning to Predict Denotational Probabilities For Modeling Entailment</i>	
Alice Lai and Julia Hockenmaier .....	720
<i>A Societal Sentiment Analysis: Predicting the Values and Ethics of Individuals by Analysing Social Media Content</i>	
Tushar Maheshwari, Aishwarya N. Reganti, Samiksha Gupta, Anupam Jamatia, Upendra Kumar, Björn Gambäck and Amitava Das .....	730

<i>Argument Strength is in the Eye of the Beholder: Audience Effects in Persuasion</i> Stephanie Lukin, Pranav Anand, Marilyn Walker and Steve Whittaker .....	741
<i>A Language-independent and Compositional Model for Personality Trait Recognition from Short Texts</i> Fei Liu, Julien Perez and Scott Nowson .....	753
<i>A Strong Baseline for Learning Cross-Lingual Word Embeddings from Sentence Alignments</i> Omer Levy, Anders Søgaard and Yoav Goldberg .....	764
<i>Online Learning of Task-specific Word Representations with a Joint Biconvex Passive-Aggressive Algorithm</i> Pascal Denis and Liva Ralaivola .....	774
<i>Nonsymbolic Text Representation</i> Hinrich Schütze .....	784
<i>Fine-Grained Entity Type Classification by Jointly Learning Representations and Label Embeddings</i> Abhishek Abhishek, Ashish Anand and Amit Awekar .....	796
<i>Event extraction from Twitter using Non-Parametric Bayesian Mixture Model with Word Embeddings</i> Deyu Zhou, Xuan Zhang and Yulan He .....	807
<i>End-to-end Relation Extraction using Neural Networks and Markov Logic Networks</i> Sachin Pawar, Pushpak Bhattacharyya and Girish Palshikar .....	817
<i>Trust, but Verify! Better Entity Linking through Automatic Verification</i> Benjamin Heinzerling, Michael Strube and Chin-Yew Lin .....	827
<i>Named Entity Recognition in the Medical Domain with Constrained CRF Models</i> Charles Jochim and Lea Deleris .....	838
<i>Learning and Knowledge Transfer with Memory Networks for Machine Comprehension</i> Mohit Yadav, Lovekesh Vig and Gautam Shroff .....	849
<i>If No Media Were Allowed inside the Venue, Was Anybody Allowed?</i> Zahra Sarabi and Eduardo Blanco .....	859
<i>Metaheuristic Approaches to Lexical Substitution and Simplification</i> Sallam Abualhaija, Tristan Miller, Judith Eckle-Kohler, Iryna Gurevych and Karl-Heinz Zimmermann .....	869
<i>Paraphrasing Revisited with Neural Machine Translation</i> Jonathan Mallinson, Rico Sennrich and Mirella Lapata .....	880
<i>Multilingual Training of Crosslingual Word Embeddings</i> Long Duong, Hiroshi Kanayama, Tengfei Ma, Steven Bird and Trevor Cohn .....	893
<i>Building Lexical Vector Representations from Concept Definitions</i> Danilo Silva de Carvalho and Minh Le Nguyen .....	904
<i>ShotgunWSD: An unsupervised algorithm for global word sense disambiguation inspired by DNA sequencing</i> Andrei Butnaru, Radu Tudor Ionescu and Florentina Hristea .....	915
<i>LanideNN: Multilingual Language Identification on Text Stream</i> Tom Kocmi and Ondřej Bojar .....	926

<i>Cross-Lingual Word Embeddings for Low-Resource Language Modeling</i> Oliver Adams, Adam Makarucha, Graham Neubig, Steven Bird and Trevor Cohn .....	936
<i>Consistent Translation of Repeated Nouns using Syntactic and Semantic Cues</i> Xiao Pu, Laura Mascarell and Andrei Popescu-Belis .....	947
<i>Psycholinguistic Models of Sentence Processing Improve Sentence Readability Ranking</i> David M. Howcroft and Vera Demberg .....	957
<i>Web-Scale Language-Independent Cataloging of Noisy Product Listings for E-Commerce</i> Pradipto Das, Yandi Xia, Aaron Levine, Giuseppe Di Fabbri and Ankur Datta .....	968
<i>Recognizing Insufficiently Supported Arguments in Argumentative Essays</i> Christian Stab and Iryna Gurevych .....	979
<i>Distributed Document and Phrase Co-embeddings for Descriptive Clustering</i> Motoki Sato, Austin J. Brockmeier, Georgios Kononatsios, Tingting Mu, John Y. Goulermas, Jun'ichi Tsujii and Sophia Ananiadou .....	990
<i>SMARTies: Sentiment Models for Arabic Target entities</i> Noura Farra and Kathy McKeown .....	1001
<i>Exploring Convolutional Neural Networks for Sentiment Analysis of Spanish tweets</i> Isabel Segura-Bedmar, Antonio Quiros and Paloma Martínez .....	1013
<i>Contextual Bidirectional Long Short-Term Memory Recurrent Neural Network Language Models: A Generative Approach to Sentiment Analysis</i> Amr Mousa and Björn Schuller .....	1022
<i>Large-scale Opinion Relation Extraction with Distantly Supervised Neural Network</i> Changzhi Sun, Yuanbin Wu, Man Lan, Shiliang Sun and Qi Zhang .....	1032
<i>Decoding with Finite-State Transducers on GPUs</i> Arturo Argueta and David Chiang .....	1043
<i>Learning to Translate in Real-time with Neural Machine Translation</i> Jiatao Gu, Graham Neubig, Kyunghyun Cho and Victor O.K. Li .....	1052
<i>A Multifaceted Evaluation of Neural versus Phrase-Based Machine Translation for 9 Language Direc- tions</i> Antonio Toral and Víctor M. Sánchez-Cartagena .....	1062
<i>Personalized Machine Translation: Preserving Original Author Traits</i> Ella Rabinovich, Raj Nath Patel, Shachar Mirkin, Lucia Specia and Shuly Wintner .....	1073
<i>Bilingual Lexicon Induction by Learning to Combine Word-Level and Character-Level Representations</i> Geert Heyman, Ivan Vulić and Marie-Francine Moens .....	1084
<i>Grouping business news stories based on salience of named entities</i> Llorenc Escoter, Lidia Pivovarova, Mian Du, Anisia Katinskaia and Roman Yangarber .....	1095
<i>Very Deep Convolutional Networks for Text Classification</i> Alexis Conneau, Holger Schwenk, Loïc Barrault and Yann Lecun .....	1106
<i>"PageRank" for Argument Relevance</i> Henning Wachsmuth, Benno Stein and Yamen Ajjour .....	1116

<i>Predicting Counselor Behaviors in Motivational Interviewing Encounters</i> Verónica Pérez-Rosas, Rada Mihalcea, Kenneth Resnicow, Satinder Singh, Lawrence Ann, Kathy J. Goggin and Delwyn Catley .....	1127
<i>Authorship Attribution Using Text Distortion</i> Efsthathios Stamatatos .....	1137
<i>Structured Learning for Temporal Relation Extraction from Clinical Records</i> Artuur Leeuwenberg and Marie-Francine Moens .....	1149
<i>Entity Extraction in Biomedical Corpora: An Approach to Evaluate Word Embedding Features with PSO based Feature Selection</i> Shweta Yadav, Asif Ekbal, Sriparna Saha and Pushpak Bhattacharyya .....	1158
<i>Distant Supervision for Relation Extraction beyond the Sentence Boundary</i> Chris Quirk and Hoifung Poon .....	1170
<i>Noise Mitigation for Neural Entity Typing and Relation Extraction</i> Yadollah Yaghoobzadeh, Heike Adel and Hinrich Schütze .....	1182
<i>Analyzing Semantic Change in Japanese Loanwords</i> Hiroya Takamura, Ryo Nagata and Yoshifumi Kawasaki .....	1194
<i>Using support vector machines and state-of-the-art algorithms for phonetic alignment to identify cognates in multi-lingual wordlists</i> Gerhard Jäger, Johann-Mattis List and Pavel Sofroniev .....	1204
<i>A Multi-task Approach to Predict Likability of Books</i> Suraj Maharjan, John Arevalo, Manuel Montes, Fabio A. González and Thamar Solorio .....	1216
<i>A Data-Oriented Model of Literary Language</i> Andreas van Cranenburgh and Rens Bod .....	1227
<i>Aye or naw, whit dae ye hink? Scottish independence and linguistic identity on social media</i> Philippa Shoemark, Debnil Sur, Luke Shrimpton, Iain Murray and Sharon Goldwater .....	1238
<i>What Do Recurrent Neural Network Grammars Learn About Syntax?</i> Adhiguna Kuncoro, Miguel Ballesteros, Lingpeng Kong, Chris Dyer, Graham Neubig and Noah A. Smith .....	1248
<i>Incremental Discontinuous Phrase Structure Parsing with the GAP Transition</i> Maximin Coavoux and Benoit Crabbé .....	1258
<i>Neural Architectures for Fine-grained Entity Type Classification</i> Sonse Shimaoka, Pontus Stenetorp, Kentaro Inui and Sebastian Riedel .....	1270

# Conference Program

Wednesday, April 5, 2017

9:30–10:50 *Invited talk: David Blei*

10:50–11:20 *Coffee break*

## Session 1A: Machine Learning

11:20–11:40 *Gated End-to-End Memory Networks*  
Fei Liu and Julien Perez

11:40–12:00 *Neural Tree Indexers for Text Understanding*  
Tsendsuren Munkhdalai and Hong Yu

12:00–12:20 *Exploring Different Dimensions of Attention for Uncertainty Detection*  
Heike Adel and Hinrich Schütze

12:20–12:40 *Classifying Illegal Activities on Tor Network Based on Web Textual Contents*  
Mhd Wesam Al Nabki, Eduardo Fidalgo, Enrique Alegre and Ivan de Paz

12:40–13:00 *When is multitask learning effective? Semantic sequence prediction under varying data conditions*  
Héctor Martínez Alonso and Barbara Plank

Wednesday, April 5, 2017 (continued)

**Session 1B: Lexical Semantics**

- 11:20–11:40 *Learning Compositionality Functions on Word Embeddings for Modelling Attribute Meaning in Adjective-Noun Phrases*  
Matthias Hartung, Fabian Kaupmann, Soufian Jebbara and Philipp Cimiano
- 11:40–12:00 *Hypernyms under Siege: Linguistically-motivated Artillery for Hypernymy Detection*  
Vered Shwartz, Enrico Santus and Dominik Schlechtweg
- 12:00–12:20 *Distinguishing Antonyms and Synonyms in a Pattern-based Neural Network*  
Kim Anh Nguyen, Sabine Schulte im Walde and Ngoc Thang Vu
- 12:20–12:40 *Unsupervised Does Not Mean Uninterpretable: The Case for Word Sense Induction and Disambiguation*  
Alexander Panchenko, Eugen Ruppert, Stefano Faralli, Simone Paolo Ponzetto and Chris Biemann
- 12:40–13:00 *Word Sense Disambiguation: A Unified Evaluation Framework and Empirical Comparison*  
Alessandro Raganato, Jose Camacho-Collados and Roberto Navigli

**Session 1C: Information Retrieval and Information Extraction**

- 11:20–11:40 *Which is the Effective Way for Gaokao: Information Retrieval or Neural Networks?*  
Shangmin Guo, Xiangrong Zeng, Shizhu He, Kang Liu and Jun Zhao
- 11:40–12:00 *If You Can't Beat Them Join Them: Handcrafted Features Complement Neural Nets for Non-Factoid Answer Reranking*  
Dasha Bogdanova, Jennifer Foster, Daria Dziedzic and Qun Liu
- 12:00–12:20 *Chains of Reasoning over Entities, Relations, and Text using Recurrent Neural Networks*  
Rajarshi Das, Arvind Neelakantan, David Belanger and Andrew McCallum
- 12:20–12:40 *Recognizing Mentions of Adverse Drug Reaction in Social Media Using Knowledge-Infused Recurrent Models*  
Gabriel Stanovsky, Daniel Gruhl and Pablo Mendes
- 12:40–13:00 *Multitask Learning for Mental Health Conditions with Limited Social Media Data*  
Adrian Benton, Margaret Mitchell and Dirk Hovy

Wednesday, April 5, 2017 (continued)

**Session 1D: Evaluation**

- 11:20–11:40 *Evaluation by Association: A Systematic Study of Quantitative Word Association Evaluation*  
Ivan Vulić, Douwe Kiela and Anna Korhonen
- 11:40–12:00 *Computational Argumentation Quality Assessment in Natural Language*  
Henning Wachsmuth, Nona Naderi, Yufang Hou, Yonatan Bilu, Vinodkumar Prabhakaran, Tim Alberdingk Thijm, Graeme Hirst and Benno Stein
- 12:00–12:20 *A method for in-depth comparative evaluation: How (dis)similar are outputs of pos taggers, dependency parsers and coreference resolvers really?*  
Don Tuggener
- 12:20–12:40 *Re-evaluating Automatic Metrics for Image Captioning*  
Mert Kilickaya, Aykut Erdem, Nazli Ikizler-Cinbis and Erkut Erdem
- 12:40–13:00 *Integrating Meaning into Quality Evaluation of Machine Translation*  
Osman Baskaya, Eray Yildiz, Doruk Tunaoglu, Mustafa Tolga Eren and A. Seza Dogruoz

**13:00–14:30** *Lunch*

**Session 2A: Parsing 1**

- 14:30–14:50 *Cross-Lingual Dependency Parsing with Late Decoding for Truly Low-Resource Languages*  
Michael Schlichtkrull and Anders Søgaard
- 14:50–15:10 *Parsing Universal Dependencies without training*  
Héctor Martínez Alonso, Željko Agić, Barbara Plank and Anders Søgaard
- 15:10–15:30 *Delexicalized Word Embeddings for Cross-lingual Dependency Parsing*  
Mathieu Dehouck and Pascal Denis

**Wednesday, April 5, 2017 (continued)**

**Session 2B: Social Media 1**

- 14:30–14:50 *Stance Classification of Context-Dependent Claims*  
Roy Bar-Haim, Indrajit Bhattacharya, Francesco Dinuzzo, Amrita Saha and Noam Slonim
- 14:50–15:10 *Exploring the Impact of Pragmatic Phenomena on Irony Detection in Tweets: A Multilingual Corpus Study*  
Jihen Karoui, Benamara Farah, Véronique Moriceau, Viviana Patti, Cristina Bosco and Nathalie Aussenac-Gilles
- 15:10–15:30 *A Multi-View Sentiment Corpus*  
Debora Nozza, Elisabetta Fersini and Enza Messina

**Session 2C: Discourse and Dialogue**

- 14:30–14:50 *A Systematic Study of Neural Discourse Models for Implicit Discourse Relation*  
Attapol Rutherford, Vera Demberg and Nianwen Xue
- 14:50–15:10 *Cross-lingual RST Discourse Parsing*  
Chloé Braud, Maximin Coavoux and Anders Søgaard
- 15:10–15:30 *Dialog state tracking, a machine reading approach using Memory Network*  
Julien Perez and Fei Liu

**Session 2D: Segmentation**

- 14:30–14:50 *Sentence Segmentation in Narrative Transcripts from Neuropsychological Tests using Recurrent Convolutional Neural Networks*  
Marcos Treviso, Christopher Shulby and Sandra Aluísio
- 14:50–15:10 *Joint, Incremental Disfluency Detection and Utterance Segmentation from Speech*  
Julian Hough and David Schlangen
- 15:10–15:30 *From Segmentation to Analyses: a Probabilistic Model for Unsupervised Morphology Induction*  
Toms Bergmanis and Sharon Goldwater
- 15:30–16:00** *Coffee break*

Wednesday, April 5, 2017 (continued)

16:00–17:15 *Session 3A: Syntax and Machine Learning (See Vol.2, SP)*

16:00–17:30 *Session 3B: Generation, Summarisation, and QA (See Vol.2, SP)*

16:00–17:30 *Session 3C: Semantics (See Vol.2, SP)*

16:00–17:15 *Session 3D: Morphology and Psycholinguistics (See Vol.2, SP)*

17:30–19:30 *Long Posters 1*

### Long Posters 1

*Creating POS Tagging and Dependency Parsing Experts via Topic Modeling*  
Atreyee Mukherjee, Sandra Kübler and Matthias Scheutz

*Universal Dependencies and Morphology for Hungarian - and on the Price of Universality*  
Veronika Vincze, Katalin Simkó, Zsolt Szántó and Richárd Farkas

*Addressing the Data Sparsity Issue in Neural AMR Parsing*  
Xiaochang Peng, Chuan Wang, Daniel Gildea and Nianwen Xue

*Generating Natural Language Question-Answer Pairs from a Knowledge Graph Using a RNN Based Question Generation Model*  
Sathish Reddy, Dinesh Raghu, Mitesh M. Khapra and Sachindra Joshi

*Enumeration of Extractive Oracle Summaries*  
Tsutomu Hirao, Masaaki Nishino, Jun Suzuki and Masaaki Nagata

*Neural Semantic Encoders*  
Tsendsuren Munkhdalai and Hong Yu

*Efficient Benchmarking of NLP APIs using Multi-armed Bandits*  
Gholamreza Haffari, Tuan Dung Tran and Mark Carman

**Wednesday, April 5, 2017 (continued)**

*Character-Word LSTM Language Models*

Lyan Verwimp, Joris Pelemans, Hugo Van hamme and Patrick Wambacq

*A Hierarchical Neural Model for Learning Sequences of Dialogue Acts*

Quan Hung Tran, Ingrid Zukerman and Gholamreza Haffari

*A Network-based End-to-End Trainable Task-oriented Dialogue System*

Tsung-Hsien Wen, David Vandyke, Nikola Mrkšić, Milica Gasic, Lina M. Rojas Barahona, Pei-Hao Su, Stefan Ultes and Steve Young

*May I take your order? A Neural Model for Extracting Structured Information from Conversations*

Baolin Peng, Michael Seltzer, Y.C. Ju, Geoffrey Zweig and Kam-Fai Wong

*A Two-stage Sieve Approach for Quote Attribution*

Grace Muzny, Michael Fang, Angel Chang and Dan Jurafsky

*Out-of-domain FrameNet Semantic Role Labeling*

Silvana Hartmann, Iliia Kuznetsov, Teresa Martin and Iryna Gurevych

*TDParse: Multi-target-specific sentiment recognition on Twitter*

Bo Wang, Maria Liakata, Arkaitz Zubiaga and Rob Procter

*Annotating Derivations: A New Evaluation Strategy and Dataset for Algebra Word Problems*

Shyam Upadhyay and Ming-Wei Chang

*An Extensive Empirical Evaluation of Character-Based Morphological Tagging for 14 Languages*

Georg Heigold, Guenter Neumann and Josef van Genabith

*Neural Multi-Source Morphological Reinflection*

Katharina Kann, Ryan Cotterell and Hinrich Schütze

*Online Automatic Post-editing for MT in a Multi-Domain Translation Environment*

Rajen Chatterjee, Gebremedhen Gebremelak, Matteo Negri and Marco Turchi

**17:30–19:30** *Short Posters 1 (See Vol.2, SP)*

**17.30–19.30** *Student Research Workshop (See Vol.4, SRW)*

**Wednesday, April 5, 2017 (continued)**

**17:30–19:30** *Demos (See Vol.3, Demos)*

**Thursday, April 6, 2017**

**9:30–10:50** *Invited talk: Devi Parikh*

**10:50–11:20** *Coffee break*

**Session 4A: TACL**

11:20–11:40 *Encoding Prior Knowledge with Eigenword Embeddings*  
Dominique Osborne, Shashi Narayan and Shay B. Cohen

11:40–12:00 *Shift-Reduce Constituent Parsing with Neural Lookahead Features*  
Jiangming Liu and Yue Zhang

12:00–12:20 *Assessing the Ability of LSTMs to Learn Syntax-Sensitive Dependencies*  
Tal Linzen, Emmanuel Dupoux, Yoav Goldberg

12:20–12:40 *Automatically Tagging Constructions of Causation and Their Slot-Fillers*  
Jesse Dunietz, Lori Levin, Jaime Carbonell

**Session 4B: Semantic Analysis**

11:20–11:40 *An Incremental Parser for Abstract Meaning Representation*  
Marco Damonte, Shay B. Cohen and Giorgio Satta

11:40–12:00 *Integrated Learning of Dialog Strategies and Semantic Parsing*  
Aishwarya Padmakumar, Jesse Thomason and Raymond J. Mooney

12:00–12:20 *Unsupervised AMR-Dependency Parse Alignment*  
Wei-Te Chen and Martha Palmer

12:20–12:40 *Improving Chinese Semantic Role Labeling using High-quality Surface and Deep Case Frames*  
Gongye Jin, Daisuke Kawahara and Sadao Kurohashi

**Thursday, April 6, 2017 (continued)**

**Session 4C: Knowledge Bases**

- 11:20–11:40 *Multi-level Representations for Fine-Grained Typing of Knowledge Base Entities*  
Yadollah Yaghoobzadeh and Hinrich Schütze
- 11:40–12:00 *The ContrastMedium Algorithm: Taxonomy Induction From Noisy Knowledge Graphs With Just A Few Links*  
Stefano Faralli, Alexander Panchenko, Chris Biemann and Simone Paolo Ponzetto
- 12:00–12:20 *Probabilistic Inference for Cold Start Knowledge Base Population with Prior World Knowledge*  
Bonan Min, Marjorie Freedman and Talya Meltzer
- 12:20–12:40 *Generalizing to Unseen Entities and Entity Pairs with Row-less Universal Schema*  
Patrick Verga, Arvind Neelakantan and Andrew McCallum

**Session 4D: Generation**

- 11:20–11:40 *Learning to Generate Product Reviews from Attributes*  
Li Dong, Shaohan Huang, Furu Wei, Mirella Lapata, Ming Zhou and Ke Xu
- 11:40–12:00 *Learning to generate one-sentence biographies from Wikidata*  
Andrew Chisholm, Will Radford and Ben Hachey
- 12:00–12:20 *Transition-Based Deep Input Linearization*  
Ratish Puduppully, Yue Zhang and Manish Shrivastava
- 12:20–12:40 *Generating flexible proper name references in text: Data, models and evaluation*  
Thiago Castro Ferreira, Emiel Kraemer and Sander Wubben

**13:00–14:30** *Lunch*

**Thursday, April 6, 2017 (continued)**

**Session 5A: Parsing 2 and Psycholinguistics**

- 14:30–14:50 *Dependency Parsing as Head Selection*  
Xingxing Zhang, Jianpeng Cheng and Mirella Lapata
- 14:50–15:10 *Tackling Error Propagation through Reinforcement Learning: A Case of Greedy Dependency Parsing*  
Minh Le and Antske Fokkens
- 15:10–15:30 *Noisy-context surprisal as a human sentence processing cost model*  
Richard Futrell and Roger Levy

**Session 5B: Entailment**

- 14:30–14:50 *Task-Specific Attentive Pooling of Phrase Alignments Contributes to Sentence Matching*  
Wenpeng Yin and Hinrich Schütze
- 14:50–15:10 *On-demand Injection of Lexical Knowledge for Recognising Textual Entailment*  
Pascual Martínez-Gómez, Koji Mineshima, Yusuke Miyao and Daisuke Bekki
- 15:10–15:30 *Learning to Predict Denotational Probabilities For Modeling Entailment*  
Alice Lai and Julia Hockenmaier

**Session 5C: Social Media 2**

- 14:30–14:50 *A Societal Sentiment Analysis: Predicting the Values and Ethics of Individuals by Analysing Social Media Content*  
Tushar Maheshwari, Aishwarya N. Reganti, Samiksha Gupta, Anupam Jamatia, Upendra Kumar, Björn Gambäck and Amitava Das
- 14:50–15:10 *Argument Strength is in the Eye of the Beholder: Audience Effects in Persuasion*  
Stephanie Lukin, Pranav Anand, Marilyn Walker and Steve Whittaker
- 15:10–15:30 *A Language-independent and Compositional Model for Personality Trait Recognition from Short Texts*  
Fei Liu, Julien Perez and Scott Nowson

**Thursday, April 6, 2017 (continued)**

**Session 5D: Word Representations**

14:30–14:50 *A Strong Baseline for Learning Cross-Lingual Word Embeddings from Sentence Alignments*  
Omer Levy, Anders Søgaard and Yoav Goldberg

14:50–15:10 *Online Learning of Task-specific Word Representations with a Joint Biconvex Passive-Aggressive Algorithm*  
Pascal Denis and Liva Ralaivola

15:10–15:30 *Nonsymbolic Text Representation*  
Hinrich Schütze

**16:00–17:30** *Session 6A: Machine Translation (See Vol.2, SP)*

**16:00–17:30** *Session 6B: Word Embeddings (See Vol.2, SP)*

**16:00–17:30** *Session 6C: Document Analysis (See Vol.2, SP)*

**16:00–17:15** *Session 6D: Dialogue (See Vol.2, SP)*

**17:30–19:30** *Long Posters 2*

Thursday, April 6, 2017 (continued)

## Long Posters 2

*Fine-Grained Entity Type Classification by Jointly Learning Representations and Label Embeddings*

Abhishek Abhishek, Ashish Anand and Amit Awekar

*Event extraction from Twitter using Non-Parametric Bayesian Mixture Model with Word Embeddings*

Deyu Zhou, Xuan Zhang and Yulan He

*End-to-end Relation Extraction using Neural Networks and Markov Logic Networks*

Sachin Pawar, Pushpak Bhattacharyya and Girish Palshikar

*Trust, but Verify! Better Entity Linking through Automatic Verification*

Benjamin Heinzerling, Michael Strube and Chin-Yew Lin

*Named Entity Recognition in the Medical Domain with Constrained CRF Models*

Charles Jochim and Lea Deleris

*Learning and Knowledge Transfer with Memory Networks for Machine Comprehension*

Mohit Yadav, Lovekesh Vig and Gautam Shroff

*If No Media Were Allowed inside the Venue, Was Anybody Allowed?*

Zahra Sarabi and Eduardo Blanco

*Metaheuristic Approaches to Lexical Substitution and Simplification*

Sallam Abualhaija, Tristan Miller, Judith Eckle-Kohler, Iryna Gurevych and Karl-Heinz Zimmermann

*Paraphrasing Revisited with Neural Machine Translation*

Jonathan Mallinson, Rico Sennrich and Mirella Lapata

*Multilingual Training of Crosslingual Word Embeddings*

Long Duong, Hiroshi Kanayama, Tengfei Ma, Steven Bird and Trevor Cohn

*Building Lexical Vector Representations from Concept Definitions*

Danilo Silva de Carvalho and Minh Le Nguyen

*ShotgunWSD: An unsupervised algorithm for global word sense disambiguation inspired by DNA sequencing*

Andrei Butnaru, Radu Tudor Ionescu and Florentina Hristea

**Thursday, April 6, 2017 (continued)**

*LanideNN: Multilingual Language Identification on Text Stream*

## Abstract

Machine reading using differentiable reasoning models has recently shown remarkable progress. In this context, End-to-End trainable Memory Networks (MemN2N) have demonstrated promising performance on simple natural language based reasoning tasks such as factual reasoning and basic deduction. However, other tasks, namely multi-fact question-answering, positional reasoning or dialog related tasks, remain challenging particularly due to the necessity of more complex interactions between the memory and controller modules composing this family of models. In this paper, we introduce a novel end-to-end memory access regulation mechanism inspired by the current progress on the connection short-cutting principle in the field of computer vision. Concretely, we develop a Gated End-to-End trainable Memory Network architecture (GMemN2N). From the machine learning perspective, this new capability is learned in an end-to-end fashion without the use of any additional supervision signal which is, as far as our knowledge goes, the first of its kind. Our experiments show significant improvements on the most challenging tasks in the 20 bAbI dataset, without the use of any domain knowledge. Then, we show improvements on the Dialog bAbI tasks including the real human-bot conversation-based Dialog State Tracking Challenge (DSTC-2) dataset. On these two datasets, our model sets the new state of the art.

† Equal contribution

## 1 Introduction

Deeper Neural Network models are more difficult to train and recurrency tends to complicate this optimization problem (Srivastava et al., 2015b). While Deep Neural Network architectures have shown superior performance in numerous areas, such as image, speech recognition and more recently text, the complexity of optimizing such large and non-convex parameter sets remains a challenge. Indeed, the so-called vanishing/exploding gradient problem has been mainly addressed using: 1. algorithmic responses, e.g., normalized initialization strategies (LeCun et al., 1998; Glorot and Bengio, 2010); 2. architectural ones, e.g., intermediate normalization layers which facilitate the convergence of networks composed of tens of hidden layers (He et al., 2015; Saxe et al., 2014). Another problem of memory-enhanced neural models is the necessity of regulating memory access at the controller level. Memory access operations can be supervised (Kumar et al., 2016) and the number of times they are performed tends to be fixed apriori (Sukhbaatar et al., 2015), a design choice which tends to be based on the presumed degree of difficulty of the task in question. Inspired by the recent success of object recognition in the field of computer vision (Srivastava et al., 2015a; Srivastava et al., 2015b), we investigate the use of a *gating* mechanism in the context of End-to-End Memory Networks (MemN2N) (Sukhbaatar et al., 2015) in order to regulate the access to the memory blocks in a differentiable fashion. The formulation is realized by gated connections between the memory access layers and the controller stack of a MemN2N. As a result, the model is able to dynamically determine how and when to skip its memory-based reasoning process.

**Roadmap:** Section 2 reviews state-of-the-art Memory Network models, connection short-

cutting in neural networks and memory dynamics. In Section 3, we propose a differentiable gating mechanism in MemN2N. Section 4 and 5 present a set of experiments on the 20 bAbI reasoning tasks and the Dialog bAbI dataset. We report new state-of-the-art results on several of the most challenging tasks of the set, namely positional reasoning, 3-argument relation and the DSTC-2 task while maintaining equally competitive performance on the rest.

## 2 Related Work

This section starts with an introduction of the primary components of MemN2N. Then, we review two key elements relevant to this work, namely shortcut connections in neural networks and memory dynamics in such models.

### 2.1 End-to-End Memory Networks

The MemN2N architecture, introduced by Sukhbaatar et al. (2015), consists of two main components: supporting memories and final answer prediction. Supporting memories are in turn comprised of a set of input and output memory representations with memory cells. The input and output memory cells, denoted by  $\mathbf{m}_i$  and  $\mathbf{c}_i$ , are obtained by transforming the input context  $x_1, \dots, x_n$  (or stories) using two embedding matrices  $\mathbf{A}$  and  $\mathbf{C}$  (both of size  $d \times |V|$  where  $d$  is the embedding size and  $|V|$  the vocabulary size) such that  $\mathbf{m}_i = \mathbf{A}\Phi(x_i)$  and  $\mathbf{c}_i = \mathbf{C}\Phi(x_i)$  where  $\Phi(\cdot)$  is a function that maps the input into a bag of dimension  $|V|$ . Similarly, the question  $q$  is encoded using another embedding matrix  $\mathbf{B} \in \mathbb{R}^{d \times |V|}$ , resulting in a question embedding  $\mathbf{u} = \mathbf{B}\Phi(q)$ . The input memories  $\{\mathbf{m}_i\}$ , together with the embedding of the question  $\mathbf{u}$ , are utilized to determine the relevance of each of the stories in the context, yielding a vector of attention weights

$$p_i = \text{softmax}(\mathbf{u}^\top \mathbf{m}_i) \quad (1)$$

where  $\text{softmax}(a_i) = \frac{e^{a_i}}{\sum_j e^{a_j}}$ . Subsequently, the response  $\mathbf{o}$  from the output memory is constructed by the weighted sum:

$$\mathbf{o} = \sum_i p_i \mathbf{c}_i \quad (2)$$

For more difficult tasks demanding multiple supporting memories, the model can be extended

to include more than one set of input/output memories by stacking a number of memory layers. In this setting, each memory layer is named a hop and the  $(k+1)$ <sup>th</sup> hop takes as input the output of the  $k$ <sup>th</sup> hop:

$$\mathbf{u}^{k+1} = \mathbf{o}^k + \mathbf{u}^k \quad (3)$$

Lastly, the final step, the prediction of the answer to the question  $q$ , is performed by

$$\hat{\mathbf{a}} = \text{softmax}(\mathbf{W}(\mathbf{o}^K + \mathbf{u}^K)) \quad (4)$$

where  $\hat{\mathbf{a}}$  is the predicted answer distribution,  $\mathbf{W} \in \mathbb{R}^{|V| \times d}$  is a parameter matrix for the model to learn and  $K$  the total number of hops.

### 2.2 Shortcut Connections

Shortcut connections have been studied from both the theoretical and practical point of view in the general context of neural network architectures (Bishop, 1995; Ripley, 2007). More recently Residual Networks (He et al., 2016) and Highway Networks (Srivastava et al., 2015a; Srivastava et al., 2015b) have been almost simultaneously proposed. While the former utilizes a residual calculus, the latter formulates a differentiable gateway mechanism as proposed in Long-Short Terms Memory Networks (Hochreiter and Schmidhuber, 1997) in order to cope with long-term dependency issues in the dataset in an end-to-end trainable manner. These two mechanisms were proposed as a structural solution to the so-called vanishing gradient problem by allowing the model to shortcut its layered transformation structure when necessary.

### 2.3 Memory Dynamics

The necessity of dynamically regulating the interaction between the so-called controller and the memory blocks of a Memory Network model has been studied in (Kumar et al., 2016; Xiong et al., 2016). In these works, the number of exchanges between the controller stack and the memory module of the network is either monitored in a hard supervised manner in the former or fixed a priori in the latter.

In this paper, we propose an end-to-end supervised model, with an automatically learned gating mechanism, to perform dynamic regulation of memory interaction. The next section presents the formulation of this new Gated End-to-End Memory Networks (GMemN2N). This contribution can be placed in parallel to the recent transition from Memory Networks with hard attention mechanism

(Weston et al., 2015) to MemN2N with attention values obtained by a softmax function and end-to-end supervised (Sukhbaatar et al., 2015).

### 3 Gated End-to-End Memory Network

In this section, the elements behind residual learning and highway neural models are given. Then, we introduce the proposed model of memory access gating in a MemN2N.

#### 3.1 Highway and Residual Networks

Highway Networks, first introduced by Srivastava et al. (2015a), include a transform gate T and a carry gate C, allowing the network to learn how much information it should transform or carry to form the input to the next layer. Suppose the original network is a plain feed-forward neural network:

$$\mathbf{y} = \mathbf{H}(\mathbf{x}) \quad (5)$$

where  $\mathbf{H}(\mathbf{x})$  is a non-linear transformation of its input  $\mathbf{x}$ . The generic form of Highway Networks is formulated as:

$$\mathbf{y} = \mathbf{H}(\mathbf{x}) \odot \mathbf{T}(\mathbf{x}) + \mathbf{x} \odot \mathbf{C}(\mathbf{x}) \quad (6)$$

where the transform and carry gates,  $\mathbf{T}(\mathbf{x})$  and  $\mathbf{C}(\mathbf{x})$ , are defined as non-linear transformation functions of the input  $\mathbf{x}$  and  $\odot$  the Hadamard product. As suggested in (Srivastava et al., 2015a; Srivastava et al., 2015b), we choose to focus, in the following of this paper, on a simplified version of Highway Networks where the carry gate is replaced by  $\mathbf{1} - \mathbf{T}(\mathbf{x})$ :

$$\mathbf{y} = \mathbf{H}(\mathbf{x}) \odot \mathbf{T}(\mathbf{x}) + \mathbf{x} \odot (\mathbf{1} - \mathbf{T}(\mathbf{x})) \quad (7)$$

where  $\mathbf{T}(\mathbf{x}) = \sigma(\mathbf{W}_T \mathbf{x} + \mathbf{b}_T)$  and  $\sigma$  is the sigmoid function. In fact, Residual Networks can be viewed as a special case of Highway Networks where both the transform and carry gates are substituted by the identity mapping function:

$$\mathbf{y} = \mathbf{H}(\mathbf{x}) + \mathbf{x} \quad (8)$$

thereby forming a hard-wired shortcut connection  $\mathbf{x}$ .

#### 3.2 Gated End-to-End Memory Networks

Arguably, Equation (3) can be considered as a form of residuality with  $\mathbf{o}^k$  working as the residual function and  $\mathbf{u}^k$  the shortcut connection. However, as discussed in (Srivastava et al., 2015b),

in contrast to the hard-wired skip connection in Residual Networks, one of the advantages of Highway Networks is the adaptive gating mechanism, capable of learning to dynamically control the information flow based on the current input. Therefore, we adopt the idea of the adaptive gating mechanism of Highway Networks and integrate it into MemN2N. The resulting model, named *Gated End-to-End Memory Networks* (GMemN2N) and illustrated in Figure 1, is capable of dynamically conditioning the memory reading operation on the controller state  $\mathbf{u}^k$  at each hop. Concretely, we reformulate Equation (3) into:

$$\mathbf{T}^k(\mathbf{u}^k) = \sigma(\mathbf{W}_T^k \mathbf{u}^k + \mathbf{b}_T^k) \quad (9)$$

$$\mathbf{u}^{k+1} = \mathbf{o}^k \odot \mathbf{T}^k(\mathbf{u}^k) + \mathbf{u}^k \odot (\mathbf{1} - \mathbf{T}^k(\mathbf{u}^k)) \quad (10)$$

where  $\mathbf{W}_T^k$  and  $\mathbf{b}_T^k$  are the hop-specific parameter matrix and bias term for the  $k^{\text{th}}$  hop and  $\mathbf{T}^k(x)$  the transform gate for the  $k^{\text{th}}$  hop. Similar to the two weight tying schemes of the embedding matrices introduced in (Sukhbaatar et al., 2015), we also explore two types of constraints on  $\mathbf{W}_T^k$  and  $\mathbf{b}_T^k$ :

1. **Global:** all the weight matrices  $\mathbf{W}_T^k$  and bias terms  $\mathbf{b}_T^k$  are shared across different hops, i.e.,  $\mathbf{W}_T^1 = \mathbf{W}_T^2 = \dots = \mathbf{W}_T^K$  and  $\mathbf{b}_T^1 = \mathbf{b}_T^2 = \dots = \mathbf{b}_T^K$ .
2. **Hop-specific:** each hop has its specific weight matrix  $\mathbf{W}_T^k$  and bias term  $\mathbf{b}_T^k$  for  $k \in [1, K]$  and they are optimized independently.

## 4 QA bAbI Experiments

In this section, we first describe the natural language reasoning dataset we use in our experiments. Then, the experimental setup is detailed. Lastly, we present the results and analyses.

### 4.1 Dataset and Data Preprocessing

The 20 bAbI tasks (Weston et al., 2016) have been employed for the experiments (using v1.2 of the dataset). In this synthetically generated dataset, a given QA task consists of a set of statements, followed by a question whose answer is typically a single word (in a few tasks, answers are a set of words). The answer is available to the model at training time but must be predicted at test time. The dataset consists of 20 different tasks with various emphases on different forms of reasoning. For each question, only a certain subset of the statements contains information needed for the answer, and the rest are essentially irrelevant distractors.

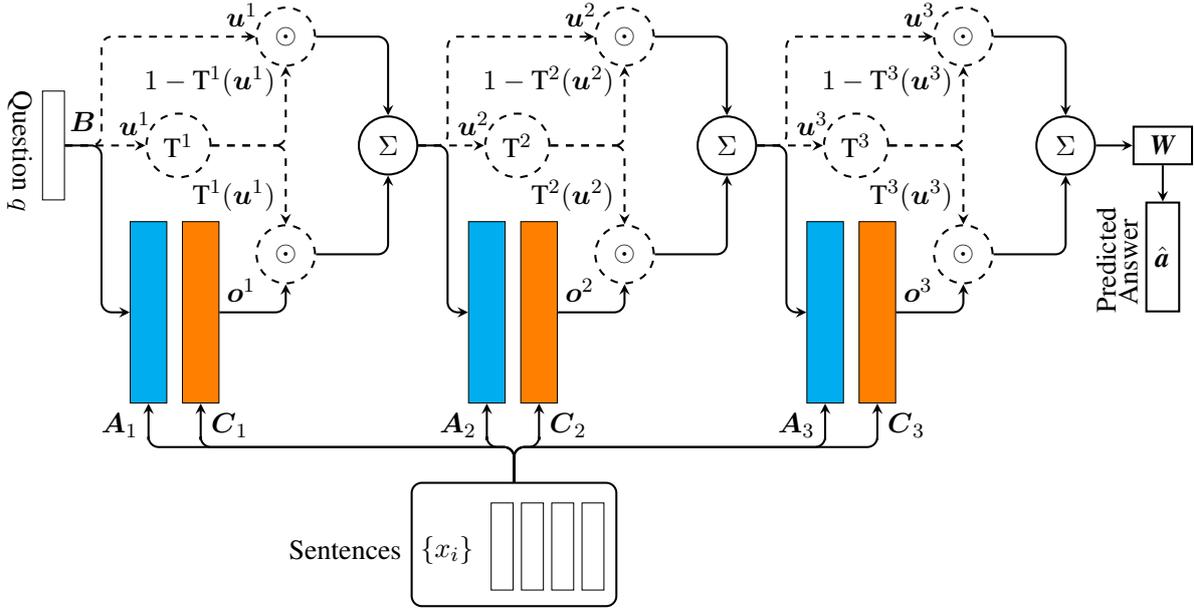

Figure 1: Illustration of the proposed GMemN2N model with 3 hops. Dashed lines indicate elements different from MemN2N (Sukhbaatar et al., 2015).

As in (Sukhbaatar et al., 2015), our model is fully end-to-end trained without any additional supervision other than the answers themselves. Formally, for one of the 20 QA tasks, we are given example problems, each having a set of  $I$  sentences  $\{x_i\}$  (where  $I \leq 320$ ), a question sentence  $q$  and answer  $a$ . Let the  $j^{\text{th}}$  word of sentence  $i$  be  $x_{ij}$ , represented by a one-hot vector of length  $|V|$ . The same representation is used for the question  $q$  and answer  $a$ . Two versions of the data are used, one that has 1,000 training problems per task and the other with 10,000 per task.

## 4.2 Training Details

As suggested in (Sukhbaatar et al., 2015), 10% of the bAbI training set was held-out to form a validation set for hyperparameter tuning. Moreover, we use the so-called position encoding, adjacent weight tying, and temporal encoding with 10% random noise. Stochastic gradient descent is used for training and the learning rate  $\eta$  is initially assigned a value of 0.005 with exponential decay applied every 25 epochs by  $\eta/2$  until 100 epochs are reached. Linear start is used in all our experiments as proposed by Sukhbaatar et al. (2015). With linear start, the softmax in each memory layer is removed and re-inserted after 20 epochs. Batch size is set to 32 and gradients with an  $\ell_2$  norm larger than 40 are divided by a scalar to have norm 40. All weights are initialized randomly from a Gaus-

sian distribution with zero mean and  $\sigma = 0.1$  except for the transform gate bias  $b_T^k$  which we empirically set the mean to 0.5. Only the most recent 50 sentences are fed into the model as the memory and the number of memory hops is 3. In all our experiments, we use the embedding size  $d = 20$ . Note that we re-use the same hyperparameter configuration as in (Sukhbaatar et al., 2015) and no grid search is performed.

As a large variance in the performance of the model can be observed on some tasks, we follow (Sukhbaatar et al., 2015) and repeat each training 100 times with different random initializations and select the best system based on the validation performance. On the 10k dataset, we repeat each training 30 times due to time constraints. Concerning the model implementation, while there are minor differences between the results of our implementation of MemN2N and those reported in (Sukhbaatar et al., 2015), the overall performance is equally competitive and, in some cases, better. It should be noted that v1.1 of the dataset was used whereas in this work, we employ the latest v1.2. It is therefore deemed necessary that we present the performance results of our implementation of MemN2N on the v1.2 dataset. To facilitate fair comparison, we select our implementation of MemN2N as the baseline as we believe that it is indicative of the true performance of MemN2N on v1.2 of the dataset.

Table 1: Accuracy (%) on the 20 QA tasks for models using 1k and 10k training examples. MemN2N:(Sukhbaatar et al., 2015). Our MemN2N: our implementation of MemN2N. GMemN2N +global: GMemN2N with global weight tying. GMemN2N +hop: GMemN2N with hop-specific weight tying. **Bold** highlights best performance. Note that in (Sukhbaatar et al., 2015), v1.1 of the dataset was used.

### 4.3 Results

Performance results on the 20 bAbI QA dataset are presented in Table 1. For comparison purposes, we still present MemN2N (Sukhbaatar et al., 2015) in Table 1 but accompany it with the accuracy obtained by our implementation of the same model with the same experimental setup on v1.2 of the dataset in the column “Our MemN2N” for both the 1k and 10k versions of the dataset. In contrast, we also list the results achieved by GMemN2N with global and hop-specific weight constraints in the GMemN2N columns.

**GMemN2N achieves substantial improvements on task 5 and 17.** The performance of GMemN2N is greatly improved, a substantial gain of more than 10 in absolute accuracy.

**Global vs. hop-specific weight tying.** Compared with the global weight tying scheme on the weight matrices of the gating mechanism, applying weight constraints in a hop-specific fashion

generates a further boost in performance consistently on both the 1k and 10k datasets.

**State-of-the-art performance on both the 1k and 10k dataset.** The best performing GMemN2N model achieves state-of-the-art performance, an average accuracy of 87.3 on the 1k dataset and 96.3 on the 10k variant. This is a solid improvement compared to MemN2N and a step closer to the strongly supervised models described in (Weston et al., 2015). Notice that the highest average accuracy of the original MemN2N model on the 10k dataset is 95.8. However, it was attained by a model with layer-wise weight tying, not adjacent weight tying as adopted in this work, and, more importantly, a much larger embedding size  $d = 100$  (therefore not shown in Table 1). In comparison, it is worth noting that the proposed GMemN2N model, a much smaller model with embeddings of size 20, is capable of achieving better accuracy.

## 5 Dialog bAbI Experiments

In addition to the text understanding and reasoning tasks presented in Section 4, we further examine the effectiveness of the proposed GMemN2N model on a collection of goal-oriented dialog tasks (Bordes and Weston, 2016). First, we briefly describe the dataset. Next, we outline the training details. Finally, experimental results are presented with analyses.

### 5.1 Dataset and Data Preprocessing

In this work, we adopt the goal-oriented dialog dataset developed by Bordes and Weston (2016) organized as a set of tasks. The tasks in this dataset can be divided into 6 categories with each group focusing on a specific objective: 1. issuing API calls, 2. updating API calls, 3. displaying options, 4. providing extra-information, 5. conducting full dialogs (the aggregation of the first 4 tasks), 6. Dialog State Tracking Challenge 2 corpus (DSTC-2). The first 5 tasks are synthetically generated based on a knowledge base consisting of facts which define all the restaurants and their associated properties (7 types, such as location and price range). The generated texts are in the form of conversation between a user and a bot, each of which is designed with a clear yet different objective (all involved in a restaurant reservation scenario). This dataset essentially tests the capacity of end-to-end dialog systems to conduct dialog with various goals. Each dialog starts with a user request with subsequent alternating user-bot utterances and it is the duty of a model to understand the intention of the user and respond accordingly. In order to test the capability of a system to cope with entities not appearing in the training set, a different set of test sets, named out-of-vocabulary (OOV) test sets, are constructed separately. In addition, a supplementary dataset, task 6, is provided with real human-bot conversations, also in the restaurant domain, which is derived from the second Dialog State Tracking Challenge (Henderson et al., 2014). It is important to notice that the answers in this dataset may no longer be a single word but can be comprised of multiple ones.

### 5.2 Training Details

At a certain given time  $t$ , a memory-based model takes the sequence of utterances  $c_1^u, c_1^r, c_2^u, c_2^r, \dots, c_{t-1}^u, c_{t-1}^r$  (alternating between the user  $c_i^u$  and the system response  $c_i^r$ ) as

the stories and  $c_t^u$  as the question. The goal of the model is to predict the response  $c_t^r$ .

As answers may be composed of multiple words, following (Bordes and Weston, 2016), we replace the final prediction step in Equation (4) with:

$$\hat{a} = \text{softmax}(\mathbf{u}^\top \mathbf{W}' \Phi(\mathbf{y}_1), \dots, \mathbf{u}^\top \mathbf{W}' \Phi(\mathbf{y}_{|C|}))$$

where  $\mathbf{W}' \in \mathbb{R}^{d \times |V|}$  is the weight parameter matrix for the model to learn,  $\mathbf{u} = \mathbf{o}^K + \mathbf{u}^K$  ( $K$  is the total number of hops),  $\mathbf{y}_i$  is the  $i^{\text{th}}$  response in the candidate set  $C$  such that  $\mathbf{y}_i \in C$ ,  $|C|$  the size of the candidate set, and  $\Phi(\cdot)$  a function which maps the input text into a bag of dimension  $|V|$ .

As in (Bordes and Weston, 2016), we extend  $\Phi$  by several key additional features. First, two features marking the identity of the speaker of a particular utterance (user or model) are added to each of the memory slots. Second, we expand the feature representation function  $\Phi$  of candidate responses with 7 additional features, each, focusing on one of the 7 properties associated with any restaurants, indicating whether there are any exact matches between words occurring in the candidate and those in the question or memory. These 7 features are referred to as the *match* features.

Apart from the modifications described above, we carry out the experiments using the same experimental setup described in Section 4.2. We also constrain ourselves to the hop-specific weight tying scheme in all our experiments since GMemN2N benefits more from it than global weight tying as shown in Section 4.3. As in (Sukhbaatar et al., 2015), since the memory-based models are sensitive to parameter initialization, we repeat each training 10 times and choose the best system based on the performance on the validation set.

### 5.3 Results

Performance results on the Dialog bAbI dataset are shown in Table 2, measured using both per-response accuracy and per-dialog accuracy (given in parentheses). While per-response accuracy calculates the percentage of correct responses, per-dialog accuracy, where a dialog is considered to be correct if and only if every response within it is correct, counts the percentage of correct dialogs. Task 1-5 are presented in the upper half of the table while the same tasks in the OOV setting are in the lower half with the dialog state tracking task as task 6 at the bottom. We

Table 2: Per-response accuracy and per-dialog accuracy (in parentheses) on the `Dialog bAbI` tasks. MemN2N: (Bordes and Weston, 2016). +match indicates the use of the match features in Section 5.2.

choose (Bordes and Weston, 2016) as the baseline which achieves the current state of the art on these tasks.

**GMemN2N with the match features sets a new state of the art on most of the tasks.** Other than on task T2 (OOV) and T3 (OOV), GMemN2N with the match features scores the best per-response and per-dialog accuracy. Even on T2 (OOV) and T3 (OOV), the model generates rather competitive results and remains within 0.3% of the best performance. Overall, the best average per-response accuracy in both the OOV and non-OOV categories is attained by GMemN2N.

**GMemN2N with the match features significantly improves per-dialog accuracy on T5.** A breakthrough in per-dialog accuracy on T5 from less than 20% to over 70%.

**GMemN2N succeeds in improving the performance on the more practical task T6.** With or without the match features, GMemN2N achieves a substantial boost in per-response accuracy on T6. Given that T6 is derived from a dataset based on real human-bot conversations, not synthetically generated, the performance gain, although far from perfect, highlights the effectiveness of GMemN2N in practical scenarios and constitutes an encouraging starting point towards end-to-end dialog system learning.

**The effectiveness of GMemN2N is more pronounced on the more challenging tasks.** The

performance gains on T5, T5 (OOV) and T6, compared with the rest of the tasks, are more pronounced. Regarding the performance of MemN2N, these tasks are relatively more challenging than the rest, suggesting that the adaptive gating mechanism in GMemN2N is capable of managing complex information flow while doing little damage on easier tasks.

## 6 Visualization and Analysis

In addition to the quantitative results, we further look into the memory regulation mechanism learned by the GMemN2N model. Figure 2 presents the three most frequently observed patterns of the  $T^k(\mathbf{u}^k)$  vectors for each of the 3 hops in a model trained on T6 of the `Dialog bAbI` dataset with an embedding dimension of 20. Each row corresponds to the gate values at a specific hop whereas each column represents a given embedding dimension. The pattern on the top indicates that the model tends to only access memory in the first and third hop. In contrast, the middle and bottom patterns only focus on the memory in either the first or last hop respectively. Figure 3 is a t-SNE projection (Maaten and Hinton, 2008) of the flattened  $[T^1(\mathbf{u}^1); T^2(\mathbf{u}^2); T^3(\mathbf{u}^3)]$  vectors obtained on the test set of the same dialog task with points corresponding to the correct and incorrect responses in red and blue respectively. Despite the relative uniform distribution of the wrong answer points, the correct ones tend to form clusters that suggest the frequently observed behavior of a successful

Story	Support	MemN2N			GMemN2N		
		Hop 1	Hop 2	Hop 3	Hop 1	Hop 2	Hop 3
Fred took the football there.	yes	0.05	0.10	0.07	0.06	0.00	0.00

Question: Who gave the football? Answer: Fred, MemN2N: <b>Mary</b> , GMemN2N: Fred							

Table 3: MemN2N vs. GMemN2N- bAbI dataset - Task 5 - 3 argument relations

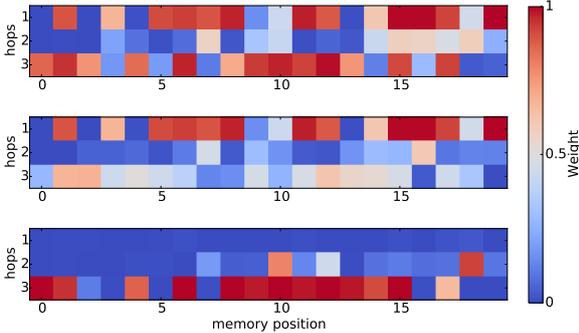

Figure 2: 3 most frequently observed gate value  $T^k(\mathbf{u}^k)$  patterns on T6 of the Dialog bAbI dataset

inference. Lastly, Table 3 shows the comparison of the attention shifting process between MemN2N and GMemN2N on a story on bAbI task 5 (3 argument relations). Not only does GMemN2N manage to focus more accurately on the supporting fact than MemN2N, it has also learned to rely less in this case on hop 1 and 2 by assigning smaller transform gate values. In contrast, MemN2N carries false and misleading information (caused by the distracting attention mechanism) accumulated from the previous hops, which eventually led to the wrong prediction of the answer.

## 7 Related Reading Tasks

Apart from the datasets adopted in our experiments, the CNN/Daily Mail (Hermann et al., 2015) has been used for the task of machine reading formalized as a problem of text extraction from a source conditioned on a given question. However, as pointed out in (Chen et al., 2016), this dataset not only is noisy but also requires little reasoning and inference, which is evidenced by a manual analysis of a randomly selected subset of the questions, showing that only 2% of the examples call for multi-sentence inference. Richard-

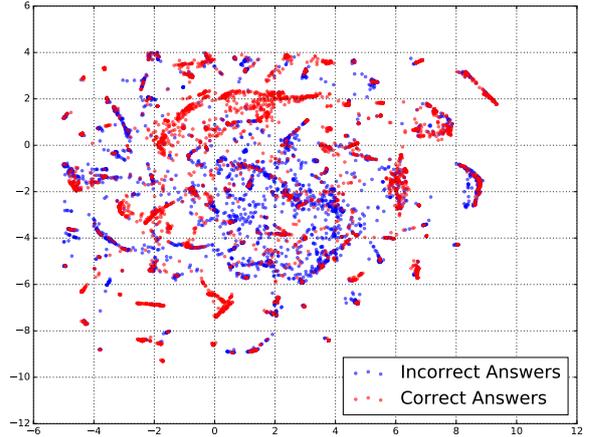

Figure 3: t-SNE scatter plot of the flattened gate values

son et al. (2013) constructed an open-domain reading comprehension task, named MCTest. Although this corpus demands various degrees of reasoning capabilities from multiple sentences, its rather limited size (660 paragraphs, each associated with 4 questions) renders training statistical models infeasible (Chen et al., 2016). Children’s Book Test (CBT) (Hill et al., 2015) was designed to measure the ability of models to exploit a wide range of linguistic context. Despite the claim in (Sukhbaatar et al., 2015) that increasing the number of hops is crucial for the performance improvements on some tasks, which can be seen as enabling MemN2N to accommodate more supporting facts, making such performance boost particularly more pronounced on those tasks requiring complex reasoning, Hill et al. (2015) admittedly reported little improvement in performance by stacking more hops and chose a single-hop MemN2N. This suggests that the necessity of multi-sentence based reasoning in this dataset is not mandatory. In the future, we plan to investigate into larger dialog datasets such as (Lowe et al., 2015).

## 8 Conclusion and Future Work

In this paper, we have proposed and developed what is, as far as our knowledge goes, the first attempt at incorporating an iterative memory access control to an end-to-end trainable memory-enhanced neural network architecture. We showed the added value of our proposition on a set of, natural language based, state-of-the-art reasoning tasks. Then, we offered a first interpretation of the resulting capability by analyzing the attention shifting mechanism and connection short-cutting behavior of the proposed model. In future work, we will investigate the use of such mechanism in the field of language modeling and more generally on the paradigm of sequential prediction and predictive learning. Furthermore, we plan to look into the impact of this method on the recently introduced Key-Value Memory Networks (Miller et al., 2016) on larger and semi-structured corpus.

# Neural Tree Indexers for Text Understanding

Tsendsuren Munkhdalai and Hong Yu

University of Massachusetts, MA, USA

{tsendsuren.munkhdalai, hong.yu}@umassmed.edu

## Abstract

Recurrent neural networks (RNNs) process input text sequentially and model the conditional transition between word tokens. In contrast, the advantages of recursive networks include that they explicitly model the compositionality and the recursive structure of natural language. However, the current recursive architecture is limited by its dependence on syntactic tree. In this paper, we introduce a robust syntactic parsing-independent tree structured model, Neural Tree Indexers (NTI) that provides a middle ground between the sequential RNNs and the syntactic tree-based recursive models. NTI constructs a *full n-ary tree* by processing the input text with its node function in a bottom-up fashion. Attention mechanism can then be applied to both structure and node function. We implemented and evaluated a binary-tree model of NTI, showing the model achieved the state-of-the-art performance on three different NLP tasks: natural language inference, answer sentence selection, and sentence classification, outperforming state-of-the-art recurrent and recursive neural networks<sup>1</sup>.

## 1 Introduction

Recurrent neural networks (RNNs) have been successful for modeling sequence data (Elman, 1990). RNNs equipped with gated hidden units and internal short-term memories, such as long short-term memories (LSTM) (Hochreiter and Schmidhuber, 1997) have achieved a notable success in

<sup>1</sup>Code for the experiments and NTI is available at <https://bitbucket.org/tsendeemts/nti>

several NLP tasks including named entity recognition (Lample et al., 2016), constituency parsing (Vinyals et al., 2015), textual entailment recognition (Rocktäschel et al., 2016), question answering (Hermann et al., 2015), and machine translation (Bahdanau et al., 2015). However, most LSTM models explored so far are sequential. It encodes text sequentially from left to right or vice versa and do not naturally support compositionality of language. Sequential LSTM models seem to learn syntactic structure from the natural language however their generalization on unseen text is relatively poor comparing with models that exploit syntactic tree structure (Bowman et al., 2015b).

Unlike sequential models, recursive neural networks compose word phrases over syntactic tree structure and have shown improved performance in sentiment analysis (Socher et al., 2013). However its dependence on a syntactic tree architecture limits practical NLP applications. In this study, we introduce Neural Tree Indexers (NTI), a class of tree structured models for NLP tasks. NTI takes a sequence of tokens and produces its representation by constructing a *full n-ary tree* in a bottom-up fashion. Each node in NTI is associated with one of the node transformation functions: leaf node mapping and non-leaf node composition functions. Unlike previous recursive models, the tree structure for NTI is relaxed, i.e., NTI does not require the input sequences to be parsed syntactically; and therefore it is flexible and can be directly applied to a wide range of NLP tasks beyond sentence modeling.

Furthermore, we propose different variants of node composition function and attention over tree for our NTI models. When a sequential leaf node transformer such as LSTM is chosen, the NTI network forms a sequence-tree hybrid model taking advantage of both conditional and compositional powers of sequential and recursive models. Figure

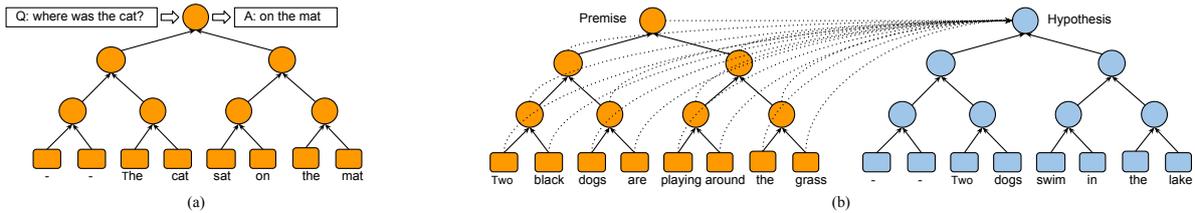

Figure 1: A binary tree form of Neural Tree Indexers (NTI) in the context of question answering and natural language inference. We insert empty tokens (denoted by  $-$ ) to the input text to form a full binary tree. (a) NTI produces answer representation at the root node. This representation along with the question is used to find the answer. (b) NTI learns representations for the premise and hypothesis sentences and then attentively combines them for classification. Dotted lines indicate attention over premise-indexed tree.

1 shows a binary-tree model of NTI. Although the model does not follow the syntactic tree structure, we empirically show that it achieved the state-of-the-art performance on three different NLP applications: natural language inference, answer sentence selection, and sentence classification.

## 2 Related Work

### 2.1 Recurrent Neural Networks and Attention Mechanism

RNNs model input text sequentially by taking a single token at each time step and producing a corresponding hidden state. The hidden state is then passed along through the next time step to provide historical sequence information. Although a great success in a variety of tasks, RNNs have limitations (Bengio et al., 1994; Hochreiter, 1998). Among them, it is not efficient at memorizing long or distant sequence (Sutskever et al., 2014). This is frequently called as information flow bottleneck. Approaches have therefore been developed to overcome the limitations. For example, to mitigate the information flow bottleneck, Bahdanau et al. (2015) extended RNNs with a soft attention mechanism in the context of neural machine translation, leading to improved the results in translating longer sentences.

RNNs are linear chain-structured; this limits its potential for natural language which can be represented by complex structures including syntactic structure. In this study, we propose models to mitigate this limitation.

### 2.2 Recursive Neural Networks

Unlike RNNs, recursive neural networks explicitly model the compositionality and the recursive structure of natural language over tree. The

tree structure can be predefined by a syntactic parser (Socher et al., 2013). Each non-leaf tree node is associated with a node composition function which combines its children nodes and produces its own representation. The model is then trained by back-propagating error through structures (Goller and Kuchler, 1996).

The node composition function can be varied. A single layer network with  $\tanh$  non-linearity was adopted in recursive auto-associate memories (Pollack, 1990) and recursive autoencoders (Socher et al., 2011). Socher et al. (2012) extended this network with an additional matrix representation for each node to augment the expressive power of the model. Tensor networks have also been used as composition function for sentence-level sentiment analysis task (Socher et al., 2013). Recently, Zhu et al. (2015) introduced S-LSTM which extends LSTM units to compose tree nodes in a recursive fashion.

In this paper, we introduce a novel attentive node composition function that is based on S-LSTM. Our NTI model does not rely on either a parser output or a fine-grained supervision of non-leaf nodes, both required in previous work. In NTI, the supervision from the target labels is provided at the root node. As such, our NTI model is robust and applicable to a wide range of NLP tasks. We introduce attention over tree in NTI to overcome the vanishing/explode gradients challenges as shown in RNNs.

## 3 Methods

Our training set consists of  $N$  examples  $\{X^i, Y^i\}_{i=1}^N$ , where the input  $X^i$  is a sequence of word tokens  $w_1^i, w_2^i, \dots, w_{T_i}^i$  and the output  $Y^i$  can be either a single target or a sequence. Each

input word token  $w_t$  is represented by its word embedding  $x_t \in R^k$ .

NTI is a *full n-ary tree* (and the sub-trees can be overlapped). It has two types of transformation function: non-leaf node function  $f^{node}(h^1, \dots, h^c)$  and leaf node function  $f^{leaf}(x_t)$ .  $f^{leaf}(x_t)$  computes a (possibly non-linear) transformation of the input word embedding  $x_t$ .  $f^{node}(h^1, \dots, h^c)$  is a function of its child nodes representation  $h^1, \dots, h^c$ , where  $c$  is the total number of child nodes of this non-leaf node.

NTI can be implemented with different tree structures. In this study we implemented and evaluated a binary tree form of NTI: a non-leaf node can take in only two direct child nodes (i.e.,  $c = 2$ ). Therefore, the function  $f^{node}(h^l, h^r)$  composes its left child node  $h^l$  and right child node  $h^r$ . Figure 1 illustrates our NTI model that is applied to question answering (a) and natural language inference tasks (b). Note that the node and leaf node functions are neural networks and are the only training parameters in NTI.

We explored two different approaches to compose node representations: an extended LSTM and attentive node composition functions, to be described below.

### 3.1 Non-Leaf Node Composition Functions

We define two different methods for non-leaf node function  $f^{node}(h^l, h^r)$ .

**LSTM-based Non-leaf Node Function (S-LSTM):** We initiate  $f^{node}(h^l, h^r)$  with LSTM. For non-leaf node, we adopt S-LSTM Zhu et al. (2015), an extension of LSTM to tree structures, to learn a node representation by its children nodes. Let  $h_t^l, h_t^r, c_t^l$  and  $c_t^r$  be vector representations and cell states for the left and right children. An S-LSTM computes a parent node representation  $h_{t+1}^p$  and a node cell state  $c_{t+1}^p$  as

$$i_{t+1} = \sigma(W_1^s h_t^l + W_2^s h_t^r + W_3^s c_t^l + W_4^s c_t^r) \quad (1)$$

$$f_{t+1}^l = \sigma(W_5^s h_t^l + W_6^s h_t^r + W_7^s c_t^l + W_8^s c_t^r) \quad (2)$$

$$f_{t+1}^r = \sigma(W_9^s h_t^l + W_{10}^s h_t^r + W_{11}^s c_t^l + W_{12}^s c_t^r) \quad (3)$$

$$c_{t+1}^p = f_{t+1}^l \odot c_t^l + f_{t+1}^r \odot c_t^r + i_{t+1} \odot \tanh(W_{13}^s h_t^l + W_{14}^s h_t^r) \quad (4)$$

$$o_{t+1} = \sigma(W_{15}^s h_t^l + W_{16}^s h_t^r + W_{18}^s c_{t+1}^p) \quad (5)$$

$$h_{t+1}^p = o_{t+1} \odot \tanh(c_{t+1}^p) \quad (6)$$

where  $W_1^s, \dots, W_{18}^s \in R^{k \times k}$  and biases (for brevity we eliminated the bias terms) are the training parameters.  $\sigma$  and  $\odot$  denote the element-wise *sigmoid* function and the element-wise vector multiplication. Extension of S-LSTM non-leaf node function to compose more children is straightforward. However, the number of parameters increases quadratically in S-LSTM as we add more child nodes.

**Attentive Non-leaf Node Function (ANF):** Some NLP applications (e.g., QA and machine translation) would benefit from a dynamic query dependent composition function. We introduce ANF as a new non-leaf node function. Unlike S-LSTM, ANF composes the child nodes attentively in respect to another relevant input vector  $q \in R^k$ . The input vector  $q$  can be a learnable representation from a sequence representation. Given a matrix  $S^{ANF} \in R^{k \times 2}$  resulted by concatenating the child node representations  $h_t^l, h_t^r$  and the third input vector  $q$ , ANF is defined as

$$m = f^{score}(S^{ANF}, q) \quad (7)$$

$$\alpha = softmax(m) \quad (8)$$

$$z = S^{ANF} \alpha^\top \quad (9)$$

$$h_{t+1}^p = ReLU(W_1^{ANF} z) \quad (10)$$

where  $W_1^{ANF} \in R^{k \times k}$  is a learnable matrix,  $m \in R^2$  the attention score and  $\alpha \in R^2$  the attention weight vector for each child.  $f^{score}$  is an attention scoring function, which can be implemented as a multi-layer perceptron (MLP)

$$m = w^\top ReLU(W_1^{score} S^{ANF} + W_2^{score} q \otimes e) \quad (11)$$

or a matrix-vector product  $m = q^\top S^{ANF}$ . The matrices  $W_1^{score}$  and  $W_2^{score} \in R^{k \times k}$  and the vector  $w \in R^k$  are training parameters.  $e \in R^2$  is a vector of ones and  $\otimes$  the outer product. We use *ReLU* function for non-linear transformation.

### 3.2 Attention Over Tree

Comparing with sequential LSTM models, NTI has less recurrence, which is defined by the tree depth,  $\log(n)$  for binary tree where  $n$  is the length of the input sequence. However, NTI still needs to compress all the input information into a single representation vector of the root. This imposes practical difficulties when processing long sequences. We address this issue with attention

Model	$d$	$ \theta _M$	Train	Test

Table 1: Training and test accuracy on natural language inference task.  $d$  is the word embedding size and  $|\theta|_M$  the number of model parameters.

mechanism over tree. In addition, the attention mechanism can be used for matching trees (described in Section 4 as Tree matching NTI) that carry different sequence information. We first define a global attention and then introduce a tree attention which considers the parent-child dependency for calculation of the attention weights.

**Global Attention:** An attention neural network for the global attention takes all node representations as input and produces an attentively blended vector for the whole tree. This neural net is similar to ANF. Particularly, given a matrix  $S^{GA} \in R^{k \times 2n-1}$  resulted by concatenating the node representations  $h_1, \dots, h_{2n-1}$  and the relevant input representation  $q$ , the global attention is defined as

$$m = f^{score}(S^{GA}, q) \quad (12)$$

$$\alpha = softmax(m) \quad (13)$$

$$z = S^{GA} \alpha^\top \quad (14)$$

$$h^{tree} = ReLU(W_1^{GA} z + W_2^{GA} q) \quad (15)$$

where  $W_1^{GA}$  and  $W_2^{GA} \in R^{k \times k}$  are training parameters and  $\alpha \in R^{2n-1}$  the attention weight vector for each node. This attention mechanism is robust as it globally normalizes the attention score  $m$  with  $softmax$  to obtain the weights  $\alpha$ . However, it does not consider the tree structure when producing the final representation  $h^{tree}$ .

**Tree Attention:** We modify the global attention network to the tree attention mechanism. The resulting tree attention network performs almost the same computation as ANF for each node. It

compares the parent and children nodes to produce a new representation assuming that all node representations are constructed. Given a matrix  $S^{TA} \in R^{k \times 3}$  resulted by concatenating the parent node representation  $h_t^p$ , the left child  $h_t^l$  and the right child  $h_t^r$  and the relevant input representation  $q$ , every non-leaf node  $h_t^p$  simply updates its own representation by using the following equation in a bottom-up manner.

$$m = f^{score}(S^{TA}, q) \quad (16)$$

$$\alpha = softmax(m) \quad (17)$$

$$z = S^{TA} \alpha^\top \quad (18)$$

$$h_t^p = ReLU(W_1^{TA} z) \quad (19)$$

and this equation is similarity to the global attention. However, now each non-leaf node attentively collects its own and children representations and passes towards the root which finally constructs the attentively blended tree representation. Note that unlike the global attention, the tree attention locally normalizes the attention scores with  $softmax$ .

## 4 Experiments

We describe in this section experiments on three different NLP tasks, natural language inference, question answering and sentence classification to demonstrate the flexibility and the effectiveness of NTI in the different settings.

We trained NTI using Adam (Kingma and Ba, 2014) with hyperparameters selected on development set. The pre-trained 300-D Glove 840B vectors (Pennington et al., 2014) were obtained for the word embeddings<sup>2</sup>. The word embeddings are fixed during training. The embeddings for out-of-vocabulary words were set to zero vector. We pad the input sequence to form a *full binary tree*. A padding vector was inserted when padding. We analyzed the effects of the padding size and found out that it has no influence on the performance (see Appendix 5.3). The size of hidden units of the NTI modules were set to 300. The models were regularized by using dropouts and an  $l_2$  weight decay.<sup>3</sup>

#### 4.1 Natural Language Inference

We conducted experiments on the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015a), which consists of 549,367/9,842/9,824 premise-hypothesis pairs for train/dev/test sets and target label indicating their relation. Unless otherwise noted, we follow the setting in the previous work (Mou et al., 2016; Bowman et al., 2016) and use an MLP for classification which takes in NTI outputs and computes the concatenation  $[h_{2n-1}^p; h_{2n-1}^h]$ , absolute difference  $h_{2n-1}^p - h_{2n-1}^h$  and elementwise product  $h_{2n-1}^p \cdot h_{2n-1}^h$  of the two sentence representations. The MLP has also an input layer with 1024 units with *ReLU* activation and a *softmax* output layer. We explored nine different task-oriented NTI models with varying complexity, to be described below. For each model, we set the batch size to 32. The initial learning, the regularization strength and the number of epoch to be trained are varied for each model.

**NTI-SLSTM:** this model does not rely on  $f^{leaf}$  transformer but uses the S-LSTM units for the non-leaf node function. We set the initial learning rate to 1e-3 and  $l_2$  regularizer strength to 3e-5, and train the model for 90 epochs. The neural net was regularized by 10% input dropouts and the 20% output dropouts.

**NTI-SLSTM-LSTM:** we use LSTM for the leaf node function  $f^{leaf}$ . Concretely, the LSTM output vectors are given to NTI-SLSTM and the memory cells of the lowest level S-LSTM were initialized with the LSTM memory states. The hyper-parameters are the same as the previous

model.

**NTI-SLSTM node-by-node global attention:** This model learns inter-sentence relation with the global attention over premise-indexed tree, which is similar to word-by-word attention model of Rocktäschel et al. (2016) in that it attends over the premise tree nodes at every time step of hypothesis encoding. We tie the weight parameters of the two NTI-SLSTMs for premise and hypothesis and no  $f^{leaf}$  transformer used. We set the initial learning rate to 3e-4 and  $l_2$  regularizer strength to 1e-5, and train the model for 40 epochs. The neural net was regularized by 15% input dropouts and the 15% output dropouts.

**NTI-SLSTM node-by-node tree attention:** this is a variation of the previous model with the tree attention. The hyper-parameters are the same as the previous model.

**NTI-SLSTM-LSTM node-by-node global attention:** in this model we include LSTM as the leaf node function  $f^{leaf}$ . Here we initialize the memory cell of S-LSTM with LSTM memory and hidden/memory state of hypothesis LSTM with premise LSTM (the later follows the work of (Rocktäschel et al., 2016)). We set the initial learning rate to 3e-4 and  $l_2$  regularizer strength to 1e-5, and train the model for 10 epochs. The neural net was regularized by 10% input dropouts and the 15% output dropouts.

**NTI-SLSTM-LSTM node-by-node tree attention:** this is a variation of the previous model with the tree attention. The hyper-parameters are the same as the previous model.

**Tree matching NTI-SLSTM-LSTM global attention:** this model first constructs the premise and hypothesis trees simultaneously with the NTI-SLSTM-LSTM model and then computes their matching vector by using the global attention and an additional LSTM. The attention vectors are produced at each hypothesis tree node and then are given to the LSTM model sequentially. The LSTM model compress the attention vectors and outputs a single matching vector, which is passed to an MLP for classification. The MLP for this tree matching setting has an input layer with 1024 units with *ReLU* activation and a *softmax* output layer.

Unlike Wang and Jiang (2016)’s matching LSTM model which is specific to matching sequences, we use the standard LSTM units and match trees. We set the initial learning rate to 3e-

<sup>2</sup><http://nlp.stanford.edu/projects/glove/>

<sup>3</sup>More detail on hyper-parameters can be found in code.

4 and  $l_2$  regularizer strength to  $3e-5$ , and train the model for 20 epochs. The neural net was regularized by 20% input dropouts and the 20% output dropouts.

**Tree matching NTI-SLSTM-LSTM tree attention:** we replace the global attention with the tree attention. The hyper-parameters are the same as the previous model.

**Full tree matching NTI-SLSTM-LSTM global attention:** this model produces two sets of the attention vectors, one by attending over the premise tree regarding each hypothesis tree node and another by attending over the hypothesis tree regarding each premise tree node. Each set of the attention vectors is given to a LSTM model to achieve full tree matching. The last hidden states of the two LSTM models (i.e. one for each attention vector set) are concatenated for classification. The training weights are shared among the LSTM models. The hyper-parameters are the same as the previous model.<sup>4</sup>

Table 1 shows the results of our models. For comparison, we include the results from the published state-of-the-art systems. While most of the sentence encoder models rely solely on word embeddings, the dependency tree CNN and the SPINN-PI models make use of sentence parser output; which present strong baseline systems. The last set of methods designs inter-sentence relation with soft attention (Bahdanau et al., 2015). Our best score on this task is 87.3% accuracy obtained with the full tree matching NTI model. The previous best performing model on the task performs phrase matching by using the attention mechanism.

Our results show that NTI-SLSTM improved the performance of the sequential LSTM encoder by approximately 2%. Not surprisingly, using LSTM as leaf node function helps in learning better representations. Our NTI-SLSTM-LSTM is a hybrid model which encodes a sequence sequentially through its leaf node function and then hierarchically composes the output representations. The node-by-node attention models improve the performance, indicating that modeling inter-sentence interaction is an important element in NLI. Aggregating matching vector between trees or sequences with a separate LSTM model is effective. The global attention seems to

be robust on this task. The tree attention were not helpful as it normalizes the attention scores locally in parent-child relationship.

## 4.2 Answer Sentence Selection

For this task, a model is trained to identify the correct sentences that answer a factual question, from a set of candidate sentences. We experiment on WikiQA dataset constructed from Wikipedia (Yang et al., 2015). The dataset contains 20,360/2,733/6,165 QA pairs for train/dev/test sets.

We used the same setup in the language inference task except that we replace the *softmax* layer with a *sigmoid* layer and model the following conditional probability distribution.

$$p_{\theta}(y = 1 | h_n^q, h_n^a) = \text{sigmoid}(o^{QA}) \quad (20)$$

where  $h_n^q$  and  $h_n^a$  are the question and the answer encoded vectors and  $o^{QA}$  denotes the output of the hidden layer of the MLP. For this task, we use NTI-SLSTM-LSTM to encode answer candidate sentences and NTI-ANF-LSTM to encode the question sentences. Note that NTI-ANF-LSTM is relied on ANF as the non-leaf node function.  $q$  vector for NTI-ANF-LSTM is the answer representation produced by the answer encoding NTI-SLSTM-LSTM model. We set the batch size to 4 and the initial learning rate to  $1e-3$ , and train the

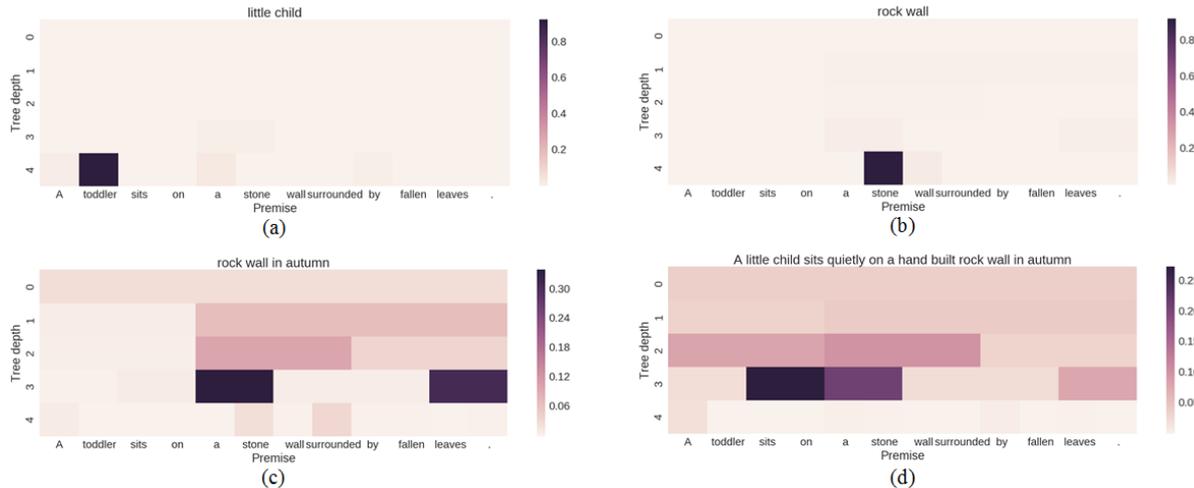

Figure 2: Node-by-node attention visualizations. The phrases shown on the top are nodes from hypothesis-indexed tree and the premise tokens are listed along the x-axis. The adjacent cells are composed in the top cell representing a binary tree and resulting a longer attention span.

a person	park for fun	Santa Claus	sad, depressed, and hatred
single person	an outdoor concert at the park	a snowmobile in a blizzard	an Obama supporter is upset
a woman	kids playing at a park outside	a Skier ski - jumping	but doesn't have any money
a young person	a mom takes a break in a park	A skier preparing a trick	crying because he didn't get cake
a guy	people play frisbee outdoors	a child is playing on christmas	trying his hardest to not fall off
a single human	takes his lunch break in the park	two men play with a snowman	is upset and crying on the ground

Table 4: Nearest-neighbor phrases based on cosine similarity between learned representations.

model for 10 epochs. We used 20% input dropouts and no  $l_2$  weight decay. Following previous work, we adopt MAP and MRR as the evaluation metrics for this task.<sup>5</sup>

Table 2 presents the results of our model and the previous models for the task.<sup>6</sup> The classifier with handcrafted features is a SVM model trained with a set of features. The Bigram-CNN model is a simple convolutional neural net. The Deep LSTM and LSTM attention models outperform the previous best result by a large margin, nearly 5-6%. NASM improves the result further and sets a strong baseline by combining variational auto-encoder (Kingma and Welling, 2014) with the soft attention. In NASM, they adopt a deep three-layer LSTM and introduced a latent stochastic attention mechanism over the answer sentence. Our NTI model exceeds NASM by approximately 0.4% on MAP for this task.

<sup>5</sup>We used *trec\_eval* script to calculate the evaluation metrics

<sup>6</sup>Inclusion of simple word count feature improves the performance by around 0.15-0.3 across the board

### 4.3 Sentence Classification

Lastly, we evaluated NTI on the Stanford Sentiment Treebank (SST) (Socher et al., 2013). This dataset comes with standard train/dev/test sets and two subtasks: binary sentence classification or fine-grained classification of five classes. We trained our model on the text spans corresponding to labeled phrases in the training set and evaluated the model on the full sentences.

We use NTI-SLSTM and NTI-SLSTM-LSTM models to learn sentence representations for the task. The sentence representations were passed to a two-layer MLP for classification. We set the batch size to 64, the initial learning rate to  $1e-3$  and  $l_2$  regularizer strength to  $3e-5$ , and train each model for 10 epochs. The NTI-SLSTM model was regularized by 10%/20% of input/output and 20%/30% of input/output dropouts and the NTI-SLSTM-LSTM model 20% of input and 20%/30% of input/output dropouts for binary and fine-grained settings.

NTI-SLSTM-LSTM (as shown in Table 5) set the state-of-the-art results on both subtasks. Our NTI-SLSTM model performed slightly worse

<b>A dog mouth holds a retrieved ball.</b>	<b>A cat nurses puppies.</b>	<b>A dog sells a woman a hat.</b>
A brown and white dog holds a tennis ball in his mouth. The dog has a ball. The dogs are chasing a ball.	A golden retriever nurses some other dogs puppies. A golden retriever nurses puppies. A mother dog checking up on her baby puppy.	The dog is a labrador retriever.
A small dog runs to catch a ball. The puppy is chasing a ball.	A girl is petting her dog. The hat wearing girl is petting a cat.	A girl is petting her dog. The dog is a shitzu.  A husband and wife making pizza. The dog is a chihuahua.

Table 5: Nearest-neighbor sentences based on cosine similarity between learned representations.

than its constituency tree-based counter part, CT-LSTM model. The CT-LSTM model composes phrases according to the output of a sentence parser and uses a node composition function similar to S-LSTM. After we transformed the input with the LSTM leaf node function, we achieved the best performance on this task.

## 5 Qualitative Analysis

### 5.1 Attention and Compositionality

To help analyzing the results, we output attention weights by our NTI-SLSTM node-by-node global attention model. Figure 2 shows the attention heatmaps for two sentences in the SNLI test set. It shows that our model semantically aligns single or multiword expressions (*"little child"* and *"toddler"*; *"rock wall"* and *"stone"*). In addition, our model is able to re-orient its attention over different parts of the hypothesis when the expression is more complex. For example, for (c) *"rock wall in autumn"*, NTI mostly focuses on the nodes in depth 1, 2 and 3 representing contexts related to *"a stone"*, *"leaves."* and *"a stone wall surrounded"*. Surprisingly, attention degree for the single word expression like *"stone"*, *"wall"* and *"leaves"* is lower to compare with multiword phrases. Sequence models lack this property as they have no explicit composition module to produce such mu-

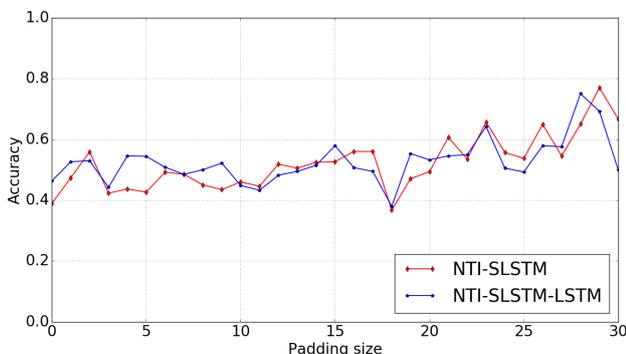

Figure 3: Fine-grained sentiment classification accuracy vs. padding size on test set of SST data.

tiword phrases.

Finally, the most interesting pattern is that the model attends over higher level (low depth) tree nodes with rich semantics when considering a (c) longer phrase or (d) full sentence. As shown in (d), the NTI model aligns the root node representing the whole hypothesis sentence to the higher level tree nodes covering larger sub-trees in the premise. It certainly ignores the lower level single word expressions and only starts to attend when the words are collectively to form rich semantics.

### 5.2 Learned Representations of Phrases and Sentences

Using cosine similarity between their representations produced by the NTI-SLSTM model, we show that NTI is able to capture paraphrases on SNLI test data. As shown in Table 4, NTI seems to distinguish plural from singular forms (similar phrases to *"a person"*). In addition, NTI captures non-surface knowledge. For example, the phrases similar to *"park for fun"* tend to align to the semantic content of *fun* and *park*, including *"people play frisbee outdoors"*. The NTI model was able to relate *"Santa Claus"* to *christmas* and *snow*. Interestingly, the learned representations were also able to connect implicit semantics. For example, NTI found that *"sad, depressed, and hatred"* is close to the phrases like *"an Obama supporter is upset"*. Overall the NTI model is robust to the length of the phrases being matched. Given a short phrase, NTI can retrieve longer yet semantically coherent sequences from the SNLI test set.

In Table 5, we show nearest-neighbor sentences from SNLI test set. Note that the sentences listed in the first two columns sound semantically coherent but not the ones in the last column. The query sentence *"A dog sells a woman a hat"* does not actually represent a common-sense knowledge and this sentence now seem to confuse the NTI model. As a result, the retrieved sentence are arbitrary and not coherent.

### 5.3 Effects of Padding Size

We introduced a special padding character in order to construct full binary tree. Does this padding character influence the performance of the NTI models? In Figure 3, we show relationship between the padding size and the accuracy on Stanford sentiment analysis data. Each sentence was padded to form a full binary tree. The x-axis represents the number of padding characters introduced. When the padding size is less (up to 10), the NTI-SLSTM-LSTM model performs better. However, this model tends to perform poorly or equally when the padding size is large. Overall we do not observe any significant performance drop for both models as the padding size increases. This suggests that NTI learns to ignore the special padding character while processing padded sentences. The same scenario was also observed while analyzing attention weights. The attention over the padded nodes was nearly zero.

## 6 Discussion and Conclusion

We introduced Neural Tree Indexers, a class of tree structured recursive neural network. The NTI models achieved state-of-the-art performance on different NLP tasks. Most of the NTI models form deep neural networks and we think this is one reason that NTI works well even if it lacks direct linguistic motivations followed by other syntactic-tree-structured recursive models (Socher et al., 2013).

CNN and NTI are topologically related (Kalchbrenner and Blunsom, 2013). Both NTI and CNNs are hierarchical. However, current implementation of NTI only operates on non-overlapping subtrees while CNNs can slide over the input to produce higher-level representations. NTI is flexible in selecting the node function and the attention mechanism. Like CNN, the computation in the same tree-depth can be parallelized effectively; and therefore NTI is scalable and suitable for large-scale sequence processing. Note that NTI can be seen as a generalization of LSTM. If we construct left-branching trees in a bottom-up fashion, the model acts just like sequential LSTM. Different branching factors for the underlying tree structure have yet to be explored. NTI can be extended so it learns to select and compose dynamic number of nodes for efficiency, essentially discovering intrinsic hierarchical structure in the input.

# Exploring Different Dimensions of Attention for Uncertainty Detection

Heike Adel and Hinrich Schütze

Center for Information and Language Processing (CIS)

LMU Munich, Germany

heike@cis.lmu.de

## Abstract

Neural networks with attention have proven effective for many natural language processing tasks. In this paper, we develop attention mechanisms for uncertainty detection. In particular, we generalize standardly used attention mechanisms by introducing *external attention* and *sequence-preserving attention*. These novel architectures differ from standard approaches in that they use external resources to compute attention weights and preserve sequence information. We compare them to other configurations along different dimensions of attention. Our novel architectures set the new state of the art on a Wikipedia benchmark dataset and perform similar to the state-of-the-art model on a biomedical benchmark which uses a large set of linguistic features.

## 1 Introduction

For many natural language processing (NLP) tasks, it is essential to distinguish uncertain (non-factual) from certain (factual) information. Such tasks include information extraction, question answering, medical information retrieval, opinion detection, sentiment analysis (Karttunen and Zelenen, 2005; Vincze, 2014a; Díaz et al., 2016) and knowledge base population (KBP). In KBP, we need to distinguish, e.g., “X may be Basque” and “X was rumored to be Basque” (uncertain) from “X is Basque” (certain) to decide whether to add the fact “Basque(X)” to a knowledge base. In this paper, we use the term *uncertain information* to refer to speculation, opinion, vagueness and ambiguity. We focus our experiments on the uncertainty detection (UD) dataset from the CoNLL2010 hedge cue detection task (Farkas

et al., 2010). It consists of two medium-sized corpora from different domains (Wikipedia and biomedical) that allow us to run a large number of comparative experiments with different neural networks and exhaustively investigate different dimensions of attention.

Convolutional and recurrent neural networks (CNNs and RNNs) perform well on many NLP tasks (Collobert et al., 2011; Kalchbrenner et al., 2014; Zeng et al., 2014; Zhang and Wang, 2015). CNNs are most often used with pooling. More recently, attention mechanisms have been successfully integrated into CNNs and RNNs (Bahdanau et al., 2015; Rush et al., 2015; Hermann et al., 2015; Rocktäschel et al., 2016; Yang et al., 2016; He and Golub, 2016; Yin et al., 2016). Both pooling and attention can be thought of as *selection mechanisms* that help the network focus on the most relevant parts of a layer, either an input or a hidden layer. This is especially beneficial for long input sequences, e.g., long sentences or entire documents. We apply CNNs and RNNs to uncertainty detection and compare them to a number of baselines. We show that attention-based CNNs and RNNs are effective for uncertainty detection. On a Wikipedia benchmark, we improve the state of the art by more than 3.5  $F_1$  points.

Despite the success of attention in prior work, the design space of related network architectures has not been fully explored. In this paper, we develop novel ways to calculate attention weights and integrate them into neural networks. Our models are motivated by the characteristics of the uncertainty task, yet they are also a first attempt to systematize the design space of attention. In this paper, we begin with investigating three dimensions of this space: weighted vs. unweighted selection, sequence-agnostic vs. sequence-preserving selection, and internal vs. external attention.

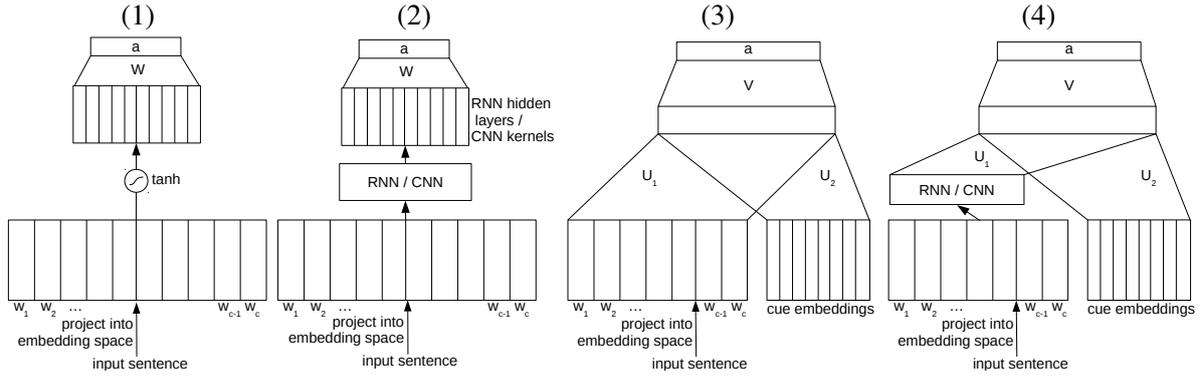

Figure 1: Internal attention on (1) input and (2) hidden representation. External attention on (3) input and (4) hidden representation. For the whole network structure, see Figure 3.

**Weighted vs. Unweighted Selection.** Pooling is unweighted selection: it outputs the selected values as is. In contrast, attention can be thought of as weighted selection: some input elements are highly weighted, others receive weights close to zero and are thereby effectively not selected. The advantage of weighted selection is that the model learns to decide based on the input how many values it should select. Pooling either selects all values (average pooling) or  $k$  values ( $k$ -max pooling). If there are more than  $k$  uncertainty cues in a sentence, pooling is not able to focus on all of them.

**Sequence-agnostic vs. Sequence-preserving Selection.**  $K$ -max pooling (Kalchbrenner et al., 2014) is sequence-preserving: it takes a long sequence as input and outputs a subsequence whose members are in the same order as in the original sequence. In contrast, attention is generally implemented as a weighted average of the input vectors. That means that all ordering information is lost and cannot be recovered by the next layer. As an alternative, we present and evaluate new sequence-preserving ways of attention. For uncertainty detection, this might help distinguishing phrases like “it is not uncertain that  $X$  is Basque” and “it is uncertain that  $X$  is not Basque”.

**Internal vs. External Attention.** Prior work calculates attention weights based on the input or hidden layers of the neural network. We call this internal attention. For uncertainty detection, it can be beneficial to give the model a lexicon of seed cue words or phrases. Thus, we provide the network with additional information to bear on identifying and summarizing features. This can simplify the training process by guiding the model to recognizing uncertainty cues. We call this external attention and show that it improves performance

for uncertainty detection.

Previous work on attention and pooling has only considered a small number of the possible configurations along those dimensions of attention. However, the internal/external and un/weighted distinctions can potentially impact performance because external resources add information that can be critical for good performance and because weighting increases the flexibility and expressivity of neural network models. Also, word order is often critical for meaning and is therefore an important feature in NLP. Although our models are motivated by the characteristics of uncertainty detection, they could be useful for other NLP tasks as well.

Our main contributions are as follows. (i) We extend the design space of selection mechanisms for neural networks and conduct an extensive set of experiments testing various configurations along several dimensions of that space, including novel sequence-preserving and external attention mechanisms. (ii) To our knowledge, we are the first to apply convolutional and recurrent neural networks to uncertainty detection. We demonstrate the effectiveness of the proposed attention architectures for this task and set the new state of the art on a Wikipedia benchmark dataset. (iii) We publicly release our code for future research.<sup>1</sup>

## 2 Models

**Convolutional Neural Networks.** CNNs have been successful for many NLP tasks since convolution and pooling can detect key features independent of their position in the sentence. Moreover, they can take advantage of word embeddings and their characteristics. Both properties are also

<sup>1</sup><http://cistern.cis.lmu.de>

essential for uncertainty detection since we need to detect cue phrases that can occur anywhere in the sentence; and since some notion of similarity improves performance if a cue phrase in the test data did not occur in the training data, but is similar to one that did. The CNN we use in this paper has one convolutional layer, 3-max pooling (see Kalchbrenner et al. (2014)), a fully connected hidden layer and a logistic output unit.

**Recurrent Neural Networks.** Different types of RNNs have been applied widely to NLP tasks, including language modeling (Bengio et al., 2000; Mikolov et al., 2010), machine translation (Cho et al., 2014; Bahdanau et al., 2015), relation classification (Zhang and Wang, 2015) and entailment (Rocktäschel et al., 2016). In this paper, we apply a bi-directional gated RNN (GRU) with gradient clipping and a logistic output unit. Chung et al. (2014) showed that GRUs and LSTMs have similar performance, but GRUs are more efficient in training. The hidden layer  $h$  of the GRU is parameterized by two matrices  $W$  and  $U$  and four additional matrices  $W_r$ ,  $U_r$  and  $W_z$ ,  $U_z$  for the reset gate  $r$  and the update gate  $z$  (Cho et al., 2014):

$$r = \sigma(W_r x + U_r h^{t-1}) \quad (1)$$

$$z = \sigma(W_z x + U_z h^{t-1}) \quad (2)$$

$$h^t = z \odot h^{t-1} + (1 - z) \odot \tilde{h}^t \quad (3)$$

$$\tilde{h}^t = \sigma(W x + U(r \odot h^{t-1})) \quad (4)$$

$t$  is the index for the current time step,  $\odot$  is element-wise multiplication and  $\sigma$  is the sigmoid.

### 3 Attention

#### 3.1 Architecture of the Attention Layer

We first define an attention layer  $a$  for input  $x$ :

$$\alpha_i = \frac{\exp(f(x_i))}{\sum_j \exp(f(x_j))} \quad (5)$$

$$a_i = \alpha_i \cdot x_i \quad (6)$$

where  $f$  is a scoring function, the  $\alpha_i$  are the attention weights and each input  $x_i$  is reweighted by its corresponding attention weight  $\alpha_i$ .

The most basic definition of  $f$  is as a linear scoring function on the input  $x$ :

$$f(x_i) = W^T x_i \quad (7)$$

$W$  are parameters that are learned in training.

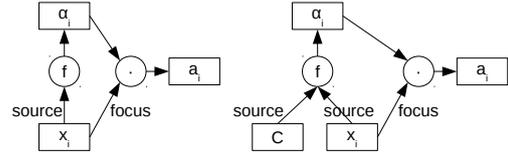

Figure 2: Schemes of focus and source: left: internal attention, right: external attention

#### 3.2 Focus and Source of Attention

In this paper, we distinguish between focus and source of attention.

The *focus* of attention is the layer of the network that is reweighted by attention weights, corresponding to  $x$  in Eq. 6. We consider two options for the application in uncertainty detection as shown in Figure 1: (i) the focus is on the input, i.e., the matrix of word vectors ((1) and (3)) and (ii) the focus is on the convolutional layer of the CNN or the hidden layers of the RNN ((2) and (4)). For focus on the input, we apply  $\tanh$  to the word vectors (see part (1) of figure) to improve results.

The *source* of attention is the information source that is used to compute the attention weights, corresponding to the input of  $f$  in Eq. 5.

Eq. 7 formalizes the case in which focus and source are identical (both are based only on  $x$ ). We call this **internal attention** (see left part of Figure 2). *An attention layer is called internal if both focus and source are based only on information internally available to the network (through input or hidden layers).*<sup>2</sup>

If we conceptualize attention in terms of source and focus, then a question that arises is whether we can make it more powerful by *increasing the scope of the source beyond the input*.

In this paper, we propose a way of expanding the source of attention by making an *external resource*  $C$  available to the scoring function  $f$ :

$$f(x_i) = f'(x_i, C) \quad (8)$$

We call this **external attention** (see right part of Figure 2). *An attention layer is called external if its source includes an external resource.*

The specific external-attention scoring function we use for uncertainty detection is parametrized by  $U_1$ ,  $U_2$  and  $V$  and defined as follows:

$$f(x_i) = \sum_j V^T \cdot \tanh(U_1 \cdot x_i + U_2 \cdot c_j) \quad (9)$$

<sup>2</sup>Gates, e.g., the weighting of  $h^{t-1}$  in Eq. 4, can also be viewed as internal attention mechanisms.

where  $c_j$  is a vector representing a cue phrase  $j$  of the training set. We compute  $c_j$  as the average of the embeddings of the constituent words of  $j$ .

This attention layer scores an input word  $x_i$  by comparing it with each cue vector  $c_j$  and summing the results. The comparison is done using a fully connected hidden layer. Its weights  $U_1, U_2$  and  $V$  are learned during training. When using this scoring function in Eq. 5, each  $\alpha_i$  is an assessment of how important  $x_i$  is for uncertainty detection, taking into account our knowledge about cue phrases. Since we use embeddings to represent words and cues, uncertainty-indicating phrases that did not occur in training, but are similar to training cue phrases can also be recognized.

We use this novel attention mechanism for uncertainty detection, but it is also applicable to other tasks and domains as long as there is a set of vectors available that is analogous to our  $c_j$  vectors, i.e., vectors that model relevance of embeddings to the task at hand (for an outlook, see Section 6).

### 3.3 Sequence-agnostic vs. Sequence-preserving Selection

So far, we have explained the basic architecture of an attention layer: computing attention weights and reweighting the input. We now turn to the *integration of the attention layer* into the overall network architecture, i.e., how it is connected to downstream components.

The most frequently used downstream connection of the attention layer is to take the **average**:

$$a = \sum_i \alpha_i \quad (10)$$

We call this the average, not the sum, because the  $\alpha_i$  are normalized to sum to 1 and the standard term for this is “weighted average”.

A variant is the **k-max average**:

$$a = \sum_{R(\alpha_j) \leq k} \alpha_j$$

where  $R(\alpha_j)$  is the rank of  $\alpha_j$  in the list of activation weights  $\alpha_i$  in descending order. This type of averaging is more similar to k-max pooling and may be more robust because elements with low weights (which may just be noise) will be ignored.

Averaging destroys order information that may be needed for NLP sequence classification tasks. Therefore, we also investigate a sequence-preserving method, **k-max sequence**:

$$a = [a_j | R(\alpha_j) \leq k] \quad (11)$$

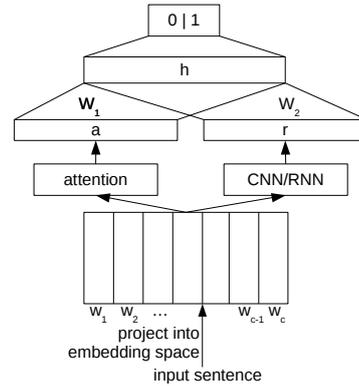

Figure 3: Network overview: combination of attention and CNN/RNN output. For details on attention, see Figure 1.

where  $[a_j | P(a_j)]$  denotes the subsequence of sequence  $A = [a_1, \dots, a_J]$  from which members not satisfying predicate  $P$  have been removed. Note that sequence  $a$  is in the original order of the input, i.e., not sorted by value.

K-max sequence selects a subsequence of input vectors. Our last integration method is **k-max pooling**. It ranks each dimension of the vectors individually, thus the resulting values can stem from different input positions. This is the same as standard k-max pooling in CNNs except that each vector element in  $a_j$  has been weighted (by its attention weight  $\alpha_j$ ), whereas in standard k-max pooling it is considered as is. Below, we also refer to k-max sequence as “per-pos” and to k-max pooling as “per-dim” to clearly distinguish it from k-max pooling done by the CNN.

### Combination with CNN and RNN Output.

Another question is whether we combine the attention result with the result of the convolutional or recurrent layer of the network. Since k-max pooling (CNN) and recurrent hidden layers with gates (RNN) have strengths complementary to attention, we experiment with concatenating the attention information to the neural sentence representations. The final hidden layer then has this form:

$$h = \tanh(W_1 a + W_2 r + b)$$

with  $r$  being either the CNN pooling result or the last hidden state of the RNN (see Figure 3).

## 4 Experimental Setup and Results

### 4.1 Task and Setup

We evaluate on the two corpora of the CoNLL2010 hedge cue detection task (Farkas

	Model	wiki	bio
(1)	Baseline SVM	62.01*	78.64*

et al., 2010): Wikipedia (11,111 sentences in train, 9634 in test) and Biomedical (14,541 train, 5003 test). It is a binary sentence classification task. For each sentence, the model has to decide whether it contains uncertain information.

For hyperparameter tuning, we split the training set into core-train (80%) and dev (20%) sets; see appendix for hyperparameter values. We use 400 dimensional word2vec (Mikolov et al., 2013) embeddings, pretrained on Wikipedia, with a special embedding for unknown words.

For evaluation, we apply the official shared task measure:  $F_1$  of the uncertain class.

## 4.2 Baselines without Attention

Our baselines are a support vector machine (SVM) and two standard neural networks without attention, an RNN and a CNN. The SVM is a reimplementation of the top ranked system on Wikipedia in the CoNLL-2010 shared task (Georgescul, 2010), with parameters set to Georgescul (2010)’s values; it uses bag-of-word (BOW) vectors that only include hedge cues. Our reimplementation is slightly better than the published result: 62.01 vs. 60.20 on wiki, 78.64 vs. 78.50 on bio.

The results of the baselines are given in Table 1. The CNN (line 3) outperforms the SVM (line 1) on both datasets, presumably because it considers all words in the sentence – instead of only predefined hedge cues – and makes effective use of this additional information. The RNN (line 2) performs better than the SVM and CNN on biomedical data,

<sup>4</sup>randomization test with  $p < .05$ .

but worse on Wikipedia. In Section 5.2, we investigate possible reasons for that.

## 4.3 Experiments with Attention Mechanisms

For the first experiments of this subsection, we use the sequence-agnostic weighted average for attention (see Eq. 10), the standard in prior work.

### Attention-only vs. Combined Architecture.

For the case of internal attention, we first remove the final pre-output layer of the standard RNN and the standard CNN to evaluate attention-only architectures. This architecture works well for RNNs but not for CNNs. The CNNs achieve better results when the pooling output (unweighted selection) is combined with the attention output (weighted selection). See Table 2 for  $F_1$  scores.

The baseline RNN has the difficult task of remembering the entire sentence over long distances – the attention mechanism makes this task much easier. In contrast, the baseline CNN already has an effective mechanism for focusing on the key parts of the sentence: k-max pooling. Replacing k-max pooling with attention decreases the performance in this setup.

Since our main goal is to explore the benefits of adding attention to existing architectures (as opposed to developing attention-only architectures), we keep the standard pre-output layer of RNNs and CNNs in the remaining experiments and combine it with the attention layer as in Figure 3.

**Focus and Source of Attention.** We distinguish different focuses and sources of attention. For focus, we investigate two possibilities: the input to the network, i.e., word embeddings (F=W); or the hidden representations of the RNN or CNN (F=H). For source, we compare internal (S=I) and external attention (S=E). This gives rise to four configurations: (i) internal attention with focus on the first layer of the standard RNN/CNN (S=I, F=H), see lines (5) and (7) in Table 2, (ii) internal attention with focus on the input (S=I, F=W), (iii) external attention on the first layer of RNN/CNN (S=E, F=H) and (iv) external attention on the input (S=E, F=W). The results are provided in Table 3.

For both RNN (8) and CNN (13), the best result is obtained by focusing attention directly on the word embeddings.<sup>5</sup> These results suggest that it is best to optimize the attention mechanism directly on the input, so that information can be extracted

<sup>5</sup>The small difference between the RNN results on bio on lines (5) and (8) is not significant.

	Model	S	F	wiki	bio
(2)	Baseline RNN	-	-	59.82*	84.69
(5)	RNN combined	I	H	58.96*	84.88
(8)	RNN combined	I	W	62.18*	84.81
(9)	RNN combined	E	H	61.19*	84.62
(10)	RNN combined	E	W	61.87*	84.41
(3)	Baseline CNN	-	-	64.94*	84.23*
(7)	CNN combined	I	H	66.49	84.69
(11)	CNN combined	I	W	65.13*	84.99
(12)	CNN combined	E	H	64.14*	84.73
(13)	CNN combined	E	W	<b>67.08</b>	<b>85.57</b>

Table 3:  $F_1$  results for UD. Focus (F) and source (S) of attention: Internal (I) vs external (E) attention; attention on word embeddings (W) vs. on hidden layers (H). Sequence-agnostic weighted average for attention. \* indicates significantly worse than best model (bold).

that is complementary to the information extracted by a standard RNN/CNN.

For focus on input (F=W), external attention (13) is significantly better than internal attention (11) for CNNs. Thus, by designing an architectural element – external attention – that makes it easier to identify hedge cue properties of words, the learning problem is apparently made easier.

For the RNN and F=W, external attention (10) is not better than internal attention (8): results are roughly tied for bio and wiki. Perhaps the combination of the external resource and the more indirect representation of the entire sentence produced by the RNN is difficult. In contrast, hedge cue patterns identified by convolutional filters of the CNN can be evaluated well based on external attention; e.g., if there is strong external-attention evidence for uncertainty, then the effect of a hedge cue pattern (hypothesized by a convolutional filter) on the final decision can be boosted.

In summary, the CNN with external attention achieves the best results overall. It is significantly better than the standard CNN that uses only pooling, both on Wikipedia and biomedical texts. This demonstrates that the CNN can make effective use of external information – a lexicon of uncertainty cues in our case.

**Sequence-agnostic vs. Sequence-preserving.** Commonly used attention mechanisms simply average the vectors in the focus of attention. This means that sequential information is not preserved. We use the term sequence-agnostic for this. In contrast, we propose to investigate sequence-preserving attention as presented in Section 3.3. We expect this to be important for many

	average		k-max sequence	
	all	k-max	per-dim	per-pos
Wiki	67.08	<b>67.52</b>	66.73	66.50
Bio	<b>85.57</b>	84.36	84.05	84.03

Table 4:  $F_1$  results for UD. Model: CNN, S=E, F=W (13). Sequence-agnostic vs. sequence-preserving attention.

NLP tasks. Sequence-preserving attention is similar to k-max pooling which also selects an ordered subset of inputs. While traditional k-max pooling is unweighted, our sequence-preserving ways of attention still make use of the attention weights.

Table 4 compares k-max pooling, attention and two “hybrid” designs, as described in Section 3.3. We run these experiments only on the CNN with external attention focused on word embeddings (Table 3, line 13), the best performing configuration in the previous experiments.

First, we investigate what happens if we “discretize” attention and only consider the values with the top k attention weights. This increases performance on wiki (from 67.08 to 67.52) and decreases it on bio (from 85.57 to 84.36). We would not expect large differences since attention values tend to be peaked, so for common values of k ( $k \geq 3$  in most prior work on k-max pooling) we are effectively comparing two similar weighted averages, one in which most summands get a weight of 0 (k-max average) and one in which most summands get weights close to 0 (average over all, i.e., standard attention).

Next, we compare sequence-agnostic with sequence-preserving attention. As described in Section 3.3, two variants are considered. In k-max pooling, we select the k largest weighted values per dimension (per-dim in Table 4). In contrast, k-max sequence (per-pos) selects all values of the k positions with the highest attention weights.

In Table 4, the sequence-preserving architectures are slightly worse than standard attention (i.e., sequence-agnostic averaging), but not significantly: performance is different by about half a point. This shows that k-max sequence and attention can similarly be used to select a subset of the information available, a parallel that has not been highlighted and investigated in detail before.

Although in this case, sequence-agnostic attention is better than sequence-preserving attention, we would not expect this to be true for all tasks. Our motivation for introducing sequence-

Model	wiki	bio
SVM (Georgescul, 2010)	62.01	78.64
HMM (Li et al., 2014)	63.97	80.15
CRF + ling (Tang et al., 2010)	55.05	<b>86.79</b>
Our CNN with external attention	<b>67.52</b>	85.57

Table 5: Comparison of our best model with the state of the art

preserving attention was that the semantic meaning of a sentence can vary depending on where an uncertainty cue occurs. However, the core of uncertainty detection is keyword and keyphrase detection; so, the overall sentence structure might be less important for this task. For tasks with a stronger natural language understanding component, such as summarization or relation extraction, on the other hand, we expect sequences of weighted vectors to outperform averaged vectors. In Section 6, we show that sequence-preserving attention indeed improves results on a sentiment analysis dataset.

#### 4.4 Comparison to State of the Art

Table 5 compares our models with the state of the art on the uncertainty detection benchmark datasets. On Wikipedia, our CNN outperforms the state of the art by more than three points. On bio, the best model uses a large number of manually designed features and an exhaustive corpus preprocessing (Tang et al., 2010). Our models achieve comparable results without preprocessing or feature engineering.

### 5 Analysis

#### 5.1 Analysis of Attention

In an analysis of examples for which pooling alone (i.e., the standard CNN) fails, but attention correctly detects an uncertainty, two patterns emerge.

In the first pattern, we find that there are many cues that have more words than the filter size (which was 3 in our experiments), e.g., “it is widely expected”, “it has also been suggested”. The convolutional layer of the CNN is not able to detect phrases longer than the filter size while for attention there is no such restriction.

The second pattern consists of cues spread over the whole sentence, e.g., “Observations of the photosphere of 47 Ursae Majoris *suggested* that the periodicity *could not* be explained by stellar activity, making the planet interpretation *more likely*” where we have set the uncertainty cues

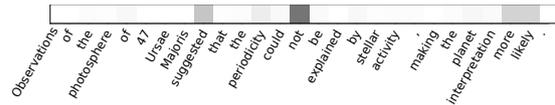

Figure 4: Attention weight heat map

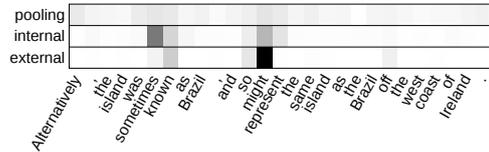

Figure 5: Pooling vs. internal vs. ext. attention

that are distributed throughout the sentence in italics. Figure 4 shows the distribution of external attention weights computed by the CNN for this sentence. The CNN pays the most attention to the three words/phrases “suggested”, “not” and “more likely” that correspond almost perfectly to the true uncertainty cues. K-max pooling of standard CNNs, on the other hand, can only select the k maximum values per dimension, i.e., it can pick at most k uncertainty cues per dimension.

#### Pooling vs. Internal vs. External Attention.

Finally, we compare the information that pooling, internal and external attention extract. For pooling, we calculate the relative frequency that a value from an n-gram centered around a specific word is picked. For internal and external attention, we directly plot the attention weights  $\alpha_i$ . Figure 5 shows the results of the three mechanisms for an exemplary sentence. For a sample of randomly selected sentences, we observed similar patterns: Pooling forwards information from different parts all over the sentence. It has minor peaks at relevant n-grams (e.g. “was sometimes known as” or “so might represent”) but also at non-relevant parts (e.g. “Alternatively” or “the same island”). There is no clear focus on uncertainty cues. Internal attention is more focused on the relevant words. External attention finally has the clearest focus. (See appendix for more examples.)

#### 5.2 Analysis of CNN vs RNN

While the results of the CNN and the RNN are comparable on bio, the CNN clearly outperforms the RNN on wiki. The datasets vary in several aspects, such as average sentence lengths (wiki: 21, bio: 27)<sup>6</sup>, size of vocabularies (wiki: 45.1k,

<sup>6</sup>number of tokens per sentence after tokenization with Stanford tokenizer (Manning et al., 2014).

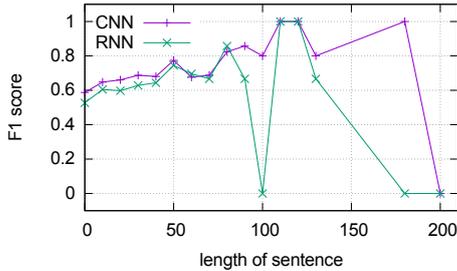

Figure 6:  $F_1$  results for different sentence lengths

bio: 25.3k), average number of out-of-vocabulary (OOV) words per sentence w.r.t. our word embeddings (wiki: 4.5, bio: 6.5), etc. All of those features can influence model performance, especially because of the different way of sentence processing: While the RNN merges all information into a single vector, the CNN extracts the most important phrases and ignores all the rest. In the following, we analyze the behavior of the two models w.r.t. sentence length and number of OOVs.

Figure 6 shows the  $F_1$  scores on Wikipedia of the CNN and the RNN with external attention for different sentence lengths. The lengths have been accumulated, i.e., index 0 on the x-axis includes the scores for all sentences of length  $l \in [0, 10)$ . Most sentences have lengths  $l < 50$ . In this range, the CNN performs better than the RNN but the difference is small. For longer sentences, however, the CNN clearly outperforms the RNN. This could be one reason for the better overall performance.

A similar plot for  $F_1$  scores depending on the number of OOVs per sentence does not give additional insights into the model behaviors: The CNN performs better than the RNN independent of the number of OOVs (Figure in appendix).

Another important difference between CNN and RNN is the distribution of precision and recall. While on bio, precision and recall are almost equal for both models, the values vary on wiki:

	P	R
CNN	52.5	85.1
CNN + external attention	58.6	78.3
RNN	75.2	49.6
RNN + external attention	76.3	52.0

Those values suggest that the RNN predicts uncertainty more reluctantly than the CNN.

## 6 Outlook: Different Task

To investigate whether our attention methods are also applicable to other tasks, we evaluate them

Model	S	F	test set
Baseline CNN	-	-	84.84
CNN attention-only	I	H	83.56
CNN combined	I	H	85.22
CNN combined	I	W	86.11
CNN combined	E	H	86.06
CNN combined	E	W	<b>86.89</b>

Table 6: Accuracy on SST-2, different focus and source of attention.

average		k-max sequence	
all	k-max	per-dim	per-pos
86.89	86.39	87.00	<b>87.22</b>

Table 7: Accuracy on SST-2, sequence-agnostic vs. sequence-preserving attention.

on the 2-class Stanford Sentiment Treebank (SST-2) dataset<sup>7</sup> (Socher et al., 2013). For a baseline model, we train a CNN similar to our uncertainty CNN but with convolutional filters of different widths, as proposed in (Kim, 2014), and extend it with our attention layer. As cues for external attention, we use the most frequent positive phrases from the train set. Our model is much simpler than the state-of-the-art models for SST-2 but still achieves reasonable results.<sup>8</sup>

The results in Table 6 show the same trends as the CNN results in Table 3, suggesting that our methods are applicable to other tasks as well. Table 7 shows that the benefit of sequence-preserving attention is indeed task dependent. For sentiment analysis on SST-2, sequence-preserving methods outperform the sequence-agnostic ones.

## 7 Related Work

**Uncertainty Detection.** Uncertainty has been extensively studied in linguistics and NLP (Kiparsky and Kiparsky, 1970; Karttunen, 1973; Karttunen and Zaenen, 2005), including modality (Saurí and Pustejovsky, 2012; De Marneffe et al., 2012; Szarvas et al., 2012) and negation (Velldal et al., 2012; Baker et al., 2012). Szarvas et al. (2012), Vincze (2014b) and Zhou et al. (2015) conducted cross domain experiments. Domains studied include news (Saurí and Pustejovsky, 2009), biomedicine (Vincze et al., 2008), Wikipedia (Ganter and Strube, 2009) and social media (Wei et al., 2013). Corpora such as FactBank (Saurí and Pustejovsky, 2009) are annotated in detail with respect to perspective, level of factuality and polar-

<sup>7</sup><http://nlp.stanford.edu/sentiment>

<sup>8</sup>The state-of-the-art accuracy is about 89.5 (Zhou et al., 2016; Yin and Schütze, 2015).

ity. De Marneffe et al. (2012) conducted uncertainty detection experiments on a version of FactBank extended by crowd sourcing. In this work, we use CoNLL 2010 shared task data (Farkas et al., 2010) since CoNLL provides larger train/test sets and the CoNLL annotation consists of only two labels (certain/uncertain) instead of various perspectives and degrees of uncertainty. When using uncertainty detection for information extraction tasks like KB population (Section 1), it is a reasonable first step to consider only two labels.

**CNNs.** Several studies showed that CNNs can handle diverse sentence classification tasks, including sentiment analysis (Kalchbrenner et al., 2014; Kim, 2014), relation classification (Zeng et al., 2014; dos Santos et al., 2015) and paraphrase detection (Yin et al., 2016). To our knowledge, we are the first to apply them to uncertainty detection.

**RNNs.** RNNs have mainly been used for sequence labeling or language modeling tasks with one output after each input token (Bengio et al., 2000; Mikolov et al., 2010). Recently, it has been shown that they are also capable of encoding and restoring relevant information from a whole input sequence. This makes them applicable to machine translation (Cho et al., 2014; Bahdanau et al., 2015) and sentence classification tasks (Zhang and Wang, 2015; Hermann et al., 2015; Rocktäschel et al., 2016). In this study, we apply them to UD for the first time and compare their results with CNNs.

**Attention** has been mainly used for recurrent neural networks (Bahdanau et al., 2015; Rush et al., 2015; Hermann et al., 2015; Rocktäschel et al., 2016; Peng et al., 2015; Yang et al., 2016). We integrate attention into CNNs and show that this is beneficial for uncertainty detection. Few studies in vision integrated attention into CNNs (Stolenga et al., 2014; Xiao et al., 2015; Chen et al., 2015) but this has not been used often in NLP so far. Exceptions are Meng et al. (2015), Wang et al. (2016) and Yin et al. (2016). Meng et al. (2015) used several layers of local and global attention in a complex machine translation model with a large number of parameters. Our reimplementation of their network performed poorly for uncertainty detection (51.51/66.57 on wiki/bio); we suspect that the reason is that Meng et al. (2015)’s training set was an order of magnitude larger than ours. Our approach makes effective use of a much smaller training set. Yin et al. (2016) compared attention based input representations and attention

based pooling. Instead, our goal is to keep the convolutional and pooling layers unchanged and combine their strengths with attention. Allamanis et al. (2016) applied a convolutional layer to compute attention weights. In this work, we concentrate on the commonly used feed forward layers for that. Comparing them to other options, such as convolution, is an interesting direction for future work.

Attention in the literature computes a weighted average with internal attention weights. In contrast, we investigate different strategies to incorporate attention information into a neural network. Also, we propose external attention. The underlying intuition is similar to attention for machine translation, which learns alignments between source and target sentences, or attention in question answering, which computes attention weights based on a question and a fact. However, these sources for attention are still internal information of the network (the input or previous output predictions). Instead, we learn weights based on an external source – a lexicon of cue phrases.

## 8 Conclusion

In this paper, we presented novel attention architectures for uncertainty detection: external attention and sequence-preserving attention. We conducted an extensive set of experiments with various configurations along different dimensions of attention, including different focuses and sources of attention and sequence-agnostic vs. sequence-preserving attention. For our experiments, we used two benchmark datasets for uncertainty detection and applied recurrent and convolutional neural networks to this task for the first time. Our CNNs with external attention improved state of the art by more than 3.5  $F_1$  points on a Wikipedia benchmark. Finally, we showed in an outlook that our architectures are applicable to sentiment classification as well. Investigations of other sequence classification tasks are future work. We made our code publicly available for future research (<http://cistern.cis.lmu.de>).

## A Supplementary Material

### A.1 Parameter Tuning

All parameters and learning rate schedule decisions are based on results on the development set (20% of the official training set). After tuning the hyperparameters (see Tables 8 and 9), the networks are re-trained on the whole training set.

We trained the CNNs with stochastic gradient descent and a fixed learning rate of 0.03. For the RNNs, we used Adagrad (Duchi et al., 2011) with an initial learning rate of 0.1. For all models, we used mini-batches of size 10 and applied L2 regularization with a weight of  $1e-5$ . To determine the number of training epochs, we looked for epochs with peak performances on the development set.

### A.2 Additional Examples: Attention Weights

Figure 7 and Figure 8 compare pooling, internal attention and external attention for randomly

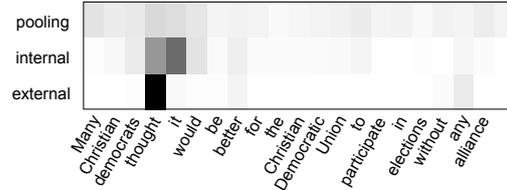

Figure 7: Pooling vs. internal attention vs. external attention

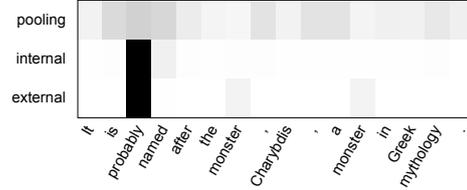

Figure 8: Pooling vs. internal attention vs. external attention

picked examples from the test set. Again, pooling extracts values from all over the sentence while internal and external attention learn to focus on words which can indicate uncertainty (e.g. “thought” or “probably”).

### A.3 Additional Figure for Analysis: Results Depending on Number of OOVs

Figure 9 plots the  $F_1$  scores of the CNN and RNN with external attention w.r.t. the number of out-of-vocabulary (OOV) words in the sentences. The number of OOVs have been accumulated, i.e., index 0 on the x-axis includes the score for all sentences with a number of OOVs in  $[0,10)$ , etc.

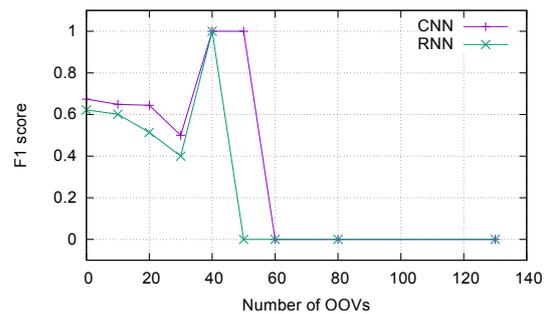

Figure 9:  $F_1$  results for different numbers of OOVs in sentence

# Classifying Illegal Activities on Tor Network Based on Web Textual Contents

## Abstract

The freedom of the Deep Web offers a safe place where people can express themselves anonymously but they also can conduct illegal activities. In this paper, we present and make publicly available<sup>1</sup> a new dataset for Darknet active domains, which we call it "Darknet Usage Text Addresses" (DUTA). We built DUTA by sampling the Tor network during two months and manually labeled each address into 26 classes. Using DUTA, we conducted a comparison between two well-known text representation techniques crossed by three different supervised classifiers to categorize the Tor hidden services. We also fixed the pipeline elements and identified the aspects that have a critical influence on the classification results. We found that the combination of TF-IDF words representation with Logistic Regression classifier achieves 96.6% of 10 folds cross-validation accuracy and a macro F1 score of 93.7% when classifying a subset of illegal activities from DUTA. The good performance of the classifier might support potential tools to help the authorities in the detection of these activities.

## 1 Introduction

If we think about the web as an ocean of data, the Surface Web is no more than the slight waves that float on the top. While in the depth, there is a lot of sunken information that is not reached by the traditional search engines. The web can be divided into Surface Web and Deep Web. The Surface Web is the portion of the web that can be crawled and

<sup>1</sup>The dataset is available upon request to the first author (email).

indexed by the standard search engines, such as Google or Bing. However, despite their existence, there is still an enormous part of the web remained without indexing due to its vast size and the lack of hyperlinks, i.e. not referenced by the other web pages. This part, that can not be found using a search engine, is known as Deep Web (Noor et al., 2011; Boswell, 2016). Additionally, the content might be locked and requires human interaction to access e.g. to solve a CAPTCHA or to enter a log-in credential to access. This type of web pages is referred to as "database-driven" websites. Moreover, the traditional search engines do not examine the underneath layers of the web, and consequently, do not reach the Deep Web. The Darknet, which is also known as Dark Web, is a subset of the Deep Web. It is not only not indexed and isolated, but also requires a specific software or a dedicated proxy server to access it. The Darknet works over a virtual sub-network of the World Wide Web (WWW) that provides an additional layer of anonymity for the network users. The most popular ones are "The Onion Router"<sup>2</sup> also known as Tor network, "Invisible Internet Project" I2P<sup>3</sup>, and Freenet<sup>4</sup>. The community of Tor refers to Darknet websites as "Hidden Services" (HS) which can be accessed via a special browser called Tor Browser<sup>5</sup>.

A study by Bergman et al. (2001) has stated astonishing statistics about the Deep Web. For example, only on Deep Web there are more than 550 billion individual documents comparing to only 1 billion on Surface Web. Furthermore, in the study of Rudesill et al. (2015) they emphasized on the immensity of the Deep Web which was estimated to be 400 to 500 times wider than the Surface Web.

The concepts of Darknet and Deep Net have ex-

<sup>2</sup>[www.torproject.org](http://www.torproject.org)

<sup>3</sup>[www.geti2p.net](http://www.geti2p.net)

<sup>4</sup>[www.freenetproject.org](http://www.freenetproject.org)

<sup>5</sup>[www.torproject.org/projects/torbrowser.html.en](http://www.torproject.org/projects/torbrowser.html.en)

isted since the establishment of World Wide Web (WWW), but what make it very popular in the recent years is when the FBI had arrested Dread Pirate Roberts, the owner of Silk Road black market, in October 2013. The FBI has estimated the sales on Silk Road to be 1.2 Billion dollars by July 2013. The trading network covered among 150,000 anonymous customers and approximately 4,000 vendors (Rudesill et al., 2015). The cryptocurrency (Nakamoto, 2008) is a hot topic in the field of Darknet since it anonymizes the financial transactions and hides the trading parties identities (Ron and Shamir, 2014).

The Darknet is often associated with illegal activities. In a study carried out by Intelliagg group (2015) over 1K samples of hidden services, they claimed that 68% of Darknet contents would be illegal. Moore et al. (2016) showed, after analyzing 5K onion domains, that the most common usages for Tor HS are criminal and illegal activities, such as drugs, weapons and all kind of pornography.

It is worth to mention about dramatic increase in the proliferation of Darknet domains which doubled their size from 30K to 60K between August 2015 and 2016 (Figure 1). However, the publicly reachable domains are no more than 6K to 7K due to the ambiguity nature of the Darknet (Ciancaglini et al., 2016).

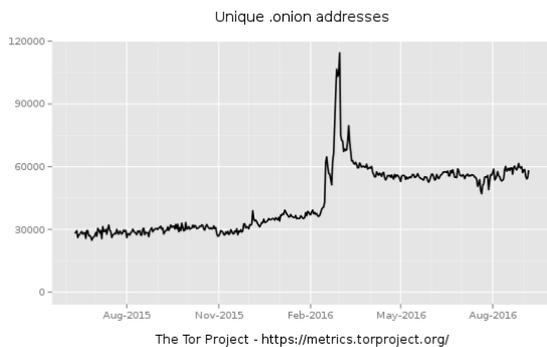

Figure 1: The number of unique \*.onion addresses in Tor network between August 2015 to August 2016

Motivated by the critical buried contents on the Darknet and its high abuse, we focused our research in designing and building a system that classifies the illegitimate practices on Darknet. In this paper, we present the first publicly available dataset called "Darknet Usage Text Addresses" (DUTA) that is extracted from the Tor HS Darknet.

DUTA contains 26 categories that cover all the legal and the illegal activities monitored on Darknet during our sampling period. Our objective is to create a precise categorization of the Darknet via classifying the textual content of the HS. In order to achieve our target, we designed and compared different combinations of some of the most well-known text classification techniques by identifying the key stages that have a high influence on the method performance. We set a baseline methodology by fixing the elements of text classification pipeline which allows the scientific community to compare their future research with this baseline under the defined pipeline. The fixed methodology we propose might represent a significant contribution into a tool for the authorities who monitor the Darknet abuse.

The rest of the paper is organized as follows: Section 2 presents the related work. Next, Section 3 explains the proposed dataset DUTA and its characteristics. After that, Section 4 describes the set of the designed classification pipelines. Then, in Section 5 we discuss the experiments performed and the results. In Section 6 we describe the technical implementation details and how we employed the successful classifier in an application. Finally, in Section 7 we present our conclusions with a pointing to our future work.

## 2 Related Work

In the recent years, many researchers have investigated the classification of the Surface Web (Dumas and Chen, 2000; Sun et al., 2002; Kan, 2004; Kan and Thi, 2005; Kaur, 2014), and the Deep Web (Su et al., 2006; Xu et al., 2007; Barbosa et al., 2007; Lin et al., 2008; Zhao et al., 2008; Xian et al., 2009; Khelghati, 2016). However, the Darknet classification literature is still in its early stages and specifically the classification of the illegal activities (Graczyk and Kinningham, 2015; Moore and Rid, 2016).

Kaur (2014) introduced an interesting survey covering several algorithms to classify web content, paying attention to its importance in the field of data mining. Furthermore, the survey included the pre-processing techniques that might help in features selection, like eliminating the HTML tags, punctuation marks and stemming. Kan et al. explored the use of Uniform Resource Locators (URL) in web classification by extracting the features through parsing and segmenting it (Kan,

2004; Kan and Thi, 2005). These techniques can not be applied to Tor HS since the onion addresses are constructed with 16 random characters. However, tools like Scallion<sup>6</sup> and Shallot<sup>7</sup> allow Tor users to create customized .onion addresses based on the brute-force technique e.g. Shallot needs 2.5 years to build only 9 customized characters out of 16. Sun et al. (2002) employed Support Vector Machine (SVM) to classify the web content by taking the advantage of the context features e.g. HTML tags and hyperlinks in addition to the textual features to build the feature set.

Regarding the Deep Web classification, Noor et al. (2011) discussed the common techniques that are used for the content extraction from the Deep Web data sources called "Query Probing", which is commonly used for supervised learning algorithms, and "Visible Form Features" (Xian et al., 2009). Su et al. (2006) have proposed a combination between SVM with query probing to classify the structured Deep Web hierarchically. Barbosa et al. (2007) proposed an unsupervised machine learning clustering pipeline, in which Term Frequency Inverse Document Frequency (TF-IDF) was used for the text representation, and the cosine similarity for distance measurement for the k-means.

With respect to the Darknet, Moore et al. in (2016) have presented a new study based on Tor hidden services to analyze and classify the Darknet. Initially, they collected 5K samples of Tor onion pages and classified them into 12 classes using SVM classifier. Graczyk et al. (2015) proposed a pipeline to classify the products of a famous black market on Darknet, called Agora, into 12 classes with 79% of accuracy. Their pipeline architecture uses the TF-IDF for text features extraction, the PCA for features selection, and SVM for features classification.

Several attempts in literature have been proposed to detect illegal activities whether on the World Wide Web (WWW) network (Biryukov et al., 2014; Graczyk and Kinningham, 2015; Moore and Rid, 2016), peer-to-peer networks (P2P) (Latapy et al., 2013; Peersman et al., 2014) and in chatting messaging systems (Morris and Hirst, 2012). Latapy et al. (2013) investigated P2P systems, e.g. eDonkey, to quantify the paedophile activity by building a tool to detect child-pornography queries

by performing a series of lexical text processing. They found that 0.25% of entered queries are related to pedophilia context, which means that 0.2% of eDonkey network users are entering such queries. However, this method is based on a predefined list of keywords which can not detect new or previously unknown words.

### 3 The Dataset

#### 3.1 Dataset Building Procedure

To best of our knowledge, there is no labeled dataset that encompasses the activities on the Darknet web pages. Therefore, we have created the first publicly available Darknet dataset and we called it *Darknet Usage Text Addresses (DUTA)* dataset. Currently, DUTA contains only Tor hidden services (HS). We built a customized crawler that utilizes Tor socket to fetch onion web pages through port 80 only i.e. the HTTP protocol. The crawler has 70 worker threads in parallel to download the HTML code behind the HS. Each thread dives into the second level in depth for each HS in order to gather as much text as possible rather than just the index page as in others work (Biryukov et al., 2014). It searches for the HS links on several famous Darknet resources like onion.city<sup>8</sup> and ahmia.fi<sup>9</sup>. We reached more than 250K HS addresses, but only 7K were alive, and the others were down or not responding. After that, we concatenated the HTML pages of every HS into a single HTML file resulting a single HTML file for each single HS domain. We collected 7,931 hidden services by running the crawler for two months between May and July 2016. For the time being, we labeled 6,831 samples.

#### 3.2 Dataset Characteristics

Darknet researchers have analyzed the HS contents and categorized them into a different number of categories. Biryukov et al. (2014) sampled 1,813 HS and detected 18 categories. Intelliagg group in (2015) analyzed 1K HS samples and classified them into 12 categories. Moore et al. (2016) studied 5,615 HS examples and categorized them into 12 classes. Based on our objective to build a multipurpose dataset and for the sake of completeness, we classified DUTA manually into 26 classes. To the best of our knowledge, this classification is the most extent and complete up to

<sup>6</sup>[www.github.com/lachesis/scallion](http://www.github.com/lachesis/scallion)

<sup>7</sup>[www.github.com/katmagic/Shallot](http://www.github.com/katmagic/Shallot)

<sup>8</sup>[www.onion.city](http://www.onion.city)

<sup>9</sup>[www.ahmia.fi](http://www.ahmia.fi)

date. The collected samples were divided among the four authors and each one labeled their designated part; if an author hesitated, it was openly discussed with the rest of the authors. Finally, to check the consistency of the manual labeling, the first author reviewed the final labeling by analyzing random samples of the categorization made by the others.

In addition to labeling the main classes, we dived into labeling the sub-classes of the HS. For example, the class *Counterfeit Personal Identification* has three sub-classes: *Identity Card*, *Driving License*, and *Passport*. Table 1 enumerates DUTA classes.

Main Class	Sub-Class	Count	Main Class	Count	
Violence	Hate	4	Art/ Music	8	
	Hitman	11	Casino/ Gambling	26	
	Weapons	47	Services	285	
Counterfeit Personal Identification	Driving-Licence	4	Cryptocurrency	586	
	ID	7	Down	608	
	Passport	37	Empty	1649	
Hosting and Software	File-Sharing	111	Forum	104	
	Folders	63	Hacking	90	
	Search-Engine	38	Wiki	29	
	Server	95	Leaked-Data	12	
	Software	121	Locked	435	
	Directory	142	Personal	405	
	Drugs	Illegal	230	Politics	8
		Legal	9	Religion	6
Marketplace	Black	63	Library/Books	27	
	White	67	Fraud	4	
Pornography	Child-pornography	914 <sup>(10)</sup>	Counterfeit Money	55	
	General-pornography	83	Counterfeit Credit Cards	240	
Social-Network	Blog	71	Human-Trafficking	2	
	Chat	47			
	Email	56			
	News	32	The total count	6831	

Table 1: DUTA dataset classes

Counterfeit is a wide class so we split it into three main classes 1) *Counterfeit Personal Identification* which is related to government documents forging. 2) *Counterfeit Money* includes currencies forging and 3) *Counterfeit Credit Cards* covers cloning credit cards, hacked PayPal accounts and fake markets cards like Amazon and eBay. The class *Services* contains the legal services that are provided by individuals or organizations. The class *Down* contains the errors that were returned by the down web pages while crawling them e.g. an SQL error in a website database or a javascript error.

We assign class *Empty* to a web page when:

<sup>10</sup>This class includes 57 unique sample plus 857 samples that are extracted from a single forum (See Section 3.2)

1) The text is very short i.e. less than 5 words, 2) It has only images with no text, 3) It contains unreadable text like special characters, numbers, or unreadable words, 4) The empty Cryptolockers pages (ransomware) (Ciancaglini et al., 2016). The class *Locked* contains the HS that require solving a CAPTCHA or a log-in credential. We noticed that some people love to present their works, projects, or even their personal information through an HS page so we labeled them into class *Personal*. The pages that fell under more than one category were labeled based on its main content. For example, we assign *Forum* label to the multi-topic forums unless the whole forum is related to a single topic. e.g. a hacking forum was assigned to *Hacking* class instead of *Forum*. The class *Marketplace* was divided into *Black* when it contained a group of illegal services like Drugs, Weapons, and Counterfeit services and *White* when the marketplace offered legal shops like mobile phones or clothes.

As we have labeled DUTA manually, we realized that some forums on HS contain numerous web pages and all of them are related to a single class i.e. we found a forum about child-pornography that has more than 800 pages of textual content, so we split it up into single samples representing one single forum page, and we added them to the dataset.

## 4 Methodology

Each classification pipeline is comprised of three main stages. First, text pre-processing, then, features extraction, and finally, classification. We used two famous text representation techniques across three different supervised classifiers resulting six different classification pipelines, and we examined every pipeline to figure out the best combination with the best parameters that can achieve high performance.

### 4.1 Text Pre-processing

Initially, we eliminated all the HTML tags, and when we detected an image tag, we preserved the image name and removed the extension. Furthermore, we filtered the training set for the non-English samples using Langdetect<sup>11</sup> python library and stemmed the text using Porter library from NLTK package<sup>12</sup>. Additionally, we re-

<sup>11</sup><https://pypi.python.org/pypi/langdetect>

<sup>12</sup><https://tartarus.org/martin/PorterStemmer/>

moved special characters and stop words thanks to SMART stop list<sup>13</sup> (Salton, 1971). At this stage, we modified the stop words list by adding 100 words more in order to make it compatible with the work domain. Moreover, we mapped all emails, URLs, and currencies into a single common token for each.

## 4.2 Features Extraction

After pre-processing the text, we used two famous text representation techniques. A) Bag-of-Words (BOW) is a well-known model for text representation that extracts the features from the text corpus by counting the words frequency. Consequently, every document is represented as a sparse feature vector where every feature corresponds to a single word in the training corpus. B) Term Frequency Inverse Document Frequency model (TF-IDF) (Aizawa, 2003) is a statistical model that assign weights for the vocabularies where it emphasizes the words that occur frequently in a given document, while at the same time de-emphasizes words that occur frequently in many documents. However, even though the BOW and TF-IDF do not take into considerations the words order, they are simple, computationally efficient and compatible with medium dataset sizes.

## 4.3 Classifier Selection

For each features representation method, we examined three different supervised machine learning algorithms which are Support Vector Machine (SVM) (Suykens and Vandewalle, 1999), Logistic Regression (LR) (Hosmer Jr and Lemeshow, 2004), and Naive Bayes (NB) (McCallum et al., 1998).

## 5 Empirical Evaluation

### 5.1 Experimental Setting

Due to the purpose of this paper to classify the Darknet illegal activities, we selected a subset of our DUTA dataset by creating eight categories trying to cover the most representative illegal activities on the Darknet. Another condition that we imposed was that each class in the selected subset should be monotopic (i.e. related to a single category) and contain a sufficient amount of samples (i.e. 40 samples minimum). The rest of the classes are assigned to a 9th category which we

<sup>13</sup><http://jmlr.csail.mit.edu/papers/volume5/lewis04a/a11-smart-stop-list/>

called *Others*. Since we are working on classifying the illegal activities, we did not consider the class *Black-Market* in the training set because its contents are related to more than one class at a single time, and we wanted the classifier to learn from pure patterns. Moreover, when a sample contains relevant images but an irrelevant text or without any textual information, we excluded it from the dataset. Therefore, we had 5,635 samples distributed over nine classes i.e. the eight classes plus the *Others* one ( Table 2). After the text pre-processing, we got 5,002 sample split it into a training set that contains 3,501 samples and a testing set of 1,501 samples.

Experiment Main Class	Count
Pornography	963
Cryptocurrency	578
Counterfeit Credit Cards	209
Drugs	169
Violence	60
Hacking	57
Counterfeit Money	46
Counterfeit Personal Identification (Driving-License, ID, Passport)	40
Others	3513

Table 2: Illegal activities dataset classes (A portion of DUTA dataset)

The dataset is highly unbalanced since the largest class has 3,513 samples while the smallest one has only 40 samples. We solved the skew in the dataset thanks to the *class-weight* parameter in Scikit-Learn library<sup>14</sup> which assigns a weight for each class proportional to the number of samples it has (Hauck, 2014). In addition to adjusting the weights of classes, we split up forums by the discussion page (See Section 3.2).

For the models tuning, we applied a grid search over different combinations of parameters with a cross-validation of 10 folds. The successful combination, which corresponds to the selected classification pipeline, is the one that can achieve the highest value of an averaged F1 score metric and an accuracy of 10 folds cross-validation.

We used Python3 with Scikit-Learn machine learning library for the pipelines implementation. We modified the parameters that have a critical influence on the performance of the models. For the BOW dictionary, we set it to 30,000 words with a minimum word frequency of 3, and we left the rest of the parameters to default. Regarding the TF-IDF, we set the maximum feature vectors length to

<sup>14</sup><http://scikit-learn.org/>

10,000 and the minimum to 3. With respect to the classifiers parameters, we kept the default setting for the NB. In contrast, for the LR, we modified only the value of the regularization parameter "C" by setting it to 10 with the balanced class-weight flag activated. For the SVM classifier, we set the decision function parameter to one-vs-rest "ovr", kernel to "RBF", "C" parameter to 10e5, balanced classes weights, and the rest were left to default.

## 5.2 Results and Discussion

Since we are working on an unbalanced multiclass problem, every class has a precision, a recall, and an F1 score. To combine these three values into a single value, we calculated the macro, micro and weighted average for each class as Table 3 shows. We can see that the pipeline of TF-IDF with LR achieves the highest value with a macro F1 score of 93.7% and the highest cross-validation accuracy of 96.6%. The state-of-the-art paper has achieved 94% accuracy on a different dataset that contains 1K samples (Intelliagg, 2015). Additionally, we plot the macro average precision-recall curve for four classifiers (Figure 2). The plot indicates that the pipeline of TF-IDF with LR achieves the highest precision-recall.

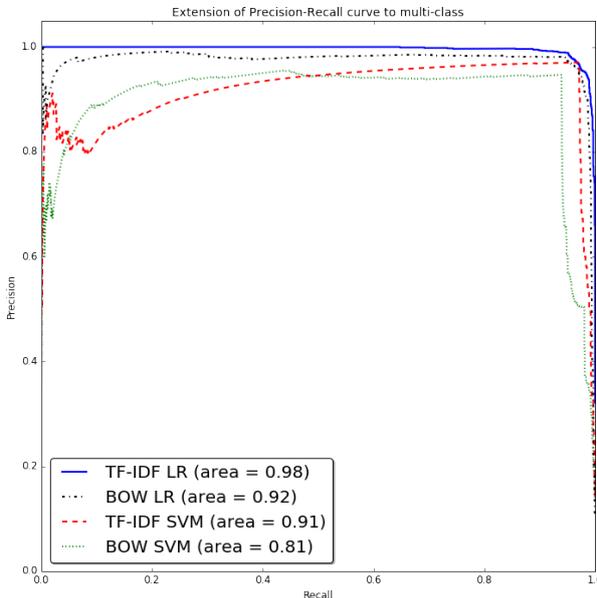

Figure 2: Macro averaging Precision-Recall curve over 4 pipelines, where the area value corresponds to the macro-average Precision-recall curve

Figure 3 shows F1 score comparison between the six classification pipelines over the nine classes. We can see that the classes *Counterfeit*

Metrics/Methods		Average (macro)	Average (micro)	Average (weighted)	CV Accuracy
BOW LR	P	0,952	0,965	0,965	0,958 +/- 0,010
	R	0,889	0,965	0,965	
	F1	0,916	0,965	0,964	
TFIDF LR	P	0,982	0,974	0,975	<b>0,966</b> +/- <b>0,010</b>
	R	0,902	0,974	0,974	
	F1	<b>0,937</b>	<b>0,974</b>	<b>0,974</b>	
BOW SVM	P	0,877	0,941	0,942	0,932 +/- 0,013
	R	0,875	0,941	0,941	
	F1	0,874	0,941	0,941	
TFIDF SVM	P	0,983	0,971	0,972	0,960 +/- 0,011
	R	0,882	0,971	0,971	
	F1	0,924	0,971	0,970

	R	0,790	0,941	0,941	
	F1	0,812	0,941	0,940	
TFIDF NB	P	0,530	0,885	0,855	0,863 +/- 0,012
	R	0,425	0,885	0,885	
	F1	0,460	0,885	0,860	

Table 3: A comparison between the classification pipelines with respect to 10 folds cross-validation accuracy (CV), precision (P), recall (R) and F1 score metrics for micro, macro and weighted averaging.

*Credit Cards* and *Hacking* have a low F1 score over all the pipelines, which is due to several reasons: firstly, the words interference between the classes. For example, the websites which offer counterfeiting credit cards services are most probably "Hack" the credit card system or "Attack" the PayPal accounts, the use sentences like "We hack credit card" or "Hacked Paypal account for sale". Moreover, those classes intersect with *Counterfeit Personal Identification* class due to their similarity from the perspective of forgery. Secondly, the number of samples that were used for training plays an important role during the learning phase, e.g. class *Violence* has 60 samples only.

Nevertheless, the learning curve for the TF-IDF LR pipeline in Figure 4 proves that the algorithm is learning correctly where the validation accuracy curve is raising up and classification accuracy is improving by increasing the number of the samples while the training accuracy curve is starting to decrease slightly. This high accuracy archived will help to build a solid model that will be able to detect illegal activity on Darknet.

## 6 Application and Implementation

The work presented in the previous sections has been included into an application that can be accessed and tested through a web browser. The implementation of the methods was developed in Python3 using Nltk library to stem the document text, Langdetect library to detect the language of

Figure 3: F1 score comparison for each class for 6 classification pipelines. When a bar is not shown, it means that its value is zero.

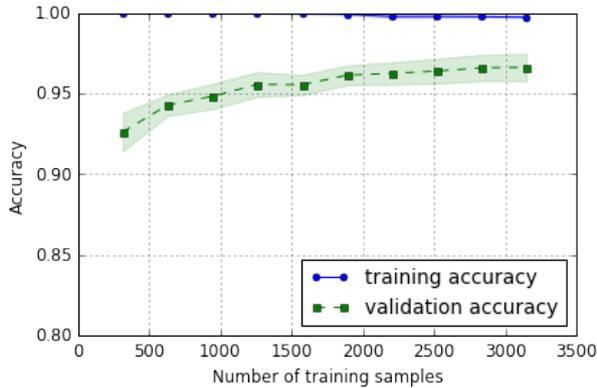

Figure 4: Learning Curve for TF-IDF with LR classifier

the documents and the Scikit-learn library to build the classifiers. The web application is made up of 3 views: one for algorithm selection, the second one for the selection of data to analyze and the third one for showing the results of the analysis (Figure 5).

The Docker image is not publicly available, neither the applications, but under email request, we will grant a temporal access to the web interface.

## 7 Conclusions and Future Work

In this paper, we have categorized illegal activities of Tor HS by using two text representation methods, TF-IDF and BOW, combined with three classifiers, SVM, LR, and NB. To support the classification pipelines, we built the dataset DUTA,

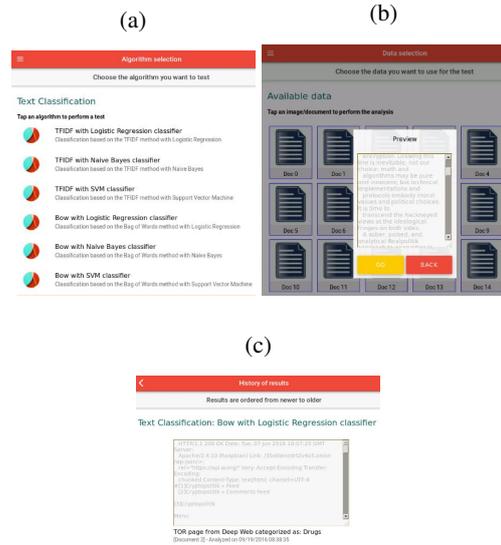

Figure 5: The application has three interfaces. (a) Pipeline selection. (b)The HS content preview. (c) The classification result.

containing 7K samples labeled manually into 26 categories. We picked out nine classes, including the *Others* class, that are related only to illegal activities e.g. drugs trading and child pornography and we used it for training our model. Furthermore, we distinguished the critical aspects that affect the classification pipeline results in term of text representation i.e. the dictionary size and the minimum word frequency influence the text representation techniques performance, and the regularization parameter on the LR and the SVM classifiers. We found that the combination of the TF-IDF text representation with the Logistic Regression classifier can achieve 96.6% accuracy over 10 folds of cross-validation and 93.7% macro F1 score. We noticed that our classifier suffers from overfitting due to the difficulty of reaching more samples of onion hidden services for some classes like counterfeiting personal identification or illegal drugs. However, our results are encouraging, and yet there is still a wide margin for future improvements. We are looking forward to enlarging the dataset by digging deeper into the Darknet by adding more HS sources, even from I2P and Freenet, and exploring ports other than the HTTP port. Moreover, we plan to get the benefit of the HTML tags and the hyperlinks by weighting some tags or parsing the hyperlinks text. Also, during the manual labeling of the dataset, we realized that a wide portion of the hidden services

advertise their illegal products graphically, i.e. the service owner uses the images instead of the text. Therefore, our aim is to build an image classifier to work in parallel with the text classification. The high accuracy we have obtained in this work might represent an opportunity to insert our research into a tool that supports the authorities in monitoring the Darknet.

## 8 ACKNOWLEDGEMENT

This research was funded by the frame agreement between the University of Len and INCIBE (Spanish National Cybersecurity Institute) under addendum 22. We also want to thank Francisco J. Rodriguez (INCIBE) for providing us the .onion web pages used to create the dataset.

## Abstract

Multitask learning has been applied successfully to a range of tasks, mostly morphosyntactic. However, little is known on *when* MTL works and whether there are data characteristics that help to determine its success. In this paper we evaluate a range of semantic sequence labeling tasks in a MTL setup. We examine different auxiliary tasks, amongst which a novel setup, and correlate their impact to data-dependent conditions. Our results show that MTL is not always effective, significant improvements are obtained only for 1 out of 5 tasks. When successful, auxiliary tasks with compact and more uniform label distributions are preferable.

## 1 Introduction

The recent success of recurrent neural networks (RNNs) for sequence prediction has raised a great deal of interest, which has lead researchers to propose competing architectures for several language-processing tasks. These architectures often rely on multitask learning (Caruana, 1997).

Multitask learning (MTL) has been applied with success to a variety of sequence-prediction tasks including chunking and tagging (Collobert et al., 2011; Søgaard and Goldberg, 2016; Bjerva et al., 2016; Plank, 2016), name error detection (Cheng et al., 2015) and machine translation (Luong et al., 2016). However, little is known about MTL for tasks which are more *semantic* in nature, i.e., tasks that aim at labeling some aspect of the meaning of words (Cruse, 1986), instead their morphosyntactic behavior. In fact, results on semantic tasks are either mixed (Collobert et al., 2011) or, due to the file drawer bias (Rosenthal, 1979), simply not reported. There is no prior study—to

the best of our knowledge—that compares data-dependent conditions with performance measures to shed some light on when MTL works for semantic sequence prediction. Besides any variation in annotation and conceptualization, the label distributions of such semantic tasks tends to be very different to the characteristic distributions expected in more frequently studied morphosyntactic tasks such as POS-tagging.

The main contribution of this work is an evaluation of MTL on semantic sequence prediction on data-dependent conditions. We derive characteristics of datasets that make them favorable for MTL, by comparing performance with information-theoretical metrics of the label frequency distribution.

We use an off-the-shelf state-of-the-art architecture based on bidirectional Long-Short Term Memory (LSTM) models (Section 3) and evaluate its behavior on a motivated set of main and auxiliary tasks. We gauge the performance of the MTL setup (Section 4) in the following ways: i) we experiment with different combinations of main and auxiliary tasks, using semantic tasks as main task and morphosyntactic tasks as auxiliary tasks; ii) we apply FREQBIN, a frequency-based auxiliary task (see Section 2.5) to a series of language-processing tasks and evaluate its contribution, and iii) for POS we experiment with different data sources to control for label inventory size and corpus source for the auxiliary task.

From our empirical study we observe the MTL architecture’s sensitivity to label distribution properties, and its preference for compact, mid-entropy distributions. Additionally, we provide a novel parametric refinement of the FREQBIN auxiliary task that is more robust. In broader terms, we expect to motivate more thorough analysis of the performance of neural networks in MTL setups.

## 2 Analyzing multi-task learning

Multitask learning systems are often designed with the intention of improving a *main* task by incorporating joint learning of one or more related *auxiliary* tasks. For example, training a MTL model for the main task of chunking and treating part-of-speech tagging (POS) as auxiliary task.

The working principle of multitask learning is to improve generalization performance by leveraging training signal contained in related tasks (Caruana, 1997). This is typically done by training a single neural network for multiple tasks jointly, using a representation that is shared across tasks. The most common form of MTL is the inclusion of one output layer per additional task, keeping all hidden layers common to all tasks. Task-specific output layers are customarily placed at the outermost layer level of the network.

In the next section, we depict all main and auxiliary tasks considered in this paper.

### 2.1 Main tasks

We use the following main tasks, aimed to represent a variety of semantic sequence labeling tasks.

**FRAMES:** We use the FrameNet 1.5 (Baker et al., 1998) annotated corpus for a joint frame detection and frame identification tasks where a word can receive a predicate label like *Arson* or *Personal success*. We use the data splits from (Das et al., 2014; Hermann et al., 2014). While frame identification is normally treated as single classification, we keep the sequence-prediction paradigm so all main tasks rely on the same architecture.

**SUPERSENSES:** We use the supersense version of SemCor (Miller et al., 1993) from (Ciaramita and Altun, 2006), with coarse-grained semantic labels like *noun.person* or *verb.change*.

**NER:** The CONLL2003 shared-task data for named entity recognition for labels *Person*, *Loc*, etc. (Tjong Kim Sang and De Meulder, 2003).

**SEMTRAITS:** We have used the EurWordNet list of ontological types for senses (Vossen et al., 1998) to convert the SUPERSENSES into coarser semantic traits like *Animate* or *UnboundedEvent*.<sup>1</sup>

**MPQA:** The Multi-Perspective Question Answering (MPQA) corpus (Deng and Wiebe, 2015), which contains sentiment information among others. We use the annotation corresponding to the

<sup>1</sup>Available at: <https://github.com/bplank/multitasksemantics>

*coarse* level of annotation, with labels like *attitude* and *direct-speech-event*.

### 2.2 Auxiliary tasks

We have chosen auxiliary tasks that represent the usual features based on frequency and morphosyntax used for prediction of semantic labels. We collectively refer to them as *lower-level tasks*.

**CHUNK:** The CONLL2003 shared-task data for noun- and verb-phrase chunking (Tjong Kim Sang and De Meulder, 2003).

**DEPREL:** The dependency labels for the English Universal Dependencies v1.3 (Nivre et al., 2016).

**FREQBIN:** The log frequency of each word, treated as a discrete label, cf. Section 2.5.

**POS:** The part-of-speech tags for the Universal Dependencies v1.3 English treebank.

### 2.3 Data properties

Table 1 lists the datasets used in this paper, both to train main tasks and auxiliary tasks. For each dataset we list the following metrics: number of sentences, number of tokens, token-type ratio (TTR), the size of the label inventory counting B-labels and I-labels as different ( $|Y|$ ), and the proportion of out-of-span labels, which we refer to as O labels.

The table also provides some of the information-theoretical measures we describe in Section 2.4. Note that DEPRELS and POS are the only datasets without any O labels, while FRAMES and SEMTRAITS are the two tasks with O labels but no B/I-span notation, as tokens are annotated individually.

### 2.4 Information-theoretic measures

In order to quantify the properties of the different label distributions, we calculate three information-theoretical quantities based on two metrics, kurtosis and entropy.

**Entropy** is the best-known information-theoretical metric. It indicates the amount of uncertainty in a distribution. We calculate two variants of entropy, one taking all labels in consideration  $H(Y_{full})$ , and another one  $H(Y_{-O})$  where we discard the O label and only measure the entropy for the named labels, such as frame names in FRAMES. The entropy of the label distribution  $H(Y_{full})$  is always lower than the entropy for the distribution disregarding the O label  $H(Y_{-O})$ . This difference is a consequence

	sentences	tokens	TTR	$ Y $	prop of O	$k(Y)$	$H(Y_{full})$	$H(Y_{-o})$
FRAMES	5.9k	119k	.12	707	.80	701.41	1.60	5.51
MPQA	1.7k	44k	.15	9	.65	2.79	1.12	1.33
NER	22.1k	303k	.10	9	.83	4.10	0.77	1.93
SEMTRAITS	20k	435k	.07	11	.66	5.68	1.29	1.89
SUPERSENSES	20k	435k	.07	83	.66	76.73	1.84	3.53
CHUNK	22.1k	303k	.10	22	.14	3.68	1.73	1.54
DEPRELS	16.6k	255k	.09	47	-	1.80	3.11	3.11
FREQBIN	<i>Same as respective main task</i>			4–7	-	<i>Depends on variant</i>		
POS	16.6k	255k	.09	17	-	-0.20	2.49	2.49

Table 1: Datasets for main tasks (above) and auxiliary tasks (below) with their number of sentences, tokens, type-token ratio, size of label inventory, proportion of O labels, kurtosis of the label distribution, entropy of the label distribution, and entropy of the label distribution without the O label.

of the O-label being often the majority class in span-annotated datasets. The only exception is CHUNK, where O-tokens make up 14% of the total, and the full-distribution entropy is higher.

**Kurtosis** indicates the skewness of a distribution and provides a complementary perspective to the one given by entropy. The kurtosis of the label distribution describes its tailedness, or lack thereof. The kurtosis for a normal distribution is 3, and higher kurtosis values indicate very tailed distributions, while lower kurtosis values indicate distributions with fewer outliers.

For instance, we can see that larger inventory sizes yield more heavy-tailed distributions, e.g. FRAMES presents a lot of outliers and has the highest kurtosis. The very low value for POS indicates a distribution that, although Zipfian, has very few outliers as a result of the small label set. In contrast, DEPRELS, coming from the same corpus, has about three times as many labels, yielding a distribution that has fewer mid-values while still being less than 3. Nevertheless, the entropy values of POS and DEPRELS are similar, so kurtosis provides a complementary perspective on the data.

## 2.5 FREQBIN variants

Recently, a simple auxiliary task has been proposed with success for POS tagging: predicting the log frequency of a token (Plank et al., 2016). The intuition behind this model is that the auxiliary loss, predicting word frequency, helps differentiate rare and common words, thus providing better predictions for frequency-sensitive labels. They refer to this auxiliary task as FREQBIN, however, focus on POS only. Plank et al. (2016) used the discretized log frequency of the current word to build the FREQBIN auxiliary task to aid POS

tagging, with good results. This auxiliary task aids the prediction of the main task (POS) in about half the languages, and improves the prediction of out of vocabulary words. Therefore, it is compelling to assess the possible contribution of FREQBIN for other tasks, as it can be easily calculated from the same training data as the main task, and requires no external resources or annotation.

We experiment with three different variants of FREQBIN, namely:

1. SKEWED<sub>10</sub>: The original formulation of  $a = \text{int}(\log_{10}(\text{freqtrain}(w)))$ , where  $a$  is the frequency label of the word  $w$ . Words not in the training data are treated as hapaxes.
2. SKEWED<sub>5</sub>: A variant using 5 as logarithm base, namely  $a = \text{int}(\log_5(\text{freqtrain}(w)))$ , aimed at providing more label resolution, e.g. for the NER data, SKEWED<sub>10</sub> yields 4 different labels, and SKEWED<sub>5</sub> yields 6.
3. UNIFORM: Instead of binning log frequencies, we take the index of the  $k$ -quantized cumulative frequency for a word  $w$ . We use this parametric version of FREQBIN with the median number of labels produced by the previous variants to examine the importance of the label distribution being skewed. For  $k=5$ , this variant maximizes the entropy of a FREQBIN five-label distribution. Note that this method still places all hapaxes and out-of-vocabulary words of the test data in the same frequency bin.

Even though we could have used a reference corpus to have the same FREQBIN for all the data, we prefer to use the main-task corpus for FREQBIN. Using an external corpus would otherwise lead to a semisupervised learning scenario which is out of the scope of our work. Moreover, in us-

ing only the input corpus to calculate frequency we replicate the setup of Plank et al. (2016) more closely.

### 3 Model

Recurrent neural networks (RNNs) (Elman, 1990; Graves and Schmidhuber, 2005) allow the computation of fixed-size vector representations for word sequences of arbitrary length. An RNN is a function that reads in  $n$  vectors  $x_1, \dots, x_n$  and produces a vector  $h_n$ , that depends on the entire sequence  $x_1, \dots, x_n$ . The vector  $h_n$  is then fed as an input to some classifier, or higher-level RNNs in stacked/hierarchical models. The entire network is trained jointly such that the hidden representation captures the important information from the sequence for the prediction task.

A bi-directional recurrent neural network (Graves and Schmidhuber, 2005) is an extension of an RNN that reads the input sequence twice, from left to right and right to left, and the encodings are concatenated. An LSTM (Long Short-Term Memory) is an extension of an RNN with more stable gradients (Hochreiter and Schmidhuber, 1997). Bi-LSTM have recently successfully been used for a variety of tasks (Collobert et al., 2011; Huang et al., 2015; Dyer et al., 2015; Ballesteros et al., 2015; Kiperwasser and Goldberg, 2016; Liu et al., 2015; Plank et al., 2016). For further details, cf. Goldberg (2015) and Cho (2015).

We use an off-the-shelf bidirectional LSTM model (Plank et al., 2016).<sup>2</sup> The model is illustrated in Figure 1. It is a context bi-LSTM taking as input word embeddings  $\vec{w}$ . Character embeddings  $\vec{c}$  are incorporated via a hierarchical bi-LSTM using a sequence bi-LSTM at the lower level (Ballesteros et al., 2015; Plank et al., 2016). The character representation is concatenated with the (learned) word embeddings  $\vec{w}$  to form the input to the context bi-LSTM at the upper layers. For hyperparameter settings, see Section 3.1.

The stacked bi-LSTMs represent the shared layers between tasks. We here use three stacked ( $h=3$ ) bi-LSTMs for the upper layer, and a single layer bi-LSTM at the lower level for the character representations. Following Collobert et al. (2011), at the outermost ( $h = 3$ ) layer separate output layers for the single tasks are added using a

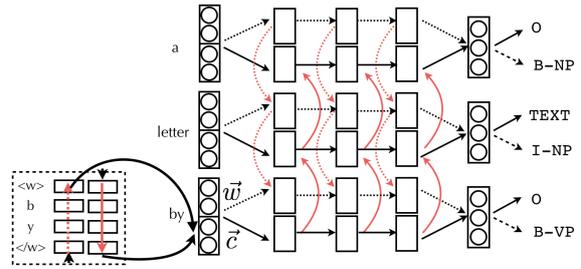

Figure 1: Multi-task bi-LSTM. The input to the model are word  $\vec{w}$  and character embeddings  $\vec{c}$  (from the lower bi-LSTM). The model is a stacked 3-layer bi-LSTM with separate output layers for the main task (solid line) and auxiliary tasks (dashed line; only one auxiliary task shown in the illustration).

softmax. We additionally experiment with predicting lower-level tasks at inner layers, i.e., predicting POS at  $h = 1$ , while the main task at  $h = 3$ , the outermost layer, following Søgaard and Goldberg (2016). During training, we randomly sample a task and instance, and backpropagate the loss of the current instance through the shared deep network. In this way, we learn a joint model for main and auxiliary task(s).

#### 3.1 Hyperparameters

All the experiments in this article use the same bi-LSTM architecture described in Section 3. We train the bi-LSTM model with default parameters, i.e., SGD with cross-entropy loss, no mini-batches, 30 epochs, default learning rate (0.1), 64 dimensions for word embeddings, 100 for character embeddings, 100 hidden states, random initialization for the embeddings, Gaussian noise with  $\sigma=0.2$ . We use a fixed random seed set upfront to facilitate replicability. The only hyperparameter we further examine is the number of epochs, which is set to 30 unless otherwise specified.

We follow the approach of Collobert et al. (2011) in that we do *not* use any task-specific features beyond word and character information, nor do we use pre-trained word embeddings for initialisation or more advanced optimization techniques.<sup>3</sup> While any of these changes would likely improve the performance of the systems, the goal of our experiments is to delimit the behavior of the bi-LSTM architecture and the interaction between main and auxiliary task(s).

<sup>2</sup>Available at: <https://github.com/bplank/bilstm-aux>

<sup>3</sup>For example, AdamTrainer or MomentumSGDTrainer in py rnn.

### 3.2 Experimental Overview

A system in our experiments is defined by a main task and up to two auxiliary tasks, plus a choice of output layers (at which layer to predict the auxiliary task, i.e.,  $h \in \{1,2,3\}$ ). For each main task, we ran the following systems:

1. Baseline, without any auxiliary task.
2. One additional system for each auxiliary task, say DEPREL.
3. A combination of each of the three versions of FREQBIN, namely SKEWED<sub>5</sub>, SKEWED<sub>10</sub> and UNIFORM, and each of the other auxiliary tasks, such as DEPREL+UNIFORM.

The total combination of systems for all five main tasks is 1440.

## 4 Results

This section describes the results of both experimental scenarios, namely the benchmarking of FREQBIN as an auxiliary task, and the combinations of semantic main task with low-level auxiliary tasks, including an analysis of the data properties. The different tasks in our experiments typically use different evaluation metrics, however we evaluate all tasks on micro-averaged F1 without the O class, which we consider the most informative overall. We do not use the O-label’s F1 score because it takes recall into consideration, and it is deceptively high for the majority class. We test for significance with a 10K-iteration bootstrap sample test, and  $p < .05$ .

### 4.1 Main semantic tasks

This section presents the results for the prediction of the main semantic tasks described in Section 2. Given the size of the space of possible task combinations for MTL, we only report the baseline and the results of the best system. Table 2 presents the results for all main semantic tasks, comparing the results of the best system with the baseline. The last column indicates the amount of systems that beat the baseline for a given certain main task. Having fixed the variant of FREQBIN to UNIFORM (see Section 4.2), and the number of epochs to 30 (see below) on development data, the total amount of systems for any main task is 22.

Out of the two main tasks over the baseline only SEMTRAITS is significantly better over BL. SEMTRAITS has a small label set, so the system is able to learn shared parameters for the label combinations of main and aux without suffering from too

	BL	$\Delta$ Best	Description	aux layer	# over
FRAMES	38.93	-8.13	+FREQBIN	outer	0
MPQA	28.26	<b>0.96</b>	+POS+FREQBIN	inner	2
NER	90.60	-0.58	+FREQBIN	inner	0
SEMTRAITS	70.42	<u>1.24</u>	+FREQBIN	outer	13
SUPERSENSES	62.36	-0.13	+POS+FREQBIN	inner	0

Table 2: Baseline (BL) and best system performance difference ( $\Delta$ ) for all main tasks—improvements in bold, significant improvements underlined—plus number of systems over baseline for each main task.

much sparsity. Compare with the dramatic loss of the already low-performing FRAMES, which has the highest kurtosis caused by the very long tail of low-frequency labels.

We have expected CHUNK to aid SUPERSENSES, but in spite of our expectations, other low-level tasks do not aid in general the prediction of high-level task. What is otherwise an informative feature for a semantic task in single-task learning does not necessarily lend itself as an equally useful auxiliary task for MTL.

For a complementary evaluation, we have also measured the precision of the O label. However, precision score is also high, above 90, for all tasks except the apparently very difficult MPQA (70.41 for the baseline). All reported systems degrade around 0.50 points with regards to the baseline, except SUPERSENSES which improves slightly from 96.27 to 96.44. The high precision obtained for the also very difficult FRAMES tasks suggests that this architecture, while not suitable for frame disambiguation, can be used for frame-target identification. Disregarding FREQBIN, the only low-level tasks that seems to aid prediction is POS.

An interesting observation from the BIO task analysis is that while the standard bi-LSTM model used here does not have a Viterbi-style decoding like more complex systems (Ma and Hovy, 2016; Lample et al., 2016), we have found very few invalid BIO sequences. For NER, there are only ten I-labels after an O-label, out of the 27K predicted by the bi-LSTM. For SUPERSENSES there are 59, out of 1,5K predicted I-labels.

The amount of invalid predicted sequences is lower than expected, indicating that an additional decoding layer plays a smaller role in prediction quality than label distribution and corpus size, e.g. NER is a large dataset with few labels, and the system has little difficulty in learning label precedences. For larger label sets or smaller data sizes,

invalid sequence errors are bound to appear because of sparseness.

**Effect of output layer choice** We observe no systematic tendency for an output layer to be a better choice, and the results of choosing the inner- or outer-layer ( $h=1$  vs  $h=3$ ) input differ only minimally. However, both systems that include POS have a preference for the inner layer having higher performance, which is consistent with the results for POS in (Søgaard and Goldberg, 2016).

**Effect of the number of training epochs** Besides all the data properties, the only hyperparameter that we examine further is the number of network training epochs.<sup>4</sup> All the results reported in this article have been obtained in a 30-epoch regime. However, we have also compared system performance with different numbers of epochs. Out of the values we have experimented (5,15,30,50) with, we recommend 30 iterations for this architecture. At 5 and 15 epochs, the performance does not reach the levels for 30 and is consistently worse for baselines and auxiliary-task systems. Moreover, the performance for 50 is systematically worse than for 30, which indicates overfitting at this point.

**Effect of training data size** We have run all systems increasing the size of the main task training data in blocks of 25%, keeping the size of the auxiliary task constant. We do not observe improvements over baseline along the learning curve for any of the main tasks except MPQA and SEMTRAITS. At smaller main task data sizes, the auxiliary task learning swamps the training of the main task. This results is consistent with the findings by Luong et al. (2016). We leave the research on the effects auxiliary data size—and its size ratio with regards to the main task—for further work.

## 4.2 Auxiliary task contribution

As follows from the results so far, the bi-LSTM will not benefit from auxiliary loss if there are many labels and entropy is too high. Auxiliary task level distribution also plays a role, as we will discuss in Section 4.3, FREQBIN-UNIFORM consistently outperforms the skewed measure with base 5 and 10.

<sup>4</sup>Number of epochs is among the most influential parameters of the system. Adding more layers did not further improve results.

	BL	$\Delta$ UD/UPOS	$\Delta$ UD/PTB	$\Delta$ WSJ/PTB
FRAMES	38.93	-14.64	-16.02	-28.18
NER	90.60	-1.36	-2.05	-2.56
MPQA	28.26	-5.62	-13.53	-14.81
SEMTRAITS	70.42	0.67	-0.3	-0.14
SUPERSENSES	62.36	-2.86	-2.83	-6.32
CHUNK	94.76	0.2	0.18	0.18
DEPRELS	88.70	-0.19	-0.18	-1.06
POS	94.36	-	0.18	-0.53

Table 3: Comparison different POS variants (data source/tag granularity): Baseline (BL) and the difference in performance on the +POS system when using the UD Corpus with UPOS (UD/UPOS) or with PTB tabs (UD/PTB), as well as the Wall Street Journal with PTB tags (WSJ/PTB).

Therefore we have also measured the effect of using different sources of POS auxiliary data to give account for the possible differences in label inventory and corpus for all tasks, high and low-level, cf. Table 3. The English UD treebank is distributed with Universal POS (UPOS), which we use throughout this article, and also with Penn Treebank (PTB) tags (Marcus et al., 1993). We have used the PTB version of the English UD corpus (UD/PTB) as well as the training section of the Wall Street Journal (WSJ) treebank as of POS (WSJ/PTB) auxiliary task. The former offers the opportunity to change the POS inventory to the three times larger PTB inventory while using the same corpus.

However, the characteristics of the UD/UPOS we have used as POS throughout the article makes it a more suitable auxiliary source, in fact it systematically outperforms the other two. We argue that UD/UPOS has enough linguistic signal to be a useful auxiliary task, while still depending on a smaller label inventory. Interestingly, if we use POS for CHUNK (cf. Table 3), note that even though the language in WSJ is closer to the language in the training corpora for CHUNK and NER, it is not the best auxiliary POS source for either task.

We observe an improvement when using UD/PTB for POS, while using WSJ/PTB worsens the results for this task. We argue that this architecture benefits from the scenario where the same corpus is used to train with two different label sets for POS, whereas using a larger label set and a different corpus does not aid prediction.

### 4.3 Analyzing FREQBIN

In this section we evaluate the interaction between all tasks and the FREQBIN auxiliary task. For this purpose, we treat all tasks (high- or low-level) as main task, and compare the performance of a single-task baseline run, with a task +FREQBIN setup. We have compared the three versions of FREQBIN (Section 2.5) but we only report UNIFORM, which consistently outperforms the other two variants, according to our expectations.

Table 4 lists all datasets with the size of their label inventory for reference ( $|Y|$ ), as well as the absolute difference in performance between the FREQBIN-UNIFORM system and the baseline ( $\Delta$ ). Systems that beat the baseline are marked in bold.

Following Plank et al. (2016), the FREQBIN system beats the baseline for the POS task. Moreover, it also aids the prediction for SEMTRAITS and MPQA. The better performance of these two systems indicates that this architecture is not necessarily only advisable for lower-level tasks, as long as the datasets have the right data properties.

	$ Y $	BL	$\Delta U$	$R^2$
FRAMES	707	38.93	-8.13	.00
MPQA	9	28.26	<b>0.44</b>	.09
NER	9	90.60	-1.31	.26
SEMTRAITS	11	70.42	<u>1.12</u>	.44
SUPERSENSES	83	62.36	-0.69	.47
CHUNK	22	94.76	-0.14	.49
POS	17	94.35	<b>0.21</b>	.68
DEPRELS	47	88.70	-0.16	.64

Table 4: Label inventory size ( $|Y|$ ), FREQBIN-baseline absolute difference in performance ( $\Delta$ )—improvements are in bold, significant improvements are underlined—and coefficient of determination for label-to-frequency regression ( $R^2$ ).

The improvement of low-level classes is clear in the case of POS. We observe an improvement from 75 to 80 for the X label, mostly made up of low-frequency items. The similarly scattered label INTJ goes from 84 to 87. While no POS label drops in performance on +FREQBIN with regards to the baseline, all the other improvements are of 1 point of less.

### 4.4 Label-frequency co-informativeness

To supplement the benchmarking of FREQBIN, we estimate how much frequency information is contained in all the linguistic sequence annotations

used in this article. We do so by evaluating the coefficient of determination ( $R^2$ ) of a linear regression model to predict the log frequency of a word given its surrounding label trigram, which we use as a proxy for sequence prediction. For instance, for ‘the *happy* child’, it would attempt to predict the log-frequency of *happy* given the ‘DET ADJ NOUN’ POS trigram. Note that this model is delexicalized, and only uses task labels because its goal is to determine how much word-frequency information is contained in e.g. the POS sequence. A high  $R^2$  indicates there is a high proportion of the variance of log frequency explained by the label trigram. We use linear regression implemented in `sklearn` with L2 regularization and report the average  $R^2$  of 10-fold cross-validation.

POS is the label set with the highest explanatory power over frequency, which is expectable: determiners, punctuations and prepositions are high-frequency word types, whereas hapaxes are more often closed-class words. DEPRELS sequences contain also plenty of frequency information. Three sequence tasks have similar scores under .50, namely CHUNK, SUPERSENSE and SEMTRAITS. They all have in common that their O class is highly indicative of function words, an argument supported by their similar values of full-distribution entropy. The one with the lowest score out of these three, namely SEMTRAITS is the one with the least grammatical information, as it does not contain part of speech-related labels. The ( $R^2$ ) is very low for the remaining tasks, and indeed, for FRAMENET it is a very small negative number which rounds up to zero.

While the co-informativeness of FREQBIN with regards to its main task is a tempting explanation, it does not fully explain when it works as an auxiliary task. Indeed, the FREQBIN contribution at handling out-of-vocabulary words seems to only affect POS and SEMTRAITS, while it does not improve DEPRELS, which normally depends on syntactic trees for accurate prediction.

## 5 Net capacity and contribution of character representation

In this section we alter the network to study the effect of network width and character representations. Multitask learning allows easy sharing of parameters for different tasks. Part of the explanation for the success of multitask learning are related to *net capacity* (Caruana, 1997). Enlarg-

ing a network’s hidden layers reduces generalization performance, as the network potentially learns dedicated parts of the hidden layer for different tasks. This means that the desirable trait of parameter sharing of MTL is lost. To test this property, we train a MTL network for all setups where we increase the size of the hidden layer by a factor  $k$ , where  $k$  is the number of auxiliary tasks.

Our results confirm that increasing the size of the hidden layers reduces generalization performance. This is the case for all setups. None of the results is better than the best systems in Table 2, and the effective number of systems that outperform the baseline are fewer (FRAMES: 0, MPQA: 2, NER: 0, SEMTRAITS: 9, SUPERSENSES: 0).

Throughout the article we used the default network structure which includes a lower-level bi-LSTM at the character level. However, we hypothesize that the character features are not equally important for all tasks. In fact, if we disable the character features, making the system only depend on word information (cf. Table 5), we observe that two of the tasks (albeit the ones with the overall lowest performance) increase their performance in about 2.5 points, namely MPQA and FRAMES. For the other two tasks we observe drops up to a maximum of 8-points for NER. Character embeddings are informative for NER, because they approximate the well-known capitalization features in traditional models. Character features are not informative for tasks that are more dependent on word identity (like FRAMES), but are indeed useful for tasks where parts of the word can be informative, such as POS or NER.

	BL ( $w + c$ )	$\Delta$ only $w$
FRAMES	38.93	+2.39
NER	90.60	-8.05
MPQA	28.26	+2.91
SEMTRAITS	70.42	-3.62
SUPERSENSES	62.36	-4.44
CHUNK	94.76	-0.96
DEPRELS	88.70	-1.87
POS	94.36	-3.18

Table 5: Comparison default hierarchical systems using a lower-level bi-LSTM for characters (BL  $w + c$ ) versus system using only words ( $w$ ).

## 6 Related Work

Multitask learning has been recently explored by a number of studies, including name error recog-

nition (Cheng et al., 2015), tagging and chunking (Collobert et al., 2011; Plank et al., 2016), entity and relation extraction (Gupta et al., 2016), machine translation (Luong et al., 2016) and machine translation quality estimation including modeling annotator bias (Cohn and Specia, 2013; Shah and Specia, 2016). Most earlier work had in common that it assumed jointly labeled data (same corpus annotated with multiple labels). In contrast, in this paper we evaluate multitask training from distinct sources to address data paucity, like done recently (Kshirsagar et al., 2015; Braud et al., 2016; Plank, 2016).

Sutton et al. (2007) demonstrate improvements for POS tagging by training a joint CRF model for both POS tagging and noun-phrase chunking. However, it is not clear under what conditions multi-task learning works. In fact, Collobert et al. (2011) train a joint feedforward neural network for POS, chunks and NER, and observe only improvements in chunking (similar to our findings, cf. Section 4.2), however, did not investigate data properties of these tasks.

To the best of our knowledge, this is the first extensive evaluation of the effect of data properties and main-auxiliary task interplay in MTL for semantic sequence tasks. The most related work is Luong et al. (2016), who focus on the effect of auxiliary data size (constituency parsing) on the main task (machine translation), finding that large amounts of auxiliary data swamp the learning of the main task. Earlier work related to MTL is the study by Ando and Zhang (2005) who learn many auxiliary task from unlabeled data to aid morphosyntactic tasks.

## 7 Conclusions and Future Work

We have examined the data-conditioned behavior of our MTL setup from three perspectives. First, we have tested three variants of FREQBIN showing that our novel parametric UNIFORM variant outperforms the previously used SKEWED<sub>10</sub>, which has a number of labels determined by the corpus size. Second, we examined main-auxiliary task combinations for five semantic tasks and up to two lower-level tasks. We observe that the best auxiliary task is either FREQBIN or FREQBIN+POS, which have low kurtosis and fairly high entropy.

We also explored three sources of POS data as auxiliary task, differing in corpus composition or

label inventory. We observe that the UPOS variant is the most effective auxiliary task for the evaluated architecture. Indeed, UPOS has fewer labels, and also a more compact distribution with lower kurtosis than its PTB counterpart.

While we propose a better variant of FREQBIN (UNIFORM) we conclude that it is not a useful auxiliary task in the general case. Rather, it helps predict low-frequency labels in scenarios where the main task is already very co-informative of word frequency. While log frequency lends itself naturally to a continuous representation so that we could use regression to predict it instead of classification, doing so would require a change of the architecture and, most importantly, the joint loss. Moreover, discretized frequency distributions allow us to interpret them in terms of entropy. Thus, we leave it to future work.

When comparing system performance to data properties, we determine the architecture’s preference for compact, mid-entropy distributions what are not very skewed, i.e., have low kurtosis. This preference explains why the system fares consistently well for a lot of POS experiments but falls short when used for task with many labels or with a very large O majority class. Regarding output layer choice, we have not found a systematic preference for inner or outer-layer predictions for an auxiliary task, as the results are often very close.

We argue strongly that the difficulty of semantic sequence predictions can be addressed as a matter of data properties and not as the antagonistic truism that morphosyntax is easy and semantics is hard. The underlying problems of semantic task prediction have often to do with the skewedness of the data, associated often to the preponderance of the O-class, and a possible detachment from mainly lexical prediction, such as the spans of MPQA.

This paper is only one step towards better understanding of MTL. It is necessarily incomplete, we hope to span more work in this direction. For instance, the system evaluated in this study has no Viterbi-style decoding for sequences. We hypothesize that such extension of the model would improve prediction of labels with strong interdependency, such as BIO-span labels, in particular for small datasets or large label inventories, albeit we found the current system predicting fewer invalid sequences than expected. In future, we would like to extend this work in several directions: comparing different MTL architectures, additional tasks,

loss weighting, and comparing the change of performance between a label set used as an auxiliary task or as a—predicted—feature.

# Learning Compositionality Functions on Word Embeddings for Modelling Attribute Meaning in Adjective-Noun Phrases

Matthias Hartung    Fabian Kaupmann    Soufian Jebbara    Philipp Cimiano  
Semantic Computing Group  
CITEC, Bielefeld University  
{mhartung, fkaupmann, sjebbara, cimiano}@techfak.uni-bielefeld.de

## Abstract

Word embeddings have been shown to be highly effective in a variety of lexical semantic tasks. They tend to capture meaningful relational similarities between individual words, at the expense of lacking the capability of making the underlying semantic relation explicit. In this paper, we investigate the *attribute* relation that often holds between the constituents of adjective-noun phrases. We use CBOW word embeddings to represent word meaning and learn a compositionality function that combines the individual constituents into a phrase representation, thus capturing the compositional attribute meaning. The resulting embedding model, while being fully interpretable, outperforms count-based distributional vector space models that are tailored to attribute meaning in the two tasks of attribute selection and phrase similarity prediction. Moreover, as the model captures a generalized layer of attribute meaning, it bears the potential to be used for predictions over various attribute inventories without re-training.

## 1 Introduction

*Attributes* such as SIZE, WEIGHT or COLOR are part of the building blocks of representing knowledge about real-world entities or events (Barsalou, 1992). In natural language, formal attributes find their counterpart in attribute nouns which can be used in order to generalize over individual properties, e.g., *big* or *small* in case of SIZE, *blue* or *red* in case of COLOR (Hartung, 2015).

In order to ascribe such properties to entities or events, adjective-noun phrases are a very frequent linguistic pattern. In these constructions, attribute

meaning is conveyed only implicitly, i.e., without being overtly realized at the phrasal surface. Hence, *attribute selection* has been defined as the task of predicting the hidden attribute meaning expressed by a property-denoting adjective in composition with a noun (Hartung and Frank, 2011b), as in the following examples:

- (1) a. *hot summer* → TEMPERATURE
- b. *hot debate* → EMOTIONALITY
- c. *hot soup* → TASTE/TEMPERATURE

Previous work on this task has largely been carried out in distributional semantic models (cf. Hartung (2015) for an overview). In the face of the recent rise of distributed neural representations as a means of capturing lexical meaning in NLP tasks (Collobert et al., 2011; Mikolov et al., 2013a; Pennington et al., 2014), our goal in this paper is to model attribute meaning based on word embeddings. In particular, we use CBOW embeddings of adjectives and nouns (Mikolov et al., 2013a) as underlying word representations and train a compositionality function in order to compute a phrase representation that is predictive of the implicitly conveyed attribute meaning.

In fact, word embeddings (also referred to as *predict models*) have been shown to be highly effective in a variety of lexical semantic tasks (Baroni et al., 2014b), compared to “traditional” distributional semantic models (or *count models*) in the tradition of Harris (1954). However, this finding has been refuted to a certain extent by Levy et al. (2015), stating that much of the perceived superiority of word embeddings is due to hyperparameter optimizations rather than principled advantages. Moreover, the authors found that in many cases, tailoring count models to a particular task at hand is both feasible and beneficial in order to outperform the more generic embeddings.

This sheds light on a definitive plus of count models, viz. their transparency and interpretability in the sense that their semantic similarity ratings can (under certain conditions) be traced back to particular semantic relations, whereas word embeddings typically yield rather vague and diversified similarities (Erk, 2016). Due to this lack in interpretability, word embeddings are not easily interoperable with symbolic lexical resources or ontologies. Thus, we argue that modelling attribute meaning poses an interesting challenge to word embeddings for two reasons: First, being rooted in ontological knowledge, attribute meaning clearly draws on interpretability of the underlying model; second, attribute meaning in adjective-noun phrases is conveyed in compositional processes (cf. Ex. (1)) which are under-researched in the context of word embeddings so far (Manning, 2015).

Our main contributions in this paper are: (i) We demonstrate that word embeddings can be successfully harnessed for attribute selection – a task that requires both compositional and interpretable representations of phrase meaning. (ii) This is achieved via a learned compositionality function  $f$  on adjective and noun embeddings that carves out attribute meaning in their compositional phrase meaning. (iii) We show that  $f$  captures generalized attribute meaning (cf. Bride et al. (2015)) that abstracts from individual attributes. Thus, after fitting the compositionality function, our model bears the potential of being applied to various application scenarios (e.g., aspect-based sentiment analysis) involving diverse attribute inventories. (iv) We show that the same model also scales to the task of predicting semantic similarity of adjective-noun phrases, which indicates both the robustness of the model and the importance of attribute meaning as a major source of phrase similarity.

## 2 Related Work

### Attribute Learning from Adjectives and Nouns.

Adjective-centric approaches to attribute learning from text date back to Almuhareb (2006) and Cimiano (2006). Bakhshandeh and Allen (2015) present a sequence tagging model in order to extract attribute nouns from adjective glosses in WordNet. Most recently, Petersen and Hellwig (2016) use a clustering approach based on adjective-noun co-occurrences in order to induce clusters of German adjectives that constitute the

value space of an attribute. However, their approach falls short of making the respective attribute explicit.

These approaches have in common that they do not consider the compositional semantics of an adjective in its phrasal context with a noun in order to derive attribute meaning. This is in contrast to Hartung and Frank (2010; 2011b) who frame attribute selection in a distributional count model which (i) encodes adjectives and nouns as distributional word vectors over attributes as shared dimensions of meaning and (ii) uses vector mixture operations in order to compose these word vectors into phrase representations that are predictive of compositional attribute meaning.

Tandon et al. (2014) propose a semi-supervised method for populating a knowledge base with triples of nouns, attributes and adjectives that are acquired from adjective-noun phrases. Being based on label propagation over monosemous adjectives as seeds, their approach depends on a lexical resource providing initial mappings between adjectives and attributes.

The present approach and the work by Hartung and Frank may be considered as pairs of opposites in two respects: First, our model is based on pre-trained CBOW word embeddings for representing adjective and noun meaning. Thus, we do not encode any attribute-specific lexical information explicitly at the level of word representation. Second, we apply function learning in order to empirically induce a compositionality function that is trained to promote aspects of attribute meaning in adjective-noun phrase embeddings.

**Compositionality.** Modelling compositional processes at the intersection of word and phrase meaning in distributional semantic models has attracted considerable attention in the last years (Erk, 2012). Mitchell and Lapata (2010) have promoted a variety of vector mixture models for the task, which have been criticized for their syntactic agnosticism (Baroni and Zamparelli, 2010; Guevara, 2010).

Focussing on adjective-noun compositionality, the latter authors propose instead to model adjective meaning as matrices encoding linear mappings between noun vectors. These attempts to integrate formal semantic principles in the tradition of Frege (1892) into a distributional framework have been generalized to a “program for compositional distributional semantics” (Baroni et al.,

2014a) that is centered around *functional application* as the general process to model compositionality in semantic spaces, thus emphasizing the insight that different linguistic phenomena require to be modeled in corresponding algebraic structures and composition operators matching these structures (cf. Widdows (2008), Grefenstette and Sadrzadeh (2011), Grefenstette et al. (2014)).

Bride et al. (2015) observe that such composition operators, by being trained on empirical corpus data, can either be tailored to specific lexical types (i.e., individual composition functions for each adjective in the corpus), or designed to capture general compositional processes in syntactic configurations (i.e., a single lexical function for all adjective-noun phrases). In line with these authors, we aim at learning a lexical function which captures attribute meaning in the compositional semantics of adjective-noun phrases, while *generalizing* over individual attributes.

Contrary to distributional count models, there is relatively few work on applying word embeddings to linguistic problems or NLP tasks related to compositionality. Notable exceptions are Socher et al. (2013) for sentiment analysis, as well as Salehi et al. (2015) and Cordeiro et al. (2016) who focus on predicting the degree of compositionality in nominal compounds rather than carving out a particular semantic relation that is expressed in their compositional semantics.

### 3 Learning Attribute Meaning in Word Embeddings

#### 3.1 Attribute Meaning in Natural Language

Natural language refers to ontological attributes in terms of attribute nouns such as *color*, *size* or *shape* (Guarino, 1992; Löbner, 2013). Therefore, despite remaining mostly implicit in adjective-noun phrases (cf. Ex. (1) above), we hypothesize that attribute meaning can be learned from contextual patterns of attribute nouns in natural language text. This leads us to the assumption that *adjectives, nouns and attributes (via attribute nouns) can be embedded in the same semantic space*.

#### 3.2 Compositional Models of Attribute Meaning

In this work, we aim at a compositional approach to attribute meaning in adjective-noun phrases. As a consequence of the above assumption, our model represents adjectives, nouns and attributes as vec-

tors  $\vec{a}$ ,  $\vec{n}$  and  $\vec{attr}$ , respectively, in one and the same embedding space  $\mathcal{S} \subseteq \mathbb{R}^d$ .

By designing a composition function  $f(\vec{a}, \vec{n})$  that produces phrase representations  $\vec{p} \in \mathcal{S}$ , we can use nearest neighbour search in  $\mathcal{S}$  in order to predict the attribute  $\widehat{attr}$  that is most likely expressed in the compositional semantics of an adjective-noun phrase  $p$ :

$$\widehat{attr} := \arg \max_{attr \in A} \cos(\vec{p}, \vec{attr}) \quad (2)$$

where  $\vec{p} = f(\vec{a}, \vec{n})$ ,  $\cos$  denotes cosine vector similarity and  $A$  the set of all attributes considered. The compositional functions that we use in this work can be divided into baseline models, largely derived from Mitchell and Lapata (2010), and trainable models.

##### 3.2.1 Baseline Models

**Adjective or Noun.** The simplest model is to skip any composition and just use the representation of the adjective or the noun as a surrogate:  $\vec{p} = \vec{a}$  or  $\vec{p} = \vec{n}$ , respectively.

**Pointwise Vector Addition.** The first step in the direction of compositionality is pointwise vector addition:  $\vec{p} = \vec{a} + \vec{n}$ . According to Mitchell and Lapata (2010), the commutativity of addition is a disadvantage because the model ignores word order and thus syntactic information is lost.

**Weighted Vector Addition.** For the latter reason, Mitchell and Lapata (2010) also propose a weighted variant of pointwise vector addition. In order to account for possibly different contributions of the constituents to phrasal composition, scalar weights  $\alpha$  and  $\beta$  are applied to the word vectors before pointwise addition:  $\vec{p} = \alpha\vec{a} + \beta\vec{n}$ .

**Pointwise Vector Multiplication.** This composition function multiplies the individual dimensions of the adjective and noun vector:  $p_i = a_i \cdot b_i$ . Mitchell and Lapata (2010) point out that vector multiplication can be seen as equivalent to logical intersection. In previous work on attribute selection in a count-based distributional framework, the best results were obtained using pointwise multiplication (Hartung, 2015).

**Dilation.** The dilation model of Mitchell and Lapata (2010) dilates one vector in the direction of the other. This is inspired by the dilation effect of matrix multiplication, but is specifically designed

to be basis-independent:

$$\vec{p} = (\vec{n} \cdot \vec{n})\vec{a} + (\lambda - 1)(\vec{n} \cdot \vec{a})\vec{a} \quad (3)$$

Here,  $\vec{n}$  is stretched by a factor  $\lambda$  to emphasize the contribution of  $\vec{a}$ .  $\lambda$  is a parameter that has to be chosen manually. Analogously, dilation of the adjective is possible as well.

### 3.2.2 Trainable Models

In this section, we present a method for supervised training of compositionality functions. We propose additive and multiplicative models that use weighting matrices or tensors to balance the contributions of adjectives and nouns. The composition is trained to specifically capture attribute meaning in the resulting phrase representation. The weights are trained as part of a shallow neural network (see Section 3.2.3).

**Full Weighted Additive Model.** Following Guevara (2010), the full additive model capitalizes on vector addition with weighting matrices for adjective and noun:

$$\vec{p} = \mathbf{A} \cdot \vec{a} + \mathbf{N} \cdot \vec{n} \quad (4)$$

As initializations of the weighting matrices, we use an identity matrix<sup>1</sup>, which is equivalent to non-parametric vector addition. As weighting schemes, we use one of (i) weighting only the adjective or noun, respectively, or (ii) weighting both adjective and noun distinctly.

Note that, in line with Guevara (2010), this model makes use of weight matrices in order to balance the contribution of adjectives and nouns to phrasal attribute meaning, whereas Mitchell and Lapata (2010) use scalar weights in their pointwise additive model (cf. Section 3.2.1). Our intuition is that full additive models should be better suited to model compositional processes that involve interactions between dimensions of meaning.

**Trained Tensor Product.** As a weighted multiplicative model, we use multiplication of adjective and noun representations with a learned third-order tensor  $\mathbf{T}$ , following Bride et al. (2015):

$$\vec{p} = \vec{a}^T \cdot \mathbf{T}^{[1:d]} \cdot \vec{n} \quad (5)$$

with  $\vec{a} \in \mathbb{R}^d$ ,  $\vec{n} \in \mathbb{R}^d$ ,  $\mathbf{T}^{[1:d]} \in \mathbb{R}^{d \times d \times d}$

<sup>1</sup>We also experimented with different initializations such as random values, all-ones, or an identity matrix with additional small random values on non-diagonal elements, but found the identity matrix to work best.

In order to compose a phrase representation  $\vec{p}$  from  $\vec{a}$  and  $\vec{n}$ ,  $\mathbf{T}$  is applied to the adjective vector in a tensor dot product. The tensor dot product multiplies components of vector and tensor and sums along the third axis of the tensor:

$$\mathbf{X}_{i,j} = \sum_{k=1}^d a_k \cdot T_{i,j,k} \quad (6)$$

with  $d$  being the dimensionality of the word embeddings. Equation (6) results in a matrix  $\mathbf{X}$  that is multiplied with the noun vector in a second step using common matrix multiplication:  $\vec{p} = \mathbf{X} \cdot \vec{n}$ .

Note that the latter step corresponds to *functional application* of the adjective to the noun as rooted in compositional distributional semantics (Baroni et al., 2014a). The result is a phrase vector with the same dimensionality as adjective and noun. For initialization, we use an identity matrix for each second-order tensor along the third axis<sup>2</sup>.

### 3.2.3 Training Method

The weights of the models in Section 3.2.2 are trained as part of a shallow neural network with no hidden layer. For each adjective-noun phrase and the corresponding ground truth attribute in the training dataset, the respective 300-dimensional vectors<sup>3</sup>  $\vec{a}$ ,  $\vec{n}$  and  $\vec{attr}$  are obtained by performing a look-up in the pre-trained word embeddings.

With  $\vec{a}$  and  $\vec{n}$  as its inputs, the neural network computes a phrase representation  $\vec{p} \in \mathbb{R}^{300}$  at the output layer. The error of the computed phrase representation to the expected attribute representation  $\vec{attr}$  is computed using the *mean squared error* between the two vectors and is used as the training signal for the network parameters. Note that we do not train the embedding vectors along with the connection weights. While this could potentially benefit the results, we aim to explore whether generally trained word embeddings can be used to retrieve attribute meaning.

For our network architectures and computations, we use the deep learning library *keras* (Chollet, 2016). Training takes 10 iterations over the training data; weights are optimized using the stochastic optimization method *Adam* (Kingma and Ba, 2015). For the use of pre-trained word

<sup>2</sup>We found a random initialization of all entries to perform substantially worse.

<sup>3</sup>This is the number of dimensions in the pre-trained word embeddings from Mikolov et al. (2013b).

vectors (Mikolov et al., 2013b)<sup>4</sup> in a Python environment, we rely on the *Gensim* library (Řehůřek and Sojka, 2010).

## 4 Attribute Selection Experiments

In this experiment, we evaluate the compositional models defined in Section 3.2 on the attribute selection task.

### 4.1 Data

We use the HeiPLAS data set (Hartung, 2015) which contains adjective-attribute-noun triples that were heuristically extracted from WordNet (Miller and Fellbaum, 1998) and manually filtered by linguistic curators. The data is separated into development and test set (comprising 869 and 729 triples, respectively, which correspond to a total of 254 target attributes). The target attributes are subdivided into various semantically homogeneous subsets, as shown in Table 1. Due to coverage issues in the pre-trained word2vec embeddings (Mikolov et al., 2013a), some adjectives and nouns from HeiPLAS cannot be projected into the embedding space<sup>5</sup>.

### 4.2 Experiment 1: Large-scale Attribute Selection

**Experimental Procedure.** Composition models as described in Section 3.2.2 are trained on all triples in HeiPLAS-Dev (following the procedure described in Section 3.2.3) and evaluated on HeiPLAS-Test. The word vector representations corresponding to the adjective and the noun in a test triple are composed into a phrase vector by applying the trained composition function. Using nearest neighbour search in  $\mathcal{S}$  as described in Section 3.2, all test attributes are ranked wrt. their similarity to the composed phrase vector. For evaluation, we use *precision-at-rank* to measure the number of times the correct attribute is ranked as most similar to the phrase vector or among the first five ranks (P@1 and P@5, respectively).

**Baseline Semantic Spaces.** We directly compare our approach against the results of two count-based distributional models, C-LDA and L-LDA (Hartung, 2015), on the same evaluation data. C-LDA and L-LDA induce distributional adjective

and noun vectors over attributes as dimensions of meaning, which are composed into phrase representations using pointwise vector multiplication. Using these models for comparison enables us to assess both the impact of different types of word representations (dense CBOW word embeddings vs. specifically tailored attribute-based distributional word vectors) and different approaches to compositionality (pre-defined vector mixture operations on attribute-specific word representations vs. trained composition functions for promoting generalized attribute meaning in word embeddings).

**Results.** Results of Experiment 1 are shown in Table 2. The upper part of the table contains the results based on word embeddings (comprising non-parametric, parametric, dilation and trainable composition models); the count-based C-LDA and L-LDA baselines are displayed below.

Focussing on the non-parametric models first, we find that relying on the adjective embedding as a surrogate of a composed representation already outperforms both count models by a wide margin. This indicates a clear advantage of CBOW embeddings over count-based representations for capturing attribute meaning at the word level. However, this holds only for adjectives; noun embeddings in isolation perform much worse.

This is confirmed by the dilation results: Dilating the noun representation into the direction of the adjective performs considerably better than vice versa, while there is no improvement beyond the non-compositional adjective baseline. These findings are in line with Hartung (2015) and Hartung and Frank (2011a) who also observed that adjective representations capture more of the compositional attribute semantics in adjective-noun phrases than noun representations do.

Considering the trained composition models, we find that weighting either the adjective or the noun in a full additive model substantially outperforms the respective non-compositional baseline. The overall best results are obtained by assigning trained weights to both the adjective and the noun embedding (P@1=0.56). This model also outperforms weighted vector addition<sup>6</sup> using scalar weights by great margins.

<sup>4</sup>Available from <https://drive.google.com/file/d/0B7XkCwpI5KDYN1NUTt1SS21pQmM/edit?usp=sharing>

<sup>5</sup>This affects 54 triples in HeiPLAS-Dev and 44 triples in HeiPLAS-Test, which were removed from the evaluation.

<sup>6</sup>The weighted vector addition scores shown in Table 2 are based on optimized parameters as reported by Mitchell and Lapata (2010):  $\alpha=0.88$  and  $\beta=0.12$ . By shifting the parameters further into the direction of the adjective (i.e.,  $\alpha=0.90$ ;  $\beta=0.10$ ), P@1 slightly increases to 0.34.

Subset	Num. Attributes	Num. Train. Triples	Example Phrases
Core	10	72	<i>silvery hair</i> (COLOR), <i>huge wave</i> (SIZE), <i>longstanding conflict</i> (DURATION)
Selected	23	153	<i>sufficient food</i> (QUANTITY), <i>grave decision</i> (IMPORTANCE), <i>broad river</i> (WIDTH)
Measurable	65	261	<i>heavy load</i> (WEIGHT), <i>short hair</i> (LENGTH), <i>slow walker</i> (SPEED)
Property	73	300	<i>young people</i> (AGE), <i>high mountain</i> (HEIGHT), <i>straight line</i> (SHAPE)
All	254	869	<i>dry paint</i> (WETNESS), <i>scentless wisp</i> (SMELL), <i>vehement defense</i> (STRENGTH)

Table 1: Overview of subsets of attributes contained in HeiPLAS data, together with example phrases

Compositional Model		P@1	P@5	
predict models	Adjective	0.33	0.50	
	Noun	0.03	0.10	
	Vector Addition ( $\oplus$ )	0.24	0.45	
	Weighted Vector Addition	0.33	0.51	
	Vector Multiplication ( $\odot$ )	0.00	0.02	
	Adj. Dilation ( $\lambda = 2$ )	0.06	0.18	
	Noun Dilation ( $\lambda = 2$ )	0.33	0.51	
	Full Add. Weighted Noun	0.33	0.54	
	Full Add. Weighted Adjective	0.46	0.71	
	Full Add. Weighted Adj. and Noun	<b>0.56</b>	<b>0.75</b>	
	Trained Tensor Product ( $\otimes$ )	0.44	0.57	
	count	C-LDA (Hartung, 2015)	0.09	n/a
		L-LDA (Hartung, 2015)	0.16	n/a

Table 2: Results of Experiment 1; evaluation on all phrases from HeiPLAS-Test

In comparison to the best full additive model, the tensor product underperforms by more than 10 points in P@1 and also falls short of weighting only the adjective. This is in line with a general preference of word embeddings for additive models (Mikolov et al., 2013a), which is also confirmed by the non-parametric composition functions. On the other hand, we conjecture that the relatively small size of the training set used here is not sufficient for optimally tuning the  $300^3$  parameters in the learned tensor.

### 4.3 Experiment 2: Generalization Power

In this experiment, we are interested in assessing the generalization power of the best-performing composition function as trained in Experiment 1. More precisely, we investigate the hypothesis that a full additive model captures a generalized compositional process in the semantics of attribute-denoting adjective-noun phrases rather than the lexical meaning of individual attributes (cf. Bride et al. (2015)).

We evaluate this hypothesis wrt. (i) the fit of the composition function to different subsets of testing

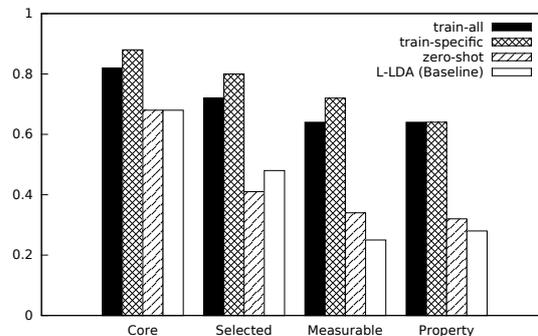

Figure 1: Attribute selection performance of the full additive model after training on all attributes, specific subsets, and in zero-shot learning

attributes, and (ii) its predictive capacity in a zero-shot learning scenario.

**Subsets of Testing Attributes.** First, we compare the fit of the composition function that has been trained on all attributes (cf. Experiment 1) on the different subsets of attributes in HeiPLAS-Test, as displayed in Table 1.

The results of this experiment are shown in Figure 1. As can be seen from the solid bars in the plot, the attribute selection performance on individual subsets is considerably stronger than on the entire inventory, ranging from P@1=0.82 on the Core subset to P@1=0.64 on the Property and Measurable subsets (compared to P@1=0.56 on all attributes; cf. Table 2). The cross-hatched bars in the figure indicate the relative differences that result from re-training a composition function on the specific subset of interest. The improvements are consistently small (max. +0.08 on the Selected and Measurable subsets); in case of the Property subset, there is no difference at all.

**Zero-Shot Learning.** As defined by Palatucci et al. (2009), zero-shot learning is the task of learning a classifier for predicting novel class labels un-

seen during training. In order to assess the selection performance of our model in a zero-shot setting, we create four zero-shot training sets by removing from HeiPLAS-Train all attributes that are contained in each of the subsets described in Table 1, respectively. The corresponding subset from HeiPLAS-Test is used for evaluation afterwards.

The zero-shot results are shown by the diagonally hatched bars in Fig. 1. We find that Core attributes, without being seen during training, can be predicted at a performance of  $P@1=0.68$ . On larger subsets, zero-shot performance decreases (down to  $P@1=0.32$  on Property attributes). Yet, we consider these results very decent overall, given that they are largely comparable or even superior (except for the Selected subset) to the best scores of the distributional L-LDA model (Hartung, 2015) as shown by the plain bars in Fig. 1.

Even though benefits from attribute-specific training cannot be denied, we find that the trained compositionality function is largely capable of generalizing over individual target attributes.

#### 4.4 Discussion

Our experiments on attribute selection show that CBOW word embeddings can be effectively harnessed for carving out attribute meaning from adjective-noun phrases. Observed improvements over the previous state-of-the-art are due to the type of word representation as such (dense neural embeddings vs. distributional count models) as well as a learned compositionality function based on a full additive model capitalizing on weight matrices for balancing the contributions of adjectives and nouns. Moreover, we were able to show that the compositionality function captures a generalized compositional process in the semantics of attribute-denoting adjective-noun phrases rather than the lexical meaning of individual attributes. Therefore, the proposed approach (i) poses an interesting alternative to previous distributional models which explicitly encode attribute meaning in word vectors and rely on vector mixture operations in order to compose them into attribute-based phrase representations, and (ii) bears the potential of being used as a generalized attribute extraction model on various domains of applications that demand for different attribute inventories.

## 5 Similarity Prediction Experiments

In this experiment, we assess the scalability of the previously trained composition models to different tasks by applying them to the prediction of semantic similarity in pairs of adjective-noun phrases.

### 5.1 Data

Our experiments are based on the adjective-noun section of the evaluation data set released by Mitchell and Lapata (2010). It consists of 108 pairs of adjective-noun phrases that were rated for similarity on a 7-point scale<sup>7</sup> by 54 human judges. In total, the data set comprises 1944 data points.

### 5.2 Experiment 3: Predicting Adjective-Noun Phrase Similarity

**Experimental Procedure.** For a given pair of adjective-noun phrases, we compute two phrase representations using word embeddings as word representations and compositionality functions trained on the HeiPLAS-Core subset, which achieved the best attribute selection results in Experiments 1 and 2. In the next step, we compute the cosine similarity between these two phrase representations. We correlate the results with human similarity ratings using Spearman’s  $\rho$  and compare the resulting correlation scores to the reported results of Mitchell and Lapata (2010).

**Baseline Models.** We compare our models against the following approaches from the literature which were evaluated on the same data set: C-LDA (Hartung and Frank, 2011a), M&L-BoW and M&L-Topic (both by Mitchell and Lapata (2010)). All baseline models are count-based distributional models which differ in their underlying representation of word meaning: M&L-BoW relies on bag-of-words context windows, M&L-Topic and C-LDA use topics and attribute nouns as dimensions of meaning, respectively.

**Results.** As shown in Table 3, the best correlation scores between human similarity judgments and model predictions are achieved by our model that is built upon word embeddings and a trained full additive composition function based on weighting adjective and noun vectors ( $\rho=0.50$ ). This model outperforms all distributional baseline models using vector mixtures as composition functions.

<sup>7</sup>A score of 1 expresses low similarity between phrases, 7 indicates high similarity.

Underlying Word Representation	$\odot$	$\oplus$	Weighted Addition	Full Additive
word2vec	0.36	0.48	0.42	<b>0.50</b>
M&L-BoW	0.46	0.36	0.44	n/a
M&L-Topic	0.25	0.37	0.38	n/a
C-LDA	0.28	0.19	n/a	n/a

Table 3: Results of Experiment 3 (Spearman’s  $\rho$  between human judgments and model predictions)

With respect to weighted addition, all results reported in Table 3 are based on the weighting parameters ( $\alpha=0.88$ ;  $\beta=0.12$ ) that have been found as optimal by Mitchell and Lapata (2010). Based on a grid search, we find  $\alpha=0.60$  and  $\beta=0.40$  to be the best weighting parameters on our data. In this setting, the performance of the weighted vector addition model on word2vec embeddings can be increased to  $\rho=0.47$ , which is still slightly below unweighted vector addition on embeddings ( $\rho=0.48$ ). Apparently, scalar weights in pointwise vector addition are quite sensitive to the underlying word representation. In the particular case of using word embeddings for similarity prediction, the contribution of the noun to the compositional semantics of the phrase seems to be relatively stronger than in the attribute selection task (cf. Experiment 1).

In total, these results indicate that compositionality functions optimized on the task of attribute selection can be effectively transferred to similarity prediction. This suggests that attribute meaning might be a prominent source of similarity in adjective-noun phrases, which will be subject to a closer investigation in the next experiment.

### 5.3 Experiment 4: Interpreting the Source of Similarity

Research in distributional semantics tends to focus on the *degree* of similarity between words or phrases, while the *source* of similarity is largely neglected (cf. Hartung (2015)). In this experiment, we hypothesize that attribute meaning provides a plausible explanation for the observed degree of similarity in phrase pairs from the M&L data set.

**Experimental Procedure.** For a given phrase pair, we compute the top-5 most similar attributes for each phrase in terms of their nearest neighbours in  $\mathcal{S}$  (cf. Section 3.2). Then, both phrases

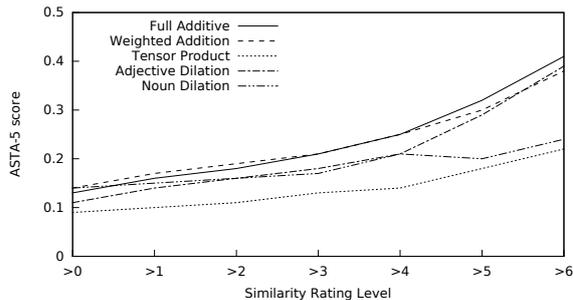

Figure 2: ASTA-5 scores over different levels of human similarity ratings (cf. Experiment 4)

are compared wrt. the proportion of shared attributes within these top-5 predictions. Averaging this score over all phrase pairs which were assigned a particular similarity rating by the human judges yields an *Average Shared Top-5 Attributes* (ASTA-5) score for this similarity level.

**Results.** Figure 2 plots ASTA-5 scores at different levels of human similarity ratings. We observe a general trend across all compositionality functions investigated: The higher the rating cutoff, the higher the number of shared attributes. Thus, with increasing similarity between two phrases (according to human ratings), the proportion of shared attributes in their compositional semantics tends to increase as well. Moreover, for highly similar pairs (rating cutoff  $>5$ ), the full additive vector addition model yields the highest ASTA-5 scores.

Beyond this quantitative analysis, two of the authors manually investigated the shared attributes in 38 high-similarity phrase pairs (rating cutoff  $>4$ ) as predicted by the weighted vector addition model wrt. their potential as plausible sources of similarity. We find that in 28 phrase pairs (73.6%), the predicted attribute is considered a plausible source of similarity, in eight others (26.4%), the predicted attribute does not explain the high similarity. The agreement between the annotators in terms of Fleiss’ Kappa amounts to  $\kappa = 0.62$ .

### 5.4 Discussion

Our results show that a full additive compositional model trained to target attribute meaning improves performance on similarity prediction. This supports the interpretation that attributes are (at least)

a partial source of similarity between adjective-noun phrases. In fact, this has been corroborated by a preliminary manual investigation of shared attributes between high-similarity phrases. However, there is also evidence for several cases in which attribute meaning falls short of explaining high phrase similarity. This holds for phrases involving abstract concepts, for instance (cf. Hartung (2015), Borghi and Binkofski (2014)).

Nevertheless, we consider it a strength of our model that it is capable of providing plausible explanations in cases where attribute meaning is the most prominent source of similarity.

## 6 Conclusions

We have presented a model of attribute meaning in adjective-noun phrases that capitalizes on CBOW word embeddings. In our experiments, the model proves remarkably versatile as it advances the state-of-the-art in the two tasks of attribute selection and phrase similarity prediction. In the latter task, the property of being fully interpretable wrt. attributes as the potential source of similarities became apparent as an additional asset rendering the model potentially interoperable with knowledge representation formalisms and resources.

Improvements over previous distributional models can be traced back to two major sources: First, CBOW word embeddings work surprisingly well at the word level for capturing attribute meaning in adjectives (not for nouns, though). Future work should investigate whether further improvements can be obtained from more adjective-specific word embeddings that are trained on symmetric coordination patterns (Schwartz et al., 2016). Second, a learned compositionality function is effective at promoting attribute meaning in composed phrase representations. Best performances across both tasks are achieved by a full additive model with distinct weight matrices for the adjective and noun constituent. A trained tensor product that comes closer to the linguistic notion of functional application also performs well beyond the previous state-of-the-art, while falling short of the additive model. Apparently, more training data is needed to exhaust the full potential of the tensor product. Alternatively, tensor decomposition techniques along the lines of Shah et al. (2015) may be a possible way of coping with the large parameter

space of the tensor approach.

Moreover, the learned compositionality function turns out to generalize well over individual attributes, which we consider a very promising result wrt. the suitability of the model in various NLP tasks such as aspect-based sentiment analysis. In future work, we are going to extend the present model to consider broader linguistic contexts and more varied syntactic configurations.

## Abstract

The fundamental role of hypernymy in NLP has motivated the development of many methods for the automatic identification of this relation, most of which rely on word distribution. We investigate an extensive number of such unsupervised measures, using several distributional semantic models that differ by context type and feature weighting. We analyze the performance of the different methods based on their linguistic motivation. Comparison to the state-of-the-art supervised methods shows that while supervised methods generally outperform the unsupervised ones, the former are sensitive to the distribution of training instances, hurting their reliability. Being based on general linguistic hypotheses and independent from training data, unsupervised measures are more robust, and therefore are still useful artillery for hypernymy detection.

## 1 Introduction

In the last two decades, the NLP community has invested a consistent effort in developing automated methods to recognize hypernymy. Such effort is motivated by the role this semantic relation plays in a large number of tasks, such as taxonomy creation (Snow et al., 2006; Navigli et al., 2011) and recognizing textual entailment (Dagan et al., 2013). The task has appeared to be, however, a challenging one, and the numerous approaches proposed to tackle it have often shown limitations.

Early corpus-based methods have exploited patterns that may indicate hypernymy (e.g. “*animals* such as *dogs*”) (Hearst, 1992; Snow et al., 2005), but the recall limitation of this approach, requiring both words to co-occur in a sentence, motivated the development of methods that rely on

adaptations of the *distributional hypothesis* (Harris, 1954).

The first distributional approaches were unsupervised, assigning a score for each  $(x, y)$  word-pair, which is expected to be higher for hypernym pairs than for negative instances. Evaluation is performed using ranking metrics inherited from information retrieval, such as Average Precision (AP) and Mean Average Precision (MAP). Each measure exploits a certain linguistic hypothesis such as the *distributional inclusion hypothesis* (Weeds and Weir, 2003; Kotlerman et al., 2010) and the *distributional informativeness hypothesis* (Santus et al., 2014; Rimell, 2014).

In the last couple of years, the focus of the research community shifted to supervised distributional methods, in which each  $(x, y)$  word-pair is represented by a combination of  $x$  and  $y$ 's word vectors (e.g. concatenation or difference), and a classifier is trained on these resulting vectors to predict hypernymy (Baroni et al., 2012; Roller et al., 2014; Weeds et al., 2014). While the original methods were based on count-based vectors, in recent years they have been used with word embeddings (Mikolov et al., 2013; Pennington et al., 2014), and have gained popularity thanks to their ease of use and their high performance on several common datasets. However, there have been doubts on whether they can actually learn to recognize hypernymy (Levy et al., 2015b).

Additional recent hypernymy detection methods include a multimodal perspective (Kiela et al., 2015), a supervised method using unsupervised measure scores as features (Santus et al., 2016a), and a neural method integrating path-based and distributional information (Shwartz et al., 2016).

In this paper we perform an extensive evaluation of various unsupervised distributional measures for hypernymy detection, using several distributional semantic models that differ by context type and feature weighting. Some measure vari-

ants and context-types are tested for the first time.<sup>1</sup>

We demonstrate that since each of these measures captures a different aspect of the hypernymy relation, there is no single measure that consistently performs well in discriminating hypernymy from different semantic relations. We analyze the performance of the measures in different settings and suggest a principled way to select the suitable measure, context type and feature weighting according to the task setting, yielding consistent performance across datasets.

We also compare the unsupervised measures to the state-of-the-art supervised methods. We show that supervised methods outperform the unsupervised ones, while also being more efficient, computed on top of low-dimensional vectors. At the same time, however, our analysis reassesses previous findings suggesting that supervised methods do not actually learn the relation between the words, but only characteristics of a single word in the pair (Levy et al., 2015b). Moreover, since the features in embedding-based classifiers are latent, it is difficult to tell what the classifier has learned. We demonstrate that unsupervised methods, on the other hand, do account for the relation between words in a pair, and are easily interpretable, being based on general linguistic hypotheses.

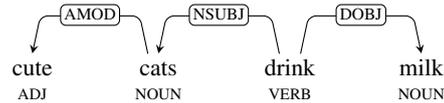

## 2 Distributional Semantic Spaces

We created multiple distributional semantic spaces that differ in their context type and feature weighting. As an underlying corpus we used a concatenation of the following two corpora: `ukWaC` (Ferraresi, 2007), a 2-billion word corpus constructed by crawling the `.uk` domain, and `WaCkypedia_EN` (Baroni et al., 2009), a 2009 dump of the English Wikipedia. Both corpora include POS, lemma and dependency parse annotations. Our vocabulary (of target and context words) includes only nouns, verbs and adjectives that occurred at least 100 times in the corpus.

**Context Type** We use several context types:

- **Window-based contexts:** the contexts of a target word  $w_i$  are the words surrounding it in a  $k$ -sized window:  $w_{i-k}, \dots, w_{i-1}, w_{i+1}, \dots, w_{i+k}$ . If the context-type is directional, words occurring before and after  $w_i$  are marked differently, i.e.:  $w_{i-k}/l, \dots, w_{i-1}/l, w_{i+1}/r, \dots, w_{i+k}/r$ .

<sup>1</sup>Our code and data are available at:  
<https://github.com/vered1986/UnsupervisedHypernymy>

**Figure 1:** An example dependency tree of the sentence *cute cats drink milk*, with the target word *cats*. The dependency-based contexts are *drink-v:nsbj* and *cute-a:amod*<sup>-1</sup>. The joint-dependency context is *drink-v#milk-n*. Differently from Chersoni et al. (2016), we exclude the dependency tags to mitigate the sparsity of contexts.

Out-of-vocabulary words are filtered out before applying the window. We experimented with window sizes 2 and 5, directional and indirectional (`win2`, `win2d`, `win5`, `win5d`).

- **Dependency-based contexts:** rather than adjacent words in a window, we consider neighbors in a dependency parse tree (Padó and Lapata, 2007; Baroni and Lenci, 2010). The contexts of a target word  $w_i$  are its parent and daughter nodes in the dependency tree (`dep`). We also experimented with a joint dependency context inspired by Chersoni et al. (2016), in which the contexts of a target word are the parent-sister pairs in the dependency tree (`joint`). See Figure 1 for an illustration.

**Feature Weighting** Each distributional semantic space is spanned by a matrix  $M$  in which each row corresponds to a target word while each column corresponds to a context. The value of each cell  $M_{i,j}$  represents the association between the target word  $w_i$  and the context  $c_j$ . We experimented with two feature weightings:

- **Frequency** - raw frequency (no weighting):  $M_{i,j}$  is the number of co-occurrences of  $w_i$  and  $c_j$  in the corpus.
- **Positive PMI (PPMI)** - pointwise mutual information (PMI) (Church and Hanks, 1990) is defined as the log ratio between the joint probability of  $w$  and  $c$  and the product of their marginal probabilities:  $PMI(w, c) = \log \frac{\hat{P}(w, c)}{\hat{P}(w)\hat{P}(c)}$ , where  $\hat{P}(w)$ ,  $\hat{P}(c)$ , and  $\hat{P}(w, c)$  are estimated by the relative frequencies of a word  $w$ , a context  $c$  and a word-context pair  $(w, c)$ , respectively. To handle unseen pairs  $(w, c)$ , yielding  $PMI(w, c) = \log(0) = -\infty$ , PPMI (Bullinaria and Levy, 2007) assigns zero to negative PMI scores:  $PPMI(w, c) = \max(PMI(w, c), 0)$ .

In addition, one of the measures we used (San-tus et al., 2014) required a third feature weighting:

- **Positive LMI (PLMI)** - positive local mutual information (PLMI) (Evert, 2005; Evert, 2008). PPMI was found to have a bias towards rare events. PLMI simply balances PPMI by multiplying it by the co-occurrence frequency of  $w$  and  $c$ :  $PLMI(w, c) = freq(w, c) \cdot PPMI(w, c)$ .

### 3 Unsupervised Hypernymy Detection Measures

We experiment with a large number of unsupervised measures proposed in the literature for distributional hypernymy detection, with some new variants. In the following section,  $\vec{v}_x$  and  $\vec{v}_y$  denote  $x$  and  $y$ 's word vectors (rows in the matrix  $M$ ). We consider the scores as measuring to what extent  $y$  is a hypernym of  $x$  ( $x \rightarrow y$ ).

#### 3.1 Similarity Measures

Following the *distributional hypothesis* (Harris, 1954), similar words share many contexts, thus have a high similarity score. Although the hypernymy relation is asymmetric, similarity is one of its properties (Santus et al., 2014).

- **Cosine Similarity** (Salton and McGill, 1986) A symmetric similarity measure:

$$\cos(x, y) = \frac{\vec{v}_x \cdot \vec{v}_y}{\|\vec{v}_x\| \cdot \|\vec{v}_y\|}$$

- **Lin Similarity** (Lin, 1998) A symmetric similarity measure that quantifies the ratio of shared contexts to the contexts of each word:

$$Lin(x, y) = \frac{\sum_{c \in \vec{v}_x \cap \vec{v}_y} [\vec{v}_x[c] + \vec{v}_y[c]]}{\sum_{c \in \vec{v}_x} \vec{v}_x[c] + \sum_{c \in \vec{v}_y} \vec{v}_y[c]}$$

- **APSyn** (Santus et al., 2016b) A symmetric measure that computes the extent of intersection among the  $N$  most related contexts of two words, weighted according to the rank of the shared contexts (with  $N$  as a hyper-parameter):

$$APSyn(x, y) = \sum_{c \in N(\vec{v}_x) \cap N(\vec{v}_y)} \frac{1}{\frac{rank_x(c) + rank_y(c)}{2}}$$

#### 3.2 Inclusion Measures

According to the *distributional inclusion hypothesis*, the prominent contexts of a hyponym ( $x$ ) are expected to be included in those of its hypernym ( $y$ ).

- **Weeds Precision** (Weeds and Weir, 2003) A directional precision-based similarity measure. This measure quantifies the weighted inclusion of  $x$ 's contexts by  $y$ 's contexts:

$$WeedsPrec(x \rightarrow y) = \frac{\sum_{c \in \vec{v}_x \cap \vec{v}_y} \vec{v}_x[c]}{\sum_{c \in \vec{v}_x} \vec{v}_x[c]}$$

- **cosWeeds** (Lenci and Benotto, 2012) Geometric mean of cosine similarity and Weeds precision:

$$\cosWeeds(x \rightarrow y) = \sqrt{\cos(x, y) \cdot WeedsPrec(x \rightarrow y)}$$

- **ClarkeDE** (Clarke, 2009) Computes degree of inclusion, by quantifying weighted coverage of the hyponym's contexts by those of the hypernym:

$$CDE(x \rightarrow y) = \frac{\sum_{c \in \vec{v}_x \cap \vec{v}_y} \min(\vec{v}_x[c], \vec{v}_y[c])}{\sum_{c \in \vec{v}_x} \vec{v}_x[c]}$$

- **balAPinc** (Kotlerman et al., 2010) Balanced average precision inclusion.

$$APinc(x \rightarrow y) = \frac{\sum_{r=1}^{N_y} [P(r) \cdot rel(c_r)]}{N_y}$$

is an adaptation of the average precision measure from information retrieval for the inclusion hypothesis.  $N_y$  is the number of non-zero contexts of  $y$  and  $P(r)$  is the precision at rank  $r$ , defined as the ratio of shared contexts with  $y$  among the top  $r$  contexts of  $x$ .  $rel(c)$  is the relevance of a context  $c$ , set to 0 if  $c$  is not a context of  $y$ , and to  $1 - \frac{rank_y(c)}{N_y + 1}$  otherwise, where  $rank_y(c)$  is the rank of the context  $c$  in  $y$ 's sorted vector. Finally,

$$balAPinc(x \rightarrow y) = \sqrt{Lin(x, y) \cdot APinc(x \rightarrow y)}$$

is the geometric mean of APinc and Lin similarity.

- **invCL** (Lenci and Benotto, 2012) Measures both distributional inclusion of  $x$  in  $y$  and distributional non-inclusion of  $y$  in  $x$ :

$$invCL(x \rightarrow y) = \sqrt{CDE(x \rightarrow y) \cdot (1 - CDE(y \rightarrow x))}$$

#### 3.3 Informativeness Measures

According to the *distributional informativeness hypothesis*, hypernyms tend to be less informative than hyponyms, as they are likely to occur in more general contexts than their hyponyms.

- **SLQS** (Santus et al., 2014)

$$SLQS(x \rightarrow y) = 1 - \frac{E_x}{E_y}$$

The informativeness of a word  $x$  is evaluated as the median entropy of its top  $N$  contexts:  $E_x = \text{median}_{i=1}^N (H(c_i))$ , where  $H(c)$  is the entropy of context  $c$ .

- **SLQS Sub** A new variant of SLQS based on the assumption that if  $y$  is judged to be a hypernym of  $x$  to a certain extent, then  $x$  should be judged to be a hyponym of  $y$  to the same extent (which is not the case for regular SLQS). This is achieved by subtraction:

$$SLQS_{sub}(x \rightarrow y) = E_y - E_x$$

It is weakly symmetric in the sense that  $SLQS_{sub}(x \rightarrow y) = -SLQS_{sub}(y \rightarrow x)$ .

SLQS and SLQS Sub have 3 hyper-parameters: i) the number of contexts  $N$ ; ii) whether to use median or average entropy among the top  $N$  contexts; and iii) the feature weighting used to sort the contexts by relevance (i.e., PPMI or PLMI).

- **SLQS Row** Differently from SLQS, SLQS Row computes the entropy of the target rather than the average/median entropy of the contexts, as an alternative way to compute the generality of a word.<sup>2</sup> In addition, parallel to SLQS we tested SLQS Row with subtraction, **SLQS Row Sub**.
- **RCTC** (Rimell, 2014) Ratio of change in topic coherence:

$$RCTC(x \rightarrow y) = \frac{TC(t_x)/TC(t_{x \setminus y})}{TC(t_y)/TC(t_{y \setminus x})}$$

where  $t_x$  are the top  $N$  contexts of  $x$ , considered as  $x$ 's *topic*, and  $t_{x \setminus y}$  are the top  $N$  contexts of  $x$  which are not contexts of  $y$ .  $TC(A)$  is the topic coherence of a set of words  $A$ , defined as the median pairwise PMI scores between words in  $A$ .  $N$  is a hyper-parameter. The measure is based on the assumptions that excluding  $y$ 's contexts from  $x$ 's increases the coherence of the topic, while excluding  $x$ 's contexts from  $y$ 's decreases the coherence of the topic. We include this measure under the informativeness inclusion, as it is based on a similar hypothesis.

### 3.4 Reversed Inclusion Measures

These measures are motivated by the fact that, even though—being more general—hypernyms are expected to occur in a larger set of contexts, sentences like “the *vertebrate* barks” or “the *mammal* arrested the thieves” are not common, since hyponyms are more specialized and are hence more appropriate in such contexts. On the other

<sup>2</sup>In our preliminary experiments, we noticed that the entropies of the targets and those of the contexts are not highly correlated, yielding a Spearman’s correlation of up to 0.448 for window based spaces, and up to 0.097 for the dependency-based ones ( $p < 0.01$ ).

dataset	relations	#instances	size

**Table 1:** The semantic relations, number of instances in each relation, and size of each dataset.

hand, hyponyms are likely to occur in broad contexts (e.g. *eat*, *live*), where hypernyms are also appropriate. In this sense, we can define the *reversed inclusion hypothesis*: “hypernym’s contexts are likely to be included in the hyponym’s contexts”. The following variants are tested for the first time.

- **Reversed Weeds**

$$RevWeeds(x \rightarrow y) = Weeds(y \rightarrow x)$$

- **Reversed ClarkeDE**

$$RevCDE(x \rightarrow y) = CDE(y \rightarrow x)$$

## 4 Datasets

We use four common semantic relation datasets: BLESS (Baroni and Lenci, 2011), EVALution (Santus et al., 2015), Lenci/Benotto (Benotto, 2015), and Weeds (Weeds et al., 2014). The datasets were constructed either using knowledge resources (e.g. WordNet, Wikipedia), crowd-sourcing or both. The semantic relations and the size of each dataset are detailed in Table 1.

In our distributional semantic spaces, a target word is represented by the word and its POS tag. While BLESS and Lenci/Benotto contain this information, we needed to add POS tags to the other datasets. For each pair  $(x, y)$ , we considered 3 pairs  $(x-p, y-p)$  for  $p \in \{noun, adjective, verb\}$ , and added the respective pair to the dataset only if the words were present in the corpus.<sup>4</sup>

<sup>3</sup>We removed the *entailment* relation, which had too few instances, and conflated relations to coarse-grained relations (e.g. *HasProperty* and *HasA* into *attribute*).

<sup>4</sup>Lenci/Benotto includes pairs to which more than one relation is assigned, e.g. when  $x$  or  $y$  are polysemous, and re-

**Table 2:** Best performing unsupervised measures on each dataset in terms of Average Precision (AP) at  $k = 100$ , for hypernym vs. all other relations and vs. each single relation. AP for  $k = all$  is also reported for completeness. We excluded the experiments of hypernym vs. random-(n, v, j) for brevity; most of the similarity and some of the inclusion measures achieve  $AP@100 = 1.0$  in these experiments.

We split each dataset randomly to 90% test and 10% validation. The validation sets are used to tune the hyper-parameters of several measures: SLQS (Sub), APSyn and RCTC.

## 5 Experiments

### 5.1 Comparing Unsupervised Measures

In order to evaluate the unsupervised measures described in Section 3, we compute the measure scores for each  $(x, y)$  pair in each dataset. We first measure the method’s ability to discriminate hypernymy from all other relations in the dataset, i.e. by considering hypernyms as positive instances, and other word pairs as negative instances. In addition, we measure the method’s ability to discriminate hypernymy from every other relation in the dataset by considering *one* relation at a time. For a relation  $\mathcal{R}$  we consider only  $(x, y)$  pairs that are annotated as either hypernyms (positive instances) or  $\mathcal{R}$  (negative instances). We rank the pairs according to the measure score and compute average precision (AP) at  $k = 100$  and  $k = all$ .<sup>5</sup>

lated differently in each sense. We consider  $y$  as a hypernym of  $x$  if hypernymy holds in some of the words’ senses. Therefore, when a pair is assigned both hypernymy and another relation, we only keep it as hypernymy.

<sup>5</sup>We tried several cut-offs and chose the one that seemed to be more informative in distinguishing between the unsupervised measures.

Table 2 reports the best performing measure(s), with respect to  $AP@100$ , for each relation in each dataset. The first observation is that there is no single combination of measure, context type and feature weighting that performs best in discriminating hypernymy from all other relations. In order to better understand the results, we focus on the second type of evaluation, in which we discriminate hypernyms from each other relation.

The results show preference to the syntactic context-types (`dep` and `joint`), which might be explained by the fact that these contexts are richer (as they contain both proximity and syntactic information) and therefore more discriminative. In feature weighting there is no consistency, but interestingly, raw frequency appears to be successful in hypernymy detection, contrary to previously reported results for word similarity tasks, where PPMI was shown to outperform it (Bullinaria and Levy, 2007; Levy et al., 2015a).

The new SLQS variants are on top of the list in many settings. In particular they perform well in discriminating hypernyms from symmetric relations (antonymy, synonymy, coordination).

The measures based on the *reversed inclusion hypothesis* performed inconsistently, achieving perfect score in the discrimination of hypernyms from unrelated words, and performing well

relation	measure	context type	feature weighting

	invCL	win2/5/5d	freq
coordination		-	

**Table 3:** Intersection of datasets’ top-performing measures when discriminating between hypernymy and each other relation.

in few other cases, always in combination with syntactic contexts.

Finally, the results show that there is no single combination of measure and parameters that performs consistently well for all datasets and classification tasks. In the following section we analyze the best combination of measure, context type and feature weighting to distinguish hypernymy from any other relation.

## 5.2 Best Measure Per Classification Task

We considered all relations that occurred in two datasets. For such relation, for each dataset, we ranked the measures by their AP@100 score, selecting those with score  $\geq 0.8$ .<sup>6</sup> Table 3 displays the intersection of the datasets’ best measures.

**Hypernym vs. Meronym** The inclusion hypothesis seems to be most effective in discriminating between hypernyms and meronyms under syntactic contexts. We conjecture that the window-based contexts are less effective since they capture topical context words, that might be shared also among holonyms and their meronyms (e.g. *car* will occur with many of the neighbors of *wheel*). However, since meronyms and holonyms often have different functions, their functional contexts, which are expressed in the syntactic context-types, are less shared. This is where they mostly differ from hyponym-hypernym pairs, which are of the same function (e.g. *cat* is a type of *animal*).

Table 2 shows that SLQS performs well in this task on BLESS. This is contrary to previous findings that suggested that SLQS is weak in discriminating between hypernyms and meronyms, as in many cases the holonym is more general than the meronym (Shwartz et al., 2016).<sup>7</sup> The

<sup>6</sup>We considered at least 10 measures, allowing scores slightly lower than 0.8 when others were unavailable.

<sup>7</sup>In the hypernymy dataset of Shwartz et al. (2016),

surprising result could be explained by the nature of meronymy in this dataset: most holonyms in BLESS are rather specific words.

BLESS was built starting from 200 basic level concepts (e.g. *goldfish*) used as the  $x$  words, to which  $y$  words in different relations were associated (e.g. *eye*, for meronymy; *animal*, for hypernymy).  $x$  words represent hyponyms in the hyponym-hypernym pairs, and should therefore not be too general. Indeed, SLQS assigns high scores to hyponym-hypernym pairs. At the same time, in the meronymy relation in BLESS,  $x$  is the holonym and  $y$  is the meronym. For consistency with EVALution, we switched those pairs in BLESS, placing the meronym in the  $x$  slot and the holonym in the  $y$  slot. As a consequence, after the switching, holonyms in BLESS are usually rather specific words (e.g., there are no holonyms like *animal* and *vehicle*, as these words were originally in the  $y$  slot). In most cases, they are not more general than their meronyms (*(eye, goldfish)*), yielding low SLQS scores which are easy to separate from hypernyms. We note that this is a weakness of the BLESS dataset, rather than a strength of the measure. For instance, on EVALution, SLQS performs worse (ranked only as high as 13th), as this dataset has no such restriction on the basic level concepts, and may contain pairs like *(eye, animal)*.

**Hypernym vs. Attribute** Symmetric similarity measures computed on syntactic contexts succeed to discriminate between hypernyms and attributes. Since attributes are syntactically different from hypernyms (in attributes,  $y$  is an adjective), it is unsurprising that they occur in different syntactic contexts, yielding low similarity scores.

nearly 50% of the SLQS false positive pairs were meronym-holonym pairs, in many of which the holonym is more general than the meronym by definition, e.g. *(mauritus, africa)*.

dataset	hyper vs. relation	best supervised				best unsupervised

						SLQS <sub>row<sub>sub</sub></sub>	joint	ppmi	

**Table 4:** Best performance on the validation set (10%) of each dataset for the supervised and unsupervised measures, in terms of Average Precision (AP) at  $k = 100$ , for hypernym vs. each single relation.

**Hypernym vs. Antonym** In all our experiments, antonyms were the hardest to distinguish from hypernyms, yielding the lowest performance. We found that SLQS performed reasonably well in this setting. However, the measure variations, context types and feature weightings were not consistent across datasets. SLQS relies on the assumption that  $y$  is a more general word than  $x$ , which is not true for antonyms, making it the most suitable measure for this setting.

**Hypernym vs. Synonym** SLQS performs well also in discriminating between hypernyms and synonyms, in which  $y$  is also not more general than  $x$ . We observed that in the `joint` context type, the difference in SLQS scores between synonyms and hypernyms was the largest. This may stem from the restrictiveness of this context type. For instance, among the most salient contexts we would expect to find informative contexts like *drinks milk* for *cat* and less informative ones like *drinks water* for *animal*, whereas the non-restrictive single dependency context *drinks* would probably be present for both.

Another measure that works well is `invCL`: interestingly, other inclusion-based measures assign high scores to  $(x, y)$  when  $y$  includes many of  $x$ 's contexts, which might be true also for synonyms (e.g. *elevator* and *lift* share many contexts). `invCL`, on the other hand, reduces with the ratio of  $y$ 's contexts included in  $x$ , yielding lower scores for synonyms.

**Hypernym vs. Coordination** We found no consistency among BLESS and Weeds. On Weeds,

inclusion-based measures (`ClarkeDE`, `invCL` and `Weeds`) showed the best results. The best performing measures on BLESS, however, were variants of SLQS, that showed to perform well in cases where the negative relation is symmetric (antonym, synonym and coordination). The difference could be explained by the nature of the datasets: the BLESS test set contains 1,185 hypernymy pairs, with only 129 distinct  $ys$ , many of which are general words like *animal* and *object*. The Weeds test set, on the other hand, was intentionally constructed to contain an overall unique  $y$  in each pair, and therefore contains much more specific  $ys$  (e.g. (*quirk*, *strangeness*)). For this reason, generality-based measures perform well on BLESS, and struggle with Weeds, which is handled better using inclusion-based measures.

### 5.3 Comparison to State-of-the-art Supervised Methods

For comparison with the state-of-the-art, we evaluated several supervised hypernymy detection methods, based on the word embeddings of  $x$  and  $y$ : concatenation  $\vec{v}_x \oplus \vec{v}_y$  (Baroni et al., 2012), difference  $\vec{v}_y - \vec{v}_x$  (Weeds et al., 2014), and ASYM (Roller et al., 2014). We downloaded several pre-trained embeddings (Mikolov et al., 2013; Pennington et al., 2014; Levy and Goldberg, 2014), and trained a logistic regression classifier to predict hypernymy. We used the 90% portion (originally the test set) as the train set, and the other 10% (originally the validation set) as a test set, reporting the best results among different vectors,

	method	AP@100 original	AP@100 switched	$\Delta$
supervised	concat, word2vec, $L_1$	0.995	0.575	-0.42
unsupervised	cosWeeds, win2d, ppmi	0.818	0.882	+0.064

**Table 5:** Average Precision (AP) at  $k = 100$  of the best supervised and unsupervised methods for hypernym vs. random-n, on the original BLESS validation set and the validation set with the artificially added switched hypernym pairs.

method and regularization factor.<sup>8</sup>

Table 4 displays the performance of the best classifier on each dataset, in a hypernym vs. a single relation setting. We also re-evaluated the unsupervised measures, this time reporting the results on the validation set (10%) for comparison.

The overall performance of the embedding-based classifiers is almost perfect, and in particular the best performance is achieved using the concatenation method (Baroni et al., 2012) with either GloVe (Pennington et al., 2014) or the dependency-based embeddings (Levy and Goldberg, 2014). As expected, the unsupervised measures perform worse than the embedding-based classifiers, though generally not bad on their own.

These results may suggest that unsupervised methods should be preferred only when no training data is available, leaving all the other cases to supervised methods. This is, however, not completely true. As others previously noticed, supervised methods do not actually learn the relation between  $x$  and  $y$ , but rather separate properties of either  $x$  or  $y$ . Levy et al. (2015b) named this the “lexical memorization” effect, i.e. memorizing that certain  $y$ s tend to appear in many positive pairs (*prototypical hypernyms*).

On that account, the Weeds dataset has been designed to avoid such memorization, with every word occurring once in each slot of the relation. While the performance of the supervised methods on this dataset is substantially lower than their performance on other datasets, it is yet well above the random baseline which we might expect from a method that can only memorize words it has seen during training.<sup>9</sup> This is an indication that supervised methods can abstract away from the words.

Indeed, when we repeated the experiment with a lexical split of each dataset, i.e., such that the train and test set consist of distinct vocabularies, we found that the supervised methods’ performance did not decrease dramatically, in contrast to the

findings of Levy et al. (2015b). The large performance gaps reported by Levy et al. (2015b) might be attributed to the size of their training sets. Their lexical split discarded around half of the pairs in the dataset and split the rest of the pairs equally to train and test, resulting in a relatively small train set. We performed the split such that only around 30% of the pairs in each dataset were discarded, and split the train and test sets with a ratio of roughly 90/10%, obtaining large enough train sets.

Our experiment suggests that rather than memorizing the verbatim *prototypical hypernyms*, the supervised models might learn that certain regions in the vector space pertain to prototypical hypernyms. For example, *device* (from the BLESS train set) and *appliance* (from the BLESS test set) are two similar words, which are both prototypical hypernyms. Another interesting observation was recently made by Roller and Erk (2016): they showed that when dependency-based embeddings are used, supervised distributional methods trace  $x$  and  $y$ ’s separate occurrences in different slots of Hearst patterns (Hearst, 1992).

Whether supervised methods only memorize or also learn, it is more consensual that they lack the ability to capture the relation between  $x$  and  $y$ , and that they rather indicate how likely  $y$  ( $x$ ) is to be a hypernym (hyponym) (Levy et al., 2015b; Santus et al., 2016a; Shwartz et al., 2016; Roller and Erk, 2016). While this information is valuable, it cannot be solely relied upon for classification.

To better understand the extent of this limitation, we conducted an experiment in a similar manner to the switched hypernym pairs in Santus et al. (2016a). We used BLESS, which is the only dataset with random pairs. For each hypernym pair  $(x_1, y_1)$ , we sampled a word  $y_2$  that participates in another hypernym pair  $(x_2, y_2)$ , such that  $(x_1, y_2)$  is not in the dataset, and added  $(x_1, y_2)$  as a random pair. We added 139 new pairs to the validation set, such as (*rifle, animal*) and (*salmon, weapon*). We then used the best supervised and unsupervised methods for hypernym vs. random-n on BLESS to re-classify the revised validation set. Table 5 displays the experiment results.

<sup>8</sup>In our preliminary experiments we also trained other classifiers used in the distributional hypernymy detection literature (SVM and SVM+RBF kernel), that performed similarly. We report the results for logistic regression, since we use the prediction probabilities to measure average precision.

<sup>9</sup>The dataset is balanced between its two classes.

The switched hypernym experiment paints a much less optimistic picture of the embeddings’ actual performance, with a drop of 42 points in average precision. 121 out of the 139 switched hypernym pairs were falsely classified as hypernyms. Examining the  $y$  words of these pairs reveals general words that appear in many hypernym pairs (e.g. *animal*, *object*, *vehicle*). The unsupervised measure was not similarly affected by the switched pairs, and the performance even slightly increased. This result is not surprising, since most unsupervised measures aim to capture aspects of the relation between  $x$  and  $y$ , while not relying on information about one of the words in the pair.<sup>10</sup>

## 6 Discussion

The results in Section 5 suggest that a supervised method using the unsupervised measures as features could possibly be the best of both worlds. We would expect it to be more robust than embedding-based methods on the one hand, while being more informative than any single unsupervised measure on the other hand.

Such a method was developed by Santus et al. (2016a), however using mostly features that describe a single word, e.g. frequency and entropy. It was shown to be competitive with the state-of-the-art supervised methods. With that said, it was also shown to be sensitive to the distribution of training examples in a specific dataset, like the embedding-based methods.

We conducted a similar experiment, with a much larger number of unsupervised features, namely the various measure scores, and encountered the same issue. While the performance was good, it dropped dramatically when the model was tested on a different test set.

We conjecture that the problem stems from the currently available datasets, which are all somewhat artificial and biased. Supervised methods which are strongly based on the relation between the words, e.g. those that rely on path-based information (Shwartz et al., 2016), manage to overcome the bias. Distributional methods, on the other hand, are based on a weaker notion of the relation between words, hence are more prone to overfit the distribution of training instances in a specific dataset. In the future, we hope that new

<sup>10</sup>Turney and Mohammad (2015) have also shown that unsupervised methods are more robust than supervised ones in a transfer-learning experiment, when the “training data” was used to tune their parameters.

datasets will be available for the task, which would be drawn from corpora and will reflect more realistic distributions of words and semantic relations.

## 7 Conclusion

We performed an extensive evaluation of unsupervised methods for discriminating hypernyms from other semantic relations. We found that there is no single combination of measure and parameters which is always preferred; however, we suggested a principled linguistic-based analysis of the most suitable measure for each task that yields consistent performance across different datasets.

We investigated several new variants of existing methods, and found that some variants of SLQS turned out to be superior on certain tasks. In addition, we have tested for the first time the `joint` context type (Chersoni et al., 2016), which was found to be very discriminative, and might hopefully benefit other semantic tasks.

For comparison, we evaluated the state-of-the-art supervised methods on the datasets, and they have shown to outperform the unsupervised ones, while also being efficient and easier to use. However, a deeper analysis of their performance demonstrated that, as previously suggested, these methods do not capture the relation between  $x$  and  $y$ , but rather indicate the “prior probability” of either word to be a hyponym or a hypernym. As a consequence, supervised methods are sensitive to the distribution of examples in a particular dataset, making them less reliable for real-world applications. Being motivated by linguistic hypotheses, and independent from training data, unsupervised measures were shown to be more robust. In this sense, unsupervised methods can still play a relevant role, especially if combined with supervised methods, in the decision whether the relation holds or not.

## Abstract

Distinguishing between antonyms and synonyms is a key task to achieve high performance in NLP systems. While they are notoriously difficult to distinguish by distributional co-occurrence models, pattern-based methods have proven effective to differentiate between the relations. In this paper, we present a novel neural network model *AntSynNET* that exploits lexico-syntactic patterns from syntactic parse trees. In addition to the lexical and syntactic information, we successfully integrate the distance between the related words along the syntactic path as a new pattern feature. The results from classification experiments show that *AntSynNET* improves the performance over prior pattern-based methods.

## 1 Introduction

Antonymy and synonymy represent lexical semantic relations that are central to the organization of the mental lexicon (Miller and Fellbaum, 1991). While antonymy is defined as the oppositeness between words, synonymy refers to words that are similar in meaning (Deese, 1965; Lyons, 1977). From a computational point of view, distinguishing between antonymy and synonymy is important for NLP applications such as Machine Translation and Textual Entailment, which go beyond a general notion of semantic relatedness and require to identify specific semantic relations. However, due to interchangeable substitution, antonyms and synonyms often occur in similar contexts, which makes it challenging to automatically distinguish between them.

Two families of approaches to differentiate between antonyms and synonyms are predominant

in NLP. Both make use of distributional vector representations, relying on the *distributional hypothesis* (Harris, 1954; Firth, 1957), that words with similar distributions have related meanings: co-occurrence models and pattern-based models. These distributional semantic models (DSMs) offer a means to represent meaning vectors of words or word pairs, and to determine their semantic relatedness (Turney and Pantel, 2010).

In *co-occurrence models*, each word is represented by a weighted feature vector, where features typically correspond to words that co-occur in particular contexts. When using word embeddings, these models rely on neural methods to represent words as low-dimensional vectors. To create the word embeddings, the models either make use of neural-based techniques, such as the skip-gram model (Mikolov et al., 2013), or use matrix factorization (Pennington et al., 2014) that builds word embeddings by factorizing word-context co-occurrence matrices. In comparison to standard co-occurrence vector representations, word embeddings address the problematic sparsity of word vectors and have achieved impressive results in many NLP tasks such as word similarity (e.g., Pennington et al. (2014)), relation classification (e.g., Vu et al. (2016)), and antonym-synonym distinction (e.g., Nguyen et al. (2016)).

In *pattern-based models*, vector representations make use of lexico-syntactic surface patterns to distinguish between the relations of word pairs. For example, Justeson and Katz (1991) suggested that adjectival opposites co-occur with each other in specific linear sequences, such as between *X* and *Y*. Hearst (1992) determined surface patterns, e.g., *X such as Y*, to identify nominal hypernyms. Lin et al. (2003) proposed two textual patterns indicating semantic incompatibility, from *X to Y* and either *X or Y*, to distinguish opposites from semantically similar

words. Roth and Schulte im Walde (2014) proposed a method that combined patterns with discourse markers for classifying paradigmatic relations including antonymy, synonymy, and hypernymy. Recently, Schwartz et al. (2015) used two prominent patterns from Lin et al. (2003) to learn word embeddings that distinguished antonyms from similar words in determining degrees of similarity and word analogy.

In this paper, we present a novel pattern-based neural method *AntSynNET* to distinguish antonyms from synonyms. We hypothesize that antonymous word pairs co-occur with each other in lexico-syntactic patterns within a sentence more often than would be expected by synonymous pairs. This hypothesis is inspired by corpus-based studies on antonymy and synonymy. Among others, Charles and Miller (1989) suggested that adjectival opposites co-occur in patterns; Fellbaum (1995) stated that nominal and verbal opposites co-occur in the same sentence significantly more often than chance; Lin et al. (2003) argued that if two words appear in clear antonym patterns, they are unlikely to represent synonymous pair.

We start out by inducing patterns between  $X$  and  $Y$  from a large-scale web corpus, where  $X$  and  $Y$  represent two words of an antonym or synonym word pair, and the pattern is derived from the simple paths between  $X$  and  $Y$  in a syntactic parse tree. Each node in the simple path combines lexical and syntactic information; in addition, we suggest a novel feature for the patterns, i.e., the distance between the two words along the syntactic path. All pattern features are fed into a recurrent neural network with long short-term memory (LSTM) units (Hochreiter and Schmidhuber, 1997), which encode the patterns as vector representations. Afterwards, the vector representations of the patterns are used in a classifier to distinguish between antonyms and synonyms. The results from experiments show that *AntSynNET* improves the performance over prior pattern-based methods. Furthermore, the implementation of our models is made publicly available<sup>1</sup>.

The remainder of this paper is organized as follows: In Section 2, we present previous work distinguishing antonyms and synonyms. Section 3 describes our proposed *AntSynNET* model. We present the induction of the patterns (Section 3.1), describe the recurrent neural network with long

short-term memory units which is used to encode patterns within a vector representation (Section 3.2), and describe two models to classify antonyms and synonyms: the pure pattern-based model (Section 3.3.1) and the combined model (Section 3.3.2). After introducing two baselines in Section 4, we describe our dataset, experimental settings, results of our methods, the effects of the newly proposed distance feature, and the effects of the various types of word embeddings. Section 6 concludes the paper.

## 2 Related Work

**Pattern-based methods:** Regarding the task of antonym-synonym distinction, there exist a variety of approaches which rely on patterns. Lin et al. (2003) used bilingual dependency triples and patterns to extract distributionally similar words. They relied on clear antonym patterns such as *from X to Y* and *either X or Y* in a post-processing step to distinguish antonyms from synonyms. The main idea is that if two words  $X$  and  $Y$  appear in one of these patterns, they are unlikely to represent synonymous pair. Schulte im Walde and Köper (2013) proposed a method to distinguish between the paradigmatic relations antonymy, synonymy and hypernymy in German, based on automatically acquired word patterns. Roth and Schulte im Walde (2014) combined general lexico-syntactic patterns with discourse markers as indicators for the same relations, both for German and for English. They assumed that if two phrases frequently co-occur with a specific discourse marker, then the discourse relation expressed by the corresponding marker should also indicate the relation between the words in the affected phrases. By using the raw corpus and a fixed list of discourse markers, the model can easily be extended to other languages. More recently, Schwartz et al. (2015) presented a symmetric pattern-based model for word vector representation in which antonyms are assigned to dissimilar vector representations. Differently to the previous pattern-based methods which used the standard distribution of patterns, Schwartz et al. used patterns to learn word embeddings.

**Vector representation methods:** Yih et al. (2012) introduced a new vector representation where antonyms lie on opposite sides of a sphere. They derived this representation with the incorporation of a thesaurus and latent semantic anal-

<sup>1</sup><https://github.com/nguyenkh/AntSynNET>

ysis, by assigning signs to the entries in the co-occurrence matrix on which latent semantic analysis operates, such that synonyms would tend to have positive cosine similarities, and antonyms would tend to have negative cosine similarities. Scheible et al. (2013) showed that the distributional difference between antonyms and synonyms can be identified via a simple word space model by using appropriate features. Instead of taking into account all words in a window of a certain size for feature extraction, the authors experimented with only words of a certain part-of-speech, and restricted distributions. Santus et al. (2014) proposed a different method to distinguish antonyms from synonyms by identifying the most salient dimensions of meaning in vector representations and reporting a new average-precision-based distributional measure and an entropy-based measure. Ono et al. (2015) trained supervised word embeddings for the task of identifying antonymy. They proposed two models to learn word embeddings: the first model relied on thesaurus information; the second model made use of distributional information and thesaurus information. More recently, Nguyen et al. (2016) proposed two methods to distinguish antonyms from synonyms: in the first method, the authors improved the quality of weighted feature vectors by strengthening those features that are most salient in the vectors, and by putting less emphasis on those that are of minor importance when distinguishing degrees of similarity between words. In the second method, the lexical contrast information was integrated into the skip-gram model (Mikolov et al., 2013) to learn word embeddings. This model successfully predicted degrees of similarity and identified antonyms and synonyms.

### 3 AntSynNET: LSTM-based Antonym-Synonym Distinction

In this section, we describe the AntSynNET model, using a pattern-based LSTM for distinguishing antonyms from synonyms. We first present the induction of patterns from a parsed corpus (Section 3.1). Section 3.2 then describes how we utilize the recurrent neural network with long short-term memory units to encode the patterns as vector representation. Finally, we present the AntSynNET model and two approaches to classify antonyms and synonyms (Section 3.3).

#### 3.1 Induction of Patterns

Corpus-based studies on antonymy have suggested that opposites co-occur with each other within a sentence significantly more often than would be expected by chance. Our method thus makes use of patterns as the main indicators of word pair co-occurrence, to enforce a distinction between antonyms and synonyms. Figure 1 shows a syntactic parse tree of the sentence “*My old village has been provided with the new services*”. Following the characterizations of a tree in graph theory, any two nodes (vertices) of a tree are connected by a simple path (or one unique path). The simple path is the shortest path between any two nodes in a tree and does not contain repeated nodes. In the example, the lexico-syntactic tree pattern of the antonymous pair *old*–*new* is determined by finding the simple path (in red) from the lemma `old` to the lemma `new`. It focuses on the most relevant information and ignores irrelevant information which does not appear in the simple path (i.e., *has*, *been*). The example pattern between  $X = \text{old}$  and  $Y = \text{new}$  in Figure 1 is represented as follows: `X/JJ/amod/2 -- village/NN/nsubj/1 -- provide/VBN/ROOT/0 -- with/IN/prep/1 -- service/NNS/pobj/2 -- Y/JJ/amod/3.`

**Node Representation:** The path patterns make use of four features to represent each node in the syntax tree: lemma, part-of-speech (POS) tag, dependency label and distance label. The lemma feature captures the lexical information of words in the sentence, while the POS and dependency features capture the morpho-syntactic information of the sentence. The distance label measures the path distance between the target word nodes in the syntactic tree. Each step between a parent and a child node represents a distance of 1; and the ancestor nodes of the remaining nodes in the path are represented by a distance of 0. For example, the node `provided` is an ancestor node of the simple path from `old` to `new`. The distances from the node `provided` to the nodes `village` and `old` are 1 and 2, respectively.

The vector representation of each node concatenates the four-feature vectors as follows:

$$\vec{v}_{node} = [\vec{v}_{lemma} \oplus \vec{v}_{pos} \oplus \vec{v}_{dep} \oplus \vec{v}_{dist}]$$

where  $\vec{v}_{lemma}$ ,  $\vec{v}_{pos}$ ,  $\vec{v}_{dep}$ ,  $\vec{v}_{dist}$  represent the embeddings of the lemma, POS tag, dependency label

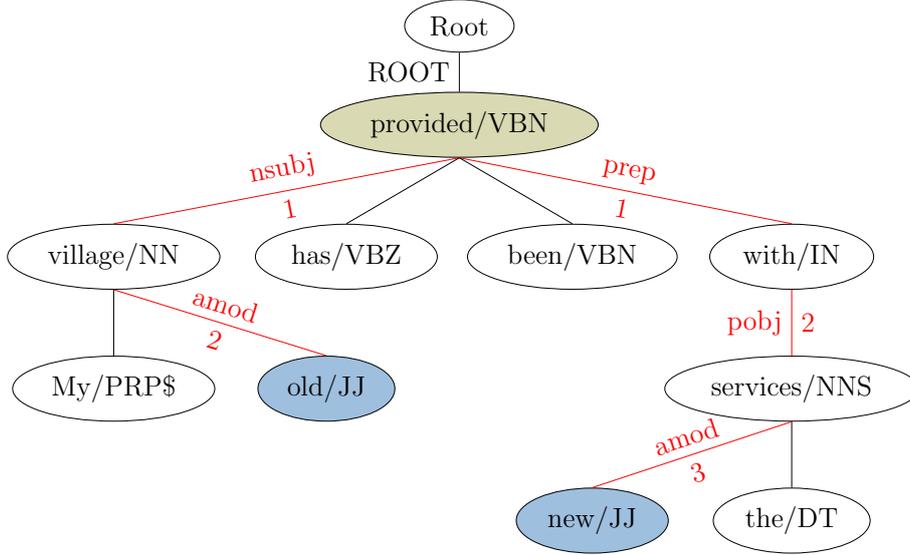

Figure 1: Illustration of the syntactic tree for the sentence “My old village has been provided with the new services”. Red lines indicate the path from the word `old` to the word `new`.

and distance label, respectively; and the  $\oplus$  denotes the concatenation operation.

**Pattern Representation:** For a pattern  $p$  which is constructed by the sequence of nodes  $n_1, n_2, \dots, n_k$ , the pattern representation of  $p$  is a sequence of vectors:  $p = [\vec{n}_1, \vec{n}_2, \dots, \vec{n}_k]$ . The pattern vector  $\vec{v}_p$  is then encoded by applying a recurrent neural network.

### 3.2 Recurrent Neural Network with Long Short-Term Memory Units

A recurrent neural network (RNN) is suitable for modeling sequential data by a vector representation. In our methods, we use a long short-term memory (LSTM) network, a variant of a recurrent neural network to encode patterns, for the following reasons. Given a sequence of words  $p = [n_1, n_2, \dots, n_k]$  as input data, an RNN processes each word  $n_t$  at a time, and returns a vector of state  $h_k$  for the complete input sequence. For each time step  $t$ , the RNN updates an internal memory state  $h_t$  which depends on the current input  $n_t$  and the previous state  $h_{t-1}$ . Yet, if the sequential input is a long-term dependency, an RNN faces the problem of gradient vanishing or exploding, leading to difficulties in training the model.

LSTM units address these problems. The underlying idea of an LSTM is to use an adaptive gating mechanism to decide on the degree that LSTM units keep the previous state and memorize the extracted features of the current input. More specif-

ically, an LSTM comprises four components: an input gate  $i_t$ , a forget gate  $f_t$ , an output gate  $o_t$ , and a memory cell  $c_t$ . The state of an LSTM at each time step  $t$  is formalized as follows:

$$\begin{aligned} i_t &= \sigma(W_i \cdot x_t + U_i \cdot h_{t-1} + b_i) \\ f_t &= \sigma(W_f \cdot x_t + U_f \cdot h_{t-1} + b_f) \\ o_t &= \sigma(W_o \cdot x_t + U_o \cdot h_{t-1} + b_o) \\ g_t &= \tanh(W_c \cdot x_t + U_c \cdot h_{t-1} + b_c) \\ c_t &= i_t \otimes g_t + f_t \otimes c_{t-1} \end{aligned}$$

$W$  refers to a matrix of weights that projects information between two layers;  $b$  is a layer-specific vector of bias terms;  $\sigma$  denotes the sigmoid function. The output of an LSTM at a time step  $t$  is computed as follows:

$$h_t = o_t \otimes \tanh(c_t)$$

where  $\otimes$  denotes element-wise multiplication. In our methods, we rely on the last state  $h_k$  to represent the vector  $\vec{v}_p$  of a pattern  $p = [\vec{n}_1, \vec{n}_2, \dots, \vec{n}_k]$ .

### 3.3 The Proposed AntSynNET Model

In this section, we present two models to distinguish antonyms from synonyms. The first model makes use of patterns to classify antonyms and synonyms, by using an LSTM to encode patterns as vector representations and then feeding those vectors to a logistic regression layer (Section 3.3.1). The second model creates combined vector representations of word pairs, which concatenate the vectors of the words and the patterns (Section 3.3.2).

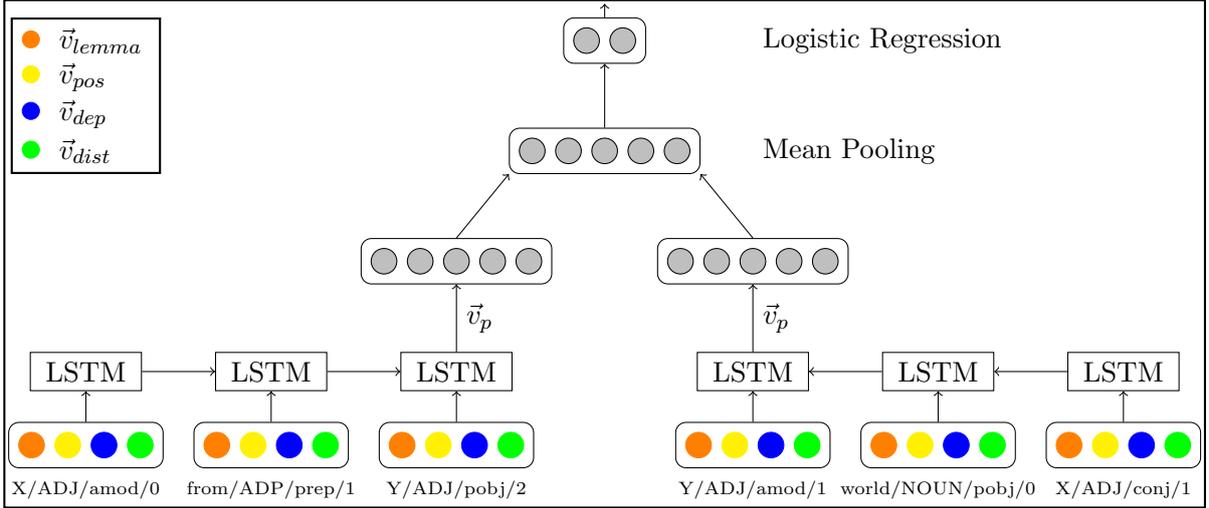

Figure 2: Illustration of the *AntSynNET* model. Each word pair is represented by several patterns, and each pattern represents a path in the graph of the syntactic tree. Patterns consist of several nodes where each node is represented by a vector with four features: lemma, POS, dependency label, and distance label. The mean pooling of the pattern vectors is the vector representation of each word pair, which is then fed to the logistic regression layer to classify antonyms and synonyms.

### 3.3.1 Pattern-based AntSynNET

In this model, we make use of a recurrent neural network with LSTM units to encode patterns containing a sequence of nodes. Figure 2 illustrates the AntSynNET model. Given a word pair  $(x, y)$ , we induce patterns for  $(x, y)$  from a corpus, where each pattern represents a path from  $x$  to  $y$  (cf. Section 3.1). We then feed each pattern  $p$  of the word pair  $(x, y)$  into an LSTM to obtain  $\vec{v}_p$ , the vector representation of the pattern  $p$  (cf. Section 3.2). For each word pair  $(x, y)$ , the vector representation of  $(x, y)$  is computed as follows:

$$\vec{v}_{xy} = \frac{\sum_{p \in P(x,y)} \vec{v}_p \cdot c_p}{\sum_{p \in P(x,y)} c_p} \quad (1)$$

$\vec{v}_{xy}$  refers to the vector of the word pair  $(x, y)$ ;  $P(x, y)$  is the set of patterns corresponding to the pair  $(x, y)$ ;  $c_p$  is the frequency of the pattern  $p$ . The vector  $\vec{v}_{xy}$  is then fed into a logistic regression layer whose target is the class label associated with the pair  $(x, y)$ . Finally, the pair  $(x, y)$  is predicted as positive (i.e., antonymous) word pair if the probability of the prediction for  $\vec{v}_{xy}$  is larger than 0.5.

### 3.3.2 Combined AntSynNET

Inspired by the supervised distributional concatenation method in Baroni et al. (2012) and the integrated path-based and distributional method for hypernymy detection in Shwartz et al. (2016), we

take into account the patterns and distribution of target pairs to create their combined vector representations. Given a word pair  $(x, y)$ , the combined vector representation of the pair  $(x, y)$  is determined by using both the co-occurrence distribution of the words and the syntactic path patterns:

$$\vec{v}_{comb(x,y)} = [\vec{v}_x \oplus \vec{v}_{xy} \oplus \vec{v}_y] \quad (2)$$

$\vec{v}_{comb(x,y)}$  refers to the combined vector of the word pair  $(x, y)$ ;  $\vec{v}_x$  and  $\vec{v}_y$  are the vectors of word  $x$  and word  $y$ , respectively;  $\vec{v}_{xy}$  is the vector of the pattern that corresponds to the pair  $(x, y)$ , cf. Section 3.3.1. Similar to the pattern-based model, the combined vector  $\vec{v}_{comb(x,y)}$  is fed into the logistic regression layer to classify antonyms and synonyms.

## 4 Baseline Models

To compare AntSynNET with baseline models for pattern-based classification of antonyms and synonyms, we introduce two pattern-based baseline methods: the distributional method (Section 4.1), and the distributed method (Section 4.2).

### 4.1 Distributional Baseline

As a first baseline, we apply the approach by Roth and Schulte im Walde (2014), henceforth R&SiW. They used a vector space model to represent pairs of words by a combination of standard lexico-

syntactic patterns and discourse markers. In addition to the patterns, the discourse markers added information to express discourse relations, which in turn may indicate the specific semantic relation between the two words in a word pair. For example, contrast relations might indicate antonymy, whereas elaborations may indicate synonymy or hyponymy.

Michael Roth, the first author of R&SiW, kindly computed the relation classification results of the pattern–discourse model for our test sets. The weights between marker-based and pattern-based models were tuned on the validation sets; other hyperparameters were set exactly as described by the R&SiW method.

## 4.2 Distributed Baseline

The *SP* method proposed by Schwartz et al. (2015) uses symmetric patterns for generating word embeddings. In this work, the authors applied an unsupervised algorithm for the automatic extraction of symmetric patterns from plain text. The symmetric patterns were defined as a sequence of 3-5 tokens consisting of exactly two wildcards and 1-3 words. The patterns were filtered based on their frequencies, such that the resulting pattern set contained 11 patterns. For generating word embeddings, a matrix of co-occurrence counts between patterns and words in the vocabulary was computed, using positive point-wise mutual information. The sparsity problem of vector representations was addressed by smoothing. For antonym representation, the authors relied on two patterns suggested by Lin et al. (2003) to construct word embeddings containing an antonym parameter that can be turned on in order to represent antonyms as dissimilar, and that can be turned off to represent antonyms as similar.

To apply the *SP* method to our data, we make use of the pre-trained *SP* embeddings<sup>2</sup> with 500 dimensions<sup>3</sup>. We calculate the cosine similarity of word pairs and then use a Support Vector Machine with Radial Basis Function kernel to classify antonyms and synonyms.

<sup>2</sup>[http://homes.cs.washington.edu/~roysch/papers/sp\\_embeddings/sp\\_embeddings.html](http://homes.cs.washington.edu/~roysch/papers/sp_embeddings/sp_embeddings.html)

<sup>3</sup>The 500-dimensional embeddings outperformed the 300-dimensional embeddings for our data.

## 5 Experiments

### 5.1 Dataset

For training the models, neural networks require a large amount of training data. We use the existing large-scale antonym and synonym pairs previously used by Nguyen et al. (2016). Originally, the data pairs were collected from WordNet (Miller, 1995) and Wordnik<sup>4</sup>.

In order to induce patterns for the word pairs in the dataset, we identify the sentences in the corpus that contain the word pair. Thereafter, we extract all patterns for the word pair. We filter out all patterns which occur less than five times; and we only take into account word pairs that contain at least five patterns for training, validating and testing. For the proportion of positive and negative pairs, we keep a ratio of 1:1 positive (antonym) to negative (synonym) pairs in the dataset. In order to create the sets of training, testing and validation data, we perform random splitting with 70% train, 25% test, and 5% validation sets. The final dataset contains the number of word pairs according to word classes described in Table 1. Moreover, Table 2 shows the average number of patterns for each word pair in our dataset.

Word Class	Train	Test	Validation	Total
Adjective	5562	1986	398	7946
Verb	2534	908	182	3624
Noun	2836	1020	206	4062

Adjective	135	131	141
Verb	364	332	396
Noun	110	132	105

Table 2: Average number of patterns per word pair across word classes.

### 5.2 Experimental Settings

We use the English Wikipedia dump<sup>5</sup> from June 2016 as the corpus resource for our methods and baselines. For parsing the corpus, we rely on spaCy<sup>6</sup>. For the lemma embeddings, we rely on the word embeddings of the dLCE

model<sup>7</sup> (Nguyen et al., 2016) which is the state-of-the-art vector representation for distinguishing antonyms from synonyms. We re-implemented this cutting-edge model on Wikipedia with 100 dimensions, and then make use of the dLCE word embeddings for initialization the lemma embeddings. The embeddings of POS tags, dependency labels, distance labels, and out-of-vocabulary lemmas are initialized randomly. The number of dimensions is set to 10 for the embeddings of POS tags, dependency labels and distance labels. We use the validation sets to tune the number of dimensions for these labels. For optimization, we rely on the cross-entropy loss function and Stochastic Gradient Descent with the Adadelta update rule (Zeiler, 2012). For training, we use the Theano framework (Theano Development Team, 2016). Regularization is applied by a dropout of 0.5 on each of component’s embeddings (dropout rate is tuned on the validation set). We train the models with 40 epochs and update all embeddings during training.

### 5.3 Overall Results

Table 3 shows the significant<sup>8</sup> performance of our models in comparison to the baselines. Concerning adjectives, the two proposed models significantly outperform the two baselines: The performance of the baselines is around .72 for  $F_1$ , and the corresponding results for the combined AntSynNET model achieve an improvement of  $>.06$ . Regarding nouns, the improvement of the new methods is just .02  $F_1$  in comparison to the

R&SiW baseline, but we achieve a much better performance in comparison to the SP baseline, an increase of .37  $F_1$ . Regarding verbs, we do not outperform the more advanced R&SiW baseline in terms of the  $F_1$  score, but we obtain higher recall scores. In comparison to the SP baseline, our models still show a clear  $F_1$  improvement.

Overall, our proposed models achieve comparatively high recall scores compared to the two baselines. This strengthens our hypothesis that there is a higher possibility for the co-occurrence of antonymous pairs in patterns over synonymous pairs within a sentence. Because, when the proposed models obtain high recall scores, the models are able to retrieve most relevant information (antonymous pairs) corresponding to the patterns. Regarding the low precision in the two proposed models, we sampled randomly 5 pairs in each population: true positive, true negative, false positive, false negative. We then compared the overlap of patterns for the true predictions (true positive pairs and true negative pairs) and the false predictions (false positive pairs and false negative pairs). We found out that there is no overlap between patterns of true predictions; and the number overlap between patterns of false predictions is 2, 2, and 4 patterns for noun, adjective, and verb classes, respectively. This shows that the low precision of our models stems from the patterns which represent both antonymous and synonymous pairs.

### 5.4 Effect of the Distance Feature

In our models, the novel distance feature is successfully integrated along the syntactic path to represent lexico-syntactic patterns. The intu-

<sup>7</sup><https://github.com/nguyenkh/AntSynDistinction>

<sup>8</sup>t-test, \* $p < 0.05$ , \*\* $p < 0.1$

Model	Word Embeddings	Adjective			Verb			Noun		
		P	R	F <sub>1</sub>	P	R	F <sub>1</sub>	P	R	F <sub>1</sub>
Pattern-based Model	GloVe	0.763	0.770	0.767	0.705	0.852	0.772	0.789	0.849	0.818
	dLCE	0.764	0.788	<b>0.776</b>	0.741	0.833	<b>0.784</b>	0.804	0.851	<b>0.827</b>
Combined Model	Glove	0.750	0.798	0.773	0.717	0.826	0.768	0.807	0.827	0.817
	dLCE	0.763	0.807	<b>0.784</b>	0.743	0.815	<b>0.777</b>	0.816	0.898	<b>0.855</b>

Table 5: Comparing pre-trained GloVe and dLCE word embeddings.

ition behind the distance feature exploits properties of trees in graph theory, which show that there exist differences in the degree of relationship between the parent node and the child nodes ( $distance = 1$ ) and in the degree of relationship between the ancestor node and the descendant nodes ( $distance > 1$ ). Hence, we use the distance feature to effectively capture these relationships.

In order to evaluate the effect of our novel distance feature, we compare the distance feature to the direction feature proposed by Shwartz et al. (2016). In their approach, the authors combined lemma, POS, dependency, and direction features for the task of hypernym detection. The direction feature represented the direction of the dependency label between two nodes in a path from  $X$  to  $Y$ .

For evaluation, we make use of the same information regarding dataset and patterns as in Section 5.3, and then replace the distance feature by the direction feature. The results are shown in Table 4. The distance feature enhances the performance of our proposed models more effectively than the direction feature does, across all word classes.

### 5.5 Effect of Word Embeddings

Our methods rely on the word embeddings of the dLCE model, state-of-the-art word embeddings for antonym-synonym distinction. Yet, the word embeddings of the dLCE model, i.e., supervised word embeddings, represent information collected from lexical resources. In order to evaluate the effect of these word embeddings on the performance of our models, we replace them by the pre-trained GloVe word embeddings<sup>9</sup> with 100 dimensions, and compare the effects of the GloVe word embeddings and the dLCE word embeddings on the performance of the two proposed models.

Table 5 illustrates the performance of our two models on all word classes. The table shows that the dLCE word embeddings are better than the

pre-trained GloVe word embeddings, by around .01  $F_1$  for the pattern-based AntSynNET model and the combined AntSynNET model regarding adjective and verb pairs. Regarding noun pairs, the improvements of the dLCE word embeddings over pre-trained GloVe word embeddings achieve around .01 and .04  $F_1$  for the pattern-based model and the combined model, respectively.

## 6 Conclusion

In this paper, we presented a novel pattern-based neural method *AntSynNET* to distinguish antonyms from synonyms. We hypothesized that antonymous word pairs co-occur with each other in lexico-syntactic patterns within a sentence more often than synonymous word pairs.

The patterns were derived from the simple paths between semantically related words in a syntactic parse tree. In addition to lexical and syntactic information, we suggested a novel path distance feature. The AntSynNET model consists of two approaches to classify antonyms and synonyms. In the first approach, we used a recurrent neural network with long short-term memory units to encode the patterns as vector representations; in the second approach, we made use of the distribution and encoded patterns of the target pairs to generate combined vector representations. The resulting vectors of patterns in both approaches were fed into the logistic regression layer for classification.

Our proposed models significantly outperformed two baselines relying on previous work, mainly in terms of recall. Moreover, we demonstrated that the distance feature outperformed a previously suggested direction feature, and that our embeddings outperformed the state-of-the-art GloVe embeddings. Last but not least, our two proposed models only rely on corpus data, such that the models are easily applicable to other languages and relations.

## Abstract

The current trend in NLP is the use of highly opaque models, e.g. neural networks and word embeddings. While these models yield state-of-the-art results on a range of tasks, their drawback is poor interpretability. On the example of word sense induction and disambiguation (WSID), we show that it is possible to develop an interpretable model that matches the state-of-the-art models in accuracy. Namely, we present an unsupervised, knowledge-free WSID approach, which is interpretable at three levels: word sense inventory, sense feature representations, and disambiguation procedure. Experiments show that our model performs on par with state-of-the-art word sense embeddings and other unsupervised systems while offering the possibility to justify its decisions in human-readable form.

## 1 Introduction

A word sense disambiguation (WSD) system takes as input a target word  $t$  and its context  $C$ . The system returns an identifier of a word sense  $s_i$  from the word sense inventory  $\{s_1, \dots, s_n\}$  of  $t$ , where the senses are typically defined manually in advance. Despite significant progress in methodology during the two last decades (Ide and Véronis, 1998; Agirre and Edmonds, 2007; Moro and Navigli, 2015), WSD is still not widespread in applications (Navigli, 2009), which indicates the need for further progress. The difficulty of the problem largely stems from the lack of domain-specific training data. A fixed sense inventory, such as the one of WordNet (Miller, 1995), may contain irrelevant senses for the given application and at the same time lack relevant domain-specific senses.

Word sense induction from domain-specific corpora is supposed to solve this problem. However, most approaches to word sense induction and disambiguation, e.g. (Schütze, 1998; Li and Jurafsky, 2015; Bartunov et al., 2016), rely on clustering methods and dense vector representations that make a WSD model uninterpretable as compared to knowledge-based WSD methods.

Interpretability of a statistical model is important as it lets us understand the reasons behind its predictions (Vellido et al., 2011; Freitas, 2014; Li et al., 2016). Interpretability of WSD models (1) lets a user understand why in the given context one observed a given sense (e.g., for educational applications); (2) performs a comprehensive analysis of correct and erroneous predictions, giving rise to improved disambiguation models.

The contribution of this paper is an interpretable unsupervised knowledge-free WSD method. The novelty of our method is in (1) a technique to disambiguation that relies on induced inventories as a pivot for learning sense feature representations, (2) a technique for making induced sense representations interpretable by labeling them with hypernyms and images.

Our method tackles the interpretability issue of the prior methods; it is interpretable at the levels of (1) sense inventory, (2) sense feature representation, and (3) disambiguation procedure. In contrast to word sense induction by context clustering (Schütze (1998), *inter alia*), our method constructs an explicit word sense inventory. The method yields performance comparable to the state-of-the-art unsupervised systems, including two methods based on word sense embeddings. An open source implementation of the method featuring a live demo of several pre-trained models is available online.<sup>1</sup>

## 2 Related Work

Multiple designs of WSD systems were proposed (Agirre and Edmonds, 2007; Navigli, 2009). They vary according to the level of supervision and the amount of external knowledge used. Most current systems either make use of lexical resources and/or rely on an explicitly annotated sense corpus.

**Supervised approaches** use a sense-labeled corpus to train a model, usually building one sub-model per target word (Ng, 1997; Lee and Ng, 2002; Klein et al., 2002; Wee, 2010). The IMS system by Zhong and Ng (2010) provides an implementation of the supervised approach to WSD that yields state-of-the-art results. While supervised approaches demonstrate top performance in competitions, they require large amounts of sense-labeled examples per target word.

**Knowledge-based approaches** rely on a lexical resource that provides a sense inventory and features for disambiguation and vary from the classical Lesk (1986) algorithm that uses word definitions to the Babelfy (Moro et al., 2014) system that uses harnesses a multilingual lexical-semantic network. Classical examples of such approaches include (Banerjee and Pedersen, 2002; Pedersen et al., 2005; Miller et al., 2012). More recently, several methods were proposed to learn sense embeddings on the basis of the sense inventory of a lexical resource (Chen et al., 2014; Rothe and Schütze, 2015; Camacho-Collados et al., 2015; Iacobacci et al., 2015; Nieto Piña and Johansson, 2016).

**Unsupervised knowledge-free approaches** use neither handcrafted lexical resources nor hand-annotated sense-labeled corpora. Instead, they induce word sense inventories automatically from corpora. Unsupervised WSD methods fall into two main categories: context clustering and word ego-network clustering.

**Context clustering approaches**, e.g. (Pedersen and Bruce, 1997; Schütze, 1998), represent an instance usually by a vector that characterizes its context, where the definition of context can vary greatly. These vectors of each instance are then clustered. Multi-prototype extensions of the skip-gram model (Mikolov et al., 2013) that use no pre-defined sense inventory learn one embedding word vector per one word sense and are commonly fitted with a disambiguation mechanism (Huang et al., 2012; Tian et al., 2014; Neelakantan et al.,

2014; Bartunov et al., 2016; Li and Jurafsky, 2015; Pelevina et al., 2016). Comparisons of the *AdaGram* (Bartunov et al., 2016) to (Neelakantan et al., 2014) on three SemEval word sense induction and disambiguation datasets show the advantage of the former. For this reason, we use *AdaGram* as a representative of the state-of-the-art word sense embeddings in our experiments. In addition, we compare to SenseGram, an alternative sense embedding based approach by Pelevina et al. (2016). What makes the comparison to the later method interesting is that this approach is similar to ours, but instead of sparse representations the authors rely on word embeddings, making their approach less interpretable.

**Word ego-network clustering methods** (Lin, 1998; Pantel and Lin, 2002; Widdows and Dorow, 2002; Biemann, 2006; Hope and Keller, 2013) cluster graphs of words semantically related to the ambiguous word. An ego network consists of a single node (ego) together with the nodes they are connected to (alters) and all the edges among those alters (Everett and Borgatti, 2005). In our case, such a network is a local neighborhood of one word. Nodes of the ego-network can be (1) words semantically similar to the target word, as in our approach, or (2) context words relevant to the target, as in the *UoS* system (Hope and Keller, 2013). Graph edges represent semantic relations between words derived using corpus-based methods (e.g. distributional semantics) or gathered from dictionaries. The sense induction process using word graphs is explored by (Widdows and Dorow, 2002; Biemann, 2006; Hope and Keller, 2013). Disambiguation of instances is performed by assigning the sense with the highest overlap between the instance’s context words and the words of the sense cluster. Véronis (2004) compiles a corpus with contexts of polysemous nouns using a search engine. A word graph is built by drawing edges between co-occurring words in the gathered corpus, where edges below a certain similarity threshold were discarded. His HyperLex algorithm detects hubs of this graph, which are interpreted as word senses. Disambiguation in this experiment is performed by computing the distance between context words and hubs in this graph.

Di Marco and Navigli (2013) presents a comprehensive study of several graph-based WSI methods including Chinese Whispers, HyperLex, curvature clustering (Dorow et al., 2005). Besides,

authors propose two novel algorithms: Balanced Maximum Spanning Tree Clustering and Squares (B-MST), Triangles and Diamonds (SquaT++). To construct graphs, authors use first-order and second-order relations extracted from a background corpus as well as keywords from snippets. This research goes beyond intrinsic evaluations of induced senses and measures impact of the WSI in the context of an information retrieval via clustering and diversifying Web search results. Depending on the dataset, HyperLex, B-MST or Chinese-Whispers provided the best results.

Our system combines several of above ideas and adds features ensuring interpretability. Most notably, we use a word sense inventory based on clustering word similarities (Pantel and Lin, 2002); for disambiguation we rely on syntactic context features, co-occurrences (Hope and Keller, 2013) and language models (Yuret, 2012).

**Interpretable approaches.** The need in methods that interpret results of opaque statistical models is widely recognised (Vellido et al., 2011; Vellido et al., 2012; Freitas, 2014; Li et al., 2016; Park et al., 2016). An interpretable WSD system is expected to provide (1) a human-readable sense inventory, (2) human-readable reasons why in a given context  $c$  a given sense  $s_i$  was detected. Lexical resources, such as WordNet, solve the first problem by providing manually-crafted definitions of senses, examples of usage, hypernyms, and synonyms. The BabelNet (Navigli and Ponzetto, 2010) integrates all these sense representations, adding to them links to external resources, such as Wikipedia, topical category labels, and images representing the sense. The unsupervised models listed above do not feature any of these representations making them much less interpretable as compared to the knowledge-based models. Ruppert et al. (2015) proposed a system for visualising sense inventories derived in an unsupervised way using graph-based distributional semantics. Panchenko (2016) proposed a method for making sense inventory of word sense embeddings interpretable by mapping it to BabelNet.

Our approach was inspired by the knowledge-based system Babelfy (Moro et al., 2014). While the inventory of Babelfy is interpretable as it relies on BabelNet, the system provides no underlying reasons behind sense predictions. Our objective was to reach interpretability level of knowledge-based models within an unsupervised framework.

### 3 Method: Unsupervised Interpretable Word Sense Disambiguation

Our unsupervised word sense disambiguation method consist of the five steps illustrated in Figure 1: extraction of context features (Section 3.1); computing word and feature similarities (Section 3.2); word sense induction (Section 3.3); labeling of clusters with hypernyms and images (Section 3.4), disambiguation of words in context based on the induced inventory (Section 3.5), and finally interpretation of the model (Section 3.6). Feature similarity and co-occurrence computation steps (drawn with a dashed lines) are optional, since they did not consistently improve performance.

#### 3.1 Extraction of Context Features

The goal of this step is to extract word-feature counts from the input corpus. In particular, we extract three types of features:

**Dependency Features.** These feature represents a word by a syntactic dependency such as “nn(•,writing)” or “prep.at(sit,•)”, extracted from the Stanford Dependencies (De Marneffe et al., 2006) obtained with the the PCFG model of the Stanford parser (Klein and Manning, 2003). Weights are computed using the Local Mutual Information (LMI) (Evert, 2005). One word is represented with 1000 most significant features.

**Co-occurrence Features.** This type of features represents a word by another word. We extract the list of words that significantly co-occur in a sentence with the target word in the input corpus based on the log-likelihood as word-feature weight (Dunning, 1993).

**Language Model Feature.** This type of features are based on a trigram model with Kneser-Ney smoothing (Kneser and Ney, 1995). In particular, a word is represented by (1) right and left context words, e.g. “office\_•\_and”, (2) two preceding words “new\_office\_•”, and (3) two succeeding words, e.g. “•\_and\_chairs”. We use the conditional probabilities of the resulting trigrams as word-feature weights.

#### 3.2 Computing Word and Feature Similarities

The goal of this step is to build a graph of word similarities, such as (table, chair, 0.78). We used the *JoBimText* framework (Biemann and Riedl,

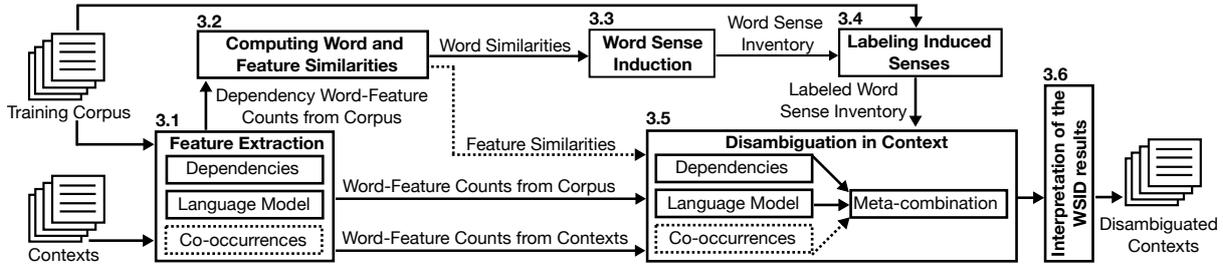

Figure 1: Outline of our unsupervised interpretable method for word sense induction and disambiguation.

2013) as it yields comparable performance on semantic similarity to state-of-the-art dense representations (Mikolov et al., 2013) compared on the WordNet as gold standard (Riedl, 2016), but is interpretable as words are represented by sparse interpretable features. Namely we use dependency-based features as, according to prior evaluations, this kind of features provides state-of-the-art semantic relatedness scores (Padó and Lapata, 2007; Van de Cruys, 2010; Panchenko and Morozova, 2012; Levy and Goldberg, 2014).

First, features of each word are ranked using the LMI metric (Evert, 2005). Second, the word representations are pruned keeping 1000 most salient features per word and 1000 most salient words per feature. The pruning reduces computational complexity and noise. Finally, word similarities are computed as a number of common features for two words. This is again followed by a pruning step in which only the 200 most similar terms are kept to every word. The resulting word similarities are browsable online.<sup>2</sup>

Note that while words can be characterized with distributions over features, features can vice versa be characterized by a distribution over words. We use this duality to compute feature similarities using the same mechanism and explore their use in disambiguation below.

### 3.3 Word Sense Induction

We induce a sense inventory by clustering of ego-network of similar words. In our case, an inventory represents senses by a word cluster, such as “chair, bed, bench, stool, sofa, desk, cabinet” for the “furniture” sense of the word “table”.

The sense induction processes one word  $t$  of the distributional thesaurus  $T$  per iteration. First, we retrieve nodes of the ego-network  $G$  of  $t$  being the  $N$  most similar words of  $t$  according to  $T$  (see

<sup>2</sup>Select the “JoBimViz” demo and then the “Stanford (English)” model: <http://www.jobimtext.org>.

Figure 2 (1)). Note that the target word  $t$  itself is not part of the ego-network. Second, we connect each node in  $G$  to its  $n$  most similar words according to  $T$ . Finally, the ego-network is clustered with Chinese Whispers (Biemann, 2006), a non-parametric algorithm that discovers the number of senses automatically. The  $n$  parameter regulates the granularity of the inventory: we experiment with  $n \in \{200, 100, 50\}$  and  $N = 200$ .

The choice of Chinese Whispers among other algorithms, such as HyperLex (Véronis, 2004) or MCL (Van Dongen, 2008), was motivated by the absence of meta-parameters and its comparable performance on the WSI task to the state-of-the-art (Di Marco and Navigli, 2013).

### 3.4 Labeling Induced Senses with Hypernyms and Images

Each sense cluster is automatically labeled to improve its interpretability. First, we extract hypernyms from the input corpus using Hearst (1992) patterns. Second, we rank hypernyms relevant to the cluster by a product of two scores: the *hypernym relevance* score, calculated as  $\sum_{w \in \text{cluster}} \text{sim}(t, w) \text{freq}(w, h)$ , and the *hypernym coverage* score, calculated as  $\sum_{w \in \text{cluster}} \min(\text{freq}(w, h), 1)$ . Here the  $\text{sim}(t, w)$  is the relatedness of the cluster word  $w$  to the target word  $t$ , and the  $\text{freq}(w, h)$  is the frequency of the hypernymy relation  $(w, h)$  as extracted via patterns. Thus, a high-ranked hypernym  $h$  has high relevance, but also is confirmed by several cluster words. This stage results in a ranked list of labels that specify the word sense, for which we here show the first one, e.g. “table (furniture)” or “table (data)”.

Faralli and Navigli (2012) showed that web search engines can be used to bootstrap sense-related information. To further improve interpretability of induced senses, we assign an image to each word in the cluster (see Figure 2) by query-

ing the Bing image search API<sup>3</sup> using the query composed of the target word and its hypernym, e.g. “jaguar car”. The first hit of this query is selected to represent the induced word sense.

```

input : Word  $t$ , context features  $C$ , sense inventory  $I$ ,
        word-feature table  $F$ , use largest cluster
        back-off  $LCB$ , use feature expansion  $FE$ .
output: Sense of the target word  $t$  in inventory  $I$  and
        confidence score.
1  $S \leftarrow \text{getSenses}(I, t)$ 
2 if  $FE$  then
3    $C \leftarrow \text{featureExpansion}(C)$ 
4 end
5 foreach  $(sense, cluster) \in S$  do
6    $\alpha[sense] \leftarrow \{\}$ 
7   foreach  $w \in cluster$  do
8     foreach  $c \in C$  do
9        $\alpha[sense] \leftarrow \alpha[sense] \cup F(w, c)$ 
10    end
11  end
12 end
13 if  $\max_{sense \in S} \text{mean}(\alpha[sense]) = 0$  then
14   if  $LCB$  then
15     return  $\arg \max_{(., cluster) \in S} |cluster|$ 
16   else
17     return  $-1$  // reject to classify
18   end
19 else
20   return  $\arg \max_{(sense, .) \in S} \text{mean}(\alpha[sense])$ 
21 end

```

---

### 3.5 Word Sense Disambiguation with Induced Word Sense Inventory

To disambiguate a target word  $t$  in context, we extract context features  $C$  and pass them to Algorithm 1. We use the induced sense inventory  $I$  and select the sense that has the largest weighted feature overlap with context features or fall back to the largest cluster back-off when context features  $C$  do not match the learned sense representations.

The algorithm starts by retrieving induced sense clusters of the target word (line 1). Next, the method starts to accumulate context feature weights of each  $sense$  in  $\alpha[sense]$ . Each word  $w$  in a sense  $cluster$  brings all its word-feature counts  $F(w, c)$ : see lines 5-12. Finally, a  $sense$  that maximizes mean weight across all context features is chosen (lines 13-21). Optionally, we can resort to the largest cluster back-off (LCB) strategy in case if no context features match sense representations.

<sup>3</sup><https://azure.microsoft.com/en-us/services/cognitive-services/search>

Note that the induced inventory  $I$  is used as a pivot to aggregate word-feature counts  $F(w, c)$  of the words in the  $cluster$  in order to build feature representations of each induced  $sense$ . We assume that the sets of similar words per sense are compatible with each other’s context. Thus, we can aggregate ambiguous feature representations of words in a sense cluster. In a way, occurrences of cluster members form the training set for the sense, i.e. contexts of {chair, bed, bench, stool, sofa, desk, cabinet}, add to the representation of “table (furniture)” in the model. Here, ambiguous cluster members like “chair” (which could also mean “chairman”) add some noise, but its influence is dwarfed by the aggregation over all cluster members. Besides, it is unlikely that the target (“table”) and the cluster member (“chair”) share the same homonymy, thus noisy context features hardly play a role when disambiguating the target in context. For instance, for scoring using language model features, we retrieve the context of the target word and substitute the target word one by one of the cluster words. To close the gap between the aggregated dependency per sense  $\alpha[sense]$  and dependencies observed in the target’s context  $C$ , we use the similarity of features: we expand every feature  $c \in C$  with 200 of most similar features and use them as additional features (lines 2-4).

We run disambiguation independently for each of the feature types listed above, e.g. dependencies or co-occurrences. Next, independent predictions are combined using the majority-voting rule.

### 3.6 Interpretability of the Method

Results of disambiguation can be interpreted by humans as illustrated by Figure 2. In particular, our approach is interpretable at three levels:

- 1. Word sense inventory.** To make induced word sense inventories interpretable we display senses of each word as an ego-network of its semantically related words. For instance, the network of the word “table” in our example is constructed from two tightly related groups of words that correspond to “furniture” and “data” senses. These labels of the clusters are obtained automatically (see Section 3.4).

While alternative methods, such as *AdaGram*, can generate sense clusters, our approach makes the senses better interpretable due to hypernyms and image labels that summarize senses.

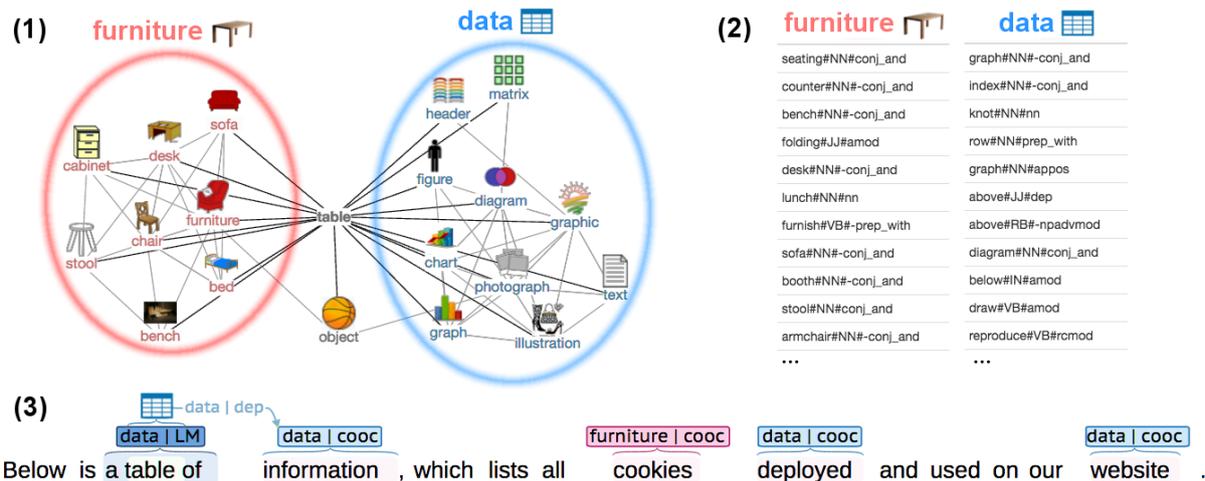

Figure 2: Interpretation of the senses of the word “table” at three levels by our method: (1) word sense inventory; (2) sense feature representation; (3) results of disambiguation in context. The sense labels (“furniture” and “data”) are obtained automatically based on cluster labeling with hypernyms. The images associated with the senses are retrieved using a search engine: “table data” and “table furniture”.

**2. Sense feature representation.** Each sense in our model is characterized by a list of sparse features ordered by relevance to the sense. Figure 2 (2) shows most salient dependency features to senses of the word “table”. These feature representations are obtained by aggregating features of sense cluster words.

In systems based on dense vector representations, there is no straightforward way to get the most salient features of a sense, which makes the analysis of learned representations problematic.

**3. Disambiguation method.** To provide the reasons for sense assignment in context, our method highlights the most discriminative context features that caused the prediction. The discriminative power of a feature is defined as the ratio between its weights for different senses.

In Figure 2 (3) words “information”, “cookies”, “deployed” and “website” are highlighted as they are most discriminative and intuitively indicate on the “data” sense of the word “table” as opposed to the “furniture” sense. The same is observed for other types of features. For instance, the syntactic dependency to the word “information” is specific to the “data” sense.

Alternative unsupervised WSD methods that rely on word sense embeddings make it difficult to explain sense assignment in context due to the use of dense features whose dimensions are not interpretable.

## 4 Experiments

We use two lexical sample collections suitable for evaluation of unsupervised WSD systems. The first one is the Turk Bootstrap Word Sense Inventory (TWSI) dataset introduced by Biemann (2012). It is used for testing different configurations of our approach. The second collection, the SemEval 2013 word sense induction dataset by Jurgens and Klapaftis (2013), is used to compare our approach to existing systems. In both datasets, to measure WSD performance, induced senses are mapped to gold standard senses. In experiments with the TWSI dataset, the models were trained on the Wikipedia corpus<sup>4</sup> while in experiments with the SemEval datasets models are trained on the ukWaC corpus (Baroni et al., 2009) for a fair comparison with other participants.

### 4.1 TWSI Dataset

#### 4.1.1 Dataset and Evaluation Metrics

This test collection is based on a crowdsourced resource that comprises 1,012 frequent nouns with 2,333 senses and average polysemy of 2.31 senses per word. For these nouns, 145,140 annotated sentences are provided. Besides, a sense inventory is explicitly provided, where each sense is represented with a list of words that can substitute target noun in a given sentence. The sense distribution across sentences in the dataset is highly

<sup>4</sup>We use a Wikipedia dump from September 2015: <http://doi.org/10.5281/zenodo.229904>

skewed as 79% of contexts are assigned to the most frequent senses. Thus, in addition to the full TWSI dataset, we also use a balanced subset featuring five contexts per sense and 6,166 sentences to assess the quality of the disambiguation mechanism for smaller senses. This dataset contains no monosemous words to completely remove the bias of the most frequent sense. Note that de-biasing the evaluation set does not de-bias the word sense inventory, thus the task becomes harder for the balanced subset.

For the TWSI evaluation, we create an explicit mapping between the system-provided sense inventory and the TWSI word senses: senses are represented as the bag of words, which are compared using cosine similarity. Every induced sense gets assigned at most one TWSI sense. Once the mapping is completed, we calculate Precision, Recall, and F-measure. We use the following baselines to facilitate interpretation of the results: (1) MFS of the TWSI inventory always assigns the most frequent sense in the TWSI dataset; (2) LCB of the induced inventory always assigns the largest sense cluster; (3) Upper bound of the induced vocabulary always selects the correct sense for the context, but only if the mapping exists for this sense; (4) Random sense of the TWSI and the induced inventories.

#### 4.1.2 Discussion of Results

The results of the TWSI evaluation are presented in Table 1. In accordance with prior art in word sense disambiguation, the most frequent sense (MFS) proved to be a strong baseline, reaching an F-score of 0.787, while the random sense over the TWSI inventory drops to 0.536. The upper bound on our induced inventory (F-score of 0.900) shows that the sense mapping technique used prior to evaluation does not drastically distort the evaluation scores. The LCB baseline of the induced inventory achieves an F-score of 0.691, demonstrating the efficiency of the LCB technique.

Let us first consider models based on single features. Dependency features yield the highest precision of 0.728, but have a moderate recall of 0.343 since they rarely match due to their sparsity. The LCB strategy for these rejected contexts helps to improve recall at cost of precision. Co-occurrence features yield significantly lower precision than the dependency-based features, but their recall is higher. Finally, the language model features yield very balanced results in terms of

both precision and recall. Yet, the precision of the model based on this feature type is significantly lower than that of dependencies.

Not all combinations improve results, e.g. combination of three types of features yields inferior results as compared to the language model alone. However, a combination of the language model with dependency features does provide an improvement over the single models as both these models bring strong signal of complementary nature about the semantics of the context. The dependency features represent syntactic information, while the LM features represent lexical information. This improvement is even more pronounced in the case of the balanced TWSI dataset. This combined model yields the best F-scores overall.

Table 2 presents the effect of the feature expansion based on the graph of similar features. For a low-recall model such the one based on syntactic dependencies, feature expansion makes a lot of sense: it almost doubles recall, while losing some precision. The gain in F-score using this technique is almost 20 points on the full TWSI dataset. However, the need for such expansion vanishes when two principally different types of features (precise syntactic dependencies and high-coverage trigram language model) are combined. Both precision and F-score of this combined model outperforms that of the dependency-based model with feature expansion by a large margin.

Figure 3 illustrates how granularity of the induced sense inventory influences WSD performance. For this experiment, we constructed three inventories, setting the number of most similar words in the ego-network  $n$  to 200, 100 and 50. These settings produced inventories with respectively 1.96, 2.98 and 5.21 average senses per target word. We observe that a higher sense granularity leads to lower F-scores. This can be explained because of (1) the fact that granularity of the TWSI is similar to granularity of the most coarse-grained inventory; (2) the higher the number of senses, the higher the chance to make a wrong sense assignment; (3) due to the reduced size of individual clusters, we get less signal per sense cluster and noise becomes more pronounced.

To summarize, the best precision is reached by a model based on un-expanded dependencies and the best F-score can be obtained by a combination of models based on un-expanded dependency features and language model features.

Model	#Senses	Full TWSI			Sense-Balanced TWSI		
		Prec.	Recall	F-score	Prec.	Recall	F-score
MFS of the TWSI inventory	2.31	0.787	0.787	0.787	0.373	0.373	0.373

Table 2: Effect of the feature expansion: performance on the full (on the left) and the sense-balanced (on the right) TWSI datasets. The models were trained on the Wikipedia corpus using the coarse inventory (1.96 senses per word). The best results overall are underlined.

## 4.2 SemEval 2013 Task 13 Dataset

### 4.2.1 Dataset and Evaluation Metrics

The task of word sense induction for graded and non-graded senses provides 20 nouns, 20 verbs and 10 adjectives in WordNet-sense-tagged contexts. It contains 20-100 contexts per word, and 4,664 contexts in total with 6,73 sense per word in average. Participants were asked to cluster instances into groups corresponding to distinct word senses. Instances with multiple senses were labeled with a score between 0 and 1.

Performance is measured with three measures that require a mapping of inventories (Jaccard Index, Tau, WNDCG) and two cluster comparison measures (Fuzzy NMI, Fuzzy B-Cubed).

### 4.2.2 Discussion of Results

Table 3 presents results of evaluation of the best configuration of our approach trained on the ukWaC corpus. We compare our approach to four SemEval participants and two state-of-the-art systems based on word sense embeddings: *AdaGram* (Bartunov et al., 2016) based on Bayesian stick-breaking process<sup>5</sup> and *SenseGram* (Pelevina et al., 2016) based on clustering of ego-network

generated using word embeddings<sup>6</sup>. The *AI-KU* system (Baskaya et al., 2013) directly clusters test contexts using the  $k$ -means algorithm based on lexical substitution features. The *Unimelb* system (Lau et al., 2013) uses one hierarchical topic model to induce and disambiguate senses of one word. The *UoS* system (Hope and Keller, 2013) induces senses by building an ego-network of a word using dependency relations, which is subsequently clustered using the MaxMax clustering algorithm. The *La Sapienza* system (Jurgens and Klapaftis, 2013), relies on WordNet for the sense inventory and disambiguation.

In contrast to the TWSI evaluation, the most fine-grained model yields the best scores, yet the inventory of the task is also more fine-grained than the one of the TWSI (7.08 vs. 2.31 avg. senses per word). Our method outperforms the knowledge-based system of *La Sapienza* according to two of three metrics metrics and the *SenseGram* system based on sense embeddings according to four of five metrics. Note that *SenseGram* outperforms all other systems according to the Fuzzy B-Cubed metric, which is maximized in the ‘‘All instances, One sense’’ settings. Thus this result may be due to

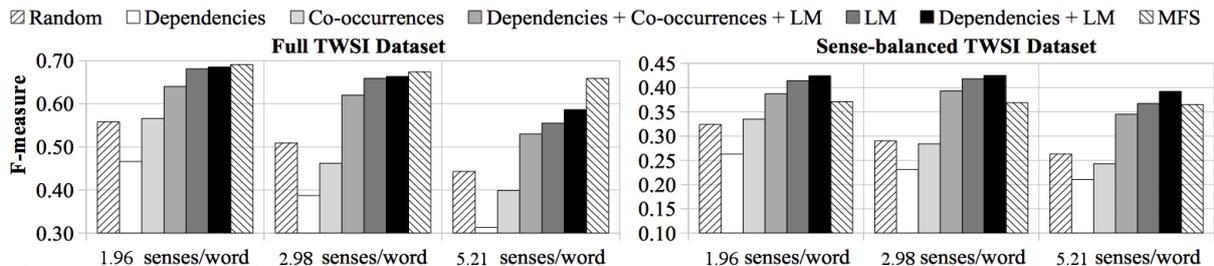

Figure 3: Impact of word sense inventory granularity on WSD performance: the TWSI dataset.

Model	Jacc. Ind.	Tau	WNDCG	Fuzzy NMI	Fuzzy B-Cubed
All Instances, One sense	0.192	0.609	0.288	0.000	0.623
1 sense per instance	0.000	0.953	0.000	0.072	0.000
Most Frequent Sense	0.552	0.560	0.412	–	–
AI-KU	0.197	0.620	<b>0.387</b>	<b>0.065</b>	0.390
AI-KU (remove5-add1000)	0.245	0.642	0.332	0.039	0.451
Unimelb (50k)	0.213	0.620	0.371	0.060	0.483
UoS (top-3)	0.232	0.625	0.374	0.045	0.448
La Sapienza (2)	0.149	0.510	0.383	–	–
AdaGram, $\alpha = 0.05$ , 100 dim. vectors	<b>0.274</b>	<b>0.644</b>	0.318	0.058	0.470
SenseGram, 100 dim., CBOW, weight, sim., $p = 2$	0.197	0.615	0.291	0.011	<b>0.615</b>
Dependencies + LM (1.96 senses/word)	0.239	0.634	0.300	0.041	<b>0.513</b>
Dependencies + LM (2.98 senses/word)	0.242	0.634	0.300	0.041	0.504
Dependencies + LM (5.21 senses/word)	<b>0.253</b>	<b>0.638</b>	<b>0.300</b>	<b>0.041</b>	0.479

Table 3: WSD performance of the best configuration of our method identified on the TWSI dataset as compared to participants of the SemEval 2013 Task 13 and two systems based on word sense embeddings (AdaGram and SenseGram). All models were trained on the ukWaC corpus.

difference in granularities: the average polysemy of the *SenseGram* model is 1.56, while the polysemy of our models range from 1.96 to 5.21.

Besides, our system performs comparably to the top unsupervised systems participated in the competition: It is on par with the top SemEval submissions (*AI-KU* and *UoS*) and the another system based on embeddings (*AdaGram*), in terms of four out of five metrics (Jaccard Index, Tau, Fuzzy B-Cubed, Fuzzy NMI).

Therefore, we conclude that our system yields comparable results to the state-of-the-art unsupervised systems. Note, however, that none of the rivaling systems has a comparable level of interpretability to our approach. This is where our method is unique in the class of unsupervised methods: feature representations and disambiguation procedure of the neural-based *AdaGram* and *SenseGram* systems cannot be straightforwardly interpreted. Besides, inventories of the existing systems are represented as ranked lists of words lacking features that improve readability, such as hypernyms and images.

## 5 Conclusion

In this paper, we have presented a novel method for word sense induction and disambiguation that relies on a meta-combination of dependency features with a language model. The majority of existing unsupervised approaches focus on optimizing the accuracy of the method, sacrificing its interpretability due to the use of opaque models, such as neural networks. In contrast, our approach places a focus on interpretability with the help of sparse readable features. While being interpretable at three levels (sense inventory, sense representations and disambiguation), our method is competitive to the state-of-the-art, including two recent approaches based on sense embeddings, in a word sense induction task. Therefore, it is possible to match the performance of accurate, but opaque methods when interpretability matters.

# Word Sense Disambiguation: A Unified Evaluation Framework and Empirical Comparison

Alessandro Raganato, Jose Camacho-Collados and Roberto Navigli

Department of Computer Science

Sapienza University of Rome

{raganato, collados, navigli}@di.uniroma1.it

## Abstract

Word Sense Disambiguation is a long-standing task in Natural Language Processing, lying at the core of human language understanding. However, the evaluation of automatic systems has been problematic, mainly due to the lack of a reliable evaluation framework. In this paper we develop a unified evaluation framework and analyze the performance of various Word Sense Disambiguation systems in a fair setup. The results show that supervised systems clearly outperform knowledge-based models. Among the supervised systems, a linear classifier trained on conventional local features still proves to be a hard baseline to beat. Nonetheless, recent approaches exploiting neural networks on unlabeled corpora achieve promising results, surpassing this hard baseline in most test sets.

## 1 Introduction

Word Sense Disambiguation (WSD) has been a long-standing task in Natural Language Processing (NLP). It lies at the core of language understanding and has already been studied from many different angles (Navigli, 2009; Navigli, 2012). However, the field seems to be slowing down due to the lack of groundbreaking improvements and the difficulty of integrating current WSD systems into downstream NLP applications (de Laccalle and Agirre, 2015). In general the field does not have a clear path, partially owing to the fact that identifying real improvements over existing approaches becomes a hard task with current evaluation benchmarks. This is mainly due to the lack of a unified framework, which prevents direct and fair comparison among systems. Even

though many evaluation datasets have been constructed for the task (Edmonds and Cotton, 2001; Snyder and Palmer, 2004; Navigli et al., 2007; Pradhan et al., 2007; Agirre et al., 2010a; Navigli et al., 2013; Moro and Navigli, 2015, *inter alia*), they tend to differ in format, construction guidelines and underlying sense inventory. In the case of the datasets annotated using WordNet (Miller, 1995), the *de facto* sense inventory for WSD, we encounter the additional barrier of having text annotated with different versions. These divergences are in the main solved individually by using or constructing automatic mappings. The quality check of such mapping, however, tends to be impractical and this leads to mapping errors which give rise to additional system inconsistencies in the experimental setting. This issue is directly extensible to the training corpora used by supervised systems. In fact, results obtained by supervised or semi-supervised systems reported in the literature are not completely reliable, because the systems may not necessarily have been trained on the same corpus, or the corpus was preprocessed differently, or annotated with a sense inventory different from the test data. Thus, together, the foregoing issues prevent us from drawing reliable conclusions on different models, as in some cases ostensible improvements may have been obtained as a consequence of the nature of the training corpus, the preprocessing pipeline or the version of the underlying sense inventory, rather than of the model itself. Moreover, because of these divergences, current systems tend to report results on a few datasets only, making it hard to perform a direct quantitative confrontation.

This paper offers two main contributions. First, we provide a complete evaluation framework for all-words Word Sense Disambiguation overcoming all the aforementioned limitations by (1) standardizing the WSD datasets and training corpora

into a unified format, (2) semi-automatically converting annotations from any dataset to WordNet 3.0, and (3) preprocessing the datasets by consistently using the same pipeline. Second, we use this evaluation framework to perform a fair quantitative and qualitative empirical comparison of the main techniques proposed in the WSD literature, including the latest advances based on neural networks.

## 2 State of the Art

The task of Word Sense Disambiguation consists of associating words in context with the most suitable entry in a pre-defined sense inventory. Depending on their nature, WSD systems are divided into two main groups: supervised and knowledge-based. In what follows we summarize the current state of these two types of approach.

### 2.1 Supervised WSD

Supervised models train different features extracted from manually sense-annotated corpora. These features have been mostly based on the information provided by the surroundings words of the target word (Keok and Ng, 2002; Navigli, 2009) and its collocations. Recently, more complex features based on word embeddings trained on unlabeled corpora have also been explored (Taghipour and Ng, 2015b; Rothe and Schütze, 2015; Iacobacci et al., 2016). These features are generally taken as input to train a linear classifier (Zhong and Ng, 2010; Shen et al., 2013). In addition to these conventional approaches, the latest developments in neural language models have motivated some researchers to include them in their WSD architectures (Kågebäck and Salomonsson, 2016; Melamud et al., 2016; Yuan et al., 2016).

Supervised models have traditionally been able to outperform knowledge-based systems (Navigli, 2009). However, obtaining sense-annotated corpora is highly expensive, and in many cases such corpora are not available for specific domains. This is the reason why some of these supervised methods have started to rely on unlabeled corpora as well. These approaches, which are often classified as *semi-supervised*, are targeted at overcoming the knowledge acquisition bottleneck of conventional supervised models (Pilehvar and Navigli, 2014). In fact, there is a line of research specifically aimed at automatically obtaining large amounts of high-quality sense-annotated corpora

(Taghipour and Ng, 2015a; Raganato et al., 2016; Camacho-Collados et al., 2016a).

In this work we compare supervised systems and study the role of their underlying sense-annotated training corpus. Since semi-supervised models have been shown to outperform fully supervised systems in some settings (Taghipour and Ng, 2015b; Başkaya and Jurgens, 2016; Iacobacci et al., 2016; Yuan et al., 2016), we evaluate and compare models using both manually-curated and automatically-constructed sense-annotated corpora for training.

### 2.2 Knowledge-based WSD

In contrast to supervised systems, knowledge-based WSD techniques do not require any sense-annotated corpus. Instead, these approaches rely on the structure or content of manually-curated knowledge resources for disambiguation. One of the first approaches of this kind was Lesk (1986), which in its original version consisted of calculating the overlap between the context of the target word and its definitions as given by the sense inventory. Based on the same principle, various works have adapted the original algorithm by also taking into account definitions from related words (Banerjee and Pedersen, 2003), or by calculating the distributional similarity between definitions and the context of the target word (Basile et al., 2014; Chen et al., 2014). Distributional similarity has also been exploited in different settings in various works (Miller et al., 2012; Camacho-Collados et al., 2015; Camacho-Collados et al., 2016b). In addition to these approaches based on distributional similarity, an important branch of knowledge-based systems found their techniques on the structural properties of semantic graphs from lexical resources (Agirre and Soroa, 2009; Guo and Diab, 2010; Ponzetto and Navigli, 2010; Agirre et al., 2014; Moro et al., 2014; Weissenborn et al., 2015; Tripodi and Pelillo, 2016). Generally, these graph-based WSD systems first create a graph representation of the input text and then exploit different graph-based algorithms over the given representation (e.g., PageRank) to perform WSD.

## 3 Standardization of WSD datasets

In this section we explain our pipeline for transforming any given evaluation dataset or sense-annotated corpus into a preprocessed unified for-

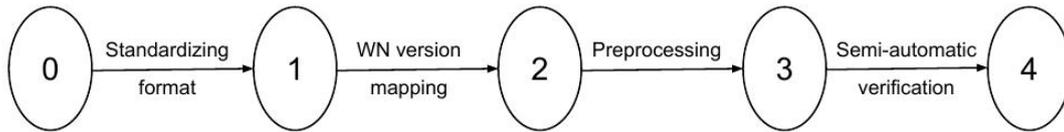

Figure 1: Pipeline for standardizing any given WSD dataset.

mat. In our pipeline we do not make any distinction between evaluation datasets and sense-annotated training corpora, as the pipeline can be applied equally to both types. For simplicity we will refer to both evaluation datasets and training corpora as WSD datasets.

Figure 1 summarizes our pipeline to standardize a WSD dataset. The process consists of four steps:

1. Most WSD datasets in the literature use a similar XML format, but they have some divergences on how to encode the information. For instance, the SemEval-15 dataset (Moro and Navigli, 2015) was developed for both WSD and Entity Linking and its format was especially designed for this latter task. Therefore, we decided to convert all datasets to a unified format. As unified format we use the XML scheme used for the SemEval-13 all-words WSD task (Navigli et al., 2013), where preprocessing information of a given corpus is also encoded.
2. Once the dataset is converted to a unified format, we map the sense annotations from its original WordNet version to 3.0, which is the latest version of WordNet used in evaluation datasets. This mapping is carried out semi-automatically. First, we use automatically-constructed WordNet mappings<sup>1</sup> (Daude et al., 2003). These mappings provide confidence values which we use to initially map senses whose mapping confidence is 100%. Then, the annotations of the remaining senses are manually checked, and re-annotated or removed whenever necessary<sup>2</sup>. Additionally, in this step we decided to remove all annotations of auxiliary verbs, following the annotation guidelines of the latest WSD datasets.
3. The third step consists of preprocessing the given dataset. We used the Stanford

<sup>1</sup><http://nlp.lsi.upc.edu/tools/download-map.php>

<sup>2</sup>This manual correction involved less than 10% of all instances for the datasets for which this step was performed.

CoreNLP toolkit (Manning et al., 2014) for Part-of-Speech (PoS) tagging<sup>3</sup> and lemmatization. This step is performed in order to ensure that all systems use the same preprocessed data.

4. Finally, we developed a script to check that the final dataset conforms to the aforementioned guidelines. In this final verification we also ensured that the sense annotations match the lemma and the PoS tag provided by Stanford CoreNLP by automatically fixing all divergences.

## 4 Data

In this section we summarize the WSD datasets used in the evaluation framework. To all these datasets we apply the standardization pipeline described in Section 3. First, we enumerate all the datasets used for the evaluation (Section 4.1). Second, we describe the sense-annotated corpora used for training (Section 4.2). Finally, we show some relevant statistics extracted from these resources (Section 4.3).

### 4.1 WSD evaluation datasets

For our evaluation framework we considered five standard all-words fine-grained WSD datasets from the Senseval and SemEval competitions:

- **Senseval-2** (Edmonds and Cotton, 2001). This dataset was originally annotated with WordNet 1.7. After standardization, it consists of 2282 sense annotations, including nouns, verbs, adverbs and adjectives.
- **Senseval-3 task 1** (Snyder and Palmer, 2004). The WordNet version of this dataset was 1.7.1. It consists of three documents from three different domains (editorial, news story and fiction), totaling 1850 sense annotations.

<sup>3</sup>In order to have a standard format which may be used by languages other than English, we provide coarse-grained PoS tags as given by the universal PoS tagset (Petrov et al., 2011).

	#Docs	#Sents	#Tokens	#Annotations	#Sense types	#Word types	Ambiguity
<b>Senseval-2</b>	3	242	5,766	2,282	1,335	1,093	5.4
<b>Senseval-3</b>	3	352	5,541	1,850	1,167	977	6.8
<b>SemEval-07</b>	3	135	3,201	455	375	330	8.5
<b>SemEval-13</b>	13	306	8,391	1,644	827	751	4.9
<b>SemEval-15</b>	4	138	2,604	1,022	659	512	5.5
<b>SemCor</b>	352	37,176	802,443	226,036	33,362	22,436	6.8
<b>OMSTI</b>	-	813,798	30,441,386	911,134	3,730	1,149	8.9

Table 1: Statistics of the WSD datasets used in the evaluation framework (after standardization).

- **SemEval-07 task 17** (Pradhan et al., 2007). This is the smallest among the five datasets, containing 455 sense annotations for nouns and verbs only. It was originally annotated using WordNet 2.1 sense inventory.
- **SemEval-13 task 12** (Navigli et al., 2013). This dataset includes thirteen documents from various domains. In this case the original sense inventory was WordNet 3.0, which is the same as the one that we use for all datasets. The number of sense annotations is 1644, although only nouns are considered.
- **SemEval-15 task 13** (Moro and Navigli, 2015). This is the most recent WSD dataset available to date, annotated with WordNet 3.0. It consists of 1022 sense annotations in four documents coming from three heterogeneous domains: biomedical, mathematics/computing and social issues.
- **OMSTI** (Taghipour and Ng, 2015a). OMSTI (*One Million Sense-Tagged Instances*) is a large corpus annotated with senses from the WordNet 3.0 inventory. It was automatically constructed by using an alignment-based WSD approach (Chan and Ng, 2005) on a large English-Chinese parallel corpus (Eisele and Chen, 2010, MultiUN corpus). OMSTI<sup>5</sup> has already shown its potential as a training corpus by improving the performance of supervised systems which add it to existing training data (Taghipour and Ng, 2015a; Iacobacci et al., 2016).

## 4.2 Sense-annotated training corpora

We now describe the two WordNet sense-annotated corpora used for training the supervised systems in our evaluation framework:

- **SemCor** (Miller et al., 1994). SemCor<sup>4</sup> is a manually sense-annotated corpus divided into 352 documents for a total of 226,040 sense annotations. It was originally tagged with senses from the WordNet 1.4 sense inventory. SemCor is, to our knowledge, the largest corpus manually annotated with WordNet senses, and is the main corpus used in the literature to train supervised WSD systems (Agirre et al., 2010b; Zhong and Ng, 2010).

<sup>4</sup>We downloaded the SemCor 3.0 version at [web.eecs.umich.edu/~mihalcea/downloads.html](http://web.eecs.umich.edu/~mihalcea/downloads.html)

## 4.3 Statistics

Table 1 shows some statistics<sup>6</sup> of the WSD datasets and training corpora which we use in the evaluation framework. The number of sense annotations varies across datasets, ranging from 455 annotations in the SemEval-07 dataset, to 2,282 annotations in the Senseval-2 dataset. As regards sense-annotated corpora, OMSTI is made up of almost 1M sense annotations, a considerable increase over the number of sense annotations of SemCor. However, SemCor is much more balanced in terms of unique senses covered (3,730 covered by OMSTI in contrast to over 33K covered by SemCor). Additionally, while OMSTI was constructed automatically, SemCor was manually built and, hence, its quality is expected to be higher.

Finally, we calculated the ambiguity level of each dataset, computed as the total number of can-

<sup>5</sup>In this paper we refer to the portion of sense-annotated data from the MultiUN corpus as OMSTI. Note that OMSTI was released along with SemCor.

<sup>6</sup>Statistics included in Table 1: number of documents (#Docs), sentences (#Sents), tokens (#Tokens), sense annotations (#Annotations), sense types covered (#Sense types), annotated lemma types covered (#Word types), and ambiguity level (Ambiguity). There was no document information in the OMSTI data released by Taghipour and Ng (2015a).

didate senses (i.e., senses sharing the surface form of the target word) divided by the number of sense annotations. The highest ambiguity is found on OMSTI, which, despite being constructed automatically, contains a high coverage of ambiguous words. As far as the evaluation competition datasets are concerned, the ambiguity may give a hint as to how difficult a given dataset may be. In this case, SemEval-07 displays the highest ambiguity level among all evaluation datasets.

## 5 Evaluation

The evaluation framework consists of the WSD evaluation datasets described in Section 4.1. In this section we use this framework to perform an empirical comparison among a set of heterogeneous WSD systems. The systems used in the evaluation are described in detail in Section 5.1, the results are shown in Section 5.2 and a detailed analysis is presented in Section 5.3.

### 5.1 Comparison systems

We include three supervised (Section 5.1.1) and three knowledge-based (Section 5.1.2) all-words WSD systems in our empirical comparison.

#### 5.1.1 Supervised

To ensure a fair comparison, all supervised systems use the same corpus for training: SemCor and Semcor+OMSTI<sup>7</sup> (see Section 4.2). In the following we describe the three supervised WSD systems used in the evaluation:

- **IMS** (Zhong and Ng, 2010) uses a Support Vector Machine (SVM) classifier over a set of conventional WSD features. IMS<sup>8</sup> is built on a flexible framework which allows an easy integration of different features. The default implementation includes surrounding words, PoS tags of surroundings words, and local collocations as features.
- **IMS+embeddings** (Taghipour and Ng, 2015b; Rothe and Schütze, 2015; Iacobacci et al., 2016). These approaches have shown the potential of using word embeddings on the WSD task. Iacobacci et al. (2016) carried

out a comparison of different strategies for integrating word embeddings as a feature in WSD. In this paper we consider the two best configurations in Iacobacci et al. (2016)<sup>9</sup>: using all IMS default features including and excluding surrounding words (IMS+emb and IMS<sub>s</sub>+emb, respectively). In both cases word embeddings are integrated using exponential decay (i.e., word weights drop exponentially as the distance towards the target word increases). Likewise, we use Iacobacci et al.’s suggested learning strategy and hyperparameters to train the word embeddings: Skip-gram model of Word2Vec<sup>10</sup> (Mikolov et al., 2013) with 400 dimensions, ten negative samples and a window size of ten words. As unlabeled corpus to train the word embeddings we use the English ukWaC corpus<sup>11</sup> (Baroni et al., 2009), which is made up of two billion words from paragraphs extracted from the web.

- **Context2Vec** (Melamud et al., 2016). Neural language models have recently shown their potential for the WSD task (Kågebäck and Salomonsson, 2016; Yuan et al., 2016). In this experiment we replicated the approach of Melamud et al. (2016, Context2Vec), for which the code<sup>12</sup> is publicly available. This approach is divided in three steps. First, a bidirectional LSTM recurrent neural network is trained on an unlabeled corpus (we considered the same ukWaC corpus used by the previous comparison system). Then, a context vector is learned for each sense annotation in the training corpus. Finally, the sense annotation whose context vector is closer to the target word’s context vector is selected as the intended sense.

Finally, as baseline we included the Most Frequent Sense (**MFS**) heuristic, which for each target word selects the sense occurring the highest number of times in the training corpus.

<sup>7</sup>As already noted by Taghipour and Ng (2015a), supervised systems trained on only OMSTI obtain lower results than when trained along with SemCor, mainly due to OMSTI’s lack of coverage in target word types.

<sup>8</sup>We used the original implementation available at <http://www.comp.nus.edu.sg/~nlp/software.html>

<sup>9</sup>We used the implementation available at [https://github.com/iacobac/ims\\_wsd\\_emb](https://github.com/iacobac/ims_wsd_emb)

<sup>11</sup><http://wacky.sslmit.unibo.it/doku.php?id=corpora>

<sup>12</sup><https://github.com/orenmel/context2vec>

### 5.1.2 Knowledge-based

In this section we describe the three knowledge-based WSD models used in our empirical comparison:

- **Lesk** (Lesk, 1986) is a simple knowledge-based WSD algorithm that bases its calculations on the overlap between the definitions of a given sense and the context of the target word. For our experiments we replicated the extended version of the original algorithm in which definitions of related senses are also considered and the conventional term frequency-inverse document frequency (Jones, 1972, *tf-idf*) is used for word weighting (Banerjee and Pedersen, 2003, Lesk<sub>ext</sub>). Additionally, we included the enhanced version of Lesk in which word embeddings<sup>13</sup> are leveraged to compute the similarity between definitions and the target context (Basile et al., 2014, Lesk<sub>ext+emb</sub>)<sup>14</sup>.
- **UKB** (Agirre and Soroa, 2009; Agirre et al., 2014) is a graph-based WSD system which makes use of random walks over a semantic network (WordNet graph in this case). UKB<sup>15</sup> applies the Personalized Page Rank algorithm (Haveliwala, 2002) initialized using the context of the target word. Unlike most WSD systems, UKB does not back-off to the WordNet first sense heuristic and it is self-contained (i.e., it does not make use of any external resources/corpora). We used both default configurations from UKB: using the full WordNet graph (UKB) and the full graph including disambiguated glosses as connections as well (UKB<sub>gloss</sub>).
- **Babelfy** (Moro et al., 2014) is a graph-based disambiguation approach which exploits random walks to determine connections between synsets. Specifically, Babelfy<sup>16</sup> uses random walks with restart (Tong et al., 2006) over BabelNet (Navigli and Ponzetto, 2012), a large semantic network integrating WordNet among other resources such as Wikipedia

<sup>13</sup>We used the same word embeddings described in Section 5.1.1 for IMS+emb.

<sup>14</sup>We used the implementation from <https://github.com/pippokill/lesk-wsd-dsm>. In this implementation additional definitions from BabelNet are considered.

<sup>15</sup>We used the last implementation available at <http://ixa2.si.ehu.es/ukb/>

<sup>16</sup>We used the Java API from <http://babelfy.org>

or Wiktionary. Its algorithm is based on a densest subgraph heuristic for selecting high-coherence semantic interpretations of the input text. The best configuration of Babelfy takes into account not only the target sentence in which the target word occurs, but also the whole document.

As knowledge-based baseline we included the **WordNet first sense**. This baseline simply selects the candidate which is considered as first sense in WordNet 3.0. Even though the sense order was decided on the basis of semantically-tagged text, we considered it as knowledge-based in this experiment as this information is already available in WordNet. In fact, knowledge-based systems like Babelfy include this information in their pipeline. Despite its simplicity, this baseline has been shown to be hard to beat by automatic WSD systems (Navigli, 2009; Agirre et al., 2014).

## 5.2 Results

Table 2 shows the F-Measure performance of all comparison systems on the five all-words WSD datasets. Since not all test word instances are covered by the corresponding training corpora, supervised systems have a maximum F-Score (*ceiling* in the Table) they can achieve. Nevertheless, supervised systems consistently outperform knowledge-based systems across datasets, confirming the results of Pilehvar and Navigli (2014). A simple linear classifier over conventional WSD features (i.e., IMS) proves to be robust across datasets, consistently outperforming the MFS baseline. The recent integration of word embeddings as an additional feature is beneficial, especially as a replacement of the feature based on the surface form of surrounding words (i.e., IMS<sub>s+emb</sub>). Moreover, recent advances on neural language models (in the case of Context2Vec a bi-directional LSTM) appear to be highly promising for the WSD task according to the results, as Context2Vec outperforms IMS in most datasets.

On the other hand, it is also interesting to note the performance inconsistencies of systems across datasets, as in all cases there is a large performance gap between the best and the worst performing dataset. As explained in Section 4.3, the ambiguity level may give a hint as to how difficult the corresponding dataset may be. In fact, WSD systems obtain relatively low results in SemEval-07, which is the most ambiguous dataset (see Table 1).

	Tr. Corpus	System	Senseval-2	Senseval-3	SemEval-07	SemEval-13	SemEval-15
Supervised	SemCor	IMS	70.9	69.3	61.3	65.3	69.5
		IMS+emb	71.0	69.3	60.9	<b>67.3</b>	71.3

		UKB <sub>gloss</sub>	60.6	54.1	42.0	59.0	61.2
		Babelfy	<b>67.0</b>	63.5	51.6	<b>66.4</b>	<b>70.3</b>
		WN 1 <sup>st</sup> sense	66.8	<b>66.2</b>	55.2	63.0	67.8

Table 2: F-Measure percentage of different models in five all-words WSD datasets.

	Nouns	Verbs	Adj.	Adv.	All
#Instances	4,300	1,652	955	346	7,253
Ambiguity	4.8	10.4	3.8	3.1	5.8

Table 3: Number of instances and ambiguity level of the concatenation of all five WSD datasets.

However, this is the dataset in which supervised systems achieve a larger margin with respect to the MFS baseline, which suggests that, in general, the MFS heuristic does not perform accurately on highly ambiguous words.

### 5.3 Analysis

To complement the results from the previous section, we additionally carried out a detailed analysis about the global performance of each system and divided by PoS tag. To this end, we concatenated all five datasets into a single dataset. This resulted in a large evaluation dataset of 7,253 instances to disambiguate (see Table 3). Table 4 shows the F-Measure performance of all comparison systems on the concatenation of all five WSD evaluation datasets, divided by PoS tag. IMS<sub>s</sub>+emb trained on SemCor+OMSTI achieves the best overall results, slightly above Context2Vec trained on the same corpus. In what follows we describe some of the main findings extracted from our analysis.

**Training corpus.** In general, the results of supervised systems trained on SemCor only (manually-annotated) are lower than training

simultaneously on both SemCor and OMSTI (automatically-annotated). This is a promising finding, which confirms the results of previous works (Raganato et al., 2016; Iacobacci et al., 2016; Yuan et al., 2016) and encourages further research on developing reliable automatic or semi-automatic methods to obtain large amounts of sense-annotated corpora in order to overcome the knowledge-acquisition bottleneck. For instance, Context2Vec improves 0.4 points overall when adding the automatically sense-annotated OMSTI as part of the training corpus, suggesting that more data, even if not perfectly clean, may be beneficial for neural language models.

**Knowledge-based vs. Supervised.** One of the main conclusions that can be taken from the evaluation is that supervised systems clearly outperform knowledge-based models. This may be due to the fact that in many cases the main disambiguation clue is given by the immediate local context. This is particularly problematic for knowledge-based systems, as they take equally into account all the words within a sentence (or document in the case of Babelfy). For instance, in the following sentence, both UKB and Babelfy fail to predict the correct sense of *state*:

*In sum, at both the federal and state government levels at least part of the seemingly irrational behavior voters display in the voting booth may have an exceedingly rational explanation.*

	Tr. Corpus	System	Nouns	Verbs	Adjectives	Adverbs	All
Supervised	SemCor	IMS	70.4	56.1	75.6	82.9	68.4
		IMS+emb	71.8	55.4	<b>76.1</b>	82.7	69.1
		IMS <sub>s</sub> +emb	<b>71.9</b>	56.9	75.9	<b>84.7</b>	<b>69.6</b>
		Context2Vec	71.0	<b>57.6</b>	75.2	82.7	69.0
		MFS	67.6	49.6	73.1	80.5	64.8
		<i>Ceiling</i>	<i>89.6</i>	<i>95.1</i>	<i>91.5</i>	<i>96.4</i>	<i>91.5</i>
	SemCor + OMSTI	IMS	70.5	<b>56.9</b>	76.8	82.9	68.8
		IMS+emb	71.0	53.3	77.1	82.7	68.3
		IMS <sub>s</sub> +emb	<b>72.0</b>	56.5	76.6	<b>84.7</b>	<b>69.7</b>
		Context2Vec	71.7	55.8	<b>77.2</b>	82.7	69.4
		MFS	65.8	45.9	72.7	80.5	62.9
		<i>Ceiling</i>	<i>90.4</i>	<i>95.8</i>	<i>91.8</i>	<i>96.4</i>	<i>92.1</i>
Knowledge	-	Lesk <sub>ext</sub>	54.1	27.9	54.6	60.3	48.7
		Lesk <sub>ext</sub> +emb	<b>69.8</b>	<b>51.2</b>	51.7	80.6	63.7
		UKB	56.7	39.3	63.9	44.0	53.2
		UKB <sub>gloss</sub>	62.1	38.3	66.8	66.2	57.5
		Babelify	68.6	49.9	73.2	79.8	<b>65.5</b>
		WN 1 <sup>st</sup> sense	67.6	50.3	<b>74.3</b>	<b>80.9</b>	65.2

Table 4: F-Measure percentage of different models on the concatenation of all five WSD datasets.

In this sentence, *state* is annotated with its *administrative districts of a nation* sense in the gold standard. The main disambiguation clue seems to be given by its previous and immediate subsequent words (*federal* and *government*), which tend to co-occur with this particular sense. However, knowledge-based WSD systems like UKB or Babelify give the same weight to all words in context, underrating the importance of this local disambiguation clue in the example. For instance, UKB disambiguates *state* with the sense defined as *the way something is with respect to its main attributes*, probably biased by words which are not immediately next to the target word within the sentence, e.g., *irrational*, *behaviour*, *rational* or *explanation*.

**Low overall performance on verbs.** As can be seen from Table 4, the F-Measure performance of all systems on verbs is in all cases below 58%. This can be explained by the high granularity of verbs in WordNet. For instance, the verb *keep* consists of 22 different meanings in WordNet 3.0, six of them denoting “possession and transfer of possession”<sup>17</sup>. In fact, the average ambiguity level of all verbs in this evaluation framework is 10.4 (see

<sup>17</sup><https://wordnet.princeton.edu/man/lexnames.5WN.html>

Table 3), considerably greater than the ambiguity on other PoS tags, e.g., 4.8 in nouns. Nonetheless, supervised systems manage to comfortably outperform the MFS baseline, which does not seem to be reliable for verbs given their high ambiguity.

**Influence of preprocessing.** As mentioned in Section 3, our evaluation framework provides a preprocessing of the corpora with Stanford CoreNLP. This ensures a fair comparison among all systems but may introduce some annotation inaccuracies, such as erroneous PoS tags. However, for English these errors are minimal<sup>18</sup>. For instance, the global error rate of the Stanford PoS tagger in all disambiguation instances is 3.9%, which were fixed as explained in Section 3.

**Bias towards the Most Frequent Sense.** After carrying out an analysis on the influence of MFS in WSD systems<sup>19</sup>, we found that all supervised systems suffer a strong bias towards the MFS, with all IMS-based systems disambiguating over 75% of instances with their MFS. Context2Vec is slightly less affected by this bias, with 71.5% (SemCor) and 74.7% (SemCor+OMSTI) of answers corre-

<sup>18</sup>Even if preprocessing plays a minimal role for English, it may be of higher importance for other languages, e.g., morphologically richer languages (Eger et al., 2016).

<sup>19</sup>See Postma et al. (2016) for an interesting discussion on the bias of current WSD systems towards the MFS.

sponding to the MFS. Interestingly, this MFS bias is also present in graph knowledge-based systems. In fact, Calvo and Gelbukh (2015) had already shown how the MFS correlates strongly with the number of connections in WordNet.

**Knowledge-based systems.** For knowledge-based systems the WN first sense baseline proves still to be extremely hard to beat. The only knowledge-based system that overall manages to beat this baseline is Babelfy, which, in fact, uses information about the first sense in its pipeline. Babelfy’s default pipeline includes a confidence threshold in order to decide whether to disambiguate or back-off to the first sense. In total, Babelfy backs-off to WN first sense in 63% of all instances. Nonetheless, it is interesting to note the high performance of Babelfy and Lesk<sub>ext</sub>+emb on noun instances (outperforming the first sense baseline by 1.0 and 2.2 points, respectively) in contrast to their relatively lower performance on verbs, adjectives<sup>20</sup> and adverbs. We believe that this is due to the nature of the lexical resource used by these two systems, i.e., BabelNet. BabelNet includes Wikipedia as one of its main sources of information. However, while Wikipedia provides a large amount of semantic connections and definitions for nouns, this is not the case for verbs, adjectives and adverbs, as they are not included in Wikipedia and their source of information mostly comes from WordNet only.

## 6 Conclusion and Future Work

In this paper we presented a unified evaluation framework for all-words WSD. This framework is based on evaluation datasets taken from Senseval and SemEval competitions, as well as manually and automatically sense-annotated corpora. In this evaluation framework all datasets share a common format, sense inventory (i.e., WordNet 3.0) and preprocessing pipeline, which eases the task of researchers to evaluate their models and, more importantly, ensures a fair comparison among all systems. The whole evaluation framework<sup>21</sup>, including guidelines for researchers to include their own sense-annotated datasets and a script to validate their conformity to the guidelines, is available at <http://lcl.uniroma1.it/wsdeval>.

<sup>20</sup>The poor performance of Lesk<sub>ext</sub>+emb on adjective instances is particularly noticeable.

<sup>21</sup>We have additionally set up a CodaLab competition based on this evaluation framework.

We used this framework to perform an empirical comparison among a set of heterogeneous WSD systems, including both knowledge-based and supervised ones. Supervised systems based on neural networks achieve the most promising results. Given our analysis, we foresee two potential research avenues focused on semi-supervised learning: (1) exploiting large amounts of unlabeled corpora for learning word embeddings or training neural language models, and (2) automatically constructing high-quality sense-annotated corpora to be used by supervised WSD systems. As far as knowledge-based systems are concerned, enriching knowledge resources with semantic connections for non-nominal mentions may be an important step towards improving their performance.

For future work we plan to further extend our unified framework to languages other than English, including SemEval multilingual WSD datasets, as well as to other sense inventories such as Open Multilingual WordNet, BabelNet and Wikipedia, which are available in different languages.

## Abstract

As one of the most important test of China, Gaokao is designed to be difficult enough to distinguish the excellent high school students. In this work, we detailed the Gaokao History Multiple Choice Questions(GKHMC) and proposed two different approaches to address them using various resources. One approach is based on entity search technique (IR approach), the other is based on text entailment approach where we specifically employ deep neural networks(NN approach). The result of experiment on our collected real Gaokao questions showed that they are good at different categories of questions, i.e. IR approach performs much better at entity questions(EQs) while NN approach shows its advantage on sentence questions(SQs). Our new method achieves state-of-the-art performance and show that it's indispensable to apply hybrid method when participating in the real-world tests.

## 1 Introduction

Gaokao, namely the National College Entrance Examination, is the most important examination for Chinese senior high school students. Every college in China, no matter it is Top10 or Top100, would only accept the exam-takers whose Gaokao score is higher than its threshold score. As there are almost 10 million students take the examination every year, Gaokao needs to be difficult enough to distinguish the excellent students. Therefore, it includes various types of questions such as multiple-choice questions, short-answer

<sup>†</sup> Both of the two authors contributed equally to this paper.

questions and essays and it covers several different subjects, like Chinese, Math, History and etc. In this work, we focus on Gaokao History Multiple Choice questions which is denoted as GKHMC. Both of the factoid question answering task and reading comprehension task are similar to GKHMC. But, the GKHMC questions have their own characteristics.

A multiple-choice question in GKHMC such as the examples shown in Figure 1 is composed of a question stem and four candidates. Our goal is to figure out the only one correct candidate. But, there are certain obstacles to achieve it. First, several background sentences and a lead-in sentence conjointly constitutes the question stem, which makes these questions more complicated than former one-sentence-long factoid questions that can be handled by the existing approaches, like (Kolomiyet and Moens, 2011; Kwiatkowski et al., 2013; Berant and Liang, 2014; Yih et al., 2015). Secondly, the background sentences generally contain various clues to figure out the historical events or personages which may be the perdue key to answer the question. These clues may include Tang poem and Song iambic verse, domain-specific expressions, even some mixture of mod-

Question Type	Candidate Type	Count
EQ	Entities	160
SQ	Sentence	584
ALL	Whatever	744

Table 1: The GKHMC dataset.

ern Chinese and excerpt from ancient books and etc. The dependence of background knowledge makes the models that are designed for reading comprehension such as (Peñas et al., 2013; Richardson et al., 2013) fail. Thirdly, the diversity of candidates’ granularity, i.e. candidates can either be entities or sentences, makes it harder to match the candidate and stem. So, the answer selection is disparate from the former approaches whose candidates are usually just entities. Lastly, as the candidates are already given, the answer generation step in former neural network approaches based question answering system is no longer necessary.

As mentioned above and shown in Figure 1, in accordance with candidates’ granularity, the GKHMC questions can be divided into two types: entity questions(EQs) and sentence questions(SQs). Entity questions are those whose candidates are all entities, no matter they are people, dynasties, warfares or something else. And, sentence questions are those whose candidates are all sentences. We observe that such two types of questions have their own specific characteristics. Most of background sentences in EQs are description of the right candidate, so it may be particularly suitable to apply information retrieval like approach to handle them. Meanwhile, as the background sentences and lead-in sentences in SQs are more like the entailing text, these questions aren’t appropriate to be addressed by lexically searching and matching. Therefore, it seems that it’s more reasonable to resolve SQs by using textual reasoning techniques.

In this paper, we wonder about which kind of approach is more effective for GKHMC. Furthermore, whether we should select specific method to work out different types of questions. In terms of various characteristics of GKHMC questions, we introduce two independent approaches to address them. One is based on entity search technique (IR approach) and the other is based on a text entailment approach where we specifically employ deep neural networks (NN approach). In IR approach, we use the key entities and relationships extracted

from questions to form a query, then inquire this query in all the text resources to get the most relevant candidate. In NN approach, we take the question text and every candidate to form four statements respectively, then judge how possible every statement is right so that we can figure out which is most likely to be the correct answer.

To test the two approaches’ performance, we collected and classified the multiple-choice questions in Gaokao test papers from 2011 to 2015 all over the country, and they are released. From the result, we find that the performance of two approaches are significantly discrepant at each kind of questions. That is, IR approach shows noticeable advantages on EQs, while NN approach performs much better on SQs. This will be further discussed in Section 4.4.

In this paper, our contributions are as follows:

- We gave a detailed description of the Gaokao History Multiple Choice Questions task and showed its importance and difficulty.
- We released a dataset<sup>1</sup> for this task. The dataset is manually collected and classified. All questions in the dataset are real Gaokao questions from 2011 to 2015.
- We introduced two different approaches for this task. Each approach achieved a promising results. We also compared this two approaches and found that they are complementary, i.e. they are good at different types of questions.
- We introduced permanent provisional memory network(PPMN) to model the joint background knowledge and sentences in question stem, and it beats existing memory networks on SQs.

## 2 Dataset

As described in the Introduction, we collected the historical multiple-choice questions from Gaokao all over the country in recent five years. However, quite a lot contain graphs or tables which require the techniques beyond natural language processing(NLP). So, we filter out this part of questions and manually classified the left into two parts: EQs and SQs. The number of different kinds of questions are listed in Table 1. The examples of

<sup>1</sup> <https://github.com/IACASNLPIR/GKHMC/tree/master/data>

different types of questions translated into English are shown in Figure 1.

It is worth mentioning that there is a special type of questions on test papers named sequential questions. The candidates of this kind of questions are just some ordered numbers. Every number stands for a certain content which is given in question stem. We simply replace every sequential number in candidates with their corresponding contents. Then, we can classify these questions as EQs or SQs according to the type of contents.

We also collected a wide diversity of resources including Baidu Encyclopedia, textbooks and practice questions as our external knowledge when inquiring the generated query. Baidu Encyclopedia which is also known as Baidu Baike, is something like Wikipedia, but the content of it is written in Chinese. We denote this resource as BAIKE. The textbooks resource contains three compulsory history textbooks published by People’s Education Press. We denote them as BOOK. And we gathered about 50,000 practice questions and their answers, and this is denoted as TIKU.

### 3 Approaches<sup>2</sup>

#### 3.1 IR Approach

The GKHMC questions require figuring out the most relevant candidate to the question stem from the four given candidates. Our IR approach is inspired by this observation. The diagram of IR approach is illustrated in Figure 2.

The pipeline of IR approach is: (1) use the classifier to automatically classify the question and select the weights according to the classification result; (2) calculate the relevance scores for every candidate (we introduce three different methods with seven score functions to calculate the relevance scores) and combine them together with specific weights; (3) choose the candidate with highest score as right answer. Despite the simplicity of it, IR approach achieves a promising result in experiment.

##### 3.1.1 Naive Bayes Classifier

We build a naive bayes classifier to classify questions. Using length of candidates, entity number of candidates and verb number of candidates as features, every question is classified as EQ or SQ. When building the classifier, we do 10-folder cross

<sup>2</sup> The codes of this project can be obtained at <https://github.com/IACASNLPIR/GKHMC>

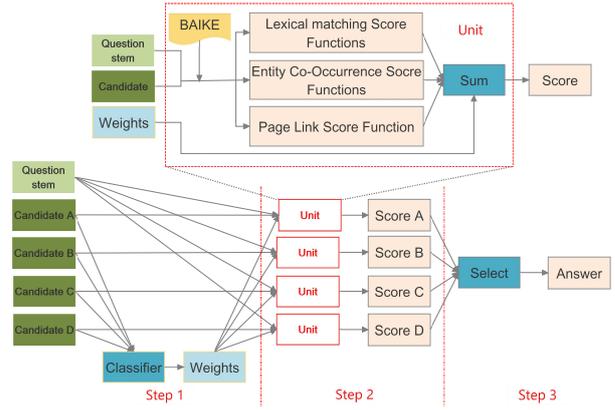

Figure 2: Pipeline of IR approach.

validation on the GKHMC dataset and the results are 90.00% precision and 84.38% recall in EQs and 95.79% precision and 97.43% recalls in SQs.

##### 3.1.2 Score Functions

To calculate the relevance between question stem and candidates, we introduce three different methods with seven score functions, which are summarized in Table 2.

**Lexical Matching Score:** Since the correct candidate usually directly related to question stem, it’s reasonable to assume that the facts in question stem may appear in documents related to them, together with the correct candidate. Here we introduce our lexical matching score functions, taking BAIKE as our external resource. The four queries are formed by each candidate and question stem separately. Then we retrieval every query and sum up the scores of the top three returned documents as the lexical matching score. We use  $score_{top_i}$  to denote the score of the top  $i$ -th returned documents.  $score_{top_i}$  is calculated by Lucene’s TFIDFSimilarity function<sup>3</sup>. The lexical matching score  $Score_{lexical}(candidate_k)$  is calculated as

$$Score_{lexical}(candidate_k) = \sum_{i=1}^3 (score_{top_i}). \quad (1)$$

We build indices for BAIKE with different grains. The index built for every BAIKE document is denoted as BAIKE Document Index(BDI). The index built for every paragraph in BAIKE is denoted as BAIKE Paragraph Index(BPI). And, the index built for every sentence in BAIKE is called BAIKE Sentence Index(BSI).

<sup>3</sup> <https://lucene.apache.org/core/>

We denote the lexical matching score function using BDI, BPI and BSI as  $Score_{BDI}$ ,  $Score_{BPI}$  and  $Score_{BSI}$  respectively.

**Entity Co-Occurrence Score:** We also consider the relevance of entities in co-occurrence aspect. If two entities often appearing together, we assume that they are relevant. We use normalized google distance (Cilibrasi and Vitanyi, 2007) to calculate the entity co-occurrence score  $Score_{co}(candidate_k)$ .

$$NGD(e_i, e_j) = \frac{Max(e_i, e_j) - \log f(e_i, e_j)}{\log N - Min(e_i, e_j)} \quad (2)$$

$$Max(e_i, e_j) = \max\{\log f(e_i), \log f(e_j)\} \quad (3)$$

$$Min(e_i, e_j) = \min\{\log f(e_i), \log f(e_j)\} \quad (4)$$

$$Score_{co}(candidate_k) = -\log(NGD(e_i, e_j)) \quad (5)$$

where

$$e_i \in E_{stem}, e_j \in E_{candidate_k}.$$

In which,  $e_i$  is entity;  $f(e_i)$  is the number of parts which contain entity  $e_i$ ;  $f(e_i, e_j)$  is the number of parts which contain both entity  $e_i$  and  $e_j$ ;  $E_{stem}$  and  $E_{candidate_k}$  denotes the entities in question stem and candidate.

The entity co-occurrence could be in document, paragraph or sentence, and they are denoted as  $Score_{BDC}$ ,  $Score_{BPC}$  and  $Score_{BSC}$  respectively.

**Page Link Score:** Inspired from PageRank algorithm (Page et al., 1999), we assume that entities have links to each other are relevant. Here we introduce the page link score function. We use  $Link(e_i, e_j)$  to denote the number of links between entities  $e_i$  and  $e_j$ . The link score  $Score_{link}(candidate_k)$  could be calculated as:

$$Score_{link}(candidate_k) = \max(Link(e_i, e_j)) \quad (6)$$

where

$$e_i \in E_{stem}, e_j \in E_{candidate_k}.$$

We only count the number of links between BAIKE documents, and it is denoted as  $Score_{BDL}$

Function	Description
$Score_{BDI}$	$Score_{lexical}$ using BDI
$Score_{BPI}$	$Score_{lexical}$ using BPI
$Score_{BSI}$	$Score_{lexical}$ using BSI
$Score_{BDC}$	document level $Score_{co}$
$Score_{BPC}$	paragraph level $Score_{co}$
$Score_{BSC}$	sentence level $Score_{co}$
$Score_{BDL}$	document link score function

Table 2: Summarization of score functions.

### 3.1.3 Training Weights

Since we have seven score functions, we need combine them together with different weights.

For a given question, we calculate the score of every candidate as follows:

$$score_{candidate_k} = \sum_{i=1}^7 (w_i * f_i(candidate_k)) \quad (7)$$

where  $k \in \{1, 2, 3, 4\}$ ,  $f_i$  is one of the seven score functions and  $w_i$  is the corresponding weight. Then we normalize the scores of all candidates:

$$score_k = \frac{score_{candidate_k}}{\sum_{i=1}^4 (score_{candidate_i})} \quad (8)$$

We suppose that the true answer of a question is the  $n$ -th candidate, where  $n \in \{1, 2, 3, 4\}$ . The loss of it is

$$loss_{question} = -\log(1 - score_n) \quad (9)$$

Now we can calculate the total loss of the dataset with  $M$  questions:

$$loss = \sum_i^M (loss_{question_i}) \quad (10)$$

All operations are derivable so that we can use gradient descent algorithm to train the weights.

### 3.2 NN Approach

As deep neural networks are widely used in natural language processing tasks and has gained great success, it's naturally to come up with building deep neural networks to handle GKHMC task. So, we built several deep neural networks in different structures. And, we used both TIKU and BOOK to train these models, in order to teach models not only how to answer the questions but also the historical knowledge.

To handle the joint inference between background knowledge and question stems in GKHMC

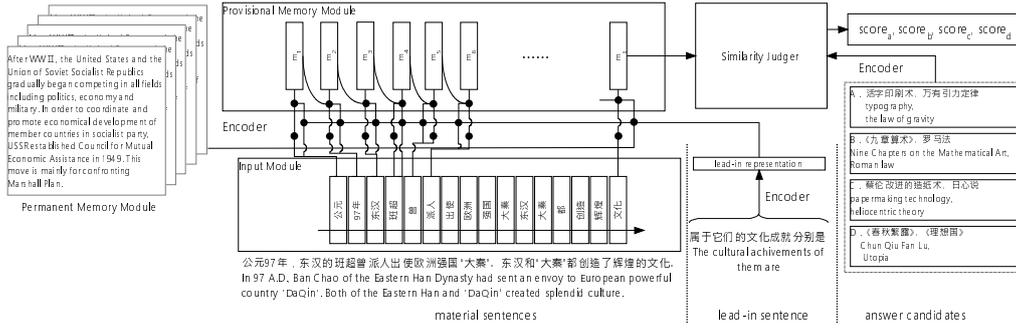

Figure 3: Diagram of PPMN. The questions hasn't been translated into English.

questions, we introduce permanent-provisional memory network (PPMN). As illuminated in Figure 3, our PPMN is composed by the following components:

1. **Permanent Memory Module** that plays the same role as a knowledge base and stores the original text from history textbooks or other relevant resource.
2. **Provisional Memory Module** that generates some contents based on the current word in background sentences, permanent knowledge and the lead-in sentence.
3. **Input Module** that reads the words sequentially in background sentences and maps them into high-dimensional vector space.
4. **Similarity Judger** that scores the similarity between the output of provisional memory and the vector representations of answer candidates.
5. **Sentence Encoder** that encodes lead-in sentence, sentences in permanent memory and answer candidates.

**Permanent Memory Module:** We denote the sentences encoded by sentence encoder in this module as  $\{k_1, k_2, \dots, k_K\}$ , where  $K$  is the scale of permanent memory. The permanent memory is a constant matrix composed by the concatenation of representation vectors of these sentences, namely  $[k_1; k_2; k_3; \dots; k_K]$ . Considering the time complexity of training PPMN, we only take the syllabus of all history courses including 198 sentences, i.e.  $K = 198$ , as the permanent memory. If necessary, all of the history text books can be taken into the permanent memory.

**Provisional Memory Module:** It first inquires the current word of background sentences in the permanent memory, then use an attention vector generated by current word and lead-in sentence as well as the following words to decide how to adjust itself. The update equations are as follow:

$$h_t = GRU(w_t, h_{t-1}) \quad (11)$$

$$p = softmax(pW^p h_t) \quad (12)$$

$$M_t = \sum_{i=1}^K p_i k_i \quad (13)$$

$$x = [h_t, M_t, l, h_t \circ l, M_t \circ l, h_t \circ M_t, |h_t - l|, |M_t - l|, |h_t - M_t|] \quad (14)$$

$$g = \sigma(W^g tanh(W^t x + b^t) + b^g) \quad (15)$$

$$m_t = g \circ M_t + (1 - g) \circ m_{t-1} \quad (16)$$

In the above equations,  $w_t$  denotes the  $t$ -th word in the background sentences,  $GRU$  is defined in equation (19-22),  $h_{t-1}$  and  $h_t$  are the hidden representation of  $w_{t-1}$  and  $w_t$  respectively,  $l$  stands for the lead-in sentence encoded by the sentence encoder,  $\circ$  is element-wise multiplication and  $m_t$  is the computational result of current step. The final output of this module is the last provisional memory vector  $m_n$  where  $n$  is the length of background sentences.

**Input Module:** This module takes the same weight matrices in sentence encoder and calculates the hidden states of every word sequentially. All the words in background sentences are first mapped into the hidden states in this module and then can be taken as input by other modules. The calculation of hidden states are the same as equation (19-22).

**Similarity Judge:** This module takes the concatenation of the output from provisional memory and representation of answer candidate as input and use a classifier based on logistic regression to score it. The judging procedure is defined as follow:

$$\hat{p} = \sigma(W^l[m_K; a] + b^l) \quad (17)$$

$$score = softmax(\hat{p}) \begin{bmatrix} 0 \\ 1 \end{bmatrix} \quad (18)$$

where  $W^l$  is a matrix that can map the concatenation vector  $[m_K; a]$  into a vector  $\hat{p}$  of length 2 and  $a$  stands for the answer candidate encoded by sentence encoder.

**Sentence Encoder:** We experimented several recurrent neural networks with different structures as the sentence encoder. Both of Long-Short Term Memory (LSTM)(Hochreiter and Schmidhuber, 1997) and Gated Recurrent Unit (GRU)(Cho et al., 2014) perform much better than the standard *tanh* RNN. However, considering that the computation of LSTM is more complicated and time-consuming, we choose GRU as the sentence encoder. The calculation of GRU denoted as  $h_t = GRU(w_t, h_{t-1})$  is as follow:

$$z = \sigma(W^z w_t + U^z w_t + b^z) \quad (19)$$

$$r = \sigma(W^r w_t + U^r w_t + b^r) \quad (20)$$

$$s = tanh(W^s w_t + U^s(r \circ h_{t-1}) + b^s) \quad (21)$$

$$h_t = (1 - z) \circ s + z \circ h_{t-1} \quad (22)$$

In the above equations,  $w_t$  is extracted from a word embedding matrix  $W_e$  initialized by word2vec(Mikolov et al., 2013) through an id number that indicates which word it is.

**Loss Function:** Intuitively, as we want to encourage the score as same to the true score (0 or 1) as possible, a negative log-likelihood loss function is introduced:

$$L = -\log(\hat{p}y) \quad (23)$$

where  $y$  would be  $[0 \ 1]^T$  if  $a$  is the right answer or  $[1 \ 0]^T$  otherwise.

**Optimization Algorithm:** We use the AdaDelta introduced by (Zeiler, 2012) to minimize the loss  $L$ , and use back propagation through time to optimize the calculation results of intermediate results.

	Accuracy
EQ- $W_{EQ}$	49.38%
SQ- $W_{SQ}$	28.60%

Table 3: Accuracy of SQs and EQs with their corresponding best weights.

## 4 Experiment

### 4.1 Experiments of IR Approach

To find the best weights for EQ and SQ, We use TIKU as the training dataset. Using gradient descent to optimize parameters, we get the best weights for EQs and SQs separately, that is,  $W_{EQ}$  is the weight best for EQs and  $W_{SQ}$  is the weight best for SQs. We test the weights on EQs and SQs of GKHMC with their corresponding weights, and result is shown in Table 3. As we can see, with these weights, we achieve promising result.

We use GKHMC as the dataset to test the performance of IR approach with naive bayes classifier. The precision of EQs and SQs are 48.75%, 28.42% respectively. It's clear that the accuracy of both EQs and SQs decreased with automatic classification. But still, IR approach achieves much better results on EQs than SQs.

### 4.2 Results of NN Approach

We take some other neural network models with memory capability as our baseline models including the standard *tanh* recurrent neural network(RNN), long-short term memory network(LSTM)(Hochreiter and Schmidhuber, 1997), gated recurrent unite(GRU)(Cho et al., 2014), end-to-end memory network(MemNN)(Sukhbaatar et al., 2015) and dynamic memory network(DMN)(Kumar et al., 2016). As for our PPMN, we summarize the syllabus of all history textbooks for senior school students to cover as much knowledge points as possible and we get 198 sentences which are taken into the permanent memory module. For all the above models, we used rmsprop(Hinton et al., 2012) with 0.001 as the learning rate to train them, the size of hidden units as well as the size of memory were both set to 400 and the size of batches were set to 1000. Also, we used dropout(Srivastava et al., 2014) to prevent the models from overfitting and the probability of it was set to 0.5. We test all these models and the results are shown in Table 4.

From the result, we observe that our PPMN

Model	EQs	SQs	All
RNN	36.25%	29.74%	31.18%
LSTM	40.63%	40.41%	40.46%
GRU	40.63%	40.24%	40.32%
MemNN	43.75%	36.13%	37.77%
DMN	44.38%	45.38%	45.16%
PPMN	<b>45.63%</b>	<b>45.72%</b>	<b>45.70%</b>
Random	25.00%	25.00%	25.00%

Table 4: Results of all neural network models.

gains best performance on all kinds of GKHMC questions and all memory-capable neural network models beat RNN. It’s interesting that MemNN performs much worse than other memory-capable models on SQs whereas it shows promising capability on EQs.

### 4.3 Combine IR Approach and NN Approach

It can be easily observed from the above experiments that IR approach and NN approach are some kind of complementary, namely they performs better to each other on different categories of questions. So, we combine the two approaches together via a weights matrix  $W^c \in \mathbb{R}^{2 \times 2}$  as follows:

$$score_{EQ} = W_1^c \begin{bmatrix} score_{IR} \\ score_{NN} \end{bmatrix} \quad (24)$$

$$score_{SQ} = W_2^c \begin{bmatrix} score_{IR} \\ score_{NN} \end{bmatrix} \quad (25)$$

where the  $W_i^c$  means the  $i$ -th row of  $W^c$  and  $score_{IR}, score_{NN}$  are the scores calculated by IR and NN approaches respectively. Here, the categories of questions are given by the naive bayes classifier. The performance of combined model and its comparison to the two individual approaches are illustrated in Figure 4.

### 4.4 Discussion

From the global aspect, it can be easily observed that IR approach are more proficient on EQs(49.38% vs 40.63%), whereas NN approach expand superior to it on SQs(28.60% vs 40.24%). And the hybrid method composed by two approaches get the best performance(42.60%).

As for the IR approach itself, the performance on EQs is much better than on SQs. This may be because that IR approach is based on the relevance between candidates and question stem. In EQs, the information given by the question stem is usually the description of the key entity which only

disappeared in the right candidate. So it’s easy for the correct candidate to achieve a higher relevance score than others. And, that’s why IR approach achieves promising result on EQs. Whereas, in SQs, the key entity doesn’t appear in any candidate. And, it needs to be inferred out from question stem. No matter in aspect of lexical matching, entity co-occurrence or page link, the relevance between question stem and correct candidate may be as low as other candidates. Therefore, it’s not surprised that IR approach is not sufficient to figure out the right choice on SQs. After adding the classifier in IR approach, we notice the decrease of accuracy on both EQs and SQs. This is because of the misclassification on the questions, which demonstrates that the weights  $W_{EQ}, W_{SQ}$  are particularly efficient on EQs, SQs.

The experiment of NN approach declared that our PPMN does show its advantages on GKHMC questions. During the training, the performance of RNN model is labile, i.e. the precision are still variational when loss is convergent. In contrast, other model’s performance is more stable. Hence, we consider that the memory mechanism helps model to “remember” the knowledge that appeared in the training data. Compared with the “inside”<sup>4</sup> memory of LSTM and GRU, the specially designed memory component in MemNN, DMN and PPMN are more powerful to find out the relationships between the question stem and answer candidates in GKHMC questions. However, the limited performance of MemNN on SQs indicates that the sequences of words in GKHMC questions are especially important for questions containing no distinct entities. Last but not least, the best performance of PPMN may due highly on the novel permanent memory module which can helps finding the implicit relationships with the stored background knowledge.

The state-of-the-art performance of hybrid method indicates that combination of IR approach and NN approach is the best strategy to address the GKHMC questions. As illustrated in Figure 4, the combined method shows its enormous advantage on EQs. This may because both character and word embedding are more sufficient to cover the lexical meaning. And, some of EQs may be more suitable to be handled as SQs. Compared to the NN approach separately, the hybrid way does

<sup>4</sup> We consider that the memory of LSTM and GRU are kind of stored inside the weight matrices.

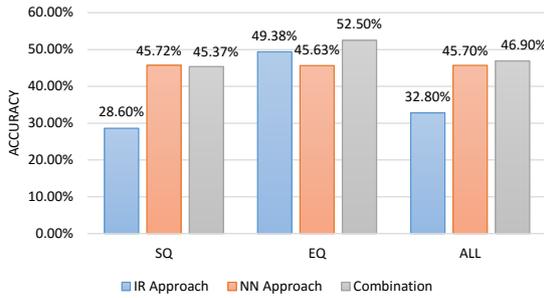

Figure 4: Result of different methods.

a little poorly on SQs, which may be caused by the loss of classification.

## 5 Related Work

Answering real world questions in various subjects already gained attention from the beginning of this century. The ambitious Project Halo (Friedland et al., 2004) was proposed to create a "digital" Aristotle that can encompass most of the world's scientific knowledge and be capable of addressing complex problems with novel answers. In this project, (Angele et al., 2003) employed hand-crafted rules to answer chemistry questions, (Gunning et al., 2010) took the physics and biology into account. Another important trial is solving the mathematical questions. (Mukherjee and Garain, 2008) attempted to answer them via transforming the natural language description into formal queries with hand-crafted rules, whereas recent works (Hosseini et al., 2014) started to employ learning techniques. However, none of these methods are suitable for history questions which require large background knowledge, the same to the Aristo Challenge (Clark, 2015) focused on Elementary Grade Tests which is for 6-11 year olds.

The Todai Robot Project (Fujita et al., 2014) aims to build a system that can pass the University of Tokyo's entrance examination. As part of this project, (Kanayama et al., 2012) mainly focus on addressing the yes-no questions via determining the correctness of the original proposition, and (Miyao et al., 2012) mainly focus on recognizing textual entailment between a description in Wikipedia and each option of question. But, these two methods are separated for different kinds of questions and none of them introduced neural network approach.

It's inevitable to compare the GKHMC with the factoid questions. (Berant and Liang, 2014) takes

the question as a kind of semantic parsing which can not handle the specific expressions with lots of background knowledge. Although (Yih et al., 2015) employed knowledge base, but still failed on multiple sentences questions which is beyond the scope of semantic parsing. However, the diversity of candidates in GKHMC makes these models fail to match the question with the right candidate. Another nonnegligible task is machine comprehension, also called reading comprehension. Although in several different datasets introduced by (Smith et al., 2008; Richardson et al., 2013; Weston et al., 2015), questions are open-domain and candidates may be entities or sentences, understanding these questions don't require as much background knowledge as in GKHMC and these models cannot handle the joint inference between the background knowledge and words in questions.

We are not the first to take up the Gaokao challenge, but former information retrieval approach doesn't fit to part of the questions in GKHMC and resources in their system are limited. In contrast, we introduced two different approaches to this task, compared their performance on different types of questions, combined them and gained a state-of-the-art result.

## 6 Conclusion and Future Work

In this work, we detailed the multiple choice questions in subject History of Gaokao, present two different approaches to address them and compared these approaches' performance on all categories of questions. We find that the IR approach are more sufficient on EQs cause the words in these questions are usually the description of right answer, whereas the NN approach performs much better on SQs, and this may be because neural network models can find out the semantic relationship between questions and candidates. When combining them together, we get the state-of-the-art performance on GKHMC, better than any individual approach. This points out that combining different approaches may be a better method to deal with the real-world questions.

In future work, we will explore whether key-value memory network proposed by (Miller et al., 2016) can help improve the performance of PPMN, what content in textbook or encyclopedia should be taken into the permanent memory, how to mathematically organize the permanent mem-

ory to make it can be reasoned on as well as whether transforming the knowledge described in natural language into formal representation is beneficial. As a long-term goal, it's necessary to introduce discourse analysis, semantic parsing to help the model truly understand the material sentences, questions and candidates.

# If You Can't Beat Them Join Them: Handcrafted Features Complement Neural Nets for Non-Factoid Answer Reranking

Dasha Bogdanova, Jennifer Foster, Daria Dzendzik and Qun Liu

ADAPT Centre

School of Computing, Dublin City University

Dublin, Ireland

firstname.lastname@adaptcentre.ie

## Abstract

We show that a neural approach to the task of non-factoid answer reranking can benefit from the inclusion of tried-and-tested handcrafted features. We present a novel neural network architecture based on a combination of recurrent neural networks that are used to encode questions and answers, and a multilayer perceptron. We show how this approach can be combined with additional features, in particular, the discourse features presented by Jansen et al. (2014). Our neural approach achieves state-of-the-art performance on a public dataset from Yahoo! Answers and its performance is further improved by incorporating the discourse features. Additionally, we present a new dataset of Ask Ubuntu questions where the hybrid approach also achieves good results.

## 1 Introduction

The task of Question Answering (QA) is arguably one of the oldest tasks in Natural Language Processing (NLP), attracting high levels of interest from both industry and academia. The QA track at the Text Retrieval Evaluation Conference (TREC) was introduced in 1999 and since then has encouraged many research studies by providing a platform for evaluation and making labeled datasets available. However, most research has focused on factoid questions, e.g. the TREC questions *What is the name of the managing director of Apricot Computer?* and *What was the monetary value of the Nobel Prize in 1989?* The TREC QA track organizers took care to “select questions with straightforward, obvious answers” (Voorhees and Tice, 1999) to facilitate manual assessment. In contrast, research on answering non-factoid (NF)

questions, such as manner, reason, difference and opinion questions, has been rather piecemeal. This was largely due to the absence of available labeled data for the task. This is changing, however, with the growing popularity of Community Question Answering (CQA) websites, such as Quora,<sup>1</sup> Yahoo! Answers<sup>2</sup> and the Stack Exchange<sup>3</sup> family of forums.

One of the main components of a non-factoid question answering system is the answer reranking module. Given a question, it aims to rearrange the answers in order to boost the community-selected best answer to the top position. Most previous attempts to perform non-factoid answer reranking on CQA data are supervised, feature-based, learning-to-rank approaches (Jansen et al., 2014; Fried et al., 2015; Sharp et al., 2015). These methods represent the candidate answers as meaningful handcrafted features based on syntactic, semantic and discourse parses (Surdeanu et al., 2011; Jansen et al., 2014), web correlation (Surdeanu et al., 2011), and translation probabilities (Fried et al., 2015; Surdeanu et al., 2011). The resulting feature vectors are then passed to a supervised ranking algorithm, such as SVMrank (Joachims, 2006), which ranks the candidates.

There has been a recent shift in Natural Language Processing towards neural approaches involving minimal feature engineering. Several recent studies present purely neural approaches to answer reranking, with most of them focusing on the task of passage-level answer selection (dos Santos et al., 2016; Tan et al., 2015), rather than answer reranking in CQA websites (Bogdanova and Foster, 2016). These neural approaches aim to obviate the need for any feature engineering and instead focus on developing a neural architecture

<sup>1</sup><http://quora.com>

<sup>2</sup><http://answers.yahoo.com>

<sup>3</sup><http://stackexchange.com>

that learns the representations and the ranking. However, while it is possible to view a purely neural approach as an alternative to machine learning involving domain knowledge in the form of handcrafted features, there is no reason why the two approaches cannot be applied in tandem. In this paper we show that handcrafted features which encode information about discourse structure can be used to improve the performance of a neural approach to CQA answer reranking.

First, we present a novel neural approach to answer reranking that achieves competitive results on a public dataset of Yahoo! Answers (YA) that was previously introduced by Jansen et al. (2014) and later used in several other studies (Fried et al., 2015; Sharp et al., 2015; Bogdanova and Foster, 2016). Our approach is based on a combination of recurrent neural networks (RNN) and a multilayer perceptron (MLP) that receives the encodings produced by the RNNs and *interaction transformation features* that are based on the outputs of the RNNs and which aim to represent the semantic interaction between the encoded sequences. We also show how this approach can be combined with discourse features previously shown to be beneficial for the task of answer reranking.

The previous best result on the YA dataset – 37.17 P@1 and 56.82 MRR – is reported by Bogdanova and Foster (2016). Our approach achieves similar performance – 37.13 P@1 and 57.56 MRR. In contrast to the (Bogdanova and Foster, 2016) approach, which is also purely neural but requires a large in-domain corpus for pretraining, our model requires only a relatively small training set and no pretraining. The hybrid approach that includes the discourse features outperforms the neural approach on the same dataset and achieves 38.74 P@1 and 58.37 MRR. We also report experiments on a new dataset of Ask Ubuntu<sup>4</sup> questions and answers. The model shows good performance on this dataset too, with the hybrid approach being about 2% more accurate in terms of P@1 than the neural approach on its own. Our error analysis provides insights into the main challenges posed by answer reranking in CQAs. These are the subjective nature of both the questions and the user choice of the best answer.

The main contributions of this paper are as follows: 1) we propose a novel neural approach for non-factoid answer reranking that achieves state-

of-the-art performance on a public dataset of Yahoo! Answers; 2) we combine this approach with an approach based on discourse features that was introduced by Jansen et al. (2014), with the hybrid approach outperforming the neural approach and the previous state-of-the-art; 3) we introduce a new dataset of Ask Ubuntu questions and answers.

This paper is organized as follows: an overview of previous work on non-factoid question answering is provided in Section 2, our neural architecture is introduced in Section 3, the discourse features that are incorporated into our neural approach are described in Section 4, the results of our experiments with these new models are presented and analysed in Section 5, and suggestions for further research are provided in Section 6.

## 2 Related Work

Previous work on supervised non-factoid answer reranking on CQA datasets focused mainly on feature-rich approaches. Surdeanu et al. (2011) show that CQAs such as Yahoo! Answers are a good source of knowledge for non-factoid QA. They employ four types of features in their answer reranking model: (1) similarity features: the similarity between a question and an answer based on the length-normalized BM25 formula (Robertson et al., 1994); (2) translation features: probability of the question being a translation of the answer computed using IBM’s Model 1 (Brown et al., 1993); (3) features measuring frequency and density of the question terms in the answer, such as the number of non-stop question words in the answer, the number of non-stop nouns, verbs and adjectives in the answer that do not appear in the question and tree kernel values for question and answer syntactic structures; (4) web correlation features based on Corrected Conditional Probability (Magnini et al., 2002) between the question and the answer. They explore these features both separately and in combination and find that the combination of all four feature types is most beneficial for answer reranking models.

Jansen et al. (2014) describe answer reranking experiments on YA using a diverse range of lexical, syntactic and discourse features. In particular, they show how discourse information can complement distributed lexical semantic information obtained with a skip-gram model (Mikolov et al., 2013). In this paper we use their features (discussed in detail in Section 4) in combination with

---

<sup>4</sup><http://askubuntu.com>

a neural approach. Fried et al. (2015) improve on the lexical semantic models of Jansen et al. (2014) by exploiting indirect associations between words using higher-order models.

Methods based purely on neural models have gained popularity in various areas of NLP in recent years. The main advantage of these models is that they are often able to achieve state-of-the-art results while obviating the need for manual feature engineering. These approaches have been successful in the area of question answering. Several studies proposed models based on convolution neural networks (Severyn and Moschitti, 2015; Tymoshenko et al., 2016; Feng et al., 2015) for answer sentence selection for factoid question answering and models based on combinations of convolutional and recurrent neural networks for the task of passage-level non-factoid answer reranking (Tan et al., 2015; dos Santos et al., 2016). Recurrent neural networks and memory networks were successfully applied to the task of reading comprehension (Xiong et al., 2016; Sukhbaatar et al., 2015; Weston et al., 2015). A simple purely neural approach to non-factoid answer reranking in CQAs was proposed by Bogdanova and Foster (2016). The question-answer pairs are represented with Paragraph Vector (Le and Mikolov, 2014) distributed representations, and a multilayer perceptron is used to estimate the probability of the answer being good for the given question. The approach achieves state-of-the-art results. However, it requires unsupervised pretraining of the Paragraph Vector model on a relatively big in-domain dataset.

Recently, the Wide and Deep learning model for recommendation systems was proposed (Cheng et al., 2016). This model trains a *wide* linear model based on sparse features alongside a deep neural model, thus combining the benefits of memorization provided by the former part and the generalization provided by the latter.

In this paper, we propose a hybrid approach to answer reranking. Similarly to the wide and deep model, it combines traditional feature-based and deep neural approaches. However, in this paper we enhance the neural model with discourse chunk features that were previously found useful for this task. The features are combined with a neural model that consists of two bidirectional RNNs that encode the question and the answer and a multilayer perceptron that receives the neural encodings

and the discourse features and makes the final prediction.

### 3 Learning to rank answers with RNNs and MLP

We illustrate our approach to answer reranking in Figure 1. Following previous research on neural answer reranking (Severyn and Moschitti, 2015; Bogdanova and Foster, 2016), we employ the pointwise approach to ranking, i.e. we cast the ranking task as a classification task. Given a question  $q$  and an answer  $a$ , we first use two separate bidirectional RNNs<sup>5</sup> to encode the question and the answer. Let  $(w_1^q, w_2^q, \dots, w_k^q)$  be the sequence of question words and  $(w_1^a, w_2^a, \dots, w_p^a)$  be the sequence of answer words.<sup>6</sup> The first RNN encodes the sequence of question words into the sequence of context vectors  $(h_1^q, h_2^q, \dots, h_k^q)$ , i.e.

$$f_{RNN}^q(w_i^q, \theta_q) = h_i^q \quad (1)$$

where  $\theta_q$  denote the trainable parameters of the network. More specifically, the bidirectional RNN consists of two RNNs: the forward RNN that reads the question starting from the first word until the last word and encodes it as a sequence of forward context vectors  $(\overrightarrow{h_1^q}, \overrightarrow{h_2^q}, \dots, \overrightarrow{h_k^q})$ , and the reverse RNN that encodes the question starting from the last word until the first word:  $(\overleftarrow{h_k^q}, \overleftarrow{h_{k-1}^q}, \dots, \overleftarrow{h_1^q})$ . The resulting context vectors are concatenations of the forward and reverse context vectors at each step, i.e.  $h_i^q = [\overrightarrow{h_i^q}, \overleftarrow{h_i^q}]$ . As the encoded vector representation of the question, we use the concatenation of the context vectors, i.e.

$$enc^q = [h_1^q, \dots, h_k^q] \quad (2)$$

The second bidirectional RNN encodes the answer in the same way:

$$f_{RNN}^a(w_i^a, \theta_a) = h_i^a \quad (3)$$

$$enc^a = [h_1^a, \dots, h_p^a] \quad (4)$$

where  $\theta_a$  denote the trainable parameters of the network. We also want to optionally explicitly encode the interaction between the question’s context vectors and the answer’s context vectors. To

<sup>5</sup>We use an RNN with Gated Recurrent Units (GRU) (Bahdanau et al., 2015). Using an LSTM instead provides similar results.

<sup>6</sup>The questions and answers have to be padded to  $k$  and  $p$  words respectively.

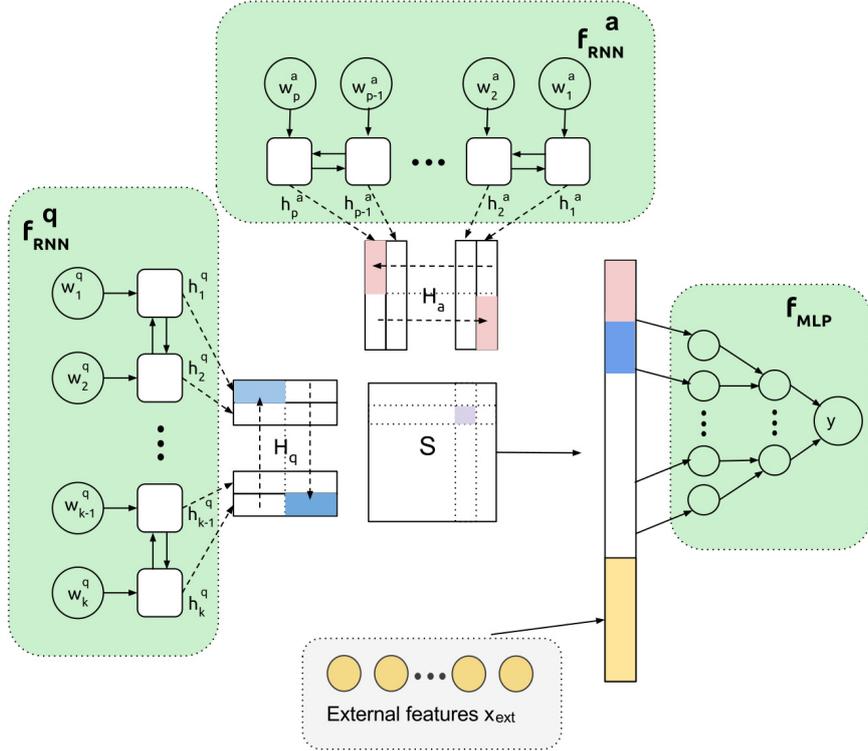

Figure 1: Our model takes a question-answer pair as an input and encodes them using separate RNNs denoted as  $f_{RNN}^q$  and  $f_{RNN}^a$ . Then a similarity matrix  $S$  over the encodings is computed and optionally concatenated with external features  $x_{ext}$ , the result is passed to a multilayer perceptron  $f_{MLP}$  that outputs the final prediction.

do this we apply the *interaction transformation* to the context vectors. More specifically, let  $H_q$  denote the matrix composed of the outputs of the question encoder RNN:

$$H_q = \begin{pmatrix} h_{1,1}^q & h_{1,2}^q & \cdots & h_{1,k}^q \\ h_{2,1}^q & h_{2,2}^q & \cdots & h_{2,k}^q \\ \vdots & \vdots & \ddots & \vdots \\ h_{d,1}^q & h_{d,2}^q & \cdots & h_{d,k}^q \end{pmatrix}$$

and  $H_a$  denote the matrix composed of the outputs of the answer RNN:

$$H_a = \begin{pmatrix} h_{1,1}^a & h_{1,2}^a & \cdots & h_{1,p}^a \\ h_{2,1}^a & h_{2,2}^a & \cdots & h_{2,p}^a \\ \vdots & \vdots & \ddots & \vdots \\ h_{d,1}^a & h_{d,2}^a & \cdots & h_{d,p}^a \end{pmatrix}$$

$d$  is a dimensionality parameter to be experimentally tuned. We calculate the similarity matrix  $S$  between  $H_q$  and  $H_a$ , so that each element  $s_{ij}$  of the  $S$  matrix is a dot product between the corresponding encodings:

$$s_{ij} = h_i^q \cdot h_j^a$$

The similarity matrix  $S$  is unrolled and passed to the multilayer perceptron along with the question and answer encodings. They are optionally concatenated with external features  $x_{ext}$ :

$$y = f_{MLP}([S, enc^q, enc^a, x_{ext}], \theta_s) \quad (5)$$

where  $\theta_s$  denote the trainable parameters of the network. The network is trained by minimizing cross-entropy:

$$L(y, \theta) = -\bar{y} \log(y) - (1 - \bar{y}) \log(1 - y)$$

where  $\theta$  are all network's parameters, i.e.  $\theta_q, \theta_a, \theta_s$  and  $\bar{y}$  is the true label:

$$\bar{y} = \begin{cases} 1 & \text{if } a \text{ is the best answer of the question } q \\ 0 & \text{otherwise} \end{cases}$$

## 4 Discourse Features

Based on the intuition that modelling question-answer structure both within and across sentences could be useful, Jansen et al. (2014) propose an answer reranking model based on discourse features

Q: How did Darth *Vader* eat?

A: *Vader* doesn't enjoy *eating* **but** he forces himself. He could *eat* with his mouth **only** inside a hyperbaric chamber.

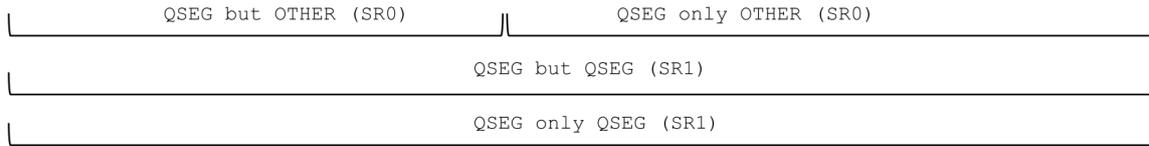

Figure 2: Feature generation for the discourse marker model of Jansen et al. (2014): first, the answer is searched for the discourse markers (in **bold**). For each discourse marker, there are several features that represent if there is an overlap (QSEG) with the question before and after the discourse marker. The features are extracted for sentence range from 0 (the same range) to 2 (two sentences before and after).

combined with lexical semantics. We experimentally evaluate these discourse features – added to our model described in Section 3 (the additional features  $x_{ext}$ ) and on their own. We reuse their discourse marker model (DMM) combined with their lexical semantics model (LS). The DMM model is based on the findings of Marcu (1998), who showed that certain cue phrases indicate boundaries between elementary textual units with sufficient accuracy. These cue phrases are further referred to as discourse markers. For English, these markers include *by*, *as*, *because*, *but*, *and*, *for* and *of* – the full list can be found in Appendix B in (Marcu, 1998).

We illustrate the feature extraction process of Jansen et al. (2014) in Figure 2. First, the answer is searched for discourse markers. Each marker divides the text into two arguments: preceding and following the marker. Both arguments are searched for words overlapping with the question. Each feature denotes the discourse marker and whether there is an overlap with the question (QSEG) or not (OTHER) in the two arguments defined by the marker. The sentence range (SR) denotes the length (in sentences) of the marker’s arguments. For example, QSEG by OTHER SR0 means that in the sentence containing the *by* marker there is an overlap with the question before the marker and there is no overlap with the question after the marker. This results in 1384 different features. To assign values to each feature, the similarity between the question and each of the two arguments is computed, and the average similarity is assigned as the value of the feature. Jansen et al. (2014) use cosine similarity over *tf.idf* and over the vector space built with a skip-gram model (Mikolov et al., 2013). Further details

can be found in (Jansen et al., 2014).

## 5 Experiments

### 5.1 Data

In our experiments, we use two datasets from different CQAs. For comparability, we use the dataset created by Jansen et al. (2014) which contains 10K *how* questions from Yahoo! Answers. 50% of it is used for training, 25% for development and 25% for testing. Each question in this dataset contains at least four user-generated answers. Some examples can be found in Table 1. Further details about this dataset can be found in (Jansen et al., 2014).

To evaluate our approach on a more technical domain, we create a dataset of Ask Ubuntu (AU) questions containing 13K questions, of which 10K are used for training, 0.5K for development and 2.5K for testing. The Ask Ubuntu community is a part of the Stack Exchange family of forums. Forums of this family share the same interface and guidelines. They allow users to post questions and answers and to vote them up and down, resulting in every question and every answer having a score representing the votes it received. The author of the question may select the *best answer* to their question. We create the AU dataset in the same way as the YA dataset was created: for each question, we only rank answers provided in response to this question, and the answer labelled as the best by the question’s author is considered to be the correct answer. We make sure that the dataset contains only questions that have at least three user-provided answers and have the best answer selected, and that this answer has a non-negative score. Example questions from this dataset can be

**Question:** how do you cut onions without crying?

**Gold:** Use a sharp knife because if the onions are cut cleanly instead of slightly torn (because of a dull knife) they will release less of the chemical that makes you cry. Lighting a candle also helps with this, ( ... ) I hope this helps.

**Other Answers:**

- Watch a comedy.
- Put onion in the chop blender
- close ur eyes...
- Sprinkle the surrounding area with lemon juice.
- Choose one of the followings after cutting the head and tail of the onion, split in half and peel off the skin. 1. Keep on chopping with your knife 2. Cut in quarters and put in choppers.

---

Table 1: Example question from the Yahoo! Answers dataset.

**Question:** Can't shutdown through terminal. When ever i use the following `sudo shutdown now; sudo reboot; sudo shutdown -h my laptop` goes on halt ( ... ) is there something wrong with my installation?

**Gold:** Try the following code `sudo shutdown -P now ( ... ) -P` Requests that the system be powered off after it has been brought down. `-c` Cancels a running shutdown. `-k` Only send out the warning messages and disable logins, do not actually bring the system down.

**Other Answers:**

- Try `sudo shutdown -h now` command to shutdown quickly.
- Try `init 0` init process shutdown all of the spawned processes/daemons as written in the init files

---

Table 2: Example question from the Ask Ubuntu dataset.

found in Table 2.

There are significant differences between the two datasets. While the Yahoo! Answers dataset has very short questions (10.8 on average) and relatively long answers (50.5 words), Ask Ubuntu questions can be very long, as they describe non-trivial problems rather than just ask questions. The average length of the Ask Ubuntu questions is 112.14 words, with the average answer being about 95 words long.

## 5.2 Experimental Setup

Following Jansen et al. (2014) and Fried et al. (2015), we implement two baselines: the baseline that selects an answer randomly and the candidate retrieval (CR) baseline. The CR baseline uses the same scoring as in Jansen et al. (2014): the questions and the candidate answers are represented using *tf-idf* over lemmas; the candidate answers are ranked according to their cosine similarity to the respective question. Additionally, we evaluate the discourse features described in Section 4 alone: we use them as the representation of the question-answer pairs that are then used as the input to a multilayer perceptron with five hidden layers. On the YA dataset, we also compare our results to the ones reported by Jansen et al. (2014) and by Bogdanova and Foster (2016).

The model described in Section 3 is regularized with L2-regularization and dropout. The development sets are used solely for early stopping

and hyperparameter selection. We tune the hyperparameters (learning rate, L2 regularization rate, dropout probabilities, dimensionality of the embeddings, the network architecture (the number of hidden layers and units, the use of GRU versus LSTM)) on the development sets. All neural networks use the rectified linear activation function (ReLU). The word embeddings are initialized randomly, no pretrained embeddings are used. We use the software provided by Jansen et al. (2014)<sup>7</sup> to extract the discourse features described in Section 4 and referred to as  $x_{ext}$  in Section 3. These discourse features require that word embeddings be trained in order to calculate the similarity. Following Jansen et al. (2014), we train them using the skip-gram model (Mikolov et al., 2013) We use the L6 Yahoo dataset<sup>8</sup> to train the skip-gram model for the YA dataset and the Ask Ubuntu September 2015 data dump for the AU dataset. The neural model described in Section 3 does not require pre-training of word embeddings, the embeddings are used only to extract external discourse features. To evaluate all the models, we use standard implementations of P@1 and mean reciprocal rank (MRR).

## 5.3 Results

We experimentally evaluate the following models:

---

<sup>7</sup><http://nlp.sista.arizona.edu/releases/acl2014/>

<sup>8</sup><http://webscope.sandbox.yahoo.com/>

- **MLP-discourse:** The discourse features are extracted as described in Section 4, an MLP is used to produce the ranking;
- **GRU-MLP:** The system described in Section 3 without the interaction matrix  $S$  and any other external features ( $x_{ext}$  in Section 3 and in Figure 1);
- **GRU-MLP-Sim:** The system described in Section 3 with the interaction matrix  $S$  and no external features;
- **GRU-MLP-Sim-Discourse:** The system described in Section 3 with the interaction matrix  $S$  and the discourse features as the external features  $x_{ext}$ ;

Table 3 reports the answer reranking P@1 and MRR of the described models along with the results of the baseline systems. The models were frozen on their best development epoch, the test set had been used neither for model selection nor for parameter tuning.<sup>9</sup>

Table 3 shows that the discourse features on their own with an MLP (MLP-Discourse) outperform the random and the CR baselines for both datasets. They also perform better than the approach of Jansen et al. (2014) who used SVMrank with a linear kernel. This might be due to the ability of the MLP to model non-linear dependencies. Nonetheless, the MLP-Discourse approach performs worse than the approach of Bogdanova and Foster (2016), which is based on distributed representations of documents, which probably capture more information relevant to the task.

The system described in Section 3 with no interaction transformation (only the encodings are passed to the MLP) and without any external features ( $x_{ext}$  in Section 3 and in Figure 1), referred to as GRU-MLP, outperforms the CR and the Random baselines and the systems based on the discourse features. However, it performs slightly worse than the approach of (Bogdanova and Foster, 2016). One possible reason is that the latter uses a large corpus for unsupervised pretraining.

<sup>9</sup>We report the results obtained with a bidirectional RNN with GRU cell, MLP with 5 hidden layers (with 5120, 2048, 1024, 512, 128 units), batch size 100, learning rate 0.01, weight decay 0.0005, dropout keep probability 0.6, and the word embedding dimensionalities and RNN outputs set to 100. The questions and answers are padded: the lengths are set to 15 words for the question and 100 words for the answer in the YA dataset and 200 and 150 words for the AU dataset.

Yahoo! Answers		
Model	P@1	MRR
Random Baseline	15.74	37.40
CR Baseline	22.63	47.17
Jansen et al. (2014)	30.49	51.89
Bogdanova and Foster (2016)	37.17	56.82
MLP-Discourse	32.72*	53.54*
GRU-MLP	36.12*	56.63*
GRU-MLP-Sim	37.13*	57.56*
GRU-MLP-Sim-Discourse	<b>38.74*</b>	<b>58.37*</b>
Ask Ubuntu		
Model	P@1	MRR
Random Baseline	26.60	53.64
CR Baseline	35.36	60.17
MLP-Discourse	37.80*	61.75*
GRU-MLP	38.56*	62.53*
GRU-MLP-Sim	39.28*	62.64*
GRU-MLP-Sim-Discourse	<b>41.40*</b>	<b>64.42*</b>

Table 3: The systems results versus the baselines. \* The improvements over the CR and Random baselines are statistically significant with  $p < 0.05$ . All significance tests are performed with one-tailed bootstrap resampling with 10,000 iterations.

The GRU-MLP systems does not use any external data, and learns only from the small training set.

The system enriched with the interaction matrix, GRU-MLP-Sim, clearly outperforms all the baselines on both datasets, including the MLP-Discourse system. On the YA dataset, the results are better than Jansen et al. (2014) and very similar to Bogdanova and Foster (2016). On the AU dataset the improvement over the CR and the MLP-discourse systems is less remarkable, yet statistically significant. This indicates the benefit of explicitly providing the interaction features to the MLP.

The same approach with the additional discourse features described in Section 4, referred to as GRU-MLP-Sim-Discourse in Table 3, achieves the highest P@1 and MRR on the YA dataset and the AU dataset. Surprisingly, the discourse features are very helpful on the AU dataset which is highly technical, with significant parts of the information represented as commands and code.

Even though the results achieved on both datasets are similar in absolute values, the datasets are very different and the errors might be of a different nature. We provide some insights into the

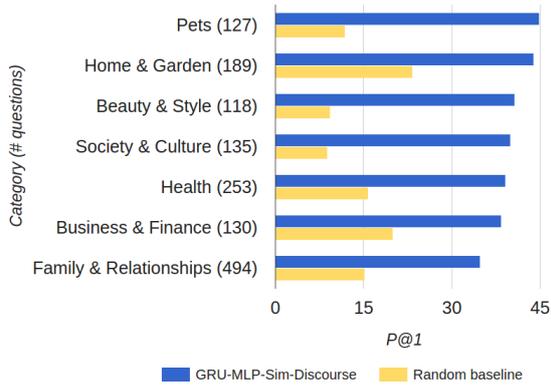

Figure 3: Average P@1 of the GRU-MLP-Sim-Discourse versus the Random baseline on the test questions from most common YA categories.

challenges raised by the two datasets in the next section.

#### 5.4 Error Analysis

By conducting an error analysis on the YA dataset we were able to pinpoint the main causes of error as follows:

1. Despite containing only *how* questions, the dataset contains a large amount of questions asking for an **opinion** or **advice**, e.g. *How should I do my eyes?*, *How do I look?* or *How do you tell your friend you're in love with him?* rather than **information**, e.g. *How do you make homemade lasagna?* and *how do you convert avi to mpg?* About half of the questions where the best system was still performing incorrectly were of the opinion-seeking nature. This is a problem for automatic answer reranking, since the nature of the question makes it very hard to predict the quality of the answers.
2. The choice of the best answer purely relies on the user. Inspection of the data reveals that these user-provided gold labels are not always reliable. In many cases the users tend to select as the best those answers that are most **sympathetic** (see (Q1) in Table 4) or **funny** (see (Q2) and (Q3) in Table 4), rather than the ones providing more useful information.

In order to gain more insights into the reasons behind errors on the YA data, we calculated av-

erage P@1 per category.<sup>10</sup> Figure 3 shows average P@1 of the GRU-MLP-Sim-Discourse system versus the Random baseline for the most common categories. From this figure it is clear that the most challenging category for answer reranking is Family & Relationships. This category is also the most frequent in the dataset, with 494 out of 2500 questions belonging to it. Our system achieves about 4% lower P@1 on the questions from Family & Relationships category than on the whole test set, while the random baseline performs as well as on the whole test set (the average number of answers per question in this category does not differ much from the dataset average). The low P@1 on this category is related to the reasons pointed out above: most questions in this category are of an opinion-seeking nature: *How do I know if my boyfriend really loves me?*, *How do I fix my relationship?*, *How do I find someone that loves me?*, making it hard to assess the quality of the answers.

The Ask Ubuntu dataset is rather different. In contrast to the YA dataset, which contains many subjective questions, most Ask Ubuntu questions relate to a complex technology and usually require deep domain knowledge to be answered. Moreover, many questions and answers contain code, screenshots and links to external resources. Reliably reranking such answers based on textual information alone might be an unattainable goal. The technical complexity of the questions can give rise to ambiguity. For instance, in (Q2) in Table 5 it is not clear if the question refers to the metapackage *ubuntu-desktop* or to ubuntu default packages in general. Another potential source of difficulty comes from the fact that the technologies being discussed on Ask Ubuntu change rapidly: some answers selected as best might be outdated (see (Q1) in Table 5).

## 6 Conclusions and Future Work

In this paper we presented a neural approach to open-domain non-factoid answer reranking. Previous studies in this area have either been feature-based or purely neural approaches that require no manual feature engineering. We show that these two approaches can be successfully combined. We propose a novel neural architecture whereby the question-answer pairs are first encoded using two

<sup>10</sup>We first mapped the low-level categories provided in the dataset to the 26 high-level YA categories. We only consider categories that contained at least 100 questions.

(Q1) How does someone impress a person during a conversation that u are as good as an oxford/harvard grad.?
(Gold) i think you're chasing down the wrong path. but hell, what do i know?
(Prediction) There are two parts. Understanding your area well, and being creative. The understanding allows you the material for your own opinions to have heft and for you to analyse the opinions of others. After that, it's just good vocabulary which comes from reading a great deal and speaking with others. Like many other endeavors practice is what makes your performance improve.
(Q2) How to get my mom to stop smoking?
(Gold) Throw a glass of water on her every time she sparks one up
(Prediction) Never nag her. Instead politely insist on your right to stay free of all the risks associated with another person's smoking. For example, do not allow her to smoke inside the car, the house or anywhere near you ( ... )
(Q3) How do i hip hop dance??!?!?
(Gold) Basically, you shake what your mother gave you.
(Prediction) Listen to previous freestyle flows and battles by great artists ( ... ) Understand the techniques those artists use to flow and battle ( ... )

Table 4: Example incorrect predictions of the system on the Yahoo! Answers dataset.

(Q1) How do I add the kernel PPA? I can get Ubuntu mainline kernels from this kernel PPA - is there a way to add it to my repository list the same as regular Launchpad PPAs?
(Gold) Warning : This answer is outdated. As of writing this warning (6.10.2013) the kernel-ppa used here is no longer updated. Please disregard this answer. <code>sudo apt-add-repository ppa:kernel-ppa/ppa</code> <code>sudo apt-get update</code> <code>sudo apt-get install PACKAGENAME</code>
(Prediction) Since the kernel ppa is not really maintained anymore, here's a semi-automatic script: <a href="https://github.com/medigeek/kmp-downloader">https://github.com/medigeek/kmp-downloader</a>
(Q2) Which language is ubuntu-desktop mostly coded in? I heard it is Python
(Gold) Poked around in Launchpad: ubuntu-desktop to and browsed the source for a few mins. It appears to be a mix of Python and shell scripts.
(Prediction) I think the question referred to the language used to write the applications running on the default installation. It's hard to say which language is used the most, but i would guess C or C++. This is just a guess and since all languages are pretty equal in terms of outcome, it doesn't really matter.

Table 5: Example incorrect predictions of the system on the Ask Ubuntu dataset.

recurrent neural networks, then the interaction matrix is calculated, concatenated with external features, and passed as an input to a multilayer perceptron. As external features, we evaluate the discourse features that were found useful for this task by Jansen et al. (2014). The combined approach achieves new state-of-the-art results on two CQA datasets.

However, despite these encouraging results, the P@1 is still below 40%. As the error analysis shows, this is due to the nature of the dataset: the user choice of the best answer is not always reliable and the questions are often seeking opinions rather than information. The ceiling for this task could be very low. Manual annotation of CQA data might help in determining the upper bound.

Future work should aim to create more reliable gold standards for this task. As we show in this paper, the CQAs contain various types of question: some of which are seeking information and some not. Existing corpora of opinion questions, such as

the OpQA corpus (Stoyanov et al., 2005), could be used in future research to distinguish those from the information-seeking questions. Another possible direction for future work is in combining the neural approach with other external features, such as features based on web correlation between the question and the answer, and similarities between their syntactic structures.

# Chains of Reasoning over Entities, Relations, and Text using Recurrent Neural Networks

Rajarshi Das, Arvind Neelakantan, David Belanger, Andrew McCallum

College of Information and Computer Sciences

University of Massachusetts, Amherst

{rajarshi, arvind, belanger, mccallum}@cs.umass.edu

## Abstract

Our goal is to combine the rich multi-step inference of symbolic logical reasoning with the generalization capabilities of neural networks. We are particularly interested in complex reasoning about entities and relations in text and large-scale knowledge bases (KBs). Neelakantan et al. (2015) use RNNs to obtain dense representations of multi-hop paths in KBs; however for multiple reasons, the approach lacks accuracy and practicality. This paper proposes three significant modeling advances: (1) we learn to jointly reason about relations, *entities*, and *entity-types*; (2) we use neural attention modeling to incorporate *multiple paths*; (3) we learn to *share strength in a single RNN* that represents logical composition across all relations. On a large-scale Freebase+ClueWeb prediction task, we achieve 25% error reduction, and a 53% error reduction on sparse relations. On chains of reasoning in WordNet we reduce error in mean quantile by 84% versus the previous state of the art.<sup>1</sup>

## 1 Introduction

There is a rising interest in extending neural networks to perform more complex reasoning, formerly addressed only by symbolic and logical reasoning systems. So far this work has mostly focused on small or synthetic data (Grefenstette, 2013; Bowman et al., 2014; Rocktäschel and Riedel, 2016). Our interest is primarily in reasoning about large knowledge bases (KBs) with diverse semantics, populated from text. One method

Table 1: Several highly probable clauses learnt by our model. The textual relations are shown in quotes and italicized. Our model has the ability to combine textual and schema relations.  $r^{-1}$  is the inverse relation  $r$ , i.e.  $r(a, b) \Leftrightarrow r^{-1}(b, a)$ .

for populating a KB from text (and for representing diverse semantics in the KB) is *Universal Schema* (Riedel et al., 2013; Verga et al., 2016), which learns vector embeddings of relation types - the union of all input relation types, both from the schemas of multiple structured KBs, as well as expressions of relations in natural language text.

An important reason to populate a KB is to support not only look-up-style question answering, but reasoning on its entities and relations in order to make inferences not directly stored in the KB. KBs are often highly incomplete (Min et al., 2013), and reasoning can fill in these missing facts. The “matrix completion” mechanism that underlies the common implementation of Universal Schema can thus be seen as a simple type of reasoning, as can other work in tensor factorization (Nickel et al., 2011; Bordes et al., 2013; Socher et al., 2013). However these methods can be understood as operating on single pieces of evidence: for example, inferring that *Microsoft-located-in-Seattle* implies *Microsoft-HQ-in-Seattle*.

A highly desirable, richer style of reasoning

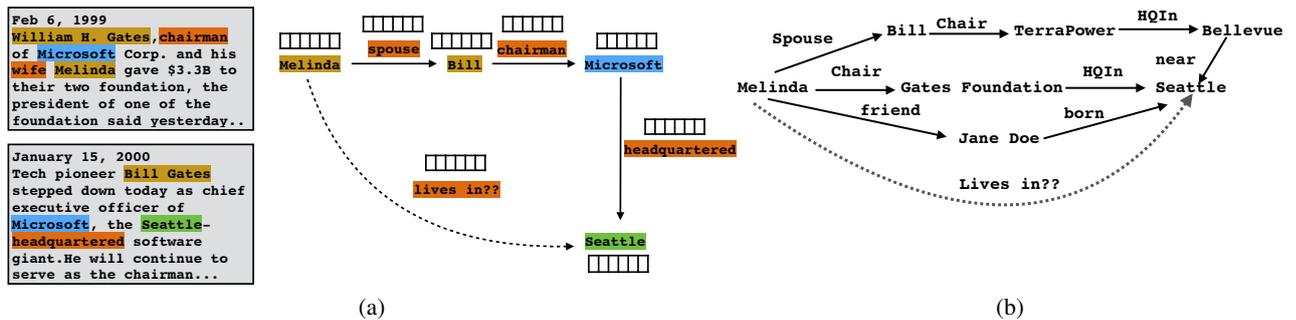

Figure 1: The nodes in the knowledge graphs represent entities and the labeled edges represent relations. (a) A path between ‘Melinda’ and ‘Seattle’ combining relations from two different documents. (b) There are multiple paths between entities in a knowledge graph. The top two paths are predictive of the fact that Melinda may ‘live in’ Seattle, but the bottom (fictitious) path isn’t.

makes inferences from Horn clauses that form multi-hop paths containing three or more entities in the KB’s entity-relation graph. For example, we may have no evidence directly linking Melinda Gates and Seattle. However, we may infer with some likelihood that Melinda–lives-in–Seattle, by observing that the KB contains the path Melinda–spouse–Bill–chairman–Microsoft–HQ-in–Seattle (Fig. 1a).

Symbolic rules of this form are learned by the Path Ranking Algorithm (PRA) (Lao et al., 2011). Dramatic improvement in generalization can be obtained by reasoning about paths, not in terms of relation-symbols, but Universal Schema style relation-vector-embeddings. This is done by Neelakantan et al. (2015), where RNNs compose the per-edge relation embeddings along an arbitrary-length path, and output a vector embedding representing the inferred relation between the two entities at the end-points of the path. This approach thus represents a key example of complex reasoning over Horn clause chains using neural networks. However, for multiple reasons detailed below it is inaccurate and impractical.

This paper presents multiple modeling advances that significantly increase the accuracy and practicality of RNN-based reasoning on Horn clause chains in large-scale KBs. (1) Previous work, including (Lao et al., 2011; Neelakantan et al., 2015; Guu et al., 2015) reason about chains of relations, but not the entities that form the nodes of the path. In our work, we jointly learn and reason about relation-types, entities, and entity-types. (2) The same previous work takes only a single path as evidence in inferring new predictions. However, as shown in Figure 1b, multiple paths can provide ev-

idence for a prediction. In our work, we use neural attention mechanisms to reason about multiple paths. We use a pooling function which does soft attention during *gradient step* and find it to work better. (3) The most problematic impracticality of the above previous work<sup>2</sup> for application to KBs with broad semantics is their requirement to train a separate model for each relation-type to be predicted. In contrast, we train a single, high-capacity RNN that can predict all relation types. In addition to efficiency advantages, our approach significantly increases accuracy because the multi-task nature of the training shares strength in the common RNN parameters.

We evaluate our new approach on a large scale dataset of Freebase entities, relations and ClueWeb text. In comparison with the previous best on this data, we achieve an error reduction of 25% in mean average precision (MAP). In an experiment specially designed to explore the benefits of sharing strength with a single RNN, we show a 54% error reduction in relations that are available only sparsely at training time. We also evaluate on a second data set, chains of reasoning in WordNet. In comparison with previous state-of-the-art (Guu et al., 2015) our model achieves a 84% reduction in error in mean quantile.

## 2 Background

In this section, we introduce the compositional model (Path-RNN) of Neelakantan et al. (2015). The Path-RNN model takes as input a path between two entities and infers new relations between them. Reasoning is performed non-

<sup>2</sup>with exception of (Guu et al., 2015)

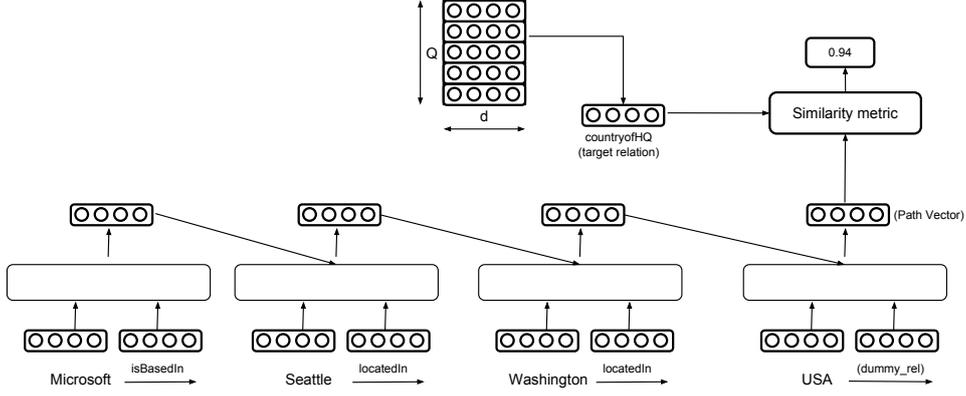

Figure 2: At each step, the RNN consumes both entity and relation vectors of the path. The entity representation can be obtained from its types. The path vector  $\mathbf{y}_\pi$  is the last hidden state. The parameters of the RNN and relation embeddings are shared across all query relations. The dot product between the final representation of the path and the query relation gives a confidence score, with higher scores indicating that the query relation exists between the entity pair.

atomically about conjunctions of relations in an arbitrary length path by composing them with a recurrent neural network (RNN). The representation of the path is given by the last hidden state of the RNN obtained after processing all the relations in the path.

Let  $(e_s, e_t)$  be an entity pair and  $\mathcal{S}$  denote the set of paths between them. The set  $\mathcal{S}$  is obtained by doing random walks in the knowledge graph starting from  $e_s$  till  $e_t$ . Let  $\pi = \{e_s, r_1, e_1, r_2, \dots, r_k, e_t\} \in \mathcal{S}$  denote a path between  $(e_s, e_t)$ . The length of a path is the number of relations in it, hence,  $(\text{len}(\pi) = k)$ . Let  $\mathbf{y}_{r_t} \in \mathbb{R}^d$  denote the vector representation of  $r_t$ . The Path-RNN model combines all the *relations* in  $\pi$  sequentially using a RNN with an intermediate representation  $\mathbf{h}_t \in \mathbb{R}^h$  at step  $t$  given by

$$\mathbf{h}_t = f(\mathbf{W}_{hh}^r \mathbf{h}_{t-1} + \mathbf{W}_{ih}^r \mathbf{y}_{r_t}^r). \quad (1)$$

$\mathbf{W}_{hh}^r \in \mathbb{R}^{h \times h}$  and  $\mathbf{W}_{ih}^r \in \mathbb{R}^{d \times h}$  are the parameters of the RNN. Here  $r$  denotes the query relation. Path-RNN has a specialized model for predicting each query relation  $r$ , with separate parameters  $(\mathbf{y}_{r_t}^r, \mathbf{W}_{hh}^r, \mathbf{W}_{ih}^r)$  for each  $r$ .  $f$  is the sigmoid function. The vector representation of path  $\pi$  ( $\mathbf{y}_\pi$ ) is the last hidden state  $\mathbf{h}_k$ . The similarity of  $\mathbf{y}_\pi$  with the query relation vector  $\mathbf{y}_r$  is computed as the dot product between them:

$$\text{score}(\pi, r) = \mathbf{y}_\pi \cdot \mathbf{y}_r \quad (2)$$

Pairs of entities may have several paths connecting them in the knowledge graph (Figure 1b). Let  $\{s_1, s_2, \dots, s_N\}$  be the similarity scores (Equation

2) for  $N$  paths connecting an entity pair  $(e_s, e_t)$ . Path-RNN computes the probability that the entity pair  $(e_s, e_t)$  participates in the query relation ( $r$ ) by,

$$\mathbb{P}(r|e_s, e_t) = \sigma(\max(s_1, s_2, \dots, s_N)) \quad (3)$$

where  $\sigma$  is the *sigmoid* function.

Path-RNN and other models such as the Path Ranking Algorithm (PRA) and its extensions (Lao et al., 2011; Lao et al., 2012; Gardner et al., 2013; Gardner et al., 2014) makes it impractical to be used in downstream applications, since it requires training and maintaining a model for each relation type. Moreover, parameters are not shared across multiple target relation types leading to large number of parameters to be learned from the training data.

In (3), the Path-RNN model selects the maximum scoring path between an entity pair to make a prediction, possibly ignoring evidence from other important paths. Not only is this a waste of computation (since we have to compute a forward pass for all the paths anyway), but also the relations in all other paths do not get any gradient updates during training as the max operation returns zero gradient for all other paths except the maximum scoring one. This is especially ineffective during the initial stages of the training since the maximum probable path will be random.

The Path-RNN model and other multi-hop relation extraction approaches (such as Guu et al. (2015)) ignore the entities in the path. Consider the following paths JFK-locatedIn-

NYC-locatedIn-NY and Yankee Stadium-locatedIn-NYC-locatedIn-NY. To predict the *airport\_serves* relation, the Path-RNN model assigns the same scores to both the paths even though the first path should be ranked higher. This is because the model does not have information about the entities and just uses the relations in the path for prediction.

### 3 Modeling Approach

#### 3.1 Shared Parameter Architecture

Previous section discussed the problems associated with per-relation modeling approaches. In response, we *share* the relation type representation and the composition matrices of the RNN across all target relations enabling lesser number of parameters for the same training data. We refer to this model as *Single-Model*. Note that this is just *multi-task learning* (Caruana, 1997) among prediction of target relation types with an underlying shared parameter architecture. The RNN hidden state in (1) is now given by:

$$\mathbf{h}_t = f(\mathbf{W}_{hh}\mathbf{h}_{t-1} + \mathbf{W}_{ih}\mathbf{y}_{rt}). \quad (4)$$

Readers should take note that the parameters here are independent of each target relation  $r$ .

#### Model Training

We train the model using existing observed facts (triples) in the KB as positive examples and unobserved facts as negative examples. Let  $\mathcal{R} = \{\gamma_1, \gamma_2, \dots, \gamma_n\}$  denote the set of all query relation types that we train for. Let  $\Delta_{\mathcal{R}}^+, \Delta_{\mathcal{R}}^-$  denote the set of positive and negative triples for *all* the relation types in  $\mathcal{R}$ . The parameters of the model are trained to minimize the negative log-likelihood of the data.

$$\begin{aligned} L(\Theta, \Delta_{\mathcal{R}}^+, \Delta_{\mathcal{R}}^-) = & -\frac{1}{M} \sum_{e_s, e_t, r \in \Delta_{\mathcal{R}}^+} \log \mathbb{P}(r|e_s, e_t) \\ & + \sum_{\hat{e}_s, \hat{e}_t, \hat{r} \in \Delta_{\mathcal{R}}^-} \log(1 - \mathbb{P}(\hat{r}|\hat{e}_s, \hat{e}_t)) \end{aligned} \quad (5)$$

Here  $M$  is the total number of training examples and  $\Theta$  denotes the set of all parameters of the model (lookup table of embeddings (shared) and parameters of the RNN (shared)). It should be noted that the Path-RNN model has a separate loss function for each relation  $r \in \mathcal{R}$  which depends only on the relevant subset of the data.

#### 3.2 Score Pooling

In this section, we introduce new methods of score pooling that takes into account multiple paths between an entity pair. Let  $\{s_1, s_2, \dots, s_N\}$  be the similarity scores (Equation 2) for  $N$  paths connecting an entity pair  $(e_s, e_t)$ . The probability for entity pair  $(e_s, e_t)$  to participate in relation  $r$  (Equation 3) is now given by,

1. Top- $(k)$ : A straightforward extension of the ‘max’ approach in which we average the top  $k$  scoring paths. Let  $\mathcal{K}$  denote the indices of top- $k$  scoring paths.

$$\mathbb{P}(r|e_s, e_t) = \sigma\left(\frac{1}{k} \sum_j s_j\right), \forall j \in \mathcal{K}$$

2. Average: Here, the final score is the average of scores of all the paths.

$$\mathbb{P}(r|e_s, e_t) = \sigma\left(\frac{1}{N} \sum_{i=1}^N s_i\right)$$

3. LogSumExp: In this approach the pooling layer is a smooth approximation to the ‘max’ function - LogSumExp (LSE). Given a vector of scores, the LSE is calculated as

$$\text{LSE}(s_1, s_2, \dots, s_N) = \log\left(\sum_i \exp(s_i)\right)$$

and hence the probability of the triple is,

$$\mathbb{P}(r|e_1, e_2) = \sigma(\text{LSE}(s_1, s_2, \dots, s_N))$$

The average and the LSE pooling functions apply non-zero weights to *all* the paths during inference. However only a few paths between an entity pair are predictive of a query relation. LSE has another desirable property since  $\frac{\partial \text{LSE}}{\partial s_i} = \frac{\exp(s_i)}{\sum_i \exp(s_i)}$ . This means that during the back-propagation step, every path will receive a share of the gradient proportional to its score and hence this is a kind of attention during the gradient step. In contrast, for averaging, every path will receive equal ( $\frac{1}{N}$ ) share of the gradient. Top- $(k)$  (similar to max) receives sparse gradients.

#### 3.3 Incorporating Entities

A straightforward way of incorporating entities is to include entity representations (along with relations) as input to the RNN. Learning separate

representations of entity, however has some disadvantages. The distribution of entity occurrence is heavy tailed and hence it is hard to learn good representations of rarely occurring entities. To alleviate this problem, we use the entity types present in the KB as described below.

Most KBs have annotated types for entities and each entity can have multiple types. For example, Melinda Gates has types such as *CEO*, *Duke University Alumni*, *Philanthropist*, *American Citizen* etc. We obtain the entity representation by a simple addition of the entity type representations. The entity type representations are learned during training. We limit the number of entity types for an entity to 7 most frequently occurring types in the KB. Let  $\mathbf{y}_{e_t} \in \mathbb{R}^m$  denote the representation of entity  $e_t$ , then 4 now becomes

$$\mathbf{h}_t = f(\mathbf{W}_{hh}\mathbf{h}_{t-1} + \mathbf{W}_{ih}\mathbf{y}_{r_t} + \mathbf{W}_{eh}\mathbf{y}_{e_t}) \quad (6)$$

$\mathbf{W}_{eh} \in \mathbb{R}^{m \times h}$  is the new parameter matrix for projecting the entity representation. Figure 2 shows our model with an example path between entities (*Microsoft*, *USA*) with *country-OfHQ* (country of head-quarters) as the query relation.

## 4 Related Work

Two early works on extracting clauses and reasoning over paths are SHERLOCK (Schoenmackers et al., 2010) and the Path Ranking Algorithm (PRA) (Lao et al., 2011). SHERLOCK extracts purely symbolic clauses by exhaustively exploring relational paths of increasing length. PRA replaces exhaustive search by random walks. Observed paths are used as features for a per-target-relation binary classifier. Lao et al. (2012) extend PRA by augmenting KB-schema relations with observed text patterns. However, these methods do not generalize well to millions of distinct paths obtained from random exploration of the KB, since each unique path is treated as a singleton, where no commonalities between paths are modeled. In response, pre-trained vector representations have been used in PRA to tackle the feature explosion (Gardner et al., 2013; Gardner et al., 2014) but still rely on a classifier using atomic path features. Yang et al. (2015) also extract horn rules, but they restrict it to a length of 3 and the literals are restricted to schema types in the knowledge base. Zeng et al. (2016) show improvements in relation extraction by incorporating sentences which

Stats	#
# Freebase relation types	27,791
# textual relation types	23,599
# query relation types	46
# entity pairs	3.22M
# unique entity types	2218
Avg. path length	4.7
Max path length	7
Total # paths	191M

Table 2: Statistics of the dataset.

contain one entity.

Guu et al. (2015) introduce new compositional techniques by modeling additive and multiplicative interactions between relation matrices in the path. However they model only a *single* path between an entity pair in-contrast to our ability to consider multiple paths. Toutanova et al. (2016) improves upon them by additionally modeling the intermediate entities in the path and modeling multiple paths. However, in their approach they have to store scores for intermediate path length for *all* entity pairs, making it prohibitive to be used in our setting where we have more than 3M entity pairs. They also model entities as just a scalar weight whereas we learn both entity and type representations. Lastly it has been shown by Neelakantan et al. (2015) that non-linear composition function out-performs linear functions (as used by them) for relation extraction tasks.

The performance of relation extraction methods have been improved by incorporating entity types for their candidate entities, both in sentence level (Roth and Yih, 2007; Singh et al., 2013) and KB relation extraction (Chang et al., 2014), and in learning entailment rules (Berant et al., 2011). Serban et al. (2016) use RNNs to generate factoid question from Freebase.

## 5 Results

### Data and Experimental Setup

We apply our models to the dataset released by Neelakantan et al. (2015), which is a subset of Freebase enriched with information from ClueWeb. The dataset is comprised of a set of triples  $(e_1, r, e_2)$  and also the set of paths connecting the entity pair  $(e_1, e_2)$  in the knowledge graph. The triples extracted from ClueWeb consists of sentences that contain entities linked to Freebase (Orr et al., 2013). The raw text between the two entities in the sentence forms the relation

type. To limit the number of textual relations, we retain the two following words after the first entity and two words before the second entity. We also collect the entity type information from Freebase. Table 2 summarizes some important statistics. For the PathQA experiment, we use the same train/dev/test split of WordNet dataset released by Guu et al. (2015) and hence our results are directly comparable to them. The WordNet dataset has just 22 relation types and 38194 entities which is order of magnitudes less than the dataset we use for relation extraction tasks.

The dimension of the relation type representations and the RNN hidden states are  $d, h = 250$  and the entity and type embeddings have  $m = 50$  dimensions. The Path-RNN model has sigmoid units as their activation function. However, we found rectifier units (ReLU) to work much better (Le et al., 2015), even when compared to LSTMs (73.2 vs 72.4 in MAP). For the path-query experiment, the dimension of entity, relation embeddings and hidden units are set to 100 (as used by Guu et al. (2015)). As our evaluation metric, we use the average precision (AP) to score the ranked list of entity pairs. The MAP score is the mean AP across all query relations. AP is a strict metric since it penalizes when an incorrect entity is ranked higher above correct entities. Also MAP approximates the area under the Precision Recall curve (Manning et al., 2008). We use Adam (Kingma and Ba, 2014) for optimization for all our experiments with the default hyperparameter settings (learning rate =  $1e^{-3}$ ,  $\beta_1 = 0.9$ ,  $\beta_2 = 0.999$ ,  $\epsilon = 1e^{-8}$ ). Statistical significance for scores reported in Table 3 were done with a paired- $t$  test.

### 5.1 Effect of Pooling Techniques

Section 1 of Table 3 shows the effect of the various pooling techniques presented in section 3.2. It is encouraging to see that *LogSumExp* gives the best results. This demonstrates the importance of considering information from all the paths. However, Avg. pooling performs the worst, which shows that it is also important to weigh the paths scores according to their values. Figure 3 plots the training loss w.r.t gradient update step. Due to non-zero gradient updates for all the paths, the LogSumExp pooling strategy leads to faster training vs. max pooling, which has sparse gradients. This is especially relevant during the early stages of training, where the argmax path is essentially a random

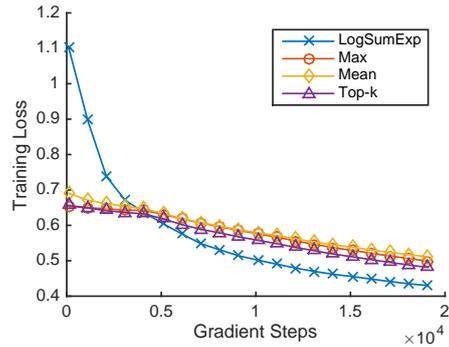

Figure 3: Comparison of the training loss w.r.t gradient update steps of various pooling methods. The loss of LogSumExp decreases the fastest among all pooling methods and hence leads to faster training.

guess. The scores of max and LSE pooling are significant with ( $p < 0.02$ ).

### 5.2 Comparison with multi-hop models

We next compare the performance of the Single-Model with two other multi-hop models - Path-RNN and PRA(Lao et al., 2011). Both of these approaches train an individual model for each query relation. We also experiment with another extension of PRA that adds bigram features (PRA + Bigram). Additionally, we run an experiment replacing the max-pooling of Path-RNN with LogSumExp. The results are shown in the second section of Table 3. It is not surprising to see that the Single-Model, which leverages parameter sharing improves performance. It is also encouraging to see that LogSumExp makes the Path-RNN baseline stronger. The scores of Path-RNN (with LSE) and Single-Model are significant with ( $p < 0.005$ ).

### 5.3 Effect of Incorporating Entities

Next, we provide quantitative results supporting our claim that modeling the entities along a KB path can improve reasoning performance. The last section of Table 3 lists the performance gain obtained by injecting information about entities. We achieve the best performance when we represent entities as a function of their annotated types in Freebase (Single-Model + Types) ( $p < 0.005$ ). In comparison, learning separate representations of entities (Single-Model + Entities) gives slightly worse performance. This is primarily because we encounter many new entities during test time, for

Model	Performance (%MAP)	Pooling
Single-Model	68.77	Max
Single-Model	55.80	Avg.
Single-Model	68.20	Top( $k$ )
Single-Model	<b>70.11</b>	LogSumExp
PRA	64.43	n/a
PRA + Bigram	64.93	n/a
Path-RNN	65.23	Max
Path-RNN	68.43	LogSumExp
Single-Model	<b>70.11</b>	LogSumExp
PRA + Types	64.18	n/a
Single-Model	70.11	LogSumExp
Single-Model + Entity	71.74	LogSumExp
Single-Model + Types	<b>73.26</b>	LogSumExp
Single-Model + Entity + Types	72.22	LogSumExp

Table 3: The first section shows the effectiveness of LogSumExp as the score aggregation function. The next section compares performance with existing multi-hop approaches and the last section shows the performance achieved using joint reasoning with entities and types.

which our model does not have a learned representation. However the relatively limited number of entity types helps us overcome the problem of representing unseen entities. We also extend PRA to include entity type information (PRA + Types), but this did not yield significant improvements.

#### 5.4 Performance in Limited Data Regime

In constructing our dataset, we selected query relations with reasonable amounts of data. However, for many important applications we have very limited data. To simulate this common scenario, we create a new dataset by randomly selecting 23 out of 46 relations and removing all but 1% of the positive and negative triples previously used for training.

Effectively, the difference between Path-RNN and Single-Model is that Single-Model does multitask learning, since it shares parameters for different target relation types. Therefore, we expect it to outperform Path-RNN on this small dataset, since this multitask learning provides additional regularization. We also experiment with an extension of Single-Model where we introduce an additional task for multitask learning, where we seek to predict annotated types for entities. Here, parameters for the entity type embeddings are shared with the Single-Model. Supervision for this task is provided by the entity type annotation in the KB. We train with a Bayesian Personalized Ranking loss of Rendle et al. (2009). The results are listed in Table 4. With Single-Model there is a clear jump in performance as we expect. The additional multitask training with types gives a very incremental gain.

Model	Performance (%MAP)
Path-RNN	22.06
Single-Model	63.33
Single-Model + MTL	64.81

Table 4: Model performance when trained with a small fraction of the data.

#### 5.5 Answering Path Queries

Guu et al. (2015) introduce a task of answering questions formulated as path traversals in a KB. Unlike binary fact prediction, to answer a path query, the model needs to find the set of correct target entities ‘ $t$ ’ that can be reached by starting from an initial entity ‘ $s$ ’ and then traversing the path ‘ $p$ ’. They model additive and multiplicative interactions of relations in the path. It should be noted that the compositional Trans-E and Bilinear-diag have comparable number of parameters to our model since they also represent relations as vectors, however the Bilinear model learns a dense square *matrix* for each relation and hence has a lot more number of parameters. Hence, we compare with Trans-E and Bilinear-diag models. Bilinear-diag has also been shown to outperform Bilinear models (Yang et al., 2015).

Instead of combining relations using simple additions and multiplications, we propose to combine the intermediate hidden representations  $h_i$  obtained from a RNN (via (4)) after consuming relation  $r_i$  at each step. Let  $\mathbf{h}$  denote the sum of all intermediate representations  $h_i$ . The score of a triple  $(s, p, t)$  by our model is given by  $x_s^\top \text{diag}(\mathbf{h})x_t$  where  $\text{diag}(\mathbf{h})$  represents a diagonal

Horn Clause (Body)	Without Entities	With Entities	Universal
$\text{location.contains}(x, a) \wedge \text{location.contains}(a, y)$	0.9149	0.949	Y
$(\text{person.nationality})^{-1}(x, a) \wedge \text{place.birth}(a, y)$	0.7702	0.9256	N

Table 5: Body of two clauses both of which are predictive of  $\text{location.contains}(x, y)$ . First fact is universally true but the truth value of the second clause depends on the value of the entities in the clause. The model without entity parameters cannot discriminate this and outputs a lower overall confidence score.

Model	MQ
Comp. Bilinear Diag	90.4
Comp. Trans-E	93.3
Our Model	<b>98.94</b>

Table 6: Performance on path queries in WordNet.

matrix with vector  $\mathbf{h}$  as its diagonal elements.

We compare to the results reported by Guu et al. (2015) on the WordNet dataset. It should be noted that the dataset is fairly small with just 22 relation types and an average path length of 3.07. More importantly, there are only few *unseen paths* during test time and only *one* path between an entity pair, suggesting that this dataset is not an ideal test bed for compositional neural models. The results are shown in table 6. Mean Quantile(MQ) is the fraction of incorrect entities which have been scored lower than the correct entity. Our model achieves a 84% reduction in error when compared to their best model.

## 6 Qualitative Analysis

**Entities as Existential Quantifiers:** Table 5 shows the body of two horn clauses. Both the clauses are predictive of the fact  $\text{location.contains}(x, b)$ . The first clause is *universally* true irrespective of the entities present in the chain (transitive property). However the value of the second clause is only true *conditional* on the instantiations of the entities. The score of the Path-RNN model is independent of the entity values, whereas our model outputs a different score based on the entities in the chain. We average the scores across entities, which are connected through this path and for which the relation holds in column 3 (With Entities).

For the first clause, which is independent of entities, both models predict a high score. However for the second clause, the model without entity information predicts a lower score because this path is seen in both positive and negative training ex-

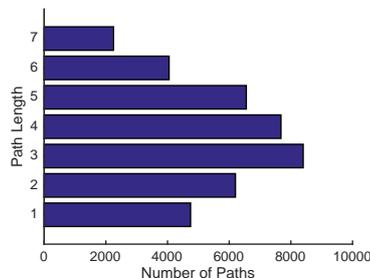

Figure 4: Length distribution of top-scoring paths

amples and the model cannot condition on the entities to learn to discriminate. However our model predicts the true relations with high confidence. This is a first step towards the capturing existential quantification for logical inference in vector space.

**Length of Clauses:** Figure 4 shows the length distribution of top scoring paths in the test set. The distribution peaks at lengths=  $\{3, 4, 5\}$ , suggesting that previous approaches (Yang et al., 2015) which restrict the length to 3 might limit performance and generalizability.

**Limitation:** A major limitation of our model is inability to handle long textual patterns because of sparsity. Compositional approaches for modeling text (Toutanova et al., 2015; Verga et al., 2016) are a right step in this direction and we leave this as future work.

## 7 Conclusion

This paper introduces a single high capacity RNN model which allows chains of reasoning across multiple relation types. It leverages information from the intermediate entities present in the path between an entity pair and mitigates the problem of unseen entities by representing them as a function of their annotated types. We also demonstrate that pooling evidence across multiple paths improves both training speed and accuracy. Finally, we also address the problem of reasoning about infrequently occurring relations and show significant performance gains via multitasking.

## Abstract

Recognizing mentions of Adverse Drug Reactions (ADR) in social media is challenging: ADR mentions are context-dependent and include long, varied and unconventional descriptions as compared to more formal medical symptom terminology. We use the CADEC corpus to train a recurrent neural network (RNN) transducer, integrated with knowledge graph embeddings of DBpedia, and show the resulting model to be highly accurate (93.4 F1). Furthermore, even when lacking high quality expert annotations, we show that by employing an active learning technique and using purpose built annotation tools, we can train the RNN to perform well (83.9 F1).

## 1 Introduction

Identifying medical concepts in social media narratives is the task of recognizing certain phrases in the context of a user's post. Each phrase is also assigned a label from a set of predefined medical types. For instance, given the sentence “*Aspirin cured my terrible headache, but made me sleepy*”, the following medical concepts can be identified: “*Aspirin*” is identified as **Drug**, “*terrible headache*” as a **Symptom** and “*made me sleepy*” should be spotted as a **Adverse Drug Reaction**.

Having an automatic identification process can help domain experts examine large quantities of unstructured data, and quickly identify emerging trends. For example, associating previously unknown side effects with a given drug, or identifying an unforeseen impact to a change in the manufacturing process.

There are several challenges in addressing this task. First, *context* is crucial to type assignment. Compare the previous example with “*Aspirin cured my sleepiness but gave me a terrible headache*”, while the medical concepts are similar, their context determines their particularly associated type label.

The social media domain poses additional challenges. User narratives on social platforms tend to be non-grammatical, use colloquialisms, slang, and generally informal language. For example, a user may express sleepiness as “*hard time getting some Z's*”. This hinders the use of pre-trained statistical parsers or simple string matching techniques.

In this work we focus on the identification of *Adverse Drug Reactions* (ADR). These are unwanted side effects which the user clearly identifies as caused by the intake of a drug. ADRs are particularly challenging to spot, as they can be articulated in a variety of ways and can often be confounded with the symptoms addressed by the drug.

Previous work in this field has mainly used carefully built lexicons and hand-coded rule based systems (Iqbal et al., 2015). While each individual system achieves good results in the particular domain, porting these rules to another domain is non-trivial. For example, identifying psychiatric drug adverse reactions will probably consist of a much different lexicon than that of cardiac medication.

In this work we address ADR mention recognition by with recurrent neural network (RNN) transducers (Graves, 2012). We propose a framework which makes novel use of general, non-task-specific medical knowledge from DBpedia (Lehmann et al., 2015).

Our contributions are two fold: first, we use the high-quality annotation of the CSIRO Adverse Drug Event Corpus (CADEC) (Karimi et al., 2015) to train accurate models, achieving perfor-

\* Work performed while at IBM Research Almaden.

mance of 93.4 F1 on the CADEC test section. Analyzing the performance of our models, we show that the theoretically unbounded memory of the RNN is good at capturing the context of the narratives, and that external DBpedia knowledge provides additional improvements.

Second, in most medical domains there is no large preexisting collection of expert annotation (i.e., gold standard test and training data) and obtaining one is an expensive prospect. We therefore address the following research question: “How quickly can our system converge on ‘good enough’ annotations?”.

For that end, we use only the test portion of CADEC to test a model trained on non-expert annotation. To expedite this process, we use a purpose built annotation tool in conjunction with an active learning technique to sample the most informative examples to annotate. This approach achieves reasonable results in a very short time (83.9 F1 in only one hour of human annotation). We suggest that this framework is a promising avenue for researches exploring low-resource domains, alleviating the need to first commit to an expensive annotation endeavor.

## 2 Background

In this section we describe the CADEC corpus, which we use to train and test our model, and DBpedia, along with the recent paradigm of knowledge graph embeddings integrated into our RNN.

### 2.1 CSIRO Adverse Drug Event Corpus

The recently created CSIRO Adverse Drug Event Corpus (CADEC) (Karimi et al., 2015) contains medical concepts annotation in posts from `Ask a Patient`<sup>1</sup>, an online forum collecting medical patient narratives.

For example, a forum entry regarding a certain drug starts with “*I experienced one night of agonising upper stomach pain, diarrhoea and sleeplessness*”.

CADEC used `brat` (Stenetorp et al., 2012) to annotate five types of medical concepts: (1) *Drug*, names of medicine or drug, e.g., “*Diclofenac*” or “*Aspirin*”; (2) *Adverse Drug Reaction*, an unwanted reaction which according to the text is clearly associated with taking the drug, e.g., “*acute stomach pain*”; (3) *Disease*, the reason for taking the drug, e.g., “*insomnia*” or “*aggression*”;

<sup>1</sup><http://www.askapatient.com>

(4) *Symptom*, manifestations of the disease, e.g., “*trouble sleeping*” or “*constantly angry*”; and finally (5) *Finding*, a clinical finding that does not pertain to any of the above categories.

Each annotation consists of a word span (possibly non-contiguous) and a mapping of the marked span to medical ontologies (SNOMED (Cote et al., 1977), AMT<sup>2</sup>, and MedDRA (Brown et al., 1999)).

Each post is annotated by either a medical student or a computer scientist, screened by the authors of the papers, and finally reviewed by a clinical terminologist. The annotations spanned 1,244 posts relating to 12 drugs divided into two groups (medications with Diclofenac as an active ingredient, and Lipitor). Corpus statistics are presented in Table 1.

In the course of this work we will use the CADEC Adverse Drug Reaction annotations to train and test our models.

### 2.2 DBpedia and Knowledge Graph Embeddings

DBpedia is a large-scale cross-domain multilingual knowledge base extracted from Wikipedia (Lehmann et al., 2015). DBpedia uses a schema with over 320 entity types and 1,600 property types to describe nearly 4 million entities. Besides the common Person, Location and Organization entity types, it also includes descriptions of drugs, diseases, symptoms and disorders, among others.

Using a knowledge graph such as DBpedia requires an intimate knowledge of its entity and relation types, as well as its subtle representation decisions. This creates challenges with using knowledge graphs in a machine learning (ML) setting, where the signals are coming from different sources and are often normalized and assimilated to make the final prediction.

<sup>2</sup><https://goo.gl/xRCGPN>

	Train	Test	All
# Posts	935	309	1244
# Sentences	5723	1874	7597
# Words	95979	31855	127834
# Unique Words	5788	3373	9161

Table 1: Statistics for the CADEC corpus (See section 2).

In order to allow ML algorithms to make use of the information encapsulated in such graphs, a recent line of work (Bordes et al., 2011; Bordes et al., 2013; Wang et al., 2014; Ji et al., 2016) has compellingly suggested to embed entities as  $d$  dimensional dense real vectors, and relations as two projection matrices:  $R^{lhs}$  and  $R^{rhs}$ . Similarly to word embedding techniques (Collobert et al., 2011; Mikolov et al., 2013), a deep learning model is trained to differentiate between observed (positive) and non-observed (negative) triples, by minimizing the following score for positive triples ( $E_i, R, E_j$ ):

$$\|R^{lhs}E_i - R^{rhs}E_j\| \quad (1)$$

During training, the model learns the entity and relation embeddings, desirably encoding some of the semantics and co-occurrence information of the original knowledge graph.

### 3 Recognizing Mentions of Adverse Drug Reaction

In this section we formally define the task of in-context recognition of Adverse Drug Reactions (ADR) mentions and describe our proposed problem modeling.

#### 3.1 Task Formulation

We follow CADEC’s definition for ADR, as described in Section 2.

Formally, we define the ADR mention recognition task as a sentence level chunking task, where each word can either be: (1) Beginning of an ADR span (B); (2) Inside an ADR span (I); or (3) Outside of the span of an ADR (O);

For example (tags in subscript):

“ $I_o$  stopped $_o$  taking $_o$  Ambien $_o$  after $_o$  three $_o$  weeks $_o$  –  $i_o$  gave $_o$  me $_o$  a $_o$  terrible $_B$  headache $_I$ ”

This formulation, termed BIO tagging (Ramshaw and Marcus, 1995; Sang and Veenstra, 1999), is equivalent to noun phrase (NP) chunking annotation convention with a single type of NP.

While Ratinov and Roth (2009) have shown that a more elaborate tagging scheme (BILOU)<sup>3</sup> improved performance in their experiments in Named Entity Recognition, those experiments are out of the scope for this work.

<sup>3</sup>BILOU uses tags for: Beginning, Inside, Last and Unit length chunks.

This task depends heavily upon context, as the same word span can appear as an ADR in one text, and as a Symptom in another. For example, the first entry in Table 2 mentions several ADRs (“made me gain 30 lbs”, “made my BP go up so high”, “gave me more anxiety”) associating each with a different drug (“Klonopin”, “Lexapro”, etc.), while the second entry in the table uses some of the same surface forms to refer to an addressed Symptoms (e.g., “It helped both my anxiety and IBS”).

Furthermore, our model will need to cope with texts from social media which tend to be colloquial, non-grammatical, variably spelled and overall employ highly informal phrasing. The rest of the entries in Table 2 present several snippets from the Ask a Patient corpus, illustrating some of these challenges.

#### 3.2 Recurrent Neural Networks Transducer

Formulated this way, and given that the sentences in Ask a Patient are of arbitrary length, it seems applicable to model the task using Recurrent Neural Networks (RNNs). This approach was proven to be effective in many recent NLP papers. For a recent and extensive survey of RNNs in NLP see (Goldberg, 2015).

Specifically, we use a bi-directional LSTM transducer (Graves, 2012) which outputs a probability distribution over the three possible labels (B, I, and O) per word, taking into account arbitrary length contexts from both past as well as future words.

**Pretrained word embeddings** It is common in recent neural networks frameworks to initialize the model’s word embeddings with pretrained parameters, from a much larger (often unsupervised) corpus. We experiment with initializing our word embeddings from both out of domain (and out of the box) word embeddings from Google (Mikolov et al., 2013), as well as with purpose trained embeddings utilizing predicate-argument structure from Open-IE (Etzioni et al., 2008) (following (Stanovsky et al., 2015)) from the Blekko medical corpus (a 2GB corpus of web pages categorized as “medical domain” by the Blekko search engine<sup>4</sup>).

#### 4 Augmenting RNNs with DBpedia

Despite the original motivation for knowledge graph embedding, few efforts were made to use

<sup>4</sup><https://en.wikipedia.org/wiki/Blekko>

Text Snippet	Challenges
"I've tried Klonopin which gave me nightmarish side effects, Lexapro which made me gain 30 lbs and that gave me more anxiety and borderline depression, Effexor which made my BP go up so high I was hospitalized for 4 days (high bp runs in the family), and Buspar which did n't even touch my anxiety."	Long post describing Adverse Drug Reactions caused by various previous drugs.
"It helped both my anxiety and IBS immensely."	Describes cure from symptoms (not ADRs).
"After the second pill the same progression of symptoms only now the abdominal gas, cramps and pain would be with me all day."	Coordination leads to non-contiguous ADR spans (" <i>abdominal cramps</i> ", " <i>abdominal pain</i> ").
"I had the usual problems as most people. Driving, buying things online, cooking, eating, sexual activity."	The qualifier "while asleep" is implied by "as most people" but never explicitly stated.
"Short term more loss"	Ungrammatical.
"started having tension headaches. did not relate to Ambien."	The first sentence implies ADRs, while the second negates them.

Table 2: Examples from the Ask a Patient forum.

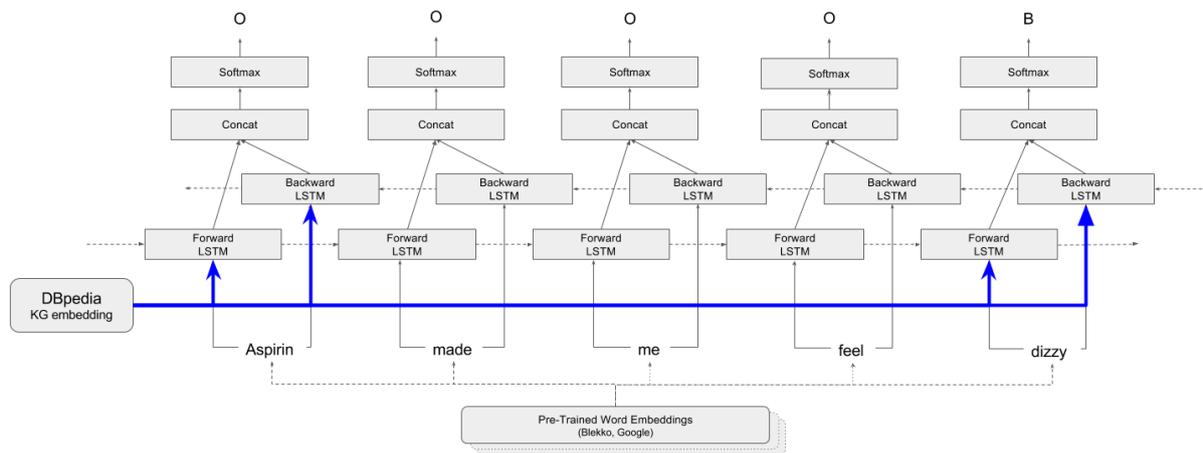

Figure 1: The bi-LSTM transducer, integrated with DBpedia knowledge graph embedding (left). We experiment with several corpora for training external word embeddings (bottom) and override them for DBpedia concepts (e.g., “Aspirin”, “dizzy”). See Sections 3 and 4 for details.

such embeddings as components in larger NLP frameworks. Instead, previous research has focused on embedding techniques, as outlined in section 2. In this section we describe a novel framework which utilizes DBpedia concepts embeddings, in addition to the common use of pre-trained word embeddings. We specifically use DBpedia due to its good coverage of our domain of interest. Furthermore, since it relies on Wikipedia, it might also be applicable for non-medical domains. The presented approach, however, is not limited to any particular knowledge base and in future work we plan to extend it beyond DBpedia.

The motivation for using external knowledge bases in our case stems from the relatively small size of the CADEC corpus (see Table 1), in comparison with other neural models training corpora. For example, The Penn Treebank (Marcus et al., 1993) which is often used for training dependency parsing algorithms, consists of roughly 7M tokens, versus only about 95K tokens in CADEC.

#### 4.1 Overriding Word Embeddings with DBpedia Concepts

We augment our model with a pretrained knowledge graph embedding of the “Drug” and “Disease” categories from DBpedia, training as discussed in Section 2.2. When a word in a CADEC entry is a lexical match with one of the DBpedia entities we override its features with the DBpedia embeddings. Intuitively, this framework introduces complex semantic relations between prominent and task relevant words in the Ask a Patient posts. For example, DBpedia draws “Aspirin” and “Ibuprofen” closer in the embedding space as both appear under the “Non-steroidal anti-inflammatory drug” category (a relation which is modeled in DBpedia). While this changes the embedding of a small subset of the words, these are meaningful and frequently occurring in our setting (see details in Section 6).

Figure 1 shows the complete architecture of our model, including the RNN transducer LSTM and the pretrained word embeddings augmented with DBpedia entity embeddings. The loss from the network propagates back to the word embeddings, allowing them to assimilate task-specific information during training.

## 5 Human in the Loop

From our experience, real world applications often do not have a pre-existing rich gold standard corpus from which they can efficiently train high quality models. This lack creates a serious impediment to entering and exploring the opportunities for text analytics in such domains, due to the high cost of producing the requisite semantic assets.

The medical domain is one where this is especially true. Even within a particular specialty, e.g., oncology, very different information may need to be extracted depending on the type of cancer being explored. In domains where the patient’s verbatim comments are critical (e.g., psychiatric, physical rehabilitation) there can be even more variability and ambiguity. For instance, a comment of feeling “pins and needles” could be a result of peripheral neurological issues, or a panic attack, and may be expressed with multiple misspellings, punctuation and grammar variations.

To that end, we test our suggested model in a human-in-the-loop approach to gauge how quickly an analytic developer might obtain “good enough” training and test data to develop first generation code and begin to explore the results.

To simulate this for an experiment, we ignore the CADEC training annotations and instead interleave adjudication of small batches (100 sentences) with iterations of model training (see Figure 2). To allow for these fast iterations we need to provide solutions in several areas. For quicker annotation, we developed RASCAL (Rapid Adjudication of Semantic Classes to Accelerate Learning), a purpose built annotation tool which expedites the annotation and adjudication process. Furthermore we employ an active learning technique to focus the human adjudicator’s time on examples that the model finds most confusing.

This process, as elaborated below, has two outcomes: (1) Expedited machine-assisted production of an annotated gold standard; and (2) Rapid training of high precision models due to the active learning technique.

### 5.1 Bootstrap

While the learning process can be initiated by simply beginning to annotate the corpus, we find a more rapid start up is achieved by employing an extensive lexicon of Adverse Drug Reaction phrases. Fortunately, lexicon expansion techniques (Codon et al., 2012) provide a way to

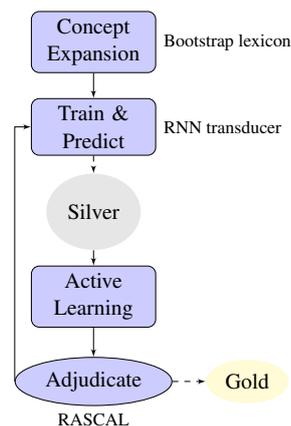

Figure 2: Train-Predict-Adjudicate loop

rapidly bootstrap this portion of the problem. Typically the user provides a few ( $\sim 3$ ) examples of the type desired, and the system comes back with dozens of suggestions of potential new phrases. The user approves or rejects these and the system repeats with this additional knowledge. The process typically generates a couple of hundred candidate terms in a few minutes.

### 5.2 Active Learning

The bootstrap lexicon can then be used to obtain a preliminary noisy CADEC training set for the RNN, by marking each occurrence of a lexicon term as an ADR. After we train our model, we want to choose informative samples to adjudicate and refine our training set (and subsequently, our model) in the next iteration.

A process in which a model chooses its next training examples is often referred to as *active learning*, and is a well researched area of machine learning (see (Settles, 2010) for an extensive survey). For our purposes, we use the uncertainty sampling criterion (Lewis and Gale, 1994). Intuitively, this ranks the samples according to the model’s belief it will mislabel them.

Formally, we sort all samples  $(x, y)$  according to the following measure:

$$1 - \Pr(\hat{y}|x) \quad (2)$$

Where:

$$\hat{y} = \operatorname{argmax}_{y \in \{B, I, O\}} \Pr(y|x) \quad (3)$$

We choose the top 100 samples according to this metric, and adjudicate them, as described below. In order to assess the impact of this step we also perform the same process with random sampling of 100 sentences at each iteration.

### 5.3 Adjudication

At this stage, a human adjudicator examines the sentences chosen in the previous phase. They then either accept or reject each automatically recognized ADR span in these sentences. Additionally the annotator can mark new spans that were missed.

While the `brat` annotator (Stenetorp et al., 2012) is a popular tool for creating and modifying annotations, it is a bit cumbersome and error prone for tasks such as the one outlined in CADEC.

Notably, the CADEC creators mention that the `brat` annotations required an additional cleaning phase. For example `brat` annotates character spans instead of aligning marked spans to the word level (e.g. an annotator might wrongfully mark “*pai*” instead of “*pain*”). While some of `brat`’s more complex features are a good fit for other annotation tasks, they reduce agility and do not add much value in ours. We therefore implemented a simple rapid adjudication system (code-named RASCAL) that is tuned to the particular task of adjudicating and adding annotations in the context of ADR mention recognition.

RASCAL introduces simplifications such as single click removal of incorrect annotations, automatic alignment of the spans to include whole tokens, and single key “approve and move to next document” support. This results in very fast annotation times. As the system improves its understanding of the entity to tag, much of the annotator’s time is spent simply approving annotations, with about one in four requiring their addition of a missed span.

Over the 1,100 annotations we found an average time of about 3 seconds per sentence. In a controlled experiment comparing the annotation of 100 sentences in `brat` versus RASCAL, this represented at least a four fold improvement over comparable `brat` times without pre-annotation. Since we find `brat` is slower at removing errors and entering split annotations we anticipate the discrepancy may be even higher with pre-annotation.

This improvement does have a cost, however; RASCAL only allows a single annotation type at a time, so the annotation of two predefined types (e.g., Drug and ADR) requires two passes. Second, RASCAL does not support non-contiguous span annotations. This is of especial trouble when there are coordinated spans (e.g., “*my neck and*

*back are both spasming*” should be “*neck spasming*” and “*back spasming*”).

While these were uncommon in our corpus (see detailed analysis in Section 6), it does suggest that perhaps performing some of the annotations with `brat` after doing the initial ones with RASCAL might help improve precision if desired.

### 5.4 Repeat

Given these adjudicated annotations, we can refine our bootstrap lexicon (with the newly acquired ADR mentions) and automatically re-annotate the entire training corpus according to it, generating a new iteration of the training data which closes the loop back to training and predicting (Section 5.2).

Knowing when to stop is always a challenge with learning systems. For the sake of these experiments we chose to stop after an hour of an annotator time (the initial lexicon expansion bootstrap and annotating/adjudicating 1,100 sentences).

However the human annotator using RASCAL gets a fairly good sense of what kind of annotations are being spotted and what is being missed. By looking at the net change in the pre-annotation to post-annotation spans for an iteration it is possible to get a sense of when the learning is leveling off.

In future work, it may also be possible to look at the total uncertainty the RNN finds in the training corpus before and after a training session as a measure of how much more productive learning there may be left.

## 6 Evaluation

In this section we evaluate our recurrent neural transducer in two scenarios: (1) Using the high quality annotations of the CADEC corpus and (2) Simulating a task with low resources in an active learning scenario and using RASCAL for non-expert annotations, as described in Section 5. Results are shown in Table 3.

**Label imbalance** The CADEC corpus is imbalanced between the different labels, assigning the label “O” (Outside) to 87.34% of the words. This is due to the fact that most of the text in the `Ask a Patient` forum describes background situation and is not directly related to an ADR (see, for example, the first entry in Table 2). This poses a problem for training accuracy oriented models, as such imbalanced class distribution discourages the learning process to move from a model which

assigns a constantly higher probability to the Outside label, regardless of the input sentence (He and Garcia, 2009). Subsequently, this leads to trivial solutions which achieve 0% ADR recall (as no ADRs are retrieved) and 100% ADR precision (as there are also no false positives).

To address this problem we use the SMOTE (Synthetic Minority Over-Sampling) technique (Chawla et al., 2002) which skews the sample distribution by oversampling the minority classes (B and I) during training to get a synthetically balanced training set.

## 6.1 Experimental setup

We implemented the bi-LSTM transducer model using the Keras framework (Chollet, 2015) with a TensorFlow backend (Abadi et al., 2015). Open IE word embeddings (300 dimensions) were trained on Blekko medical corpus (1 billion tokens) using Open IE 4<sup>5</sup> and Word2Vec (Mikolov et al., 2013), as described in (Stanovsky et al., 2015). For DBpedia embeddings (300 dimensions), we used the code published in (Nickel et al., 2015). We used the code published in (Lemaître et al., 2016) for SMOTE class resampling. Finally, we used the `libact` library (Yang et al., 2015) for the active learning sampling. All models were trained for 100 epochs.

## 6.2 Results

Several observations can be made based on the results of our experiments (Table 3):

**RASCAL achieves good results at a fraction of the annotation effort** - RASCAL results are obtained after just 11 cycles of annotation by single annotator (roughly an hour of work), and are then tested against the independently annotated test set of CADEC. The performance of RASCAL is a promising indication that adequately performing models can be obtained very quickly using our framework, when moving to a new annotation task where training data is scarce.

**External knowledge improves performance in both scenarios** - As can be seen from the ablation test in Table 3, in both supervised and annotator development settings, our pretrained embeddings improve performance by at least 13 points

<sup>5</sup><https://github.com/allenai/openie-standalone>

in F1, with a significant edge to Blekko embeddings. This is in part due to its better coverage of the CADEC lexicon, only 408 (7.05% of the CADEC lexicon) unique words were Out Of Vocabulary (OOV) using Blekko, compared with 724 (12.51%) OOV words using Google’s embedding. DBpedia provides embeddings for 232 words (4%) and further adds 2-4 points in both recall and precision.

## Uncertainty sampling boosts the learning rate

- Figure 3 shows the progression of the best performance obtained at each training iteration. The uncertainty sampling (see Section 5.2) boosts the learning curve, achieving models performing around 80 F1 after just 25 minutes of RASCAL annotation (note the red vertical dotted line).

The relatively small change when increasing the number of annotated instances from 400 to 800 (i.e., before and after the vertical dotted line) is probably due to the long tail nature of the problem: active learning chooses the most prominent examples first, then there is a sharp decline in the novelty of the chosen examples. Further experimentation with active learning techniques may improve performance, yet this falls out of the scope of this paper, and is left as a topic for future research. Overall, it can be seen from Figure 3 that our active learning technique is indeed already superior to random sampling (notice the brown dotted line indicating performance with random sampling).

**Context matters** - We tested an oracle ADR baseline which had access to the lexicon of all of the ADRs in CADEC. This oracle ignored context and marked every occurrence of a phrase from the lexicon as an ADR. As can be seen in Table 3 (ADR Oracle), this baseline obviously achieves 100% recall, yet, more interestingly, it achieves only 55.2% in precision. Thus in 44.8% of the cases the surrounding context negated the ADR phrase (for example, see the last entry in Table 2).

## 6.3 Error analysis

In analyzing the RASCAL model, we find that it relatively lacks in recall. This is due to our limited annotation effort having predictably limited coverage. Examining our annotations, we find 449 unique ADRs annotated in RASCAL out of the total 3685 unique ADR phrases in the full CADEC annotation. The RNN model is in fact able to generalize these mentions and find approximately

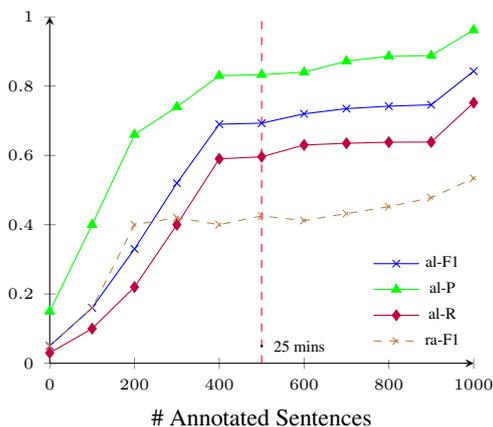

Figure 3: Model performance per annotation cycle (see Section 6). Solid lines represent precision, recall and F1 for active learning, and the dashed line represents F1 for random sampling (precision and recall follow the same trend and are omitted for clarity).

	P	R	F1
String matching	78.6	37.0	50.3
RASCAL	64.0	53.8	58.0
RASCAL+ Google	88.4	68.2	76.8
RASCAL+ Blekko	91.3	70.0	79.4
<b>RASCAL+ DBpedia+ Blekko</b>	<b>96.2</b>	<b>75.2</b>	<b>83.9</b>
ADR Oracle	55.2	100	71.1
CADEC	69.6	74.6	71.9
CADEC + Google	85.3	86.2	85.7
CADEC + Blekko	90.5	90.1	90.3
<b>CADEC + DBpedia+ Blekko</b>	<b>92.2</b>	<b>94.5</b>	<b>93.4</b>

Table 3: Performance of the different baselines by training from RASCAL annotations (top) vs. CADEC training data (bottom). See Section 6 for more details.

75% of the mentions, yet it is likely that having a larger RASCAL training set would help improve the coverage of our model. Furthermore, the design choices made in RASCAL trade annotation speed with accuracy. As mentioned in Section 5.3 RASCAL is currently unable to annotate non-contiguous spans, which account for 1005 (15.9%) of the ADRs annotated in CADEC.

Finally, both of our models predict BIO word labels at the sentence level which in some cases does not provide enough context to arrive at the correct label. See, for example, the bottom example in Table 2, in which a very probable ADR phrase in the first sentence (“*tension headaches*”) is negated in the second sentence (“*did not relate to Ambien*”).

## 7 Related Work

To the best of our knowledge, there has been no previous work attempting to recognize in-context adverse drug reaction mentions on the CADEC corpus. There are, however, several papers which addressed the same task on a different corpus, and others who have used the CADEC corpus for orthogonal tasks. In this section we survey two such recent papers.

Limsopatham and Collier (2016) have used CADEC for the normalization of medical concepts. They take as input an out-of-context ADR (e.g., “*I couldn’t sleep all night*” or “*head explodes*”) and predict its normalized form (e.g., “*insomnia*” or “*headache*”, respectively), based on a predefined vocabulary. They use an RNN model and report accuracy of 79.98. This task can be seen a subsequent task to ours. The ADR spans we output can serve as an input for ADR normalization, giving medical experts a consolidated summary of the reported adverse events.

Iqbal et al. (2015) share our motivation to identify ADR mentions in the context of electronic health records (medical correspondence, discharge letters, etc.), which are more formal, as opposed to our focus on social media domain. They take a rule based approach, and come up with an expert built lexicon, which achieves 85 F1 on their test set.

While their approach is carefully built to the specific data set, we show the portability of our model by testing both in a supervised scenario as well as in annotation development scenario.

## 8 Conclusions and Future Work

We presented a novel model which consists of an LSTM transducer RNN augmented with external knowledge from medically oriented Web crawl and a knowledge graph embedding of medical entities in DBpedia. We showed that the model achieves good results (93.4 F1) when trained and tested on the CADEC corpus.

Furthermore, ignoring the CADEC training data, we showed that through active learning and a task-dedicated annotation tool we can get a reasonably performing model (83.95 F1 on CADEC’s test set) with just an hour of annotation effort. This suggests a promising methodology for researchers wanting to explore new domain annotations, without first committing to a heavyweight and expensive annotation effort.

Future work may make further use of the CADEC annotations (e.g., for multi-task learning or concept normalization), and extend RASCAL to get better recall and allow for non-contiguous and multiple label annotations.

## Acknowledgments

We would like to thank the IBM Almaden Intelligence Augmentation Team (Alfredo Alba, Linda Kato, Chris Kau, Joe Terdiman and Steve Welch) for many fruitful discussions, and the anonymous reviewers for their helpful comments.

## Abstract

Language contains information about the author’s demographic attributes as well as their mental state, and has been successfully leveraged in NLP to predict either one alone. However, demographic attributes and mental states also interact with each other, and we are the first to demonstrate how to use them jointly to improve the prediction of mental health conditions across the board. We model the different conditions as tasks in a multitask learning (MTL) framework, and establish for the first time the potential of deep learning in the prediction of mental health from online user-generated text. The framework we propose significantly improves over all baselines and single-task models for predicting mental health conditions, with particularly significant gains for conditions with limited data. In addition, our best MTL model can predict the presence of conditions (neuroatypicality) more generally, further reducing the error of the strong feed-forward baseline.

## 1 Introduction

Mental health conditions, like depression or anxiety, are still one of the leading causes of death worldwide. Suicide, often the direct outcome of mental health conditions, is the 11th most frequent cause of death in the US (Anderson, 2001). Detecting mental health risk factors early is key to preventing many of these deaths. Unfortunately, traditional diagnosis methods require access to and willingness to talk with a psychologist, and rely mainly on impressions formed during short

sessions. Consequently, conditions leading to preventable suicides can often not be accurately diagnosed.

Automated monitoring and risk assessment of patients’ language have the potential to overcome the logistic and time constraints associated with traditional assessment methods. Written text carries implicit information about the author, a relationship that has been exploited in natural language processing (NLP) to predict author characteristics, such as age (Goswami et al., 2009; Rosenthal and McKeown, 2011; Nguyen et al., 2011; Nguyen et al., 2014), gender (Sarawgi et al., 2011; Ciot et al., 2013; Liu and Ruths, 2013; Alowibdi et al., 2013; Volkova et al., 2015; Hovy, 2015), personality and stance (Schwartz et al., 2013b; Schwartz et al., 2013a; Volkova et al., 2014; Plank and Hovy, 2015; Park et al., 2015; Preotiuc-Pietro et al., 2015), or occupation (Preotiuc-Pietro et al., 2015a; Preotiuc-Pietro et al., 2015b). The same signal has also been effectively used to predict mental health conditions, such as depression (Coppersmith et al., 2015b; Schwartz et al., 2014), suicidal ideation (Coppersmith et al., 2016; Huang et al., 2015), schizophrenia (Mitchell et al., 2015) or post-traumatic stress disorder (PTSD) (Pedersen, 2015), often more accurately than by traditional diagnoses.

However, these studies typically model each condition in isolation and ignore other author attributes that can improve prediction, thereby artificially limiting performance. Existing research, however, indicates that 1) incorporating demographic attributes can help text classification (Volkova et al., 2013; Hovy, 2015), and 2) learning several auxiliary tasks which share common structures (e.g., part-of-speech tagging, parsing, and NER) can improve performance, as the learning implicitly exploits interactions between the tasks (Caruana, 1993; Sutton et al., 2007; Rush et al.,

<sup>1</sup>Now at Google Research.

2010; Collobert et al., 2011; Sogaard and Goldberg, 2016).

In this paper, we propose such a multitask learning (MTL) approach to mental health prediction. The main tasks of our model are predictions of *neurotypicality* (i.e., the absence of any mental health conditions), *anxiety*, *depression*, *suicide attempt*, *eating disorder*, *panic attacks*, *schizophrenia*, *bipolar disorder*, and *post-traumatic stress disorder (PTSD)*. All of the above, plus gender prediction, also serve as auxiliary tasks.

The auxiliary tasks reflect the observation that several conditions frequently occur together (comorbidity), and that they correlate with demographic factors. The MTL framework allows us to share information across predictions. We use a neural architecture that enables the inclusion of several loss functions with a common shared underlying representation. This experimental setup is flexible enough to extend this model to further factors than the ones shown here, provided suitable data.

We also explore the effect of auxiliary-task selection on model performance for a given prediction task. Similar to Caruana (1996), we find that choosing auxiliary tasks which are prerequisites or related to the main task is critical for learning a strong model.

### Our contributions

1. We are the first to apply MTL to predict mental health conditions from user content on Twitter – a notoriously difficult task (Coppersmith et al., 2015a; Coppersmith et al., 2015b).
2. We explore the influence of auxiliary-task selection on prediction performance, including the effect of gender
3. We show how to model tasks with a *large* number of positive examples to improve the prediction accuracy of tasks with a *small* number of positive examples.
4. We increase the True Positive Rate at 10% false alarms by up to 9.7% absolute (for anxiety), a result with direct impact for clinical applications.

## 2 Model Architecture

We opt for a neural architecture to exploit the synergies between mental conditions. Our choice is based on practical more than ideological reasons: previous work (Collobert et al., 2011; Caruana,

1996; Caruana, 1993) has indicated that this is a promising model architecture, which allows us to share parameters across tasks, can be trained on large amounts of data, and accounts for varying degrees of annotation across tasks.<sup>1</sup>

Even within the neural model framework, however, there are many variations to consider. In the following, we outline some attributes and decisions.

Previous approaches have shown considerable improvements over single task models by using MTL (Caruana, 1993). The arguments are convincing: predicting multiple related tasks should allow us to exploit any correlations between the predictions.

However, we note that the benefit of using a MTL model is only one possible explanation, and that another, more salient factor might have been overlooked: the difference in the general model class, i.e., neural architectures vs. discriminative or generative models, or, more generally, the *expressivity* of the model. Some comparisons might therefore have inadvertently compared apples to oranges.

We compare the multitask demographics and risk prediction with models with equal expressivity. We evaluate the performance of a standard logistic regression model (a standard approach to text-classification problems), a multilayer perceptron single-task learning (STL) model, and a neural MTL model, the latter two with equal numbers of parameters. This ensures a fair comparison by isolating the unique properties of MTL from the dimensionality-reduction aspects of deep architectures in general.

The neural models we evaluate come in two forms. The first, depicted in plate notation in Figure 1, is the STL model. These are feedforward networks with two hidden layers, trained independently to predict each task. On the right of Figure 1 is the MTL model, where the first hidden layer from the bottom is shared between all tasks. An additional per-task hidden layer is used to give the model flexibility to map from the task-agnostic representation to a task-specific one. Each hidden layer uses a rectified linear unit as non-linearity. The output layer uses a logistic non-linearity, since all tasks are binary predictions.

---

<sup>1</sup>We also experimented with a graphical model architecture, but found that it did not scale as well and provided less traction.

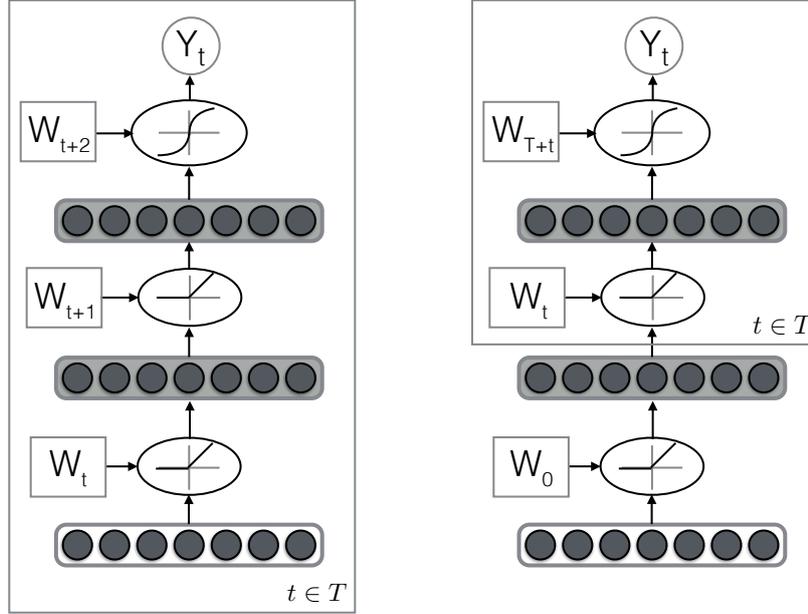

Figure 1: STL model in plate notation (left): weights trained independently for each task  $t$  (e.g., anxiety, depression) of the  $T$  tasks. MTL model (right): shared weights trained jointly for all tasks, with task-specific hidden layers.

Curves in ovals represent the type of activation used at each layer (rectified linear unit or sigmoid). Hidden layers are shaded.

The MTL model can easily be extended to a stack of shared hidden layers, allowing for a more complicated mapping from input to shared space.<sup>2</sup>

As noted in (Collobert et al., 2011), MTL benefits from mini-batch training, which both allows optimization to jump out of poor local optima, and take more stochastic gradient steps in a fixed amount of time (Bottou, 2012). In that paper, the authors use a randomized selection over the tasks to train. In our paper, we create mini-batches by sampling from the users in our data. Each of these users has some subset of the mental conditions we are trying to predict, and may or may not be annotated with gender. At each mini-batch gradient step we update weights for all tasks. This not only allows for randomization and faster convergence, it also provides a speed-up over the individual selection process in (Collobert et al., 2011).

One of the advantages of our setup is that we do not need complete information for every instance: instead, learning can proceed with asynchronous updates dependent on what the data in each batch

<sup>2</sup>We tried training a 4-shared-layer MTL model to predict targets on a separate dataset, but did not see any gains over the standard 1-shared-layer MTL model in our application.

has been annotated for, while sharing representations throughout. This effectively learns a joint model with a common representation for several different tasks, and allows the use of several “disjoint” data sets, some with limited annotated instances.

**Optimization and Model Selection** Even in a relatively simple neural model, there are a number of parameters that can (and have to) be tuned to achieve good performance. We perform a line search for every model we use, sweeping over  $L_2$  regularization and hidden layer width. We select the best model based on the development loss. Figure 5 shows the performance on the corresponding test sets (plot smoothed by rolling mean of 10 for visibility).

In our experiments, we sweep over the  $L_2$  regularization constant applied to all weights in  $\{10^{-4}, 10^{-3}, 10^{-2}, 0.1, 0.5, 1.0, 5.0, 10.0\}$ , and hidden layer width (same for all layers in the network) in  $\{16, 32, 64, 128, 256, 512, 1024, 2048\}$ . We fix the mini-batch size to 256, and 0.05 dropout on the input layer. We found that choosing a small mini-batch size and the model with low-

Task	# of users
Neurotypicality	4820
Anxiety	2407
Depression	1400
Suicide attempt	1208
Eating disorder	749
Schizophrenia	349
Panic disorder	263
Bipolar disorder	234
PTSD	191
Female   Male	788   248
total	9611

Table 1: Number of users with each self-stated condition and human-annotated gender in the joined dataset.

est development loss was sufficient to account for overfitting.

We train each model for 5,000 iterations, jointly updating all weights in our models. After this initial joint training, we select each task separately, and only update the task-specific layers of weights independently for another 1,000 iterations (selecting the set of weights achieving lowest development loss for each task individually). Weights are updated using mini-batch Adagrad (Duchi et al., 2011) – we found this to converge more quickly than other optimization schemes we experimented with. We evaluate the tuning loss every 10 epochs, and evaluate the model with the lowest tuning loss.

### 3 Data

We train our models on a union of multiple Twitter user datasets: 1) users identified as having anxiety, bipolar disorder, depression, panic disorder, eating disorder, PTSD, or schizophrenia (Coppersmith et al., 2015a), 2) those who had attempted suicide (Coppersmith et al., 2015c), and 3) those identified as having either depression or PTSD from the 2015 Computational Linguistics and Clinical Psychology Workshop shared task (Coppersmith et al., 2015b), along with neurotypical gender-matched controls (Twitter users not identified as having a mental condition). Users were identified as having one of these conditions if they stated explicitly they were diagnosed with this condition on Twitter (verified by a human annotator). For a subset of 1,101 users, we also have manually-annotated gender. The final dataset contains 9,611 users in total, with an average of 3521 tweets per

user. The number of users with each condition is included in Table 1. Users in this joined dataset may be tagged with multiple conditions, thus the counts in this table do not sum to the total number of users.

We use the entire Twitter history of each user as input to the model, and split it into character 1-to-5-grams, which have been shown to capture more information than words for many Twitter text classification tasks (McNamee and Mayfield, 2004; Coppersmith et al., 2015a). We compute the relative frequency of the 5,000 most frequent  $n$ -gram features for  $n \in \{1, 2, 3, 4, 5\}$  in our data, and then feed this as input to all models. This input representation is common to all models, allowing for fair comparison.

## 4 Experiments

Our task is to predict any number of mental conditions for each of the users in these data, possibly using gender prediction as an auxiliary task to improve our prediction performance.

We evaluate three classes of models: a baseline logistic regression over character  $n$ -gram features (LR), feed-forward multilayer perceptrons trained to predict each task separately (STL), and a multi-task network predicting a set of conditions simultaneously (MTL). We also perform ablation experiments, to see which subsets of auxiliary tasks help us learn an MTL model that predicts a particular mental condition best. For all experiments, data were divided into five equal-sized folds, three for training, one for tuning, and one for testing (we report the performance on this).

All our models are implemented in Keras<sup>3</sup> with Theano backend and GPU support. We train the models for a total of up to 15,000 epochs, using mini-batches of 256 instances. Training time on all five training folds ranged from one to eight hours on a machine with Tesla K40M.

**Evaluation Setup** We compare the accuracy of each model at predicting each task separately.

In clinical settings, we are interested in minimizing the number of false positives, i.e., incorrect diagnoses, which can cause undue stress to the patient. We are thus interested in bounding this quantity. To evaluate the performance, we plot the false positive rate (FPR) against the true positive rate (TPR). This gives us a receiver operating characteristics (ROC) curve, allowing us to inspect the

<sup>3</sup><http://keras.io/>

performance of each model on a specific task at any level of FPR.

While the ROC gives us a sense of how well a model performs at a fixed true positive rate, it makes it difficult to compare the individual tasks at a low false positive rate, which is also important for clinical application. We therefore report two more measures: the area under the ROC curve (AUC) and TPR performance at FPR=0.1 (TPR@FPR=0.1). We do not compare our models to a majority baseline model, since this model would achieve an expected AUC of 0.5 for all tasks, and F-score and TPR@FPR=0.1 of 0 for all mental conditions – users exhibiting a condition are the minority, meaning a majority baseline classifier would achieve zero recall.

## 5 Results

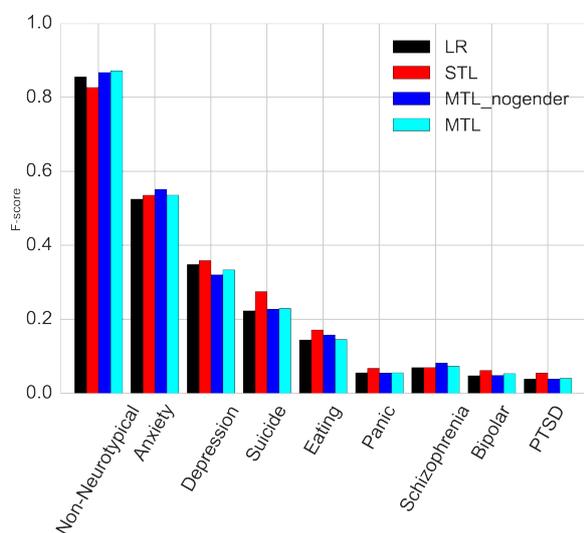

Figure 2: F1-score for predicting each condition.

Figure 2 shows the F1-score of each model at predicting each task separately, Figure 3 shows the AUC-score, and Figure 4. Precision-recall curves for each of model/task are in Figure 6.

STL corresponds to a multilayer perceptron with two hidden layers (with a similar number of parameters as the proposed MTL model). The MTL\_nogender and MTL models predict all tasks simultaneously, but are only evaluated on the main respective task.

MTL often outperforms the LR baseline in terms of AUC and TPR@F=0.1, but the difference is less clear when comparing F1-scores.

In terms of AUC and TPR@F=0.1, STL models do not perform nearly as well as MTL or LR. This is likely because the neural networks learned by

STL cannot be guided by the inductive bias provided by MTL training. Note, however, that STL and MTL are oftentimes comparable in terms of F1-score.

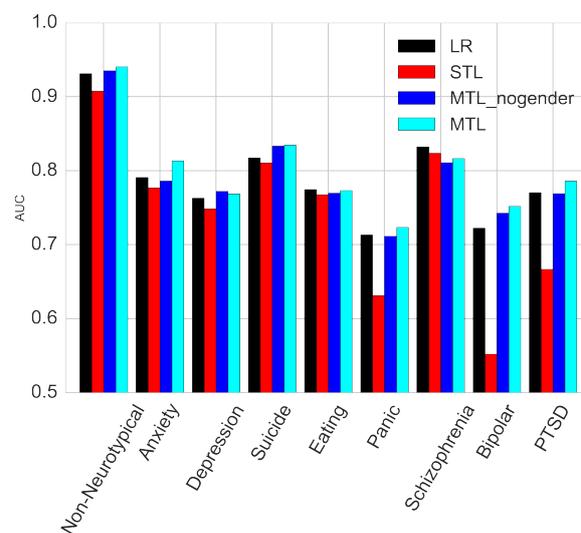

Figure 3: AUC for predicting different tasks

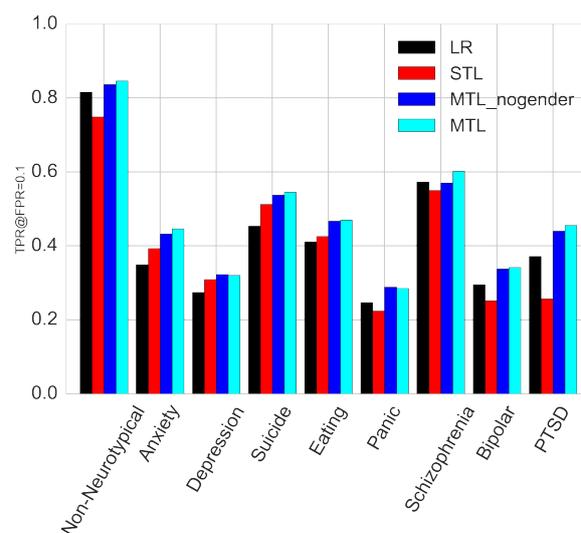

Figure 4: TPR at 0.10 FPR for predicting different tasks

### MTL Leveraging Comorbid Conditions Improves Prediction Accuracy

We find that the prediction of the conditions with the least amount of data – *bipolar disorder* and *PTSD* – are significantly improved by forcing the model to also predict comorbid conditions which have substantially more data: *depression* and *anxiety*. We are able to increase the AUC for predicting PTSD to 0.786 by MTL, from 0.770 by LR, whereas STL fails to perform as well with an AUC of

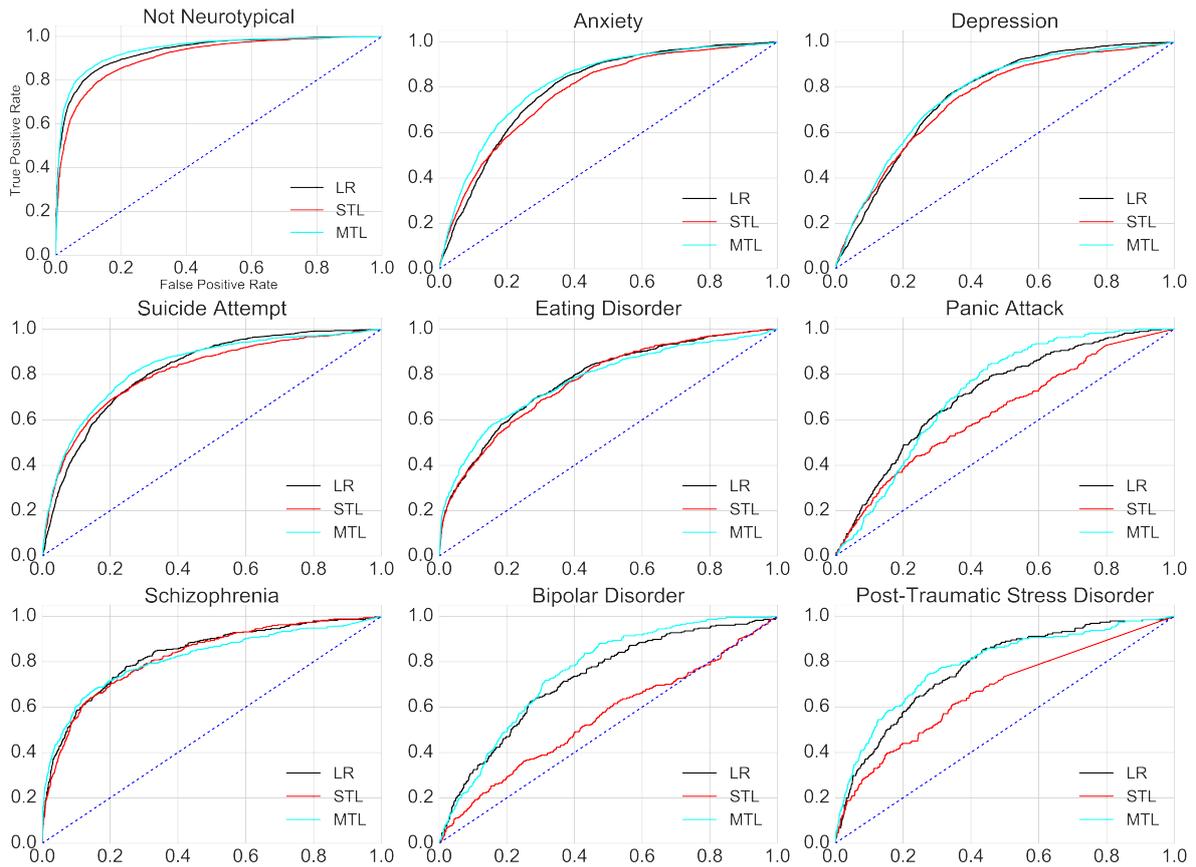

Figure 5: ROC curves for predicting each condition. The precision (diagnosed, correctly labeled) is on the  $y$ -axis, while the proportion of false alarms (control users mislabeled as diagnosed) is on the  $x$ -axis. Chance performance is indicated by the dotted diagonal line.

0.667. Similarly for predicting bipolar disorder (MTL:0.723, LR:0.752, STL:0.552) and panic attack (MTL:0.724, LR:0.713, STL:0.631).

These differences in AUC are significant at  $p = 0.05$  according to bootstrap sampling tests with 5000 samples. The wide difference between MTL and STL can be explained in part by the increased feature set size – MTL training may, in this case, provide a form of regularization that STL cannot exploit. Further, modeling the common mental health conditions with the most data (depression, anxiety) helps in pulling out more rare conditions that also manifest in these common health conditions.

This is clear evidence that an MTL model provides strong gains for predicting elusive conditions by using large data for common conditions, and only a small amount of data for the related, small-data conditions.

**Utility of Authorship Attributes** Figures 3 and 4 both suggest that adding gender as an auxiliary task leads to more predictive models, even

though the difference is not statistically significant for most tasks. This is in line with the suggestions in Volkova et al. (2013), Hovy (2015). Interestingly, though, the MTL model is worse at predicting gender itself. While this could be a direct result of data sparsity (recall that we have only a small subset annotated for gender), which could be remedied by annotating additional users for gender, this appears unlikely given the other findings of our experiments, where MTL helped in specifically these sparse scenarios.

However, it has been pointed out by Caruana (1996) that not all tasks benefit from a MTL setting in the same way, and that some tasks serve purely auxiliary functions. Here, gender prediction does not benefit from including mental conditions, but helps vice versa. In other words, predicting gender is qualitatively different from predicting mental health conditions: it seems likely that the signals for anxiety are much more similar to the ones for depression than for, say, being male, and can therefore add to detecting de-

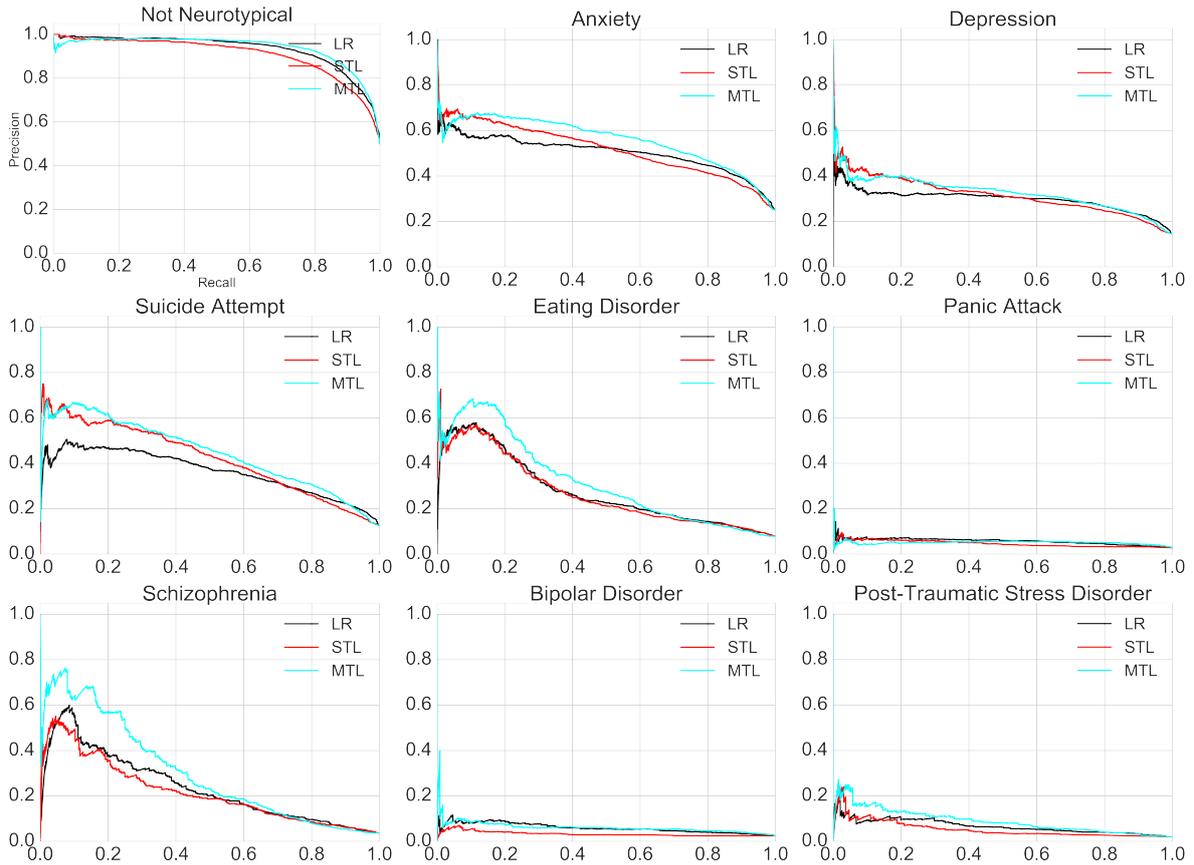

Figure 6: Precision-recall curves for predicting each condition.

pression. However, the distinction between certain conditions does not add information for the distinction of gender. The effect may also be due to the fact that these data were constructed with inferred gender (used to match controls), so there might be a degree of noise in the data.

**Choosing Auxiliary Tasks** Although MTL tends to dominate STL in our experiments, it is not clear whether auxiliary tasks just introduce a beneficial bias in MTL models in general, or if there exists a specific subset of auxiliary tasks for predicting each condition. We perform ablation experiments by training MTL models on only a subset of the tasks, and evaluate them at predicting a single target. We focus on four conditions we want to predict well: anxiety, depression, suicide attempts, and bipolar disorder. For each task, we vary the auxiliary tasks we train the MTL model with, and evaluate how well it predicts the main task. Since considering all possible subsets of tasks as auxiliary tasks is combinatorily unfeasible, we choose the following task subsets as auxiliary:

- *all*: all mental conditions along with gender

- *all conds*: only all mental conditions (gender omitted)
- *neuro*: only neurotypicality
- *neuro+mood*: neurotypicality, depression, and bipolar disorder (mood disorders)
- *neuro+anx*: neurotypicality, anxiety, and panic attack (anxiety conditions)
- *neuro+targets*: neurotypicality, anxiety, depression, suicide attempt, and bipolar disorder
- *none*: no auxiliary tasks, equivalent to STL model

Table 2 shows AUC for the four prediction tasks with different subsets of auxiliary tasks. Statistically significant improvements over the respective LR baselines are denoted by superscript. Restricting the auxiliary tasks to a small subset tends to hurt performance for most tasks. This suggests that the biases induced by predicting any mental condition are all mutually beneficial – e.g., models that predict depression, are also useful at predicting anxiety.

It is thus best not to think of MTL as one single “black box” model that can predict all mental con-

Auxiliary Tasks	Main Task			
	anxiety	bipolar	depression	suicide attempt
<i>all</i>	0.813 <sup>*†</sup>	0.752 <sup>*†</sup>	0.769 <sup>†</sup>	0.835 <sup>*†</sup>

ditions at the same time, but a framework to exploit auxiliary tasks as regularization to effectively combat data paucity and less-than-trustworthy labels.

## 6 Discussion

Our results indicate that the proposed MTL setting results in significant gains for the prediction of mental health conditions with limited data, benefiting from predicting related mental conditions and demographic attributes simultaneously.

We experimented with all the optimizers that Keras provides, and found that Adagrad seems to converge fastest to a good optimum, although all the adaptive learning rate optimizers (such as Adam, etc.) tend to converge quickly. This indicates that the gradient is significantly steeper along certain parameters than others. Default stochastic gradient descent (SGD) was not able to converge as quickly, since it is not able to adaptively scale the learning rate for each parameter in the model – taking too small steps in directions where the gradient is shallow, and too large steps where the gradient is steep. We further note an interesting behavior: all of the adaptive learning rate optimizers yield a strange “step-wise” training loss learning curve, which hits a plateau, but then drops after about 900 iterations, only to hit another plateau, and so on. Obviously, we would prefer to have a smooth training loss curve. We can indeed achieve this using SGD, but it takes much longer to converge than, for example, Adagrad. This suggests that a well-tuned SGD would be the best optimizer

Learning Rate	Loss	L2	Loss	Hidden Width	Loss
$10^{-4}$	5.1	$10^{-3}$	2.8	32	3.0
$5 * 10^{-4}$	2.9	$5 * 10^{-3}$	2.8	64	3.0
$10^{-3}$	2.9	$10^{-2}$	2.9	128	2.9
$5 * 10^{-3}$	2.4	$5 * 10^{-2}$	3.1	256	2.9
$10^{-2}$	2.3	0.1	3.4	512	3.0
$5 * 10^{-2}$	2.2	0.5	4.6	1024	3.0
0.1	20.2	1.0	4.9		

Table 3: Average dev loss over epochs 990-1000 of joint training on all tasks as a function of different learning parameters. Optimized using Adagrad with hidden layer width 256.

for this problem, a step that would require some more experimentation and is left for future work.

We also found that feature counts have a pronounced effect on the loss curves: relative feature frequencies yield models that are much easier to train than raw feature counts.

As indicated by the effect of raw vs. relative counts, feature representations are another area of optimization, such as different ranges of character  $n$ -grams (e.g.,  $n > 5$ ) and word unigrams. We decided on character 1-to-5-grams, since we believe that these features generalize better to a new domain (e.g., Facebook) than word unigrams. However, there is no fundamental reason not to choose longer character  $n$ -grams, other than time constraints in regenerating the data, and sufficiently accounting for overfitting with proper regularization.

Initialization is often listed as a decisive factor in neural models, and Goldberg (2015) recommends repeated restarts with differing initializations to find the optimal model. In an earlier experiment, we tried initializing a MTL model (albeit without task-specific hidden layers) with pre-trained word2vec embeddings of unigrams trained on the Google News  $n$ -gram corpus. However, we did not notice an improvement in F-score. This could be due to the other factors, though, such as feature sparsity.

Table 3 displays sweeps over learning parameters with hidden layer width 256, training the MTL model to predict multiple mental conditions jointly for the Qntfy self-stated data (character trigrams as input features). The sweet spots in this table are probably good starting points for training models.

## 7 Related Work

MTL was introduced by Caruana (1993), based on the observation that humans rarely learn things in isolation, and that it is the similarity between related tasks that helps us get better.

Some of the first works on MTL have been motivated by medical risk prediction (Caruana et al., 1996), and it is now being rediscovered for this purpose (Lipton et al., 2016). The latter use a long short-term memory (LSTM) structure to provide several medical diagnoses from health care features (yet no textual or demographic information), and find small, but probably not significant improvements over a structure similar to the STL we use here.

However, in both cases, the target was medical conditions as detected in patient records, not mental health conditions in online data. The main focus in this work has been on the correlation between individual conditions and linguistic markers, to establish the possibility of detecting risk in written data. While some of the approaches have looked at more than one condition, none of them have done so in an MTL framework, foregoing the possibility of modeling comorbidity and correlation with demographic factors.

The framework proposed by Collobert et al. (2011) allows for predicting any number of NLP tasks from a convolutional neural network (CNN) representation of the input text. The model we present is much simpler, just a feed-forward network with  $n$ -gram input layer. Our contribution is to show that constraining  $n$ -gram embeddings to be predictive of various mental health condition also helps. We chose to experiment with a feed-forward network against independent logistic regression models since this was the simplest way to test our hypothesis. Comparing more complicated models is possible, but distracts from the question whether or not MTL training with extra-linguistic targets helps us.

## 8 Conclusion and Future Work

In this paper, we develop neural MTL models for 10 prediction tasks (eight mental health conditions, neurotypicality, and gender). We compare their performance with STL models trained to predict each task independently.

Our results show that the most complex MTL model performs significantly better than independent LR models, reaching 0.846 TPR where

FPR=0.1 and reducing the error rate in identifying anxiety by up to 11.9%. We also investigate the influence of the depth of the model, by comparing to progressively deeper STL feed-forward networks with the same number of parameters. We find: (1) Most of the modeling power stems from the expressiveness conveyed by deep architectures. (2) Choosing the correct set of auxiliary tasks for a given mental condition can yield a significantly more predictive model. (3) The MTL model dramatically improves for conditions with the smallest amount of data. (4) Gender prediction does not follow the two previous points, but improves performance when added as an auxiliary task.

Accuracy of the MTL approach is not yet ready to be used in isolation in the clinical setting. However, our experiments suggest this is a promising direction moving forward. There are strong gains to be made in using multitask learning to aid clinicians in their evaluations, and with further partnerships between the clinical and machine learning community, we foresee improved suicide prevention efforts.

In the future, we plan to explore the possibility of hierarchical models, encoding the fact that certain tasks inform others more than vice versa.

## Acknowledgements

The authors would like to thank Kristy Hollingshead Seitz, Glen Coppersmith, and H. Andrew Schwartz, as well as the organizers and funders of the Johns Hopkins Jelinek Summer School 2016, where large parts of this work were conducted. We are also grateful for the invaluable feedback on MTL from Yoav Goldberg, Stephan Gouws, Ed Greffentette, Karl Moritz Hermann, and Anders Sjøgaard.

## Abstract

Recent work on evaluating representation learning architectures in NLP has established a need for evaluation protocols based on subconscious cognitive measures rather than manually tailored intrinsic similarity and relatedness tasks. In this work, we propose a novel evaluation framework that enables large-scale evaluation of such architectures in the free word association (WA) task, which is firmly grounded in cognitive theories of human semantic representation. This evaluation is facilitated by the existence of large manually constructed repositories of word association data. In this paper, we (1) present a detailed analysis of the new quantitative WA evaluation protocol, (2) suggest new evaluation metrics for the WA task inspired by its direct analogy with information retrieval problems, (3) evaluate various state-of-the-art representation models on this task, and (4) discuss the relationship between WA and prior evaluations of semantic representation with well-known similarity and relatedness evaluation sets. We have made the WA evaluation toolkit publicly available.

## 1 Introduction

The quality of word representations in semantic models is often measured using intrinsic evaluations that capture particular types of relationships (typically semantic similarity and relatedness) between word pairs (Finkelstein et al., 2002; Hill et al., 2015; Schnabel et al., 2015; Tsvetkov et al., 2015, *inter alia*).

Whereas the notions of semantic *similarity* and *relatedness* constitute key concepts in such evaluations, they are in fact vaguely defined (Batchkarov

et al., 2016; Ettinger and Linzen, 2016). The construction of ground truth evaluation sets that reflect these relations, such as SimLex-999 (Hill et al., 2015), SimVerb-3500 (Gerz et al., 2016), MEN (Bruni et al., 2014) or Rare Words (Luong et al., 2013), relies on manually constructed guidelines that trigger subjective human interpretation of the task at hand. This in turn introduces inter-annotator variability (Batchkarov et al., 2016) and does not account for the fact that human similarity judgments are asymmetric by nature (Tversky, 1977).

What is more, given that humans perform linguistic comparisons between concepts on a subconscious level (Kutas and Federmeier, 2011), it is at least debatable whether current similarity/relatedness evaluation sets fully capture the implicit relational structure underlying human language representation and understanding.

As evidenced by recent workshops on evaluation of semantic representations<sup>1</sup>, the community appears to recognise that current evaluation methods are inadequate. To fill in this gap, recent work has proposed using subconscious cognitive measures of semantic connection instead, as a proxy for measuring the ability of statistical models to tackle various problems in human language understanding (Ettinger and Linzen, 2016; Søgaard, 2016; Mandera et al., 2017).

Motivated by these insights, this work proposes an evaluation framework based on the word association (WA) task, firmly rooted in and described by the psychology literature, e.g., Nelson et al. (2000) and Griffiths et al. (2007)<sup>2</sup>. Word associations, provided as simple (*cue, response*) concept pairs, are naturally asymmetric: they tend to be given as a repository of ranked lists of concepts col-

<sup>1</sup>E.g. RepEval, <https://sites.google.com/site/repevalacl16/>

<sup>2</sup>The WA task is a free-association task, in which participants are asked to produce the first word that came into their head in *response* to a *cue* or *query* word.

lected as responses (i.e., associations) given a target cue/query concept. The ranking of the response list is based on the WA strength between the cue and each generated response. WAs are directly tied to language use and the memory systems that support online linguistic processing (Till et al., 1988; Nelson et al., 1998).

We build our WA evaluation framework around a large repository of the University of South Florida (USF) association norms (Nelson et al., 2000; Nelson et al., 2004). After post-processing, the repository contains ~5K queries, and ~70,000 (*cue, response*) pairs, making it one of the largest semantic evaluation databases available (by contrast, the largest word pair scoring data sets in NLP, SimVerb and MEN, contain 3,500 and 3,000 word pairs respectively). This new resource enables comprehensive quantitative studies of WA and may be used to guide the future development of representation learning architectures.

While parts of the USF data set have been used for evaluation in NLP before (Michelbacher et al., 2007; Silberer and Lapata, 2012; Kiela et al., 2014; Hill and Korhonen, 2014, *inter alia*), we conduct the first full study regarding the evaluation on the quantitative WA task. We compare a wide variety of different semantic representation models, discuss various evaluation metrics and analyse the links between word association and semantic similarity and relatedness. In summary, the main contributions of this paper are as follows:<sup>3</sup>

**(C1)** We present an end-to-end evaluation framework for the WA task, and provide new evaluation metrics and detailed guidelines for evaluating semantic models on the WA task.

**(C2)** We conduct a systematic study and comparison of current state-of-the-art representation learning architectures on the WA task.

**(C3)** We present a systematic quantitative analysis of the connections between the models' performance on the subconscious WA task and their performance on benchmarking similarity and relatedness evaluation sets.

## 2 Motivation: Association and USF

**Implicit Cognitive Measures: Means of Semantic Evaluation?** Several studies have shown clear correspondence between implicit cognitive

<sup>3</sup>All evaluation scripts and detailed evaluation guidelines are freely available at:  
<https://github.com/cambridge/tl/wa-eval/>

measures (most notably *semantic priming*) and semantic relations encountered in vector space models (VSMs) (McDonald and Brew, 2004; Jones et al., 2006; Padó and Lapata, 2007; Herdağdelen et al., 2009), suggesting that some of the implicit relation structure in the human brain is already reflected in current statistical models of meaning.

These findings encouraged Ettinger and Linzen (2016) to propose a preliminary evaluation framework based on *semantic priming* experiments (Meyer and Schvaneveldt, 1971).<sup>4</sup> They demonstrate the feasibility of such an evaluation using a subconscious language processing task. They use the online database of the Semantic Priming Project (SPP), which compiles priming data for over 6,000 word pairs.

Here, we go one step further and demonstrate that another subconscious language processing task, with much more available data, can also be used to evaluate representations. We construct an evaluation framework based on the USF free word association (WA) norms quantifying the strength of association between cue and response concepts for more than 70,000 concept pairs.

**Word Association** WA has been a long-standing research topic in cognitive psychology, as evidenced by the following statement (Deese, 1966):

Are there any more fascinating data in psychology than tables of association? (Deese, 1966)

Word association still remains one of the fundamental questions in cognitive psychology, as emphasised by e.g. Griffiths et al. (2007):

Association has been part of the theoretical armory of cognitive psychologists since Thomas Hobbes used the notion to account for the structure of our “trayne of thoughts” in 1651.

These insights illustrate how WA can provide a useful benchmark for evaluating models of human semantic representation. WA norms are commonly used in constructing memory experiments (Dennis and Humphreys, 2001; Steyvers and Malmberg, 2003), and statistics derived from them have been shown to be important in predicting cued recall

<sup>4</sup>Semantic priming measures a response time with a human subject performing a simple language task (e.g., classifying strings into words vs. non-words). It was shown that human subjects are able to solve the task more quickly if the word to which they are responding is preceded by a semantically related word. The magnitude of the speed-up can be taken as the strength of relation between the two concepts.

Table 1: Example (*cue, response*) pairs of free word association from the USF data set. #G stands for the number of participants serving in the group norming the word, while #P denotes the number participants producing a particular response.

and recognition (Nelson et al., 1998), and false memories (Roediger et al., 2001).<sup>5</sup>

**WA Evaluation Set: USF** The USF norms data set (hereafter **USF**) is the largest database of free word association collected for English (Nelson et al., 2004). It was generated by presenting human subjects with one of 5,000 cue concepts and asking them to write the first word coming to their mind that is associated with that concept. Each cue concept was normed by at least 100 participants, resulting in a set of associates (or *responses*) for each cue, for a total of  $\sim 72,000$  (*cue, response*) pairs. A sample of the USF data is presented in Tab. 1. The data are accessible online.<sup>6</sup>

For each such pair, the proportion of participants that produced the response  $w^r$  when presented with cue word  $w^c$  can be used as a proxy for the strength of association between the two words (FSG in Tab. 1). BSG denotes the backward association strength, when the roles of a cue and a response are reversed, shows that the WA relation is inherently asymmetrical.

<sup>5</sup>From another viewpoint, the WA evaluation aims to answer a different question than a typical intrinsic evaluation on data sets such as SimLex-999, MEN, WordSim-353, or SimVerb-3500. The goal of the latter is to assess the quality of learned text representations as a proxy towards downstream NLP tasks. The goal of the former is to assess the capability of representation learning and NLP architectures to help in advancing our understanding and modeling of human cognitive processes (occurring on a sub-conscious level), while at the same time it could still be used as a proxy evaluation in NLP.

<sup>6</sup><http://w3.usf.edu/FreeAssociation/>

### 3 Evaluation Protocol

**Terminology**  $\mathcal{W}^c = \{w_1^c, \dots, w_i^c, \dots, w_{|\mathcal{W}^c|}^c\}$  denotes a set of  $|\mathcal{W}^c|$  *cue* or *normed* words (more generally, concepts) in the evaluation set. For each cue word  $w_i^c$ , the data set contains a *ranked list* of concepts or *responses*  $\mathcal{R}_i$  sorted according to the strength of forward association, from cue to response (i.e., the FSG field in Tab. 1). The list  $\mathcal{R}_i$  contains entries of the format  $w_{r,j} : \text{fsg}_{i,j}$ , where  $w_{r,j}$  is the  $j^{\text{th}}$  most associated concept in the ranked list, and  $\text{fsg}_{i,j}$  is the accompanying strength of forward association between cue  $w_i^c$  and response  $w_{r,j}$ . Let  $\mathcal{R}_i^g$  refer to the ground truth ranked list for  $w_i^c$ , which contains only responses where  $\text{fsg}_{i,j} > 0$  in the USF data, and  $\mathcal{R}_i^s$  to the ranked list retrieved by an automatic system.

The vocabulary or search space from which responses for all cues are drawn is labeled  $V^r$ . Note that  $V^r$  may also contain words from  $\mathcal{W}^c$  and that  $V^r$  may contain words that do not occur in any of the ground truth lists  $\mathcal{R}_i^g$ .

**Why Evaluate on Word Association?** A standard evaluation protocol with word pair scoring evaluation sets such as SimLex-999 or MEN is to compute Spearman’s  $\rho$  correlations between the ranking obtained by an automatic system and the ground truth ranking. This protocol, however, is not directly applicable to the USF test data. First, the evaluated relation of WA is *asymmetric*, and the pairs  $(X, Y)$  and  $(Y, X)$  may differ dramatically in their WA scores (see the difference in FSG and BSG values from Tab. 1). Second, instead of one global list of pairs, the data comprises a series of ranked lists conditioned on the cue/normed word  $w^c$  (see Tab. 1 again). Finally, unlike with SimLex-999 or MEN scores where it is difficult to interpret “what a similarity/relatedness of 7.69 exactly means” (Batchkarov et al., 2016; Avraham and Goldberg, 2016), the USF FSG scores have a direct meaningful interpretation (i.e.,  $FSG = \#P/\#G$ ). To fully capture all aspects of the ground truth USF data set, an evaluation protocol should ideally be based not only on response rankings, but also on the actual scores, i.e., the association strength.

In this paper, we propose and investigate two different families of evaluation metrics on the USF data: Sect. 3.1 discusses rank correlation evaluation metrics inspired by recent work on the evaluation of vector space models in distributional semantics (Bruni et al., 2014; Hill et al., 2015; Vulić et al.,

2016, inter alia). Sect. 3.2 draws inspiration from research on evaluation in information retrieval (IR). We show that the problem of evaluating USF association lists may be naturally framed as an ad-hoc IR task (Manning et al., 2008). This enables the application of standard IR evaluation methodology.

### 3.1 Rank Correlation Evaluation

#### Averaged Standard Spearman’s Correlation

The first protocol, labeled  $\rho$ -std, first computes the standard Spearman’s  $\rho$  correlation between  $\mathcal{R}_i^g$  and  $\mathcal{R}_i^s$ . The system list  $\mathcal{R}_i^s$  is pruned so that it contains only those items that also occur in  $\mathcal{R}_i^g$ . The two lists are then correlated to obtain the score  $\rho_i$  for cue  $w_i^c$ .

Following that, the correlation scores are averaged. First, we apply the Fisher  $z$ -transformation (Fisher, 1915) and then average over the transformed scores:

$$z_i = \frac{1}{2} \ln \left( \frac{1 + \rho_i}{1 - \rho_i} \right) = \operatorname{arctanh}(\rho_i) \quad (1)$$

$$z_{avg} = \sum_{i=1}^{|\mathcal{W}^c|} z_i \quad (2)$$

The final output score is obtained by applying the inverse  $z$ -transformation on  $z_{avg}$ :

$$\rho_{avg} = \tanh(z_{avg}) \quad (3)$$

#### Averaged Weighted Spearman’s Correlation

The previous protocol treats all ranks equally, despite the fact that the system should be rewarded more for getting the strongest responses correct (and penalised when failing to do so). Therefore, we also experiment with weighted rank correlation measures, which weigh the distance between two ranks, and assign more importance to higher ranks (i.e., in our setting, to stronger associates).

Several weighted correlation metrics have been proposed (Blest, 2000; Pinto da Costa and Soares, 2005; Dancelli et al., 2013; Pinto da Costa, 2015). We show results with the weighted Spearman’s correlation (further labelled  $\rho$ -w) from Pinto da Costa (2015).<sup>7</sup> Let us denote  $Q_1 = [Q_{1,1}, Q_{1,2}, \dots, Q_{1,n}]$  and  $Q_2 = [Q_{2,1}, Q_{2,2}, \dots, Q_{2,n}]$  two vectors of ranks obtained on a sample of size  $n$ . The weighted rank correlation  $\rho$  between the vectors is computed as:

<sup>7</sup>We also experimented with other weighted variants, but detected similar trends in reported model rankings.

$$1 - \frac{6 \sum_{i=1}^n (Q_{1,i} - Q_{2,i})((n - Q_{1,i} + 1) + (n - Q_{2,i} + 1))}{n^4 + n^3 - n^2 - n} \quad (4)$$

We refer the interested reader to the relevant literature (Pinto da Costa, 2015) for further details, theoretical implications and property proofs related to Eq. (4).  $\rho_i$  scores for all cue words  $\mathcal{W}^c$  are then obtained using Eq. (4), and the averaged score  $\rho_{avg}$  is computed as before, see Eq. (1)-Eq. (3).

While the two metrics are intuitive and capture the ability of models to correctly rank (a subset of) associates/responses, note that they have deficiencies. They only evaluate the rankings of words occurring in  $\mathcal{R}_i^g$ , which effectively reduces the search space  $V^r$  to the small subset  $\{w_1, \dots, w_{|\mathcal{R}_i^g|}\} \subset V^r$ . This effectively means that the final score simply ignores incorrect responses that are ranked highly by a system but that do not occur in  $\mathcal{R}_i^g$ . It also does not take into account the actual strength of association.

### 3.2 IR-Inspired Evaluation

**Intuition** Another set of evaluation metrics is inspired by the resemblance of the USF data structure to the typical output of ad-hoc IR systems (Manning et al., 2008; Pound et al., 2010). That is, each cue word  $w^c$  can be thought of as an input *query* issued against some *target concept collection*  $V^r$ , where the goal of our *association retrieval system* is to rank items from the target collection according to their *relevance* (i.e., their association strength) to the issued query. The output of the system is the ranked list  $\mathcal{R}_i^s$  of length  $|V^r|$ , with ground truth relevance assessments provided in  $\mathcal{R}_i^g$ .

**MRR and MAP** The first two metrics assume non-weighted or binary relevance: the retrieved response is either relevant to the issued cue (labeled 1) or it is non-relevant (0). We assume that all responses found in the ground truth lists  $\mathcal{R}_i^g$  where  $fsg_{i,j} > t$  are relevant responses, where  $t$  is a threshold.<sup>8</sup> We label this reduced set of relevant responses  $\mathcal{R}\mathcal{R}_i^g$ .

The most lenient evaluation metric is Mean Reciprocal Rank (MRR) (Voorhees, 1999; Craswell,

<sup>8</sup>In our experiments, we impose a simple heuristic and take responses as relevant if they were generated by at least 3 different human subjects in the USF experiments. This heuristic reduces the noise in human answers and provides a more coherent set of responses.

2009). The reciprocal rank of a query response is the multiplicative inverse of the rank of the first relevant answer, and the final score is then averaged over all  $|\mathcal{W}^c|$  queries/cues. More formally:

$$MRR(\mathcal{W}^c) = \frac{1}{|\mathcal{W}^c|} \sum_{i=1}^{|\mathcal{W}^c|} \frac{1}{rank_i} \quad (5)$$

where  $rank_i$  is the rank position of the first relevant response (i.e., the first response found in the set  $\mathcal{R}\mathcal{R}_i^g$ ) for the cue word  $w_i^c$ .

Since MRR cannot assess multiple correct answers and their ranking in the retrieved list, an alternative metric is Mean Average Precision (MAP):

$$MAP(\mathcal{W}^c) = \frac{1}{|\mathcal{W}^c|} \sum_{i=1}^{|\mathcal{W}^c|} AP(w_i^c) \quad (6)$$

$$AP(w_i^c) = \frac{\sum_{k=1}^N P_k \cdot irel_k}{|\mathcal{R}\mathcal{R}_i^g|} \quad (7)$$

Here,  $AP(w_i^c)$  denotes Average Precision for query/cue  $w_i^c$ ,  $N \leq |V^r|$  denotes the number of responses retrieved by the system.  $P_k$  is the precision at cut-off  $k$  in the list, and  $irel_k$  is an indicator function which 'turns on' only if the response at rank  $k$  is the relevant response (i.e., present in  $\mathcal{R}\mathcal{R}_i^g$ ). The average is computed over all relevant responses, and the non-retrieved relevant responses from  $V^r$  get a precision score of 0.  $N \ll |V^r|$  is typically used (e.g., standard values are  $N = 100$  or  $N = 1000$ ) to reduce the execution time of the evaluation procedure, since it is expected that a good retrieval system should obtain a majority of relevant responses in the first  $N$  responses.

Compared to measures from Sect. 3.1, MRR and MAP are better estimators of the model's ability to capture word association, as they operate over the entire search space  $V^r$  for each cue word. This effectively means that systems get rewarded if they are able to consistently rank relevant responses higher than non-relevant responses. However, these metrics still rely on binary non-weighted relevance judgements, and are therefore unable to reward models that rank highly relevant responses (i.e., strongly associated responses, see Tab. 1) higher than weakly relevant responses.

**NDCG@k** In other words, the most expressive evaluation metric should be able to distinguish that cue-response pairs such as (*lunch, dinner*) and (*lunch, food*) should be ranked higher than weakly associated pairs such as (*lunch, box*) or (*lunch,*

*sandwich*). In addition, the metric should still reward models that rank relevant responses higher than non-relevant ones.

An IR metric which takes all these aspects into account is Discounted Cumulative Gain (DCG) (Järvelin and Kekäläinen, 2002). DCG operates with weighted relevance values: in the USF scenario, these are forward association strengths, i.e., scores  $fs_{g_{i,j}}$ . The main idea behind using DCG is that highly relevant responses appearing lower in a ranked list should be penalised. The penalty is implemented by reducing the weighted relevance value logarithmically proportional to the position of the particular response. We opt for a more recent variant of DCG which puts more emphasis on retrieving relevant responses (Burges et al., 2005). DCG@k, the DCG score accumulated at a particular rank position  $k$  is computed as follows:

$$DCG@k = \sum_{i=1}^k \frac{2^{wrel_i} - 1}{\log_2(i + 1)} \quad (8)$$

$wrel_i$  is the graded relevance of the response at rank  $i$  given by the ground truth data, i.e.,  $fs_{g_{i,j}}$  if the cue-response pair occurs in  $\mathcal{R}\mathcal{R}_i^g$ , or 0 otherwise.

To make results comparable across different queries, a normalised variant of DCG is typically used. First, all relevant responses are sorted by their graded relevance value, producing the maximum possible DCG at each position  $k$ . The score of the ideal ranking at rank  $k$  is called Ideal DCG (IDCG@k). NDCG@k for a single query is then:

$$NDCG@k = \frac{DCG@k}{IDCG@k} \quad (9)$$

Finally, the mean NDCG@k is produced for the entire collection  $\mathcal{W}^c$  by averaging over all single NDCG@k values. In all experiments we rely on a standard choice for  $k$ : NDCG@100, while similar trends are observed with NDCG@10.

## 4 Experimental Setup and Models

**LDA-Based Approach** First, we evaluate an approach based on latent topic modeling, rooted in the psychology literature (Steyvers et al., 2004; Griffiths et al., 2007; Steyvers and Griffiths, 2007).<sup>9</sup> The following quantitative model of word association has been proposed (Griffiths et al., 2007):

<sup>9</sup>Griffiths et al. (2007) also experimented with LSA (Landauer and Dumais, 1997) and found that their LDA-based approach consistently outperformed LSA-based approaches.

$$P(w^r|w^c) = \sum_{i=1}^M P(w^r|to_i)P(to_i|w^c) \quad (10)$$

where  $w^c$  is a cue word,  $w^r \in V^r$  any concept from the search space, and  $to_i$  is the  $i^{th}$  latent topic from the set of  $M$  topics induced from the corpus data (using LDA). We label this model **LDA-assoc**. The probability scores  $P(w^r|to_i)$  select words that are highly descriptive for each particular topic.  $P(to_i|w^c)$  scores are computed as in prior work, by assuming topic independence and applying Bayes' rule on the LDA output per-topic word distributions  $P(\cdot|to_i)$  (Steyvers and Griffiths, 2007; Vulić and Moens, 2013).<sup>10</sup> We train LDA with 1,000 topics using suggested parameters (Griffiths et al., 2007).

**Count-Based Models** We evaluate the best performing reduced count-based model from (Baroni et al., 2014). We label this model **count-ppmi-500d**.<sup>11</sup> For a more detailed description of the model's training data and setup we refer the reader to the original work and supplementary material.

**Vector Space Models** We also compare the performance of prominent representation models on the WA USF task. We include: (1) unsupervised models that learn from distributional information in text, including Glove (Pennington et al., 2014) with  $d = 50$  and  $d = 300$  dimensions (**glove-6B-50d** and **glove-6B-300d**), the skip-gram negative-sampling (SGNS) 300-dimensional vectors (Mikolov et al., 2013) with various contexts (*bow* = bag-of-words; *deps* = dependency contexts) as in (Levy and Goldberg, 2014) and (Schwartz et al., 2015) (**sgns-pw-bow-w2**, **sgns-pw-bow-w5**, **sgns-pw-deps**, **sgns-8b-bow-w2**), and the symmetric-pattern based vectors by Schwartz et al. (2015) (**sympat-500d**); (2) Models that rely on linguistic hand-crafted resources or curated knowledge bases. Here, we use vectors fine-tuned to a paraphrase database (**paragram-25d**,

<sup>10</sup>The generative model closely resembles the actual process in the human brain (Griffiths et al., 2007) - when we generate responses, we first tend to associate that word with a related semantic/cognitive concept, i.e., a latent topic (the factor  $P(to_i|w^c)$ ), and then, after establishing the concept, we output a list of words that we consider the most prominent/descriptive for that concept (words with high scores in the factor  $P(w^r|to_i)$ ).

<sup>11</sup>We have also experimented with simple count-based asymmetric association measures proposed by Michelbacher et al. (2007), estimated using the same corpus as the *count-ppmi-500d* model. We do not report the results with these measures, as they show a very poor performance when compared to all other models in our comparison.

**paragram-300d**, (Wieting et al., 2015)) further refined using linguistic constraints (**paragram+cf-300d**, (Mrkšić et al., 2016)); (3) Multilingual embedding models from Luong et al. (2015) (**biskip-256d**) and Faruqui and Dyer (2014) (**bicca-512d**). More detailed descriptions of all VSM models are available in the listed papers and supplementary material attached to this work.

**USF Data Processing and Parameters** Only USF pairs where both words are single word expressions were retained, and the rest was discarded. This yields 4,992 single word queries in total. The total number of finally retained USF pairs is  $\approx 70,000$ . Note that this evaluation set is by an order of magnitude larger than current benchmarking word pair scoring datasets such as MEN (3000 word pairs in total), SimVerb (3500), SimLex (999) and Rare Words (2034), and thus allows for a truly comprehensive evaluation of quantitative WA models. Only responses generated by at least 3 human subjects in each list of responses are taken as relevant in all experiments (see Foot. 7 in Sect. 3.2), all other (*cue, response*) pairs and pairs not present in the USF data are considered non-relevant.<sup>12</sup>

## 5 Results and Discussion

**Exp. I: Making the Evaluation Tractable** Computational complexity is not an issue for standard semantic benchmarks such as SimLex-999 or MEN: these data sets require only  $N_{gt}$  similarity computations in total, where  $N_{gt}$  is the number of word pairs in each benchmark (999 or 3000). However, complexity plays a major role in the USF evaluation: the system has to compute  $|\mathcal{W}^c| \cdot |V^r|$  similarity scores, where  $|\mathcal{W}^c| \approx 5,000$ , and  $|V^r|$  is large for large vocabularies (typically covering  $> 100K$  words). In addition, each list of  $|V^r|$  has to be sorted according to the WA strength: this means that the complexity is  $O(|\mathcal{W}^c| \cdot (|V^r| + |V^r| \log |V^r|))$ .

Since this is prohibitively expensive, our solution is to restrict the search space  $V^r$  only to words (both cues and responses) occurring in USF:  $|V^r| = 10,070$ .<sup>13</sup> Besides the gains in evaluation efficiency, when using the USF vocabulary all models operate over exactly the same search space:

<sup>12</sup>For efficiency reasons with IR metrics, we evaluate results only over the top  $N = 1000$  retrieved responses for each cue.

<sup>13</sup>Prior work shows that the USF data represents a good range of distinct semantic phenomena (Hill et al., 2015), which suggests that the USF vocabulary represents a balanced sample of the English vocabulary.

Table 3: Results on the USF WA task using different evaluation metrics proposed in Sect. 3.  $V^r = USF$  for all models. The best results per column are in bold, second best in italic.

therefore, their results are directly comparable as the data coverage bias should be largely mitigated.

To fully support this choice, we perform a simple experiment using a subset of models from Sect. 4. In the first evaluation,  $V^r$  contains the most frequent 100K words for all models, where frequency was computed on their respective training data. In the second evaluation,  $V^r$  contains only the USF vocabulary words. The results with IR-style metrics are shown in Tab. 2, and similar trends are observed with Spearman’s  $\rho$  correlations.

The results support several conclusions. (i) Coverage over cue words is very high for all models (the model with the lowest coverage from Tab. 2 has a coverage of 98.2%). This, along with the same search space (the USF vocabulary) indicates a fair comparison of different models. (ii) Different IR metrics produce consistent model rankings, with a slight variation in the middle of the rankings. Interestingly, the best scoring model is Glove, a model which uses document-level co-occurrence, which steers it towards learning topical similarity. On the

other hand, the worst performing model relies on dependency-based contexts which better capture functional similarity (Levy and Goldberg, 2014) and outperform other context choices in word similarity tasks on SimLex and SimVerb (Melamud et al., 2016; Gerz et al., 2016). (iii) Most importantly, the reduction of  $V^r$  again yields consistent rankings with all metrics, which are also fairly consistent with the rankings obtained in the ten times larger 100K search space. Therefore, in all further experiments we use the USF vocabulary as our search space.

**Exp. II: Results on USF WA** Next, we evaluate all models from Sect. 3 on the WA task. The results with different metrics are summarised in Tab. 3. The results suggest that all proposed evaluation metrics indeed reflect the ability of different models to capture WA. We observe strong correlations of the models’ rankings with all five metrics (Tab. 4).  $\rho$ -w is a slightly more conservative metric than  $\rho$ -std on average, but it does not affect model rankings at all (see also Tab. 4).

Further, the LDA-based WA model (Griffiths et al., 2007) is largely outperformed by VSM-based approaches. As expected, similar VSMS with more dimensions are more expressive and score higher (e.g., note the scores with *glove* and *paragram* models). Additionally, models trained on larger corpora are also able to improve the overall results (e.g., note the scores with *sgns* trained on the Polyglot Wikipedia (PW, 2B tokens) vs. the 8B *word2vec* corpus). The *paragram* models specialised for similarity tasks are unable to match unsupervised VSMS that train on running text (e.g., *paragram+cf-300d* obtains a SimLex score of 0.74 compared to 0.46 with *sgns-8b-bow-w2*).

Two models using bilingual training (*biskip-256d* and *bicca-512d*) seem unable to match the

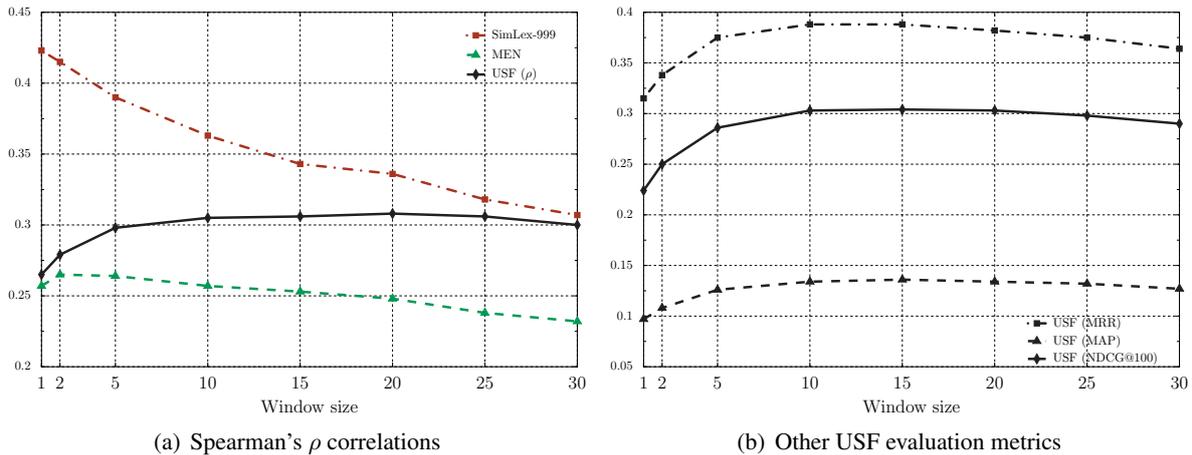

Figure 1: Influence of the window size on the ability of vector space models to capture Similarity (evaluated on SimLex-999), Relatedness (MEN), and Association (USF) (a) Spearman's  $\rho$ -std correlations on all three data sets; (b) Behaviour of other evaluation metrics used in the USF evaluation. All tested models are SGNS,  $d = 300$ , and the only varied hyper-parameter is the window size.

	Association (WA)					Similarity		Relatedness

Table 4: Spearman's  $\rho$  correlations between different evaluation protocols for vector space models divided into (a) Association, (b) Similarity, and (c) Relatedness. The correlation scores are based on the rankings of all the evaluated models (see Sect. 4.1) in each experiment. The lower-left part of the table (below the main diagonal, in lighter gray) reports standard Spearman's  $\rho$ -std correlations between different model rankings, while  $\rho$ -w is reported in the upper-right part (in darker gray). We report model rankings based on the 5 different metrics introduced for the WA USF evaluation. Model rankings for Similarity and Relatedness experiments are according to the  $\rho$ -std correlation on the respective ground truth data sets.

best performing monolingual models: however, we plan to further analyse the influence of bilingual information in the WA task in future work.

Finally, a comparison of *sgns-pw*-\* models (where the only varied parameter is the context used in training) reveals that (i) larger windows improve WA scores (we test this phenomenon further in Exp. III), (ii) *sgns-pw-deps*, which captures functional similarity through dependency-based contexts, yields lower WA scores, while it improves on SimLex-999 compared to the other two models. This insight leads us to further investigate this phenomenon in Exp. IV.

**Exp. III: Window Size** In the next experiment, we analysed the effect of the window size on

models' ability to capture similarity, relatedness, and association. We train the *sgns-pw-bow* model ( $d = 300$ ) with varying window sizes in the interval  $[1, 30]$ . The results on similarity (SimLex-999), relatedness (MEN), and WA benchmarks (USF) are presented in Fig. 1(a)-1(b). It is clear that using larger windows deteriorates the performance on SimLex-999 as the focus of the model is shifted from functional to topical similarity. This shift has been detected in prior work on vector space models (Kiela and Clark, 2014). However, we also observe a similar trend with MEN scores, although an opposite effect was expected, which questions the ability of MEN to accurately evaluate relatedness. The opposite effect is, however, visible with the WA evaluation, where it is evident that larger win-

dows (leading to topical similarity) lead to better WA estimates. This also provides the first hint that WA and semantic similarity capture two completely distinct semantic phenomena.

**Exp. IV: WA vs. Similarity vs. Relatedness** We delve deeper into this conjecture by computing correlations between model rankings on the WA task and two prominent similarity and relatedness data sets. The results from Tab. 4 indicate the following. First, semantic relatedness and similarity are correlated although they clearly refer to two distinct semantic phenomena as emphasised in prior work (Hill et al., 2015). The correlations between different metrics proposed for the WA task are very high (e.g., the lowest correlation score among any of the two is  $\rho = 0.921$ ). Second, WA and similarity capture very distinct relations (this is evident from low, even negative  $\rho$  correlation scores). Third, WA and relatedness are strongly correlated,<sup>14</sup> but the correlation is not as high as expected, given that the two are often considered equivalent, e.g., (Kiela et al., 2015). Future work should investigate whether the difference originates from inadequate evaluation data and protocols (see Fig. 1(a)-1(b) again), or whether the difference is fundamental.

## 6 Conclusion and Future Work

We have proposed and released a new end-to-end evaluation framework for the task of free word association (WA). We have also provided new evaluation metrics inspired by research in IR, and guidelines for evaluating semantic representation models on the quantitative WA task.

Besides serving as a gold standard in NLP, the comprehensive WA evaluation resource and accompanying evaluation protocol should enable the development of data-driven automatic systems that can capture the notion of word association, and further analysis on how humans perceive (types of) semantic relatedness and similarity (Spence and Owens, 1990; Maki and Buchanan, 2008; De Deyne et al., 2013). These systems, as discussed in this paper, may additionally facilitate research in cognitive psychology pertaining to human semantic representation and memory.

<sup>14</sup>Although it comes as slightly counter-intuitive, research in statistics has shown that transitivity between correlation coefficients does not hold in general (Langford et al., 2001; Castro Sotos et al., 2009). Therefore, the observed behaviour is possible: Relatedness indeed correlates both with Association and with Similarity, while at the same time we do not observe any correlation between Association and Similarity.

In future work, we plan to test the portability of the evaluation protocol and apply it to other repositories of word association data in English (De Deyne et al., 2016), as well as in other languages, using existing WA tables in, e.g., German (Schulte im Walde et al., 2008), Dutch (De Deyne and Storms, 2008; Brysbaert et al., 2014), Italian (Guida and Lenci, 2007), Japanese (Joyce, 2005), or Cantonese (Kwong, 2013).<sup>15</sup>

In another line of future work, we will experiment with other “cognitively plausible” evaluation data such as N400 (Kutas and Federmeier, 2011; Ettinger et al., 2016), and will analyse the similarities and differences between WA and other such “cognitive” evaluation protocols, as the one relying on semantic priming (SPP) (Hutchison et al., 2013; Ettinger and Linzen, 2016).

## Supplementary Material

### Vector Space Models

We evaluate a suite of pre-trained vector space models readily accessible online. We note that these models typically use different training data and other additional resources, and have a varying coverage of the English lexicon, but the evaluation score still reveals their ability to effectively capture word association. As mentioned in the paper, we have aimed at making the comparison fair by evaluating all models using the USF vocabulary as the search space for each model in our comparison.

(0) We evaluate a traditional count-based representation model which uses positive PMI weighting and SVD dimensionality reduction. This is the best performing reduced count-based model from (Baroni et al., 2014). The model was trained on concatenated ukWaC, the English Wikipedia and the British National Corpus with the window size 2, and dimensionality after SVD is set to  $d = 500$ . Vectors were obtained online.<sup>16</sup> We label this model **count-ppmi-500d**.

(1) Two sets of Glove vectors (Pennington et al., 2014) were used ( $d = 50$  and  $d = 30$ ) trained on the 6B corpus of concatenated Wikipedia and GigaWord:<sup>17</sup> **glove-6B-50d** and **glove-6B-300d**.

(2) Pre-trained vectors obtained using skip-gram with negative sampling (SGNS) (Mikolov et al., 2013). We use SGNS vectors from (Levy and Goldberg, 2014): **sgns-pw-bow-w2** and **sgns-pw-bow-w5** denote vectors trained with bag-of-words (BOW) contexts on the Polyglot Wikipedia (PW) (Al-Rfou et al., 2013) with window sizes 2 and 5, respectively; **sgns-pw-deps** denotes vectors trained with dependency-based contexts. All vectors are 300-dimensional.<sup>18</sup> For more details including the preprocessing procedure and the specification of the used dependency parser, we refer the reader to the original work. We evaluate another SGNS-BOW model trained on a large 8B corpus with the window size 2 and  $d = 500$  to measure the potential gains stemming from the use of larger training

corpora.<sup>19</sup> This model was used as a baseline in (Schwartz et al., 2015): **sgns-8b-bow-w2**.

(3) A template-based approach to vector space modeling introduced by Schwartz et al. (2015). Vectors are trained based on co-occurrence of words in symmetric patterns (Davidov and Rapoport, 2006). We use pre-trained dense vectors ( $d = 500$ ) trained on the 8B corpus available online:<sup>20</sup> **sympat-500d**.

(4) Models that use additional linguistic repositories to build semantically specialised improved word vectors. Wieting et al. (2015) use the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013) to learn word vectors which emphasise paraphrasability. They do this by fine-tuning, also known as retro-fitting (Faruqui et al., 2015), SGNS vectors using an objective function designed to incorporate the PPDB semantic similarity constraints. We test two variants of the Paragram model ( $d = 25$  and  $d = 300$ ) available online:<sup>21</sup> **paragram-25d** and **paragram-300d**.

Another variant of the fine-tuning procedure called counter-fitting (CF) was recently proposed by Mrkšić et al. (2016). The model further improves the Paragram vectors by injecting antonymy constraints from PPDB v2.0 (Pavlick et al., 2015) into the final vector space.  $d = 300$ . We label this model **paragram+cf-300d**.<sup>22</sup>

(5) Two multilingual pre-trained embedding models, aiming to test whether multilingual supervision can help in capturing word association the same way it helps semantic similarity tasks. We use pre-trained vectors of (Luong et al., 2015) (**biskip-256d**) which rely on word-aligned parallel data,<sup>23</sup> and CCA-based vectors of Faruqui and Dyer (2014) (**bicca-512d**) which require readily available translation lexicons.<sup>24</sup> As bilingual representations are not the main focus of this work, for further training details, we refer the reader to the literature.

## Abstract

Research on computational argumentation faces the problem of how to automatically assess the quality of an argument or argumentation. While different quality dimensions have been approached in natural language processing, a common understanding of argumentation quality is still missing. This paper presents the first holistic work on computational argumentation quality in natural language. We comprehensively survey the diverse existing theories and approaches to assess logical, rhetorical, and dialectical quality dimensions, and we derive a systematic taxonomy from these. In addition, we provide a corpus with 320 arguments, annotated for all 15 dimensions in the taxonomy. Our results establish a common ground for research on computational argumentation quality assessment.

## 1 Introduction

What is a good argument? What premises should it be based on? When is argumentation persuasive? When is it reasonable? We subsume such questions under the term *argumentation quality*; they have driven logicians, rhetoricians, linguists, and argumentation theorists since the Ancient Greeks (Aristotle, 2007). Now that the area of computational argumentation is seeing an influx of research activity, the automatic assessment of argumentation quality is coming into the focus, due to its importance for envisioned applications such as writing support (Stab and Gurevych, 2014) and argument search (Wachsmuth et al., 2017), among others.

Existing research covers the mining of argument units (Al-Khatib et al., 2016), specific types of evidence (Rinott et al., 2015), and argumentative relations (Peldszus and Stede, 2015). Other works clas-

sify argumentation schemes (Feng et al., 2014) and frames (Naderi and Hirst, 2015), analyze overall argumentation structures (Wachsmuth et al., 2015), or generate claims (Bilu and Slonim, 2016). Also, theories of argumentation quality exist, and some quality dimensions have been assessed computationally (see Section 2 for details). Until now, however, the assertion of O’Keefe and Jackson (1995) that there is neither a general idea of what constitutes argumentation quality in natural language nor a clear definition of its dimensions still holds.

The reasons for this deficit originate in the varying goals of argumentation: persuading audiences, resolving disputes, achieving agreement, completing inquiries, and recommending actions (Tindale, 2007). As a result, diverse quality dimensions play a role, which relate to the logic of arguments, to the style and rhetorical effect of argumentation, or to its contribution to a discussion. Consider the following argument against the death penalty:<sup>1</sup>

*Everyone has an inalienable human right to life, even those who commit murder; sentencing a person to death and executing them violates that right.*

Although implicit, the conclusion about the death penalty seems sound in terms of (informal) logic, and the argument is clear from a linguistic viewpoint. Some people might not accept the first stated premise, though, especially if emotionally affected by some legal case at hand. Or, they might not be persuaded that the stated argument is the most relevant in the debate on death penalty.

This example reveals three central challenges: (1) Argumentation quality is assessed on different levels of granularity; (2) many quality dimensions are subjective, depending on preconceived opinions; and (3) overall argumentation quality seems hard to measure, as the impact and interaction of the different dimensions remain unclear.

<sup>1</sup>Taken from [www.bbc.co.uk/ethics/capitalpunishment](http://www.bbc.co.uk/ethics/capitalpunishment).

This paper does *not* propose a specific approach to assess quality; rather it defines a common ground by providing a so-far-missing holistic view on argumentation quality assessment in natural language. In particular, we first briefly but comprehensively survey all major theories and computational approaches for argumentation quality. Following Blair (2012), we distinguish three main quality aspects, each associated with several quality dimensions:

- *Logical quality* in terms of the cogency or strength of an argument.
- *Rhetorical quality* in terms of the persuasive effect of an argument or argumentation.
- *Dialectical quality* in terms of the reasonableness of argumentation for resolving issues.

We organize the survey along these aspects, discussing quality at four levels of granularity: (1) *argument unit*, i.e., a segment of text that takes the role of a premise or conclusion; (2) *argument*, i.e., a composition of premises and a conclusion, some of which may be implicit; (3) (*monological*) *argumentation*, i.e., a composition of arguments on a given issue; and (4) (*dialogical*) *debate*, i.e., a series of interacting argumentation on the same issue.

To unify and to consolidate existing research, we then derive a generally applicable taxonomy of argumentation quality from the survey. The taxonomy systematically decomposes quality assessment based on the interactions of 15 widely accepted quality dimensions (including the overall quality). Moreover, we provide a new annotated corpus with 320 arguments for which three experts assessed all 15 dimensions, resulting in over 14,000 annotations. Our analysis indicates how the dimensions interact and which of them are subjective, making the corpus an adequate benchmark for future research.

In summary, the contributions of this paper are:

1. A *comprehensive survey* of research on argumentation quality assessment (Section 2).
2. A *taxonomy* of all major quality dimensions of natural language argumentation, which clarifies their roles and dependencies (Section 3).
3. An *annotated corpus* for computational argumentation quality assessment (Section 4).<sup>2</sup>

## 2 Survey of Argumentation Quality

This section briefly surveys all major existing theories and the assessment of natural language argu-

mentation quality. While we order the discussions along the three main quality aspects, we point out overlaps and interrelations where relevant.

### 2.1 Theories of Argumentation Quality

We focus on the major fields dealing with argumentation quality in natural language: argumentation theory and rhetoric. Table 1 gives an overview of the quality dimensions that we detail below.

**Logic** Formal argumentation studies the *soundness* of arguments, requiring the truth of an argument's premises and the deductive *validity* of inferring its conclusion. In case of inductive strength, the conclusion becomes probable given the premises. While sound arguments exist in natural language, most are defeasible in nature (Walton, 2006). The desired property of such arguments is *cogency*.

A cogent (or logically good) argument has individually acceptable premises that are relevant to the argument's conclusion and, together, sufficient to draw the conclusion (Johnson and Blair, 2006). Here, (*local*) *acceptability* means that a premise is rationally worthy of being believed by the target audience of the argument. It replaces truth, which is often unclear (Hamblin, 1970). A premise's (*local*) *relevance* refers to the level of support it provides for the conclusion, and (*local*) *sufficiency* captures whether the premises give enough reason to accept the conclusion. In the end, sufficiency thus presupposes relevance (Blair, 2012). While acceptability is more dialectical, overall the three dimensions of cogency are, with slight variations, acknowledged to cover the logical quality of arguments.

Damer (2009) adds that a good argument also depends on the rebuttal it gives to anticipated counterarguments (a dialectical property) as well as on its structural *well-formedness*, i.e., whether it is intrinsically consistent, avoids begging the question, and uses a valid inference rule. These dimensions adopt ideas from the argument model of Toulmin (1958), including rebuttals and warrants, and from the argumentation schemes of Walton et al. (2008), whose critical questions are meant to evaluate inference rules. While not focusing on quality, critical questions particularly help identify fallacies.

Introduced by Aristotle as invalid arguments, fallacies have been brought back to attention by Hamblin (1970). In general, a fallacy has some sort of error in reasoning (Tindale, 2007). Fallacies range from resorting to inapplicable evidence types or irrelevant premises to rhetoric-related errors, such

<sup>2</sup>The corpus is freely available at: <http://www.arguana.com>

Aspect	Quality Dimension	Granularity	Sources

Table 1: Theoretical treatment of quality dimensions in the referenced sources for the given granularities of natural language argumentation, grouped by the aspect the bold-faced high-level dimensions refer to.

as unjustified appeals to emotion. They represent an alternative assessment of logical quality. Following Damer (2009), a fallacy can always be seen as a violation of one or more dimensions of good arguments. *Fallaciousness* negatively affects an argument’s *strength* (Tindale, 2007).

Argument strength is often referred to, but its meaning remains unclear: “Is a strong argument an effective argument which gains the adherence of the audience, or is it a valid argument, which ought to gain it?” (Perelman et al., 1969). Tindale (2007) sees validity as a possible but not mandatory part of reasoning strength. Freeman (2011) speaks of the strength of support, matching the idea of inductive strength. Blair (2012) roughly equates strength with cogency, and Hoeken (2001) observes correlations between evidence strength and rhetorical persuasiveness. Such dependencies are expected, as the use of true and valid arguments represents one means of persuasion: *logos* (Aristotle, 2007).

**Rhetoric** Aristotle’s work on rhetoric is one of the most systematic to this day. He defines rhetoric as the ability to know how to persuade (Aristotle, 2007). Besides *logos*, the three means of persuasion he sees include *ethos*, referring to the arguer’s *credibility*, and *pathos*, the successful *emotional appeal* to the target audience. Govier (2010) outlines how emotions interfere with logic in arguments.

*Pathos* is not necessarily reprehensible; it just aims for an emotional state adequate for persuasion.

In overall terms, rhetorical quality is reflected by the persuasive *effectiveness*, i.e., the success in persuading a target audience of a conclusion (Blair, 2012). It has been suggested that what arguments are considered as effective is subjective (O’Keefe and Jackson, 1995). Unlike persuasiveness, which relates to the actual arguments, effectiveness covers all aspects of an argumentation, including the use of language (van Eemeren, 2015). In particular, the three means of persuasion are meant to be realized by what is said and how (Aristotle, 2007). Several linguistic quality dimensions are connected to argumentation (examples follow in Section 2.2). While many of them are distinguished by Aristotle, he groups them as the *clarity* and the *appropriateness* of style as well as the proper *arrangement*.

Clarity means the use of correct, unambiguous language that avoids unnecessary complexity and deviation from the discussed issue (Aristotle, 2007). Besides ambiguity, vagueness is a major problem impairing clarity (Govier, 2010) and can be a cause of fallacies (Tindale, 2007). So, clarity is a prerequisite of *logos*. Also, it affects credibility, since it indicates the arguer’s skills. An appropriate style in terms of the choice of words supports credibility and emotions. It is tailored to the issue and

audience (Aristotle, 2007). Arrangement, finally, addresses the structure of argumentation regarding the presentation of the issue, pros, cons, and conclusions. Damer (2009) outlines that a proper arrangement is governed by the dimensions of a good argument. To be effective, well-arranged argumentation matches the expectations of the target audience and is, thus, related to dialectic (Blair, 2012).

**Dialectic** The dialectical view of argumentation targets the resolution of differences of opinions on the merit (van Eemeren and Grootendorst, 2004). Quality is assessed for well-arranged discussions that seek agreement. In contrast to the subjective nature of effectiveness, people are good in such an assessment (Mercier and Sperber, 2011). In their pragma-dialectical theory, van Eemeren and Grootendorst (2004) develop rules for obtaining *reasonableness* in critical discussions. Reasonableness emerges from two complementary dimensions, intersubjective (*global*) *acceptability* and problem-solving validity, but effectiveness still remains the underlying goal (van Eemeren, 2015). For argumentation, global acceptability is given when the stated arguments and the way they are stated are acceptable to the whole target audience. Problem-solving validity matches the (*global*) *relevance* of argumentation that contributes to resolution, helping arrive at an ultimate conclusion (Walton, 2006).

Global relevance implicitly excludes fallacious moves, so reasonable arguments are cogent (van Eemeren, 2015). Van Eemeren sees reasonableness as a precondition for *convincingness*, the rational version of persuasiveness. Following Perelman et al. (1969), persuasive argumentation aims at a particular audience, whereas convincing argumentation aims at the universal audience, i.e., all reasonable beings. This fits the notion that dialectic examines general rather than specific issues (Aristotle, 2007).

Convincingness needs (*global*) *sufficiency*, i.e., all objections to an argumentation are countered. The dilemma here is that the number of objections could be infinite, but without global sufficiency the required support seems arbitrary (Blair, 2012). A solution is the relaxed view of Damer (2009) that only those counter-arguments that can be anticipated are to be rebutted. For debates, Cohen (2001) speaks of dialectical satisfactoriness, i.e., whether all questions and objections have been sufficiently answered. In case a reasonable debate ends up in either form of global sufficiency, this implies that the discussed difference of opinion is resolved.

**Other** Although closely related, critical thinking (Freeley and Steinberg, 2009) and persuasion research (Zhao et al., 2011) are covered only implicitly here; their views on quality largely match with argumentation theory. We have not discussed deliberation, as it is not concerned with the quality of argumentation primarily but rather with communicative dimensions of group decision-making, e.g., participation and respect (Steenbergen et al., 2003). Also, we have restricted our view to the logic found in natural language. For formal and probabilistic logic, dimensions such as degree of justification (Pollock, 2001), argument strength (Pfeifer, 2013), and premise relevance (Ransom et al., 2015) have been analyzed. As we see below, such logic influenced some practical assessment approaches.

## 2.2 Approaches to Quality Assessment

As for the theories, we survey the automatic quality assessment for natural language argumentation. All discussed approaches are listed in Table 2.

**Logic** Braunstain et al. (2016) deal with logical argument quality in community question answering: Combining relevance-oriented retrieval models and argument-oriented features, they rank sentence-level argument units according to the *level of support* they provide for an answer. Unlike classical essay scoring, Rahimi et al. (2014) score an essay's *evidence*, a quality dimension of argumentation: it captures how sufficiently the given details support the essay's thesis. On the dataset of Correnti et al. (2013) with 1569 student essays and scores from 1 to 4, they find that the concentration and specificity of words related to the essay prompt (i.e., the statement defining the discussed issue) impacts scoring accuracy. Similarly, Stab and Gurevych (2017) introduce an essay corpus with 1029 argument-level annotations of *sufficiency*, following the definition of Johnson and Blair (2006). Their experiments suggest that convolutional neural networks outperform feature-based sufficiency classification.

**Rhetoric** Persing et al. (2010) tackle the proper arrangement of an essay, namely, its *organization* in terms of the logical development of an argument. The authors rely on manual 7-point score annotations for 1003 essays from the ICLE corpus (Granger et al., 2009). In their experiments, sequences of paragraph discourse functions (e.g., introduction or rebuttal) turn out to be most effective. Organization is also analyzed by Rahimi et al. (2015) on the same dataset used for the evidence

Aspect	Quality Dimension	Granularity	Text Genres	Sources
Logic	Evidence	Argumentation	Student essays	Rahimi et al. (2014)
	Level of support	Argument unit	Wikipedia articles	Braunstein et al. (2016)

	Evaluability	Argumentation	Law comments	Park et al. (2015)
	Global coherence	Argumentation	Student essays	Feng et al. (2014)
	Organization	Argumentation	Student essays	Persing et al. (2010), Rahimi et al. (2015)
	Persuasiveness	Argument	Forum discussions	Tan et al. (2016), Wei et al. (2016)
	Prompt adherence	Argumentation	Student essays	Persing and Ng (2014)
	Thesis clarity	Argumentation	Student essays	Persing and Ng (2013)
	Winning side	Debate	Oxford-style debates	Zhang et al. (2016)
Dialectic	Acceptability	Argument	Debate portal arguments	Cabrio and Villata (2012)
	Convincingness	Argument	Debate portal arguments	Habernal and Gurevych (2016)
	Prominence	Argument	Forum discussions	Boltužić and Šnajder (2015)
	Relevance	Argument	Diverse genres	Wachsmuth et al. (2017)

Table 2: Practical assessment of quality dimensions in the referenced sources for the given granularities and text genres of natural language argumentation, grouped by the aspect the quality dimensions refer to.

approach above. Their results indicate a correlation between organization and local coherence. Feng et al. (2014) parse discourse structure to assess *global coherence*, i.e., the continuity of meaning in a text. Lacking ground-truth coherence labels, they evaluate their approach on sentence ordering and organization scoring instead. Coherence affects the clarity of style, as do the *thesis clarity* and *prompt adherence* of essays. Persing and Ng (2013) find the former to suffer from misspellings, while Persing and Ng (2014) use prompt-related keywords and topic models to capture the latter (both for 830 ICLE essays like those mentioned above). For comments in lawmaking, Park et al. (2015) develop an argumentation model that prescribes what information users should give to achieve *evaluability* (e.g., testimony evidence or references to resources).

Not only linguistic quality, but also effectiveness is assessed in recent work: Persing and Ng (2015) score the *argument strength* of essays, which they define rhetorically in terms of how many readers would be persuaded. Although potentially subjective, their manual 7-point score annotations of 1000 ICLE essays differ by at most 1 in 67% of the studied cases. Their best features are heuristic argument unit labels and part-of-speech n-grams. Recently, Wachsmuth et al. (2016) demonstrated that the output of argument mining helps in such argumentation-related essay scoring, obtaining better results for argument strength and organization. Tan et al. (2016) analyze which arguments achieve *persuasiveness* in “change my view” forum discussions, showing that multiple interactions with the view-holder are beneficial as well as an appropriate style and a high number of participants. On similar

data, Wei et al. (2016) find that also an author’s reputation impacts persuasiveness. Zhang et al. (2016) discover for Oxford-style debates that attacking the opponents’ arguments tends to be more effective than relying on one’s own arguments. These results indicate the relation of rhetoric and dialectic.

**Dialectic** Dialectical quality has been addressed by Cabrio and Villata (2012). The authors use textual entailment to find ground-truth debate portal arguments that attack others. Based on the formal argumentation framework of Dung (1995), they then assess global argument *acceptability*. Habernal and Gurevych (2016) compare arguments in terms of *convincingness*. However, the subjective nature of their crowdsourced labels actually reflects rhetorical effectiveness. Boltužić and Šnajder (2015) present first steps towards argument *prominence*. Prominence may be a product of popularity, though, making its quality nature questionable, as popularity is often not correlated with merit (Govier, 2010). In contrast, Wachsmuth et al. (2017) adapt the famous PageRank algorithm to objectively derive the *relevance* of an argument at web scale from what other arguments refer to the argument’s premises. On a large ground-truth argument graph, their approach beats several baselines for the benchmark argument rankings that they provide.

**Other** Again, we have left out deliberative quality (Gold et al., 2015). Also, we omit approaches that classify argumentation schemes (Feng and Hirst, 2011), evidence types (Rinott et al., 2015), ethos-related statements (Duthie et al., 2016), and myside bias (Stab and Gurevych, 2016); their output may help assess quality assessment, but they do not actually assess it. The same holds for argument mining,

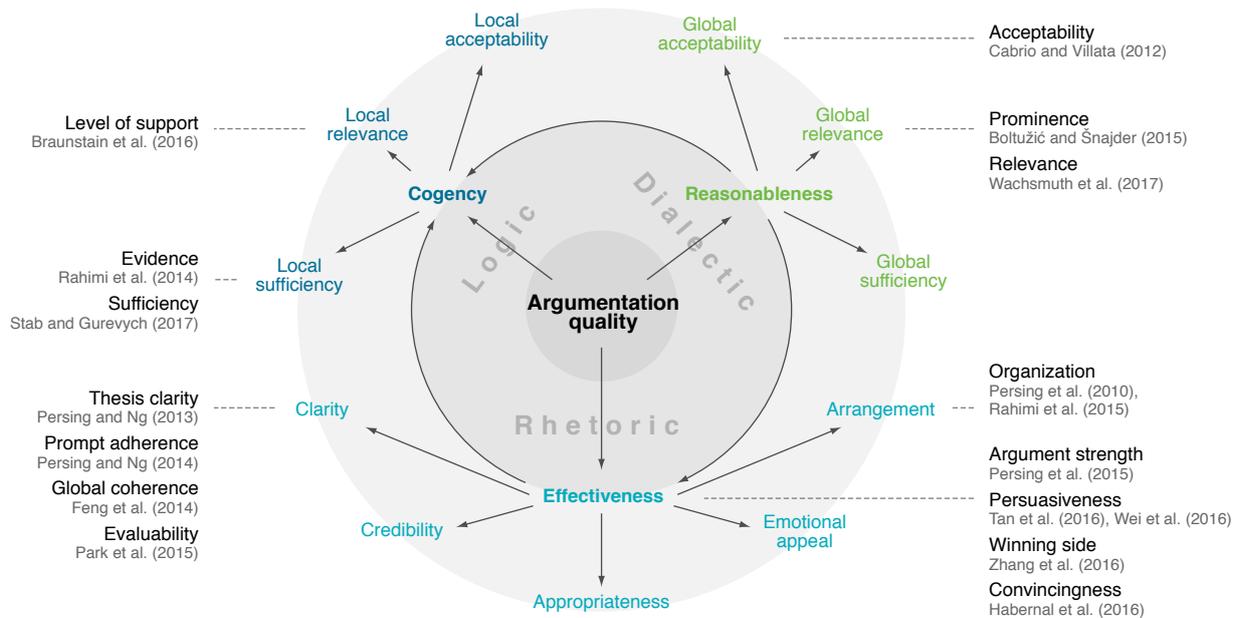

Figure 1: The proposed taxonomy of argumentation quality as well as the mapping of existing assessment approaches to the covered quality dimensions. Arrows show main dependencies between the dimensions.

even if said to aim for argument quality (Swanson et al., 2015). Much work exists for general text quality, most notably in the context of readability (Pitler and Nenkova, 2008) and classical essay scoring. Some scoring approaches derive features from discourse (Burstein et al., 1998), arguments (Ong et al., 2014; Beigman Klebanov et al., 2016; Ghosh et al., 2016), or schemes (Song et al., 2014)—all this may be indicative of quality. However, our focus is approaches that target argumentation quality at heart. Similarly, review helpfulness (Liu et al., 2008) and deception (Ott et al., 2011) are not treated, as arguments only partly play a role there. Also, only few Wikipedia quality flaws relate to arguments, e.g., verifiability (Anderka et al., 2012).

### 3 A Taxonomy of Argumentation Quality

Given all surveyed quality dimensions, we now propose a unifying taxonomy of argumentation quality. The taxonomy decomposes quality assessment systematically, thus organizing and clarifying the roles of practical approaches. It does not require a particular argumentation model, but it rests on the notion of the granularity levels from Section 1.

#### 3.1 Overview of the Theory-based Taxonomy

Our objective is not to come up with a new theory, but to provide a unified view of existing theories that is suitable for quality assessment. We aim for a common understanding of the dimensions that af-

fect quality, what interdependencies they have, and how they interact. Figure 1 illustrates the taxonomy that we propose for this purpose. The rationale behind its structure and its layout is as follows.

While Section 2 has outlined overlaps and relations between the three aspects of argumentation, we have identified one dominant high-level quality dimension of *argumentation quality* in theory for each aspect: logical *cogency*, rhetorical *effectiveness*, and dialectical *reasonableness*. The latter two benefit from cogency, and reasonableness depends on effectiveness, as discussed. Often, only one of them will be in the focus of attention in practice, or even only a sub-dimension. In particular, each high-level dimension has a set of sub-dimensions agreed upon. The sub-dimensions are shown on the outer ring in Figure 1, roughly positioned according to the aspects they refer to, e.g., *local acceptability* lies next to the other dialectical dimensions. We ordered the sub-dimensions by their interrelations (left implicit for conciseness), e.g., *appropriateness* supports *credibility* and *emotional appeal*.

Slightly deviating from theory, we match Aristotle’s *logos* dimension with cogency, which better fits real-world argumentation. Similarly, we omit those dimensions from Table 1 in the taxonomy that have unclear definitions, such as strength, or that are covered by others, such as well-formedness, which merely refines the acceptability part of cogency (Govier, 2010). Convincingness is left out,

as it is close to effectiveness and as both the feasibility and the need of persuading the universal audience has been questioned (van Eemeren, 2015). Instead, we add *global sufficiency* as part of reasonableness. While global sufficiency may be infeasible, too (Blair, 2012), it forces agreement in critical discussions and, thereby, reasonableness.

### 3.2 Definitions of the Quality Dimensions

Cogency is seen as an argument property, whereas effectiveness and reasonableness are assessed on the argumentation level usually. For generality, we give informal literature-based definitions of these dimensions and all sub-dimensions here for an author who argues about an issue to a target audience:

**Cogency** An argument is cogent if it has acceptable premises that are relevant to its conclusion and that are sufficient to draw the conclusion.

- *Local acceptability*: A premise of an argument is acceptable if it is rationally worthy of being believed to be true.
- *Local relevance*: A premise of an argument is relevant if it contributes to the acceptance or rejection of the argument’s conclusion.
- *Local sufficiency*: An argument’s premises are sufficient if, together, they give enough support to make it rational to draw its conclusion.

**Effectiveness** Argumentation is effective if it persuades the target audience of (or corroborates agreement with) the author’s stance on the issue.

- *Credibility*: Argumentation creates credibility if it conveys arguments and similar in a way that makes the author worthy of credence.
- *Emotional Appeal*: Argumentation makes a successful emotional appeal if it creates emotions in a way that makes the target audience more open to the author’s arguments.
- *Clarity*: Argumentation has a clear style if it uses correct and widely unambiguous language as well as if it avoids unnecessary complexity and deviation from the issue.
- *Appropriateness*: Argumentation has an appropriate style if the used language supports the creation of credibility and emotions as well as if it is proportional to the issue.
- *Arrangement*: Argumentation is arranged properly if it presents the issue, the arguments, and its conclusion in the right order.

**Reasonableness** Argumentation is reasonable if it contributes to the issue’s resolution in a sufficient way that is acceptable to the target audience.

- *Global acceptability*: Argumentation is acceptable if the target audience accepts both the consideration of the stated arguments for the issue and the way they are stated.
- *Global relevance*: Argumentation is relevant if it contributes to the issue’s resolution, i.e., if it states arguments or other information that help to arrive at an ultimate conclusion.
- *Global sufficiency*: Argumentation is sufficient if it adequately rebuts those counter-arguments to it that can be anticipated.

### 3.3 Organization of Assessment Approaches

The taxonomy is meant to define a common ground for assessing argumentation quality, including the organization of practical approaches. The left and right side of Figure 1 show where the approaches surveyed in Section 2.2 are positioned in the taxonomy. Some dimensions have been tackled multiple times (e.g., *clarity*), others not at all (e.g., *credibility*). The taxonomy indicates what sub-dimensions will affect the same high-level dimension.

## 4 The Dagstuhl-15512 ArgQuality Corpus

Finally, we present our new annotated *Dagstuhl-15512 ArgQuality Corpus* for studying argumentation quality based on the developed taxonomy, and we report on a first corpus analysis.<sup>3</sup>

### 4.1 Data and Annotation Process

Our corpus is based on the *UKPConvArgRank* dataset (Habernal and Gurevych, 2016), which contains rankings of 25 to 35 textual debate portal arguments for two stances on 16 issues, such as *evolution vs. creation* and *ban plastic water bottles*. All ranks were derived from crowdsourced convincingness labels. For every issue/stance pair, we took the five top-ranked texts and chose five further via stratified sampling. Thereby, we covered both high-quality arguments and different levels of lower quality. Two example texts follow below in Figure 2.

Before annotating the 320 chosen texts, we carried out a full annotation study with seven authors of this paper on 20 argumentative comments from

<sup>3</sup>The corpus and annotation guidelines are available at <http://www.arguana.com>. The corpus is named after the Dagstuhl Seminar 15512 “Debating Technologies” that initialized the research in this paper: <http://www.dagstuhl.de/15512>

Table 3: Results for the 304 corpus texts classified as argumentative by all annotators: (a) Distribution of majority scores for each dimension (2 used in case of full disagreement). (b) Krippendorff’s  $\alpha$  of the most agreeing annotator pair and full/majority agreement of all annotators. (c) Correlation for each dimension pair, averaged over the correlations of all annotators. The highest value in each column is marked bold.

the unshared task dataset of the 3rd Workshop on Argument Mining.<sup>4</sup> The annotators assessed all 15 quality dimensions in the taxonomy for each comment (including its overall quality). Due to simple initial guidelines based on the definitions from Section 3 and the subjectiveness of the task, the agreement of all seven annotators was low for all dimensions, namely, at most .22 in terms of Krippendorff’s  $\alpha$ . The three most agreeing annotators for each dimension achieved much higher  $\alpha$ -values between .23 (clarity) and .60 (credibility), though.<sup>5</sup>

The study results were discussed by all annotators, leading to a considerably refined version of the guidelines. We then selected three annotators for the corpus annotation based on their availability. They work at two universities and one company in three countries (two females, one male; two PhDs, one PhD student). For each text in the corpus, all annotators first classified whether it was actually argumentative. If so, they assessed all dimensions using ordinal scores from 1 (low) to 3 (high).<sup>6</sup> Additionally, “cannot judge” could be chosen.

## 4.2 Corpus Distribution and Agreement

Table 3(a) lists the majority scores of each dimension for the 304 corpus texts (95%) that are classified as argumentative by all annotators, all covering

<sup>4</sup>Unshared task data found at: <http://github.com/UKPLab>

<sup>5</sup>We use Krippendorff’s  $\alpha$  as is suitable for small samples, multiple ratings, and ordinal scales (Krippendorff, 2007).

<sup>6</sup>We chose a 3-point scale to foster clear decisions on the quality; in the annotation study, we used a 4-point scale but observed that the annotators only rarely chose score 1 and 4.

the whole score range. Five dimensions have the median at score 1, the others at 2. Some seem easier to master, such as *local relevance*, which received the highest majority score 124 times. Others rarely got score 3, above all *global sufficiency*. The latter is explained by the fact that only few texts include any rebuttal of counter-arguments.

Only one of the over 14,000 assessments made by the three annotators was “cannot judge” (for *global relevance*), suggesting that our guidelines were comprehensive. Regarding agreement, we see in Table 3(b) that the  $\alpha$ -values of all logical and dialectical quality dimensions except for *global sufficiency* lie above 0.4 for the most agreeing annotator pair. As expected, the rhetorical dimensions seem to be more subjective. The lowest  $\alpha$  is observed for *emotional appeal* (0.26). The annotators most agreed on the *overall quality* ( $\alpha = 0.51$ ), possibly meaning that the taxonomy adequately guides the assessment. In accordance with the moderate  $\alpha$ -values, full agreement ranges between 17.4% and 44.7% only. On the contrary, we observe high majority agreement between 87.5% and 98% for all dimensions, even where scores are rather evenly distributed, such as for *global acceptability* (95.4%). In case of full disagreement, it makes sense to use score 2. We hence argue that the corpus is suitable for evaluating argumentation quality assessment.

Figure 2 shows all scores of each annotator for two example arguments from the corpus, referring to the question whether to ban plastic water bottles. Both have majority score 3 for *overall quality* (*Ov*),

Scores	<b>Pro</b> Water bottles, good or bad? Many people believe plastic water bottles to be good. But the truth is water bottles are polluting land and unnecessary. Plastic water bottles should only be used in emergency purposes only. The water in those plastic are only filtered tap water. In an emergency situation like Katrina no one had access to tap water. In a situation like this water bottles are good because it provides the people in need. Other than that water bottles should not be legal because it pollutes the land and big companies get 1000% of the profit.															<b>Con</b> Americans spend billions on bottled water every year. Banning their sale would greatly hurt an already struggling economy. In addition to the actual sale of water bottles, the plastics that they are made out of, and the advertising on both the bottles and packaging are also big business. In addition to this, compostable waters bottle are also coming onto the market, these can be used instead of plastics to eliminate that detriment. Moreover, bottled water not only has a cleaner safety record than municipal water, but it easier to trace when a potential health risk does occur. ( <a href="http://www.friendsjournal.org/bottled-water">http://www.friendsjournal.org/bottled-water</a> ) ( <a href="http://www.cdc.gov/healthywater/drinking/bottled/">http://www.cdc.gov/healthywater/drinking/bottled/</a> )

Figure 2: The scores of each annotator and the majority score for all considered quality dimensions of one pro and one con argument from our corpus. The arguments refer to the issue *ban plastic water bottles*.

but the pro argument shows more controversy with full disagreement in case of *effectiveness* (*Ef*). Especially, *annotator B* seems to be critical, giving one point less for several dimensions. In contrast, the con argument yields majority agreement for all 15 dimensions and full agreement for seven of them. It meets main quality criteria surveyed in Section 2, such as a rebuttal or references to resources. In fact, it constitutes the only corpus text with majority score 3 for *global sufficiency* (*GS*).

### 4.3 Correlations between Quality Dimensions

Table 3(c) compares the correlations of all dimension pairs. *Cogency* (.84), *effectiveness* (.81), and *reasonableness* (.86) correlate strongly with *overall quality*, and also much with each other.

*Cogency* and *local sufficiency* (.84) go hand in hand, whereas *local acceptability* and *local relevance* show the highest correlation with their global counterparts (.75 and .68 respectively). Quite intuitively, *credibility* and *appropriateness* correlate most with the acceptability dimensions. The coefficients of *emotional appeal* seem lower than expected, in particular for *effectiveness* (.31), indicating the limitation of a correlation analysis: As reflected by the 235 texts with majority score 2 for emotional appeal, many arguments make no use of emotions, thus obliterating effects of those which do. On the other hand, *clarity* was scored 2 in most cases, too, so the very low value there (.14) is more meaningful. Clarity rather correlates with *arrangement* (.56), which in turn shows coefficients above .50 for all high-level dimensions.

Altogether, the correlations largely match the surveyed theory. While an analysis of cause and effect should follow in future work, they provide first evidence for the adequacy of our taxonomy.

## 5 Conclusion

Argumentation quality is of high importance for argument mining, debating technologies, and similar. In computational linguistics, it has been treated only rudimentarily so far. This paper defines a common ground for the automatic assessment of argumentation quality in natural language. Based on a survey of existing theories and approaches, we have developed a taxonomy that unifies all major dimensions of logical, and dialectical argumentation quality. In addition, we freely provide an annotated corpus for studying these dimensions.

The taxonomy is meant to capture *all* aspects of argumentation quality, irrespective of how they can be operationalized. The varying inter-annotator agreement we obtained suggests that some quality dimensions are particularly subjective, raising the need to model the target audience of an argumentation. Still, the observed correlations between the dimensions support the general adequacy of our taxonomy. Moreover, most dimensions have already been approached on a certain abstraction level in previous work, as outlined. While some refinement may be suitable to meet all requirements of the community, we thus propose the taxonomy as the common ground for future research on computational argumentation quality assessment and the corpus as a first benchmark dataset for this purpose.

# A method for in-depth comparative evaluation: How (dis)similar are outputs of POS taggers, dependency parsers and coreference resolvers really?

**Don Tuggener**

University of Zurich

Institute of Computational Linguistics

tuggener@cl.uzh.ch

## Abstract

This paper proposes a generic method for the comparative evaluation of system outputs. The approach is able to quantify the pairwise differences between two outputs and to unravel in detail what the differences consist of. We apply our approach to three tasks in Computational Linguistics, i.e. POS tagging, dependency parsing, and coreference resolution. We find that system outputs are more distinct than the (often) small differences in evaluation scores seem to suggest.

## 1 Introduction

While there exist well-defined procedures to evaluate system outputs against manually annotated gold data for many tasks in Computational Linguistics, generally little effort and exploration goes into identifying and analysing the differences between the outputs themselves. System outputs are usually compared in the following manner: The standard evaluation protocol for many tasks consists of comparing a system output (the *response*) to a manual annotation of the same data (the *key*). The difference between the response and key is quantified by a similarity metric such as accuracy, and different system outputs are compared to each other by ranking their scores with respect to the similarity metric.

However, comparing the scores of the similarity metric does not paint the full picture of the differences between the outputs, as we will demonstrate. There are hardly any principled or generic evaluation approaches that aim at comparing two or more system responses directly to investigate, highlight, and quantify their differences in detail. Closing this gap is desirable, because progress in many NLP tasks is often made in small steps, and it is

often left unclear what the specific contribution of a novel approach is if the comparison to related work is solely based on a (sometimes marginally) small improvement in F1 score or accuracy. Furthermore, an overall improvement regarding accuracy achieved by a new approach might come at the cost of failing in some areas where a baseline system was correct. Vice versa, a new approach might not improve overall accuracy, but solve particular problems that no other system has been able to address.

We propose an evaluation approach which aims at shedding light on the particular differences between system responses and which is intended as a complement to evaluation metrics such as F1-score and accuracy. By doing so, we strive to provide researchers with a tool that is able to give insight into the particular strengths and weaknesses of their system in comparison to others.<sup>1</sup> Our method is also useful in iterative system development, as it tracks changes in the outputs of different system versions or feature sets. Furthermore, our approach is able to compare multiple system outputs at once, which enables it to identify hard (or easy) problem areas by assessing how many of the systems solve a problem correctly and give according upper bounds for system ensembles. The performance difference between the simulated ensemble and the individual systems serves as an additional indicator of the difference between the system outputs.

We exemplify the application of our approach by aiming to answer the question of how (dis)similar are the outputs of several state-of-the-art systems for different tasks in NLP. We first motivate why using evaluation metrics such as accuracy is not suited for comparing outputs (next section). We then propose a method to do so which

<sup>1</sup>Code available at: <https://github.com/dtuggener/ComparEval>

introduces an inventory to systematically classify and quantify output differences (section 2). Next, we demonstrate how combining a set of outputs can be used to identify their divergence and to identify hard (and easy) problem areas by looking at upper bounds in performance achieved by an oracle output combination (section 3).

### 1.1 Motivation

First let us motivate why comparing accuracy or F1 scores is not a suited method for establishing the (dis)similarity of system outputs. Consider a simple synthetic problem set with four test cases  $\{A, B, C, D\}$  (e.g. a sequence of POS tags). A system response  $S_1$  solves correctly the cases  $A$  and  $B$ , while a system response  $S_2$  returns the correct answers for the cases  $C$  and  $D$ . In terms of accuracy, both responses achieve identical scores, i.e. 50%. However, their output is maximally dissimilar. Extending the set of cases, assume five problems,  $\{A, B, C, D, E\}$ , and three responses  $S_1, S_2$ , and  $S_3$  as shown in table 1. Although the three responses achieve the same accuracy (left table), their pairwise overlap in terms of identical correct responses (right table) varies considerably, i.e.  $S_1$  is much more similar to  $S_2$  (two shared answers) than to  $S_3$  (one shared answer).

Key	A	B	C	D	E	Acc.	Overlap	
$S_1$	A	B	C	D	E	60%	$S_1, S_2$	67%
$S_2$	A	B	C	D	E	60%	$S_2, S_3$	67%
$S_3$	A	B	C	D	E	60%	$S_1, S_3$	33%

Table 1: Accuracy vs. Overlap on correct answers

In fact, the establishment of the similarity of the responses  $S_1, S_2$ , and  $S_3$  is more complicated, because we have left out the overlap of the incorrect answers in the responses. Consider the full responses in table 2.

Key	A	B	C	D	E	Acc.	Overlap	
$S_1$	A	B	C	X	Y	60%	$S_1, S_2$	40%
$S_2$	Z	B	C	D	U	60%	$S_2, S_3$	60%
$S_3$	Z	W	C	D	E	60%	$S_1, S_3$	20%

Table 2: Accuracy vs. Overlap on all answers

The overlap metric (right table) now compares how many of the cells in two rows have identical answers, regardless of whether the answer is correct. The overlap-based similarities between the systems have become more diverse, i.e.  $S_1$  and  $S_3$

are more dissimilar than in the previous table, and the similarities of the pairs  $(S_1, S_2)$  and  $(S_2, S_3)$  are now distinct, because  $S_2$  and  $S_3$  share the error  $Z$  (beside the correct answers  $C$  and  $D$ ), while  $S_1$  and  $S_2$  do not share an error.

Hence, evaluating systems based on performance metrics such as accuracy and F1 scores provides no insight into the differences between the systems and is not able to accurately quantify the similarities between them. That is, a small difference in accuracy does not necessarily imply a high similarity of the outputs, and, vice versa, a larger difference in accuracy does not necessarily signify vastly dissimilar outputs.

Moreover, evaluation based on scores in performance metrics such as F1 does not detail in what regard a system performs better than another. Two systems might implement very distinct approaches, but achieve very similar scores in evaluation. Based on e.g. F1, we cannot assert whether a response  $S_2$  performs better than a response  $S_1$  because a) it solves the same problems as  $S_1$  and then some additional ones, or b) if  $S_2$  and  $S_1$  solve a quite diverse set of problems and  $S_2$  happens to solve a few more in its area of expertise. Additionally, a system that performs better than a baseline is bound to make errors where the baseline was correct. The overall accuracies cannot tell us how often this is the case.

In summary, the comparison of systems based on overall performance scores only lets us glimpse the proverbial tip of the iceberg. Therefore, our approach to comparative evaluation features three main points of interest:

1. How are the differences between system responses quantifiable?
2. What is the nature of the difference between two responses?
3. How can we assess the divergence of a set of responses, how complementary are they?

We try to answer these questions regarding three main tasks, namely POS tagging, dependency parsing, and coreference resolution. We select these tasks because they are fairly widespread procedures in Computational Linguistics and their evaluation increases in complexity. While we limit ourselves to these, we believe our approach to be generic enough to be applied to other labeling problems, such as named entity recognition and semantic role labeling.

## 2 Quantifying differences in system responses

As argued above, system responses differ both regarding the correct answers they give and the errors they make. The underlying idea of our approach is to assess how many of the labeled linguistic units (i.e. tokens) in the key have different labels in the responses, regardless of whether the labels are correct.<sup>2</sup> In a second step, we use a class inventory to analyse and quantify these differences in more detail.

Formally, given a set of tokens  $T$  and two accompanying system responses  $S_1$  and  $S_2$ , we quantify how many of the tokens  $t_i \in T$  have a different label in  $S_1$  and  $S_2$ :

$$\text{diff}(S_1, S_2 | T) = \frac{|\forall t_i \in T : \text{label}(t_i, S_1) \neq \text{label}(t_i, S_2)|}{|T|} \quad (1)$$

Note that switching the inequality condition ( $\neq$ ) to equality ( $=$ ) actually yields the accuracy metric. That is, taking  $S_1$  as the key and the  $S_2$  as the response and calculating accuracy produces the inverted results of our metric, i.e.  $1 - \text{diff}(S_1, S_2 | T)$ , since accuracy is the ratio of tokens that have identical labels. The question is then, why not simply use  $S_1$  as the key and  $S_2$  as the response and calculate accuracy? While this answers whether two systems solve a similar or diverse set of problems, it does not enable us to identify the sources of the differences that drive the better performance of one response over the other. That is, if a token has a different label in  $S_1$  and  $S_2$ , we cannot tell which and if any of the responses is correct. Hence, we need to look at the gold labels of the tokens  $T$  in a key  $K$ . This enables us to categorise differences in the outputs into three distinct and informative classes<sup>3</sup>:

- **Correction:**  $S_1$  labels a token incorrectly,  $S_2$  corrects this error
- **New error:**  $S_1$  is correct,  $S_2$  introduces an error
- **Changed error:** Both  $S_1$  and  $S_2$  are incorrect but have different labels

The general algorithm to quantify differences in two responses  $S_1$  and  $S_2$  given a set of tokens  $t_{i..n}$

<sup>2</sup>In other words, the complement of the overlap metric in tables 1 and 2.

<sup>3</sup>To motivate the nomenclature, we assume that  $S_1$  is e.g. a baseline upon which  $S_2$  tries to improve. However, the outputs can stem from any two systems.

in a key  $K$  is outlined in algorithm 1. This procedure lets us track and count how often  $S_2$  has a different label than  $S_1$ , classify the difference, and calculate the percentage of each class of difference. The approach can be applied straightforwardly to comparing outputs of POS taggers and dependency parsers.

---

### Algorithm 1 Track differences in two responses

**Input:** Key  $K \ni$  tokens  $t_{i..n}$ , Responses  $S_1, S_2$

**Output:** Difference  $D$ , Changes  $C$

```

1: for  $t_i \in K$  do
2:    $G = \text{label}(t_i, K)$ 
3:    $L_1 = \text{label}(t_i, S_1)$ 
4:    $L_2 = \text{label}(t_i, S_2)$ 
5:    $\text{TokCnt} + +$ 
6:   if  $L_1 \neq L_2$  then
7:     if  $L_2 = G$  then
8:        $C[\text{correction}][L_1, L_2] + +$ 
9:     else if  $L_1 = G$  then
10:       $C[\text{new error}][L_1, L_2] + +$ 
11:    else
12:       $C[\text{changed error}][L_1, L_2] + +$ 
13:       $\text{DiffLabel} + +$ 
14:  $D = \frac{\text{DiffLabel}}{\text{TokCnt}}$ 
15: return  $D, C$ 

```

### 2.1 POS tagging

We compare three POS taggers than can be used off-the-shelf to tag German: the Stanford POS Tagger (Toutanova et al., 2003), the TreeTagger (Schmid, 1995), and the Clevertagger (Sennrich et al., 2013, state-of-the-art). Following Sennrich et al. (2013), we use 3000 sentences from the TübaD/Z (Telljohann et al., 2004), a corpus of articles from a German newspaper, as a test set.<sup>4</sup>

Table 3 shows the labeling accuracy of the POS taggers and the percentage of correctly tagged sentences. The accuracy improvement of Clevertagger over TreeTagger is +1.27 points, and the percentage of correctly tagged sentences increases substantially (+9.9 points). In comparison to the Stanford tagger<sup>5</sup>, Clevertagger raises performance

<sup>4</sup>We change the POS tag for pronominal adverbs from PROP to PROAV in the test set, since all taggers feature only the latter tag.

<sup>5</sup>The most frequent error by the Stanford tagger is labeling some punctuation tokens (e.g. ‘-’) as ‘\$[’ instead of ‘\$(’. Considering it a minor error, we replace all ‘\$[’ labels in the Stanford response with ‘\$(’, increasing accuracy from 86.60 to 90.41%.

	Accuracy	Correct sents.
Stanford	90.41	30.07
TreeTagger	94.89	46.87
Clevertagger	96.16	56.77

	<i>diff</i>	$\Delta$ Acc.
Stanford $\leftrightarrow$ TreeTagger	<b>11.06</b>	4.48
Stanford $\leftrightarrow$ Clevertagger	9.41	<b>5.75</b>
TreeTagger $\leftrightarrow$ Clevertagger	4.96	1.27

Table 3: Accuracy and differences between POS taggers

by roughly 6 points in accuracy, but almost doubles the numbers of correctly tagged sentences.

In the lower table, we see that although the accuracy difference puts the Stanford tagger closer to the TreeTagger (4.48) than to the Clevertagger (5.75), the Stanford tagger’s response is more different from the one of TreeTagger (11.06) than from the response of Clevertagger (9.41). Comparing the two best performing taggers, we see that despite their accuracy difference of only 1.27 points, they label 4.96% of the tokens differently.

To get a more detailed understanding of the differences, we apply algorithm 1 to the two outputs, whose results are shown in table 4<sup>6</sup>, listing the five most frequent changes per difference class.<sup>7</sup> Of the 4.96% different labels in Clevertagger compared to TreeTagger, 58.71% are corrections, 33.13% are new errors, and 8.15% changed errors.<sup>8</sup> That is, one third of the changes that Clevertagger introduces are errors. This is a noteworthy observation which applies to all our system comparisons: Every improved response introduces a considerable amount of errors with respect to the baseline, i.e. it invalidates correct decisions of the baseline. While this observation is to some degree expected, our method is able to quantify and analyse such changes in detail.

Regarding the differences, we see that both the most frequent correction (NN→NE) and new error (NE→NN) evolve around the confusion of named entities and common nouns, which is especially

<sup>6</sup>For tag description see <http://www.ims.uni-stuttgart.de/forschung/ressourcen/lexika/TagSets/stts-table.html>

<sup>7</sup>Note that the change comparison can also be sorted by the biggest accuracy difference, cf. appendix table A.1.

<sup>8</sup>We here use the TreeTagger as  $S_1$  and the Clevertagger as  $S_2$ . Inverting the roles does not change the percentage values, but simply switches corrections to new errors and vice versa.

<b>Difference: 4.96%</b> (2674/53928)	
<b>Corrections: 58.71%</b> (1570/2674)	
NN→NE	27.96
PIAT→PIDAT	10.83
NN→ADJA	5.03
VVFIN→VVINF	4.52
NE→NN	3.25
<b>New errors: 33.13%</b> (886/2674)	
NE→NN	19.53
VVFIN→VVINF	9.48
NN→NE	9.26
ADV→ADJD	6.09
KOUS→PWAV	4.06
<b>Changed errors: 8.15%</b> (218/2674)	
NE→NN→FM	13.30
FM→NN→NE	7.34
NE→NN→ADJD	6.88
KOUS→KOKOM→PWAV	4.13
XY→NN→NE	2.29

Table 4: Token-based label changes comparing TreeTagger → Clevertagger (and Key → TreeTagger → Clevertagger for changed errors)

difficult for German, since capitalization cannot be exploited to distinguish the two. Furthermore, Clevertagger frequently invalidates TreeTagger’s correct labeling of finite verbs, tagging them as nonfinite (VVFIN → VVINF), although this change occurs under the most frequent corrections as well. While these are commonly known error sources for POS tagging German, our approach shows that they are in fact the main source of the differences between the output of the two top performing taggers.

## 2.2 Dependency parsing

The next task we investigate is dependency parsing. We choose English as the test language due to the lack of the availability of multiple parsers in other languages. We evaluate Google’s recently released Parsey McParseface (Andor et al., 2016, state-of-the-art) and two versions of the Stanford parser, i.e. the PCFG (Klein and Manning, 2003) and the Neural Network version (Chen and Manning, 2014). We follow the standard evaluation protocol and use section 23 of the PennTreebank (Marcus et al., 1993) as a test set and exclude punctuation tokens. We evaluate on Stanford Dependency labels (de Marneffe and Man-

ning, 2008), since Parsey support only them.<sup>9</sup> We apply the parsers and their models "as is", i.e. we do not change any configuration settings.

	<b>UAS</b>	<b>LS</b>	<b>LAS</b>	<b>Sent</b>
Stan. PCFG	87.96	92.26	85.36	24.17
Stan. NN	88.68	92.45	86.43	26.95
Parsey	92.70	92.86	88.94	28.89

	<i>diff</i>	$\Delta$ LAS
Stan. PCFG $\leftrightarrow$ Stan. NN	14.01	1.07
Stan. PCFG $\leftrightarrow$ Parsey	15.49	3.58
Stan. NN $\leftrightarrow$ Parsey	13.62	2.51

Table 5: Parser performance and difference

In table 5, we report the unlabeled attachment score (UAS), the labeling score (LS), and the labeled attachment score (LAS) for the parsers. Furthermore, we evaluate how many of the sentences are fully parsed correctly given each criterion.

We see that Parsey outperforms the Stanford parsers mainly due to the performance in attachment (UAS). The performance differences in assigning grammatical labels (LS) are comparably marginal. Parsey also features almost identical performance in both attaching and labeling tokens. However, there is a gap compared to labeled attachment score, which indicates that although Parsey attaches more tokens correctly than the other parsers, it does not necessarily assign the correct grammatical label to these tokens. Looking at the difference chart, we see that despite the rather small differences in LAS (1-4 points), the parsers attach and label around 15% of the tokens differently. The Stanford parsers only differ in 1.07 points in LAS, but this difference is based on 14.01% (*diff*) of the tokens in the test set. Parsey outperforms the Stanford NN parser by 2.51 LAS based on 13.62% of the tokens. To gain a better understanding of the differences contained in these 13.62% of the tokens, we apply algorithm 1, whose output is shown in table 6.

The table shows that half (50.22%) of the 13.62% changed token annotations from Stanford NN to Parsey are corrections. All of these changes are attachment corrections, i.e. the label of the tokens are not changed, which correlates with the small difference we saw in labeling score. The

<sup>9</sup>We convert the PennTreebank to Stanford dependencies using the Penn Treebank converter included in the Stanford parser (<http://nlp.stanford.edu/software/stanford-dependencies.shtml>).

**Difference: 13.62%** (6776/49748)

**Corrections: 50.22%** (3403/6776)

nn $\rightarrow$ nn	10.93
prep $\rightarrow$ prep	9.49

cc $\rightarrow$ cc $\rightarrow$ cc	1.89
conj $\rightarrow$ conj $\rightarrow$ conj	1.23

Table 6: Token-based analysis of parser differences (Stanford NN  $\rightarrow$  Parsey, LAS)

two most prominent corrections are the attachment of noun compound modifiers (nn) and prepositions (prep). Almost one third (31.79%) of the changes are new errors. Compared to the corrections, Parsey here changes the labels of the tokens. Contrarily, changed errors (17.99%) constitute roughly one fifth of the changes and mainly consist of changes in attachment.

### 2.3 Coreference resolution

The final task we investigate is coreference resolution. We choose three freely available systems for English, again due to the lack of available systems for other languages: the Stanford statistical coreference resolver (Clark and Manning, 2015, state-of-the-art), HOTCoref (Björkelund and Kuhn, 2014), and the Berkeley coreference system (Durrett and Klein, 2013). We use the CoNLL 2012 shared task test set (Pradhan et al., 2012).

The coreference task differs from the previous two, since not all tokens in a document partake in coreference relations (but all tokens are in syntactic relations and feature a POS tag). Furthermore, the linguistic units of coreference relations are not only single word tokens, but syntactic units called *mentions* (i.e. mostly noun phrases). Therefore, we have to adapt our similarity metric in equation 1. To quantify the difference of two corefer-

ence system outputs  $S_1$  and  $S_2$ , given a key  $K$ , we count how many of the mentions  $m$  are classified differently using a mention classification function  $c$ :

$$\text{diff}(S_1, S_2 | K) = \frac{|\forall m \in S_1 \cap S_2 \cap K : c(m, S_1) \neq c(m, S_2)|}{|\forall m \in S_1 \cap S_2 \cap K|} \quad (2)$$

The mention classification function  $c$  requires a class inventory which is not featured by the common evaluation metrics for coreference resolution.<sup>10</sup> Therefore, we adapt the mention classification paradigm introduced in the ARCS framework for coreference resolution evaluation (Tuggener, 2014) which assigns one of the following four classes to a mention  $m$  given a key  $K$  and a system response  $S$ :

- True Positive (TP):  $m$  is correctly resolved to an antecedent.
- False Positive (FP):  $m$  has no antecedent in  $K$  but one in  $S$ .
- False Negative (FN):  $m$  has no antecedent in  $S$  but one in  $K$ .
- Wrong Linkage (WL):  $m$  has an antecedent in  $K$  but is assigned an incorrect antecedent in  $S$ .

However, one issue with ARCS is to determine a criterion for the TP class, i.e. under what circumstances is  $m$  regarded as resolved correctly. Tuggener (2014) proposed to determine correct antecedents based on the requirements of prospective downstream applications.<sup>11</sup> We implement one loose criterion and regard  $m$  as correctly resolved if any of its antecedents in  $S$  is also an antecedent of  $m$  in  $K$ . Conversely, if none of the antecedents of  $m$  overlap in  $S$  and  $K$ , we label  $m$  as WL. This yields the  $\text{ARCS}_{any}$  metric. Alternatively, we require that the closest preceding nominal antecedent of  $m$  in  $S$  is also an antecedent of  $m$  in  $K$ , which yields the  $\text{ARCS}_{nom}$  metric. This metric is more conservative in assigning the TP class, but implements a more realistic criterion for

<sup>10</sup>The common metrics analyse either the links between mentions or calculate a percentage of overlapping mentions in coreference chains in the key and a response. They are not able to determine whether a given mention  $m$  is resolved correctly or assign a class to it.

<sup>11</sup>Machine translation requires pronouns to be linked to nominal antecedents, Sentiment analysis needs Named Entity antecedents (if available) etc.

correct antecedents from the perspective of downstream applications.

The official CoNLL score MELA (average of MUC, CEAFE, and BCUB) and the recently proposed LEA metric (Moosavi and Strube, 2016), which addresses several issues of the other metrics, as well as the ARCS scores, are given in table 7. Using the ARCS class inventory and equation 2, we quantify how many of the mentions are classified differently in the system responses.

	MELA	LEA	$\text{ARCS}_{any}$	$\text{ARCS}_{nom}$
Berkeley	62.06	54.80	71.25	59.13
HOTCoref	64.32	57.13	73.27	61.95
Stanford	<b>66.62</b>	<b>60.92</b>	<b>76.30</b>	<b>62.04</b>

$\text{ARCS}_{any}$	$\text{diff}$	$\Delta \text{F1}$
Stanford $\leftrightarrow$ Berkeley	27.13	5.05
Stanford $\leftrightarrow$ HOTCoref	26.30	3.03
Berkeley $\leftrightarrow$ HOTCoref	27.22	2.02

$\text{ARCS}_{nom}$	$\text{diff}$	$\Delta \text{F1}$
Stanford $\leftrightarrow$ Berkeley	35.39	2.91
Stanford $\leftrightarrow$ HOTCoref	<b>37.45</b>	<b>0.09</b>
Berkeley $\leftrightarrow$ HOTCoref	34.89	2.82

Table 7: Coreference resolution evaluation (F1) and differences (%)

The F1 scores are lowest for the LEA metric, because it gives more weight to errors regarding longer coreference chains. The  $\text{ARCS}_{any}$  metric assigns the highest scores due to the loose criterion that any antecedent is correct as long as it is in the key chain of a given mention. Furthermore, all the metrics agree on the ranking of the systems.

The mention-based differences between the systems are considerably larger than the relatively small differences in F1 scores suggest. The Stanford system outperforms HOTCoref by 2.3 MELA, 3.79 LEA F1, and 3.03  $\text{ARCS}_{any}$  F1, but the systems process one fourth (26.30%) of the mentions differently in the  $\text{ARCS}_{any}$  setting. For the  $\text{ARCS}_{nom}$  criterion, the differences are even larger. The Stanford system outperforms the Berkeley system by 2.91  $\text{ARCS}_{nom}$  F1, but the systems process 35.39% of the mentions differently. Furthermore, we observe that the differences in F1 ( $\Delta \text{F1}$ ) do not correlate with the differences of the outputs ( $\text{diff}$ ) for both ARCS metrics. Given  $\text{ARCS}_{nom}$ , we see that the smallest difference in F1 (Stanford  $\leftrightarrow$  HOTCoref: 0.09) actually occurs between the two responses that the  $\text{diff}$  metric deems most dissimilar (37.45).

Finally, we apply algorithm 1, using the  $\text{ARCS}_{nom}$  criterion and our mention classification

scheme to the two best performing systems, i.e. HOTCoref and Stanford. Results are given in table 8.

<b>Difference: 37.45%</b> (5760 / 15382)	
<b>Corrections: 44.62%</b> (2570/5760)	
wl → tp	20.09
fn → tp	12.34
fp → tn	12.19
<b>New errors: 41.65%</b> (2399/5760)	
tp → wl	17.08
tp → fn	12.33
tn → fp	12.24
<b>Changed errors: 13.73%</b> (791/5760)	
fn → wl	3.87
wl → fn	9.86

Table 8: Comparison of two coreference responses (HOTCoref → Stanford)

We see that less than 50% of the changes that the Stanford system introduces are corrections (44.62%). But this percentage is still higher than the newly introduced errors (41.65%); hence the improvement in overall F1. Furthermore, the most frequent change is wrong linkages to true positives (wl → tp). The most frequent new error also involves true mentions, i.e. attaching correctly resolved mentions to incorrect antecedents (tp → wl). Recovering false negatives and rendering true positives to false negatives occurs equally frequent, roughly. Hence, the performance difference stems mainly from attaching anaphoric mention to (nominal) antecedents, rather than from deciding which mentions to resolve, which are two sub-problems in coreference resolution.

### 3 System combination

Lastly, we combine the system outputs per task and calculate the upper bounds for perfect system combinations by deeming a token labeled correctly if at least one of the systems provides the correct label. The upper bounds are intended to be another measure of the (dis)similarity of the outputs: the higher the upper bound, the higher the divergence of the outputs. Furthermore, looking at per-label performance of all systems, we can identify labels with low scores but high upper bounds, which is an interesting starting point for future work.

### 3.1 POS tagging

We start with the POS tagging task and present the upper bound of the system combination in table 9. We also indicate the accuracy gains for the top ten most frequent POS tags relative to the best performing tagger (Clevertagger).

	Stan.	Tree.	Clever.	Upper bound	
Overall	90.41	94.38	96.16	98.52	+2.36
NN	96.01	98.47	98.06	99.55	+1.49
ART	99.62	99.32	99.43	99.85	+0.42
APPR	86.10	98.03	99.20	99.56	+0.36
NE	87.35	77.46	85.31	95.17	<b>+9.86</b>
ADJA	92.73	94.50	98.40	99.44	+1.04
ADV	89.25	91.71	90.93	95.48	<b>+4.55</b>
VVFIN	79.73	95.15	91.52	97.48	<b>+5.96</b>
VVAFIN	91.97	98.93	97.74	99.56	+1.82
KON	97.13	95.37	96.55	98.37	+1.82
ADJD	72.37	89.29	88.80	93.53	<b>+4.73</b>

Table 9: POS tagging upper bounds and accuracy (highest scores in green; lowest in red; middle in yellow)

The Stanford tagger, despite performing the lowest with respect to overall accuracy, achieves the highest accuracy on named entities (NE), while the TreeTagger struggles in this category particularly. The TreeTagger surpasses the other taggers on finite verbs (VVFIN) by a wide margin and auxiliary finite verbs (VAFIN). Clevertagger performs best overall, but interestingly, it only achieves the highest accuracy on three of the ten most frequent POS tags. Looking at the overall upper bound, we see that it more than halves the error rate of the best performing system and is near 99% accuracy. The POS tags that profit most from the combination are named entities. Interestingly, all the taggers have low accuracy with respect to this tag, but the upper bound of the combination drastically raises it. Hence, it seems that the taggers diverge mostly here, which correlates with our analysis of the difference between the two best performing systems in table 4.

### 3.2 Dependency parsing

Next, we analyse the upper bounds of the combination of the dependency parsers, given in table 10. In contrast to the POS tagging task, we find that the best performing system, Parsey (PMP) achieves highest LAS for almost all considered labels. Still, its overall LAS is drastically increased by the upper bound (+5.99) of the perfect system combination. Two of the labels that benefit the most of the combination are amod (adjec-

tival modifier), which is often confused with nn (noun compound modifier) as we saw in table 6, and advmod (adverb modifier). All parsers have below 90 LAS for these labels, but the combination raises performance to 95.26 and 91.40, respectively. Furthermore, prepositions (prep) gains considerably in LAS in the combination. We observed in table 6 that almost ten percent of the difference between Parsey and the Stanford NN parser stem from correcting attachments of prepositions. However, also more than seven percent of the difference stems from invalidating correctly attached prepositions in the Stanford NN output. The large performance jump in the combination of the systems is further evidence that the parsers are highly complementary with respect to prepositions.

	S-PCFG	S-NN	P-MP	Upper bound	
All	85.36	86.43	88.94	94.93	<b>+5.99</b>
prep	78.76	84.26	88.21	94.18	<b>+5.97</b>
pobj	94.26	95.30	96.35	98.62	+2.27
det	96.81	96.65	98.66	99.38	+0.72
nn	74.64	76.81	86.36	88.91	+2.55
nsubj	92.08	89.78	94.41	97.85	+3.44
amod	87.59	88.45	86.95	95.26	<b>+8.31</b>
root	93.79	89.67	95.74	98.63	+2.89
doj	90.19	90.88	92.91	97.47	<b>+4.56</b>
aux	97.53	97.11	97.63	99.30	+1.67
advmod	74.48	78.56	82.97	91.40	<b>+8.43</b>

Table 10: Parsing accuracy (LAS) and upper bounds.

### 3.3 Coreference resolution

For the coreference task, it is not trivial to calculate the F1 upper bound of the response combination, as the systems do not feature the same mentions in their outputs<sup>12</sup>, and disentangling the false positives is a cumbersome undertaking. Therefore, we limit our investigation to the gold mentions in the key and count for how many of them at least one of the responses produces a correct nominal antecedent, which yields the upper bound for  $ARCS_{nom}$  recall. To gain a deeper insight into the benefits of the combination and the performance of the systems, we divide the mentions into nouns (named entities and common nouns), personal pronouns (PRP), and possessive pronouns (PRP\$). Results are given in table 11.<sup>13</sup>

The system with overall best recall features the highest recall with respect to all mention types.

<sup>12</sup>The systems have to decide which NPs they consider for coreference resolution (the anaphoricity detection problem). I.e. the mentions are not known beforehand, and the systems

	Berk.	Stan.	HOT.	Upper bound	
Overall	55.72	58.13	59.34	73.39	+14.05
Nouns	59.67	59.76	60.99	73.48	+12.49
PRP	50.66	56.30	57.56	73.80	+16.24
PRP\$	62.36	64.62	65.98	80.57	+14.59

Table 11: Mention-based coreference performance ( $ARCS_{nom}$  recall) and upper bounds

However, there is a considerable difference in recall to the mention types for all systems: Possessive pronouns are more easily attached to correct nominal antecedents than nouns and personal pronouns. Furthermore, we see that upper bounds raise recall uniformly for all mention types by a considerable margin. This suggests that the outputs are indeed different in several regards, which correlates to the comparisons in tables 7 and 13.

## 4 Related work

One way to establish the difference of two system outputs is to apply statistical significance tests. However, there is generally little agreement on which test to use, and it is often not trivial to verify if all criteria are met for the application of a specific test to a given data set (Yeh, 2000). Furthermore, the significance tests provide no insight into the nature of the differences between two outputs.

Several survey papers analysed performance of state-of-the-art tools for POS tagging (Volk and Schneider, 1998; Giesbrecht and Evert, 2009; Horsmann et al., 2015) or dependency parsing (McDonald and Nivre, 2007). While these surveys provide performance results along different axes (accuracy, time, domain, frequent errors), they do not analyse the particular differences between the system responses on the token level and hence do not provide a (dis)similarity rating of the responses. Regarding dependency parsing, our work is most closely related to McDonald and Nivre (2007) and Seddah et al. (2013). Both papers analyse the performance of parsers with respect to several subproblems. McDonald and Nivre (2007) also performed output combination experiments to stress that the two parsers that they investigated are complementary to a significant degree.

Comparative system evaluation in shared tasks is usually performed by pitting scores in evalua-

will hallucinate different incorrect ones.

<sup>13</sup>Note that the HOTCoref system has better recall than the Stanford system, but the Stanford system features better precision, which leads to a higher F1 score in table 7.

tion metrics against each other, e.g. the CoNLL shared tasks on coreference (Pradhan et al., 2011; Pradhan et al., 2012) or on dependency parsing (Buchholz and Marsi, 2006; Nilsson et al., 2007). While the post task evaluation of the CoNLL shared task 2007 included an experiment of system combination which showed performance improvements, it is generally left unclear how similar are the system outputs with (sometimes marginally) small differences with respect to the evaluation metrics.

Another branch of evaluation related to our work is error analysis. Gärtner et al. (2014) presented a tool to explore coreference errors visually, but does not aggregate and classify them. Kummerfeld and Klein (2013) devised a set of error classes for coreference and analysed quantitatively which systems make which errors. Martschat and Strube (2014) presented an analysis and grouping of recall errors for coreference and evaluated a set of system responses. However, these analyses focus on the errors of one system at a time and then compare the overall error statistics, i.e. there is no direct linking or combination of the responses. Hence, we believe our approach to be complementary to the work outlined above.

## 5 Conclusion

We have presented a generic dissimilarity metric for system outputs and applied it to several systems for POS tagging, dependency parsing, and coreference resolution. We found that systems with marginal differences in accuracy scores or F1 actually have considerably distinct outputs. We combined system outputs and calculated upper bounds in performance as an additional measure of the degree of difference between the outputs.

We discussed and applied a method for analysing the specific differences between two system outputs using a class inventory to label and quantify the differences. Our analysis revealed the (often considerable) quantity of new errors that improvements introduce compared to baselines. We believe that this kind of analysis is also useful during system and method design, as it allows one to track all changes in the output when adjusting a system or a feature set.

While we have explored our approach on three core tasks in Computational Linguistics, we believe it to be applicable to other areas in the field. Our hope is that our method of comparative evalu-

ation will motivate other researchers to gain an in-depth understanding of the output of their systems and what distinguishes them from others, beyond differences in accuracy or F1 scores.

### A.2 Coreference resolution

Since the ARCS framework is relatively unknown and not widely used, we revisit the connection of our *diff* metric to accuracy and F1 outlined in section 2 in order to use one of the coreference metrics to establish the differences between the outputs. We saw that our metric is inversely equivalent to accuracy when taking one system response as the key and the other as the response. That is, we can calculate the *diff* ratio by  $1 - \frac{|t_i \in T: label(t_i, S_1) \neq label(t_i, S_2)|}{|T|}$ , which is equivalent to taking  $S_1$  as the key and  $S_2$  as the response (or vice versa). For the coreference task, we can thus use one response as the key and the other as the response. The resulting F1 score can then be used as an agreement value, which, however, does not provide any detailed analysis of the nature of the differences compared to the ARCS approach. Table 13 shows the F1 scores when using one response as the key and the second as response. Note that switching the key and the response role provides the same F1 scores for two responses; the only effect is that the recall and precision values are switched.

The table shows that using this approach, we obtain F1 scores that give quite high dissimilarities when turned into the *diff* metric, i.e.  $diff = 100 - F1$ . The average of the *diff* metric given MELA F1 is 28.90 ( $100 - 71.10$ ); given LEA F1 it is 35.22 ( $100 - 64.78$ ). Compared to the ARCS<sub>any</sub>

kilickayamert@gmail.com, {aykut, nazli, erkut}@cs.hacettepe.edu.tr

## Abstract

The task of generating natural language descriptions from images has received a lot of attention in recent years. Consequently, it is becoming increasingly important to evaluate such image captioning approaches in an automatic manner. In this paper, we provide an in-depth evaluation of the existing image captioning metrics through a series of carefully designed experiments. Moreover, we explore the utilization of the recently proposed Word Mover's Distance (WMD) document metric for the purpose of image captioning. Our findings outline the differences and/or similarities between metrics and their relative robustness by means of extensive correlation, accuracy and distraction based evaluations. Our results also demonstrate that WMD provides strong advantages over other metrics.

## 1 Introduction

There has been a growing interest in research on integrating vision and language in natural language processing and computer vision communities. As one of the key problems in this emerging area, image captioning aims at generating natural descriptions of a given image (Bernardi et al., 2016). This is a challenging problem since it requires the ability to not only understand the visual content, but also to generate a linguistic description of that content. In this regard, it can be framed as a machine translation task where the source language denotes the visual domain and the target language is a specific language such as English. The recently proposed deep image captioning studies follow this interpretation and model the process

via an encoder-decoder architecture (Vinyals et al., 2015; Xu et al., 2015; Karpathy and Fei-Fei, 2015; Jia et al., 2015). These approaches have attained considerable success in the recent benchmarks such as FLICKR8K (Hodosh et al., 2013), FLICKR30K (Young et al., 2014) and MS COCO (Lin et al., 2014) as compared to the earlier techniques which explicitly detect objects and generate descriptions by using surface realization techniques (Kulkarni et al., 2013; Li et al., 2011; Elliott and Keller, 2013).

With the size of the benchmark datasets becoming larger and larger, evaluating image captioning models has become increasingly important. Human-based evaluations become obsolete as they are costly to acquire and, more importantly, not repeatable. Automatic evaluation metrics are employed as an alternative to human evaluation in both developing new models and comparing them against the state-of-the-art. These metrics compute a score that indicates the similarity/dissimilarity between an automatically generated caption and a number of human-written reference (gold standard) descriptions.

Some of these automatic metrics such as BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Banerjee and Lavie, 2005), and TER (Snover et al., 2006) have originated from the readily available metrics for machine translation and/or text summarization. On the contrary, the more recent metrics such as CIDEr (Vedantam et al., 2015) and SPICE (Anderson et al., 2016) are specifically developed for image caption evaluation task.

Evaluation with automatic metrics has some challenges as well. As previously analyzed in (Elliott and Keller, 2014), the existing automatic evaluation measures have proven to be inadequate in successfully mimicking the human judgements for evaluating the image descriptions. The latest eval-

Table 1: A summary of the evaluation metrics considered in this study.

Metric	Proposed to evaluate	Underlying idea
BLEU (Papineni et al., 2002)	Machine translation	$n$ -gram precision
ROUGE (Lin, 2004)	Document summarization	$n$ -gram recall
METEOR (Banerjee and Lavie, 2005)	Machine translation	$n$ -gram with synonym matching
CIDEr (Vedantam et al., 2015)	Image description generation	<i>tf-idf</i> weighted $n$ -gram similarity
SPICE (Anderson et al., 2016)	Image description generation	Scene-graph synonym matching
WMD (Kusner et al., 2015)	Document similarity	Earth Mover Distance on <i>word2vec</i>

uation results of 2015 MS COCO Challenge on image captioning has also revealed some interesting findings in line with this observation (Vinyals et al., 2016). In the challenge, the recent deep models outperform the human upper bound according to automatic measures, yet they could not beat the humans when the subjective human judgements are considered. These demonstrate that we need to better understand the drawbacks of existing automatic evaluation metrics. This motivates us to present an in-depth analysis of the current metrics employed in image description evaluation.

We first review BLEU, ROUGE, METEOR, CIDEr and SPICE metrics, and discuss their main drawbacks. In this context, we additionally describe WMD metric which has been recently proposed as a distance measure between text documents in (Kusner et al., 2015). We then investigate the performance of these automatic metrics through different experiments. We analyze how well these metrics mimic human assessments by estimating their correlations with the collected human judgements. Different from the previous related work (Elliott and Keller, 2014; Vedantam et al., 2015; Anderson et al., 2016), we perform a more accurate analysis by additionally reporting the results of Williams significance test. This further allows us to figure out the differences and/or similarities between a pair of metrics, whether any two metrics complement each other or provide similar results. We then test the ability of these metrics to distinguish certain pairs of captions from one another in reference to a ground truth caption. Next, we carry out an analysis on robustness of these metrics by analyzing how well they cope with the distractions in the descriptions (Hodosh and Hockenmaier, 2016).

## 2 Evaluation Metrics

A summary of the metrics investigated in our study is given in Table 1. All these metrics ex-

cept SPICE and WMD define the similarity over words or  $n$ -grams of reference and candidate descriptions by considering different formulas. On the other hand, SPICE (Anderson et al., 2016) considers a scene-graph representation of an image by encoding objects, their attributes and relations between them, and WMD leverages word embeddings to match groundtruth descriptions with generated captions.

### 2.1 BLEU

BLEU (Papineni et al., 2002) is one of the first metrics that have been in use for measuring similarity between two sentences. It has been initially proposed for machine translation, and defined as the geometric mean of  $n$ -gram precision scores multiplied by a brevity penalty for short sentences. In our experiments, we use the smoothed version of BLEU as described in (Lin and Och, 2004).

### 2.2 ROUGE

ROUGE (Lin, 2004) is initially proposed for evaluation of summarization systems, and this evaluation is done via comparing overlapping  $n$ -grams, word sequences and word pairs. In this study, we use ROUGE-L version, which basically measures the longest common subsequences between a pair of sentences. Since ROUGE metric relies highly on recall, it favors long sentences, as also noted by (Vedantam et al., 2015).

### 2.3 METEOR

METEOR (Banerjee and Lavie, 2005) is another machine translation metric. It is defined as the harmonic mean of precision and recall of uni-gram matches between sentences. Additionally, it makes use of synonyms and paraphrase matching. METEOR addresses several deficiencies of BLEU such as recall evaluation and the lack of explicit word matching.  $n$ -gram based measures work reasonably well when there is a significant overlap

between reference and candidate sentences; however they fail to spot semantic similarity when the common words are scarce. METEOR handles this issue to some extent using WordNet-based synonym matching, however just looking at synonyms may be too restrictive to capture overall semantic similarity.

## 2.4 CIDER

CIDER (Vedantam et al., 2015) is a recent metric proposed for evaluating the quality of image descriptions. It measures the consensus between candidate image description  $c_i$  and the reference sentences, which is a set  $S_i = \{s_{i1}, \dots, s_{im}\}$  provided by human annotators. For calculating this metric, an initial stemming is applied and each sentence is represented with a set of 1-4 grams. Then, the co-occurrences of  $n$ -grams in the reference sentences and candidate sentence are calculated. In CIDER, similar to *tf-idf*, the  $n$ -grams that are common in all image descriptions are down-weighted. Finally, the cosine similarity between  $n$ -grams (referred as  $CIDER_n$ ) of the candidate and the references is computed.

CIDER is designed as a specialized metric for image captioning evaluation, however, it works in a purely linguistic manner, and only extends existing metrics with *tf-idf* weighting over  $n$ -grams. This sometimes causes unimportant details of a sentence to be weighted more, resulting in a relatively ineffective caption evaluation.

## 2.5 SPICE

Another recently proposed metric for evaluating image caption similarity is SPICE (Anderson et al., 2016). It is based on the agreement of the scene-graph tuples (Johnson et al., 2015; Schuster et al., 2015) of the candidate sentence and all reference sentences. Scene-graph is essentially a semantic representation that parses the given sentence to semantic tokens such as object classes  $C$ , relation types  $R$  and attribute types  $A$ . Formally, a candidate caption  $c$  is parsed into a scene-graph as

$$G(c) = \langle O(c), E(c), K(c) \rangle$$

where  $G(c)$  denotes the scene graph of caption  $c$ ,  $O(c) \subseteq C$  is the set of object mentions,  $E(c) \subseteq O(c) \times R \times O(c)$  is the set of hyper-edges representing relations between objects, and  $K(c) \subseteq O(c) \times A$  is the set of attributes associated with objects. Once the parsing is done, a set of tuples is

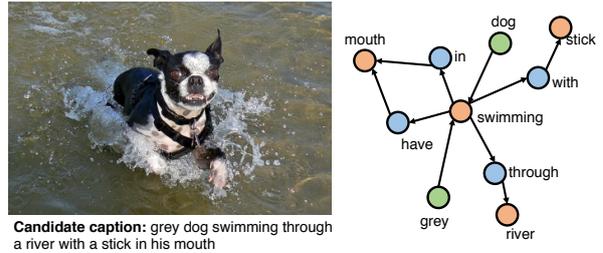

Figure 1: An example image with its Scene Graph where the parser fails to parse the candidate sentence accurately, which could result in wrong calculation of SPICE metric. See text for details.

formed by using the elements of  $G$  and their possible combinations. SPICE score is then defined as the  $F_1$ -score based on the agreement between the candidate and reference caption tuples. For tuple matching, SPICE uses WordNet synonym matching (Pedersen et al., 2004) as in METEOR (Banerjee and Lavie, 2005). One problem is that the performance becomes quite dependent on the quality of the parsing. Figure 1 illustrates an example case of failure. Here, swimming is parsed as an object, with all its relations, and dog is parsed as an attribute.

## 2.6 WMD

Two captions may not share the same words or any synonyms; yet they can be semantically similar. On the contrary, two captions may include similar objects, attributes or relations yet they may not be semantically similar. Metrics that are currently in use fail to correctly identify and assess the quality of such cases. To address this issue, we propose to use a recently introduced document distance measure called Word Mover’s Distance (WMD) (Kusner et al., 2015) for evaluating image captioning approaches. WMD casts the distance between documents as an instance of Earth Mover’s Distance (EMD) (Rubner et al., 2000), where travel costs are calculated based on *word2vec* (Mikolov et al., 2013) embeddings of the words.

For WMD, text documents (in our case image captions) are first represented by their normalized bag-of-words (nBOW) vectors, accounting for all words except stopwords. More formally, each text document is represented as vectors  $\mathbf{d} \in R^n$ , where,  $d_i = \frac{c_i}{\sum_{j=1}^n c_j}$  if a word  $i$  appears  $c_i$  times in the document. WMD incorporates semantic similarity between individual word pairs into the document similarity metric, by using the distances in

Table 2: Drawbacks of automatic evaluation metrics for image captioning. See text for details.

	Description	BLEU	METEOR	ROUGE	CIDEF	SPICE	WMD
original	a man wearing a red life jacket is sitting in a canoe on a lake	1	1	1	10	1	1
candidate	a man wearing a life jacket is in a small boat on a lake	0.45	0.28	0.67	2.19	0.40	0.19
synonyms	a <b>guy</b> wearing a life <b>vest</b> is in a small boat on a lake	<b>0.20</b>	<b>0.17</b>	0.57	<b>0.65</b>	<b>0.00</b>	<b>0.10</b>
redundancy	a man wearing a life jacket is in a small boat on a lake <b>at sunset</b>	0.45	0.28	0.66	2.01	0.36	0.18
word order	<b>in a small boat on a lake</b> a man is wearing a life jacket	<b>0.26</b>	0.26	<b>0.38</b>	<b>1.32</b>	0.40	0.19

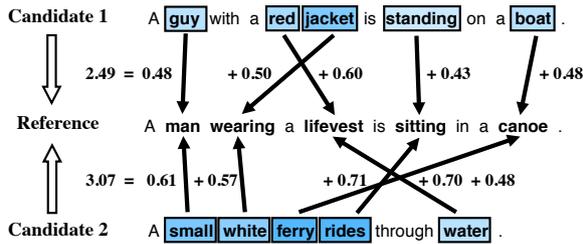

Figure 2: An illustration of the distance calculation of WMD metric comparing two candidate captions with a reference caption.

*word2vec* embedding space. Specifically, the distance between word  $i$  and word  $j$  in two documents is set as the Euclidean distance between each of the corresponding *word2vec* embeddings  $x_i$  and  $x_j$ , *i.e.*,  $c(i, j) = \|x_i - x_j\|_2$ .

The distances between words serve as building blocks to define distances between documents, hence captions. The flow between word vectors is defined with the sparse flow matrix  $\mathbf{T} \in R^{n \times n}$ , with  $T_{ij}$  representing the travel amount of word  $i$  to word  $j$ . The distance between two documents is then defined with  $\sum_{i,j} T_{ij} c(i, j)$ , *i.e.* the minimum cumulative cost required to move all words between documents. This minimum cumulative cost is found by solving the corresponding linear optimization problem, which is cast as a special case of EMD metric (Rubner et al., 2000). An example matching result is shown in Figure 2. By using *word2vec* embeddings, semantic similarities between words are more accurately identified. In our experiments, we convert the distance scores to similarities by using a negative exponential.

## 2.7 Drawbacks of the metrics

In order to illustrate the drawbacks of these automatic evaluation metrics, we provide an exam-

ple case in Table 2. In this table, an original caption is given, together with the upper bound values for each metric, *i.e.* when this original caption is compared to itself. The second line includes a candidate caption that is semantically very similar to the original one and the corresponding similarity scores according to evaluation metrics. We then modify the candidate sentence slightly and observe how the metric scores are affected from these small modifications. First, we observe that all the scores decrease when some words are replaced with their synonyms. The change is especially significant for SPICE and CIDEF. In this example, failure of SPICE is likely due to incorrect parsing or the failure of synonym matching. On the other hand, failure of CIDEF is likely due to unbalanced *tf-idf* weighting. Second, we observe that the metrics are not affected much from the introduction of additional (redundant) words in the sentences. However, when the order of the words are changed, we see that BLEU, ROUGE and CIDEF scores decrease notably, due to their dependence on  $n$ -gram matching. Note that, WMD and SPICE are not influenced from the change in word order.

## 3 Evaluation and Discussion

### 3.1 Quality

A common way of assessing the performance of a new automatic image captioning metric is to analyze how well it correlates with human judgments of description quality. However, in the literature, there is no consensus on which correlation coefficient is best suited for measuring the soundness of a metric in this way. Elliott and Keller (2014) reports Spearman’s rank correlation, which measures a monotonic relation, whereas Anderson *et al.* (2016) suggests to use Pearson’s correlation, which assumes that the relation is lin-

ear, and Kendall’s correlation, which is another rank correlation measure.

The above correlation analysis is a well-established practice for automatic metric evaluation, but it is not complete in the sense that it is not meaningful to draw conclusions from it about the differences or similarities between a pair of metrics. That is, comparing the corresponding correlations relative to each other does not say much since they are both computed on the same dataset, and thus not independent. To address this issue, Graham and Baldwin (2014) have suggested to use Williams significance test (Williams, 1959), which also takes into account the degree to which the two metrics correlate with each other, and can reveal whether one metric significantly outperforms the other. The test has shown to be valuable for evaluation of document and segment-level machine translation (Graham and Baldwin, 2014; Graham et al., 2015; Graham and Liu, 2016) and summarization metrics (Graham, 2015). In this study, we extend the previous correlation-based evaluations of image captioning metrics by providing a more conclusive analysis based on Williams significance test.

Williams test (Williams, 1959) calculates the statistical significance of differences in dependent correlations, and formulated as testing whether the population correlation between  $X_1$  and  $X_3$  equals the population correlation between  $X_2$  and  $X_3$ :

$$t(n-3) = \frac{(r_{13} - r_{23})\sqrt{(n-1)(1+r_{12})}}{\sqrt{2K\left(\frac{n-1}{n-3}\right) + \frac{(r_{23}+r_{13})^2}{4}(1-r_{12})^3}} \quad (1)$$

where  $r_{ij}$  is the correlation between  $X_i$  and  $X_j$ , and  $n$  is the size of the population, with

$$K = 1 - r_{12}^2 - r_{13}^2 - r_{23}^2 + 2r_{12}r_{13}r_{23}. \quad (2)$$

To analyze statistical significance in the automatic metrics listed in Section 2, we use the publicly available FLICKR-8K (Elliott and Keller, 2014) and COMPOSITE (Aditya et al., 2015) datasets, which we describe below. We note that in our experiments, we first lowercase and tokenize the candidate and reference captions using `ptbtokenizer.py` script from MS COCO evaluation tools<sup>1</sup>. We use the implementations of the metrics from the same evaluation kit with the ex-

<sup>1</sup><https://github.com/peteanderson80/coco-caption>

ception of WMD. For the WMD metric, we employ the code provided by Kusner et al. (2015)<sup>2</sup>.

FLICKR-8K<sup>3</sup> dataset contains quality judgements for 5822 candidate sentences for the images in its test set (Hodosh et al., 2013). These judgements are collected from 3 human experts and they are on a scale of [1, 4], with a score of 1 denoting a description totally unrelated to the image content, and 4 meaning a perfect description for the image. Candidate captions are all obtained from a retrieval based model, hence they are grammatically correct.

COMPOSITE<sup>4</sup> dataset contains human judgements for 11,985 candidate captions for the subsets of FLICKR-8K (Hodosh et al., 2013), FLICKR-30K (Young et al., 2014) and MS COCO (Lin et al., 2014) datasets. The AMT workers were asked to judge the candidate caption for an image using two aspects: (i) *correctness*, and (ii) *thoroughness* of the candidate caption, both on a scale of [1, 5] where 1 means not relevant/less detailed and 5 denotes the candidate caption perfectly describing the image. Candidate captions were sampled from the human reference captions and the captioning models in (Aditya et al., 2015; Karpathy and Fei-Fei, 2015).

Table 3 shows Pearson’s, Spearman’s and Kendall’s correlation of the metrics with the human judgements in FLICKR-8K and COMPOSITE datasets. For FLICKR-8K, we follow the methodology in (Elliott and Keller, 2014) and compute correlations with the human expert scores. On the other hand, for COMPOSITE, we report the mean of the correlations with *correctness* and *thoroughness* scores. In terms of these correlations, while SPICE produces the highest quality comparisons in FLICKR-8K, WMD and METEOR give better results in COMPOSITE in general. However, if one further inspects the score distributions of the metrics (on FLICKR-8K dataset) shown in Figure 3, while SPICE can identify irrelevant captions remarkably well, it can not effectively distinguish bad captions from relatively better ones.

In Figure 4(a), we show Spearman’s correlation between each pair of metrics, where the metrics are ordered from highest to lowest correlation with

Table 3: Correlation between automatic image captioning metrics and human judgement scores.

	FLICKR-8K			COMPOSITE		
	Pearson	Spearman	Kendall	Pearson	Spearman	Kendall
WMD	0.68	0.60	0.48	<b>0.43</b>	0.43	0.32
SPICE	<b>0.69</b>	<b>0.64</b>	<b>0.56</b>	0.40	0.42	<b>0.34</b>
CIDEr	0.60	0.56	0.45	0.32	0.42	0.32
METEOR	<b>0.69</b>	0.58	0.47	0.37	<b>0.44</b>	0.33
BLEU	0.59	0.44	0.35	0.34	0.38	0.28
ROUGE	0.57	0.44	0.35	0.40	0.39	0.29

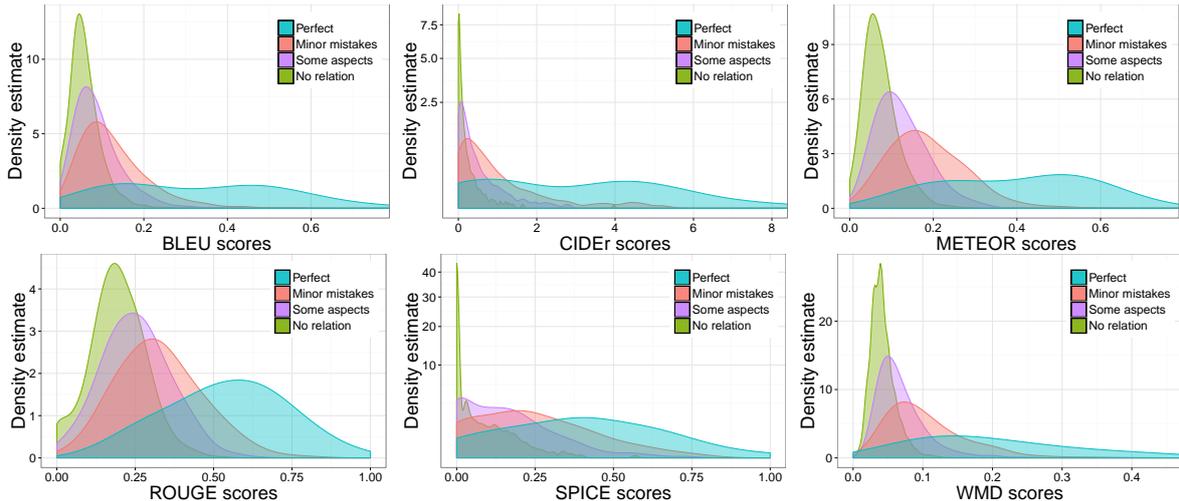

Figure 3: Score distributions of the metrics on FLICKR-8K dataset. Four different rating scales are used: 1 for no relation, 2 for minor mistakes, 3 for some true aspects and 4 for perfect match. For CIDEr and SPICE metrics, square-root transform is performed on the  $y$ -axis to better illustrate how the score distributions overlap with each other.

human judgements<sup>5</sup>. Overall, the pairwise correlations are generally high for both datasets. We additionally observe that the metrics which depend on similar structures are grouped together using these correlations. For example, the  $n$ -gram based metrics BLEU and ROUGE provide scores that are highly correlated with each other for FLICKR-8K. The correlations within COMPOSITE dataset are even very high for all the metrics that consider  $n$ -grams, namely BLEU, CIDEr, METEOR and ROUGE. On the other hand, the correlations of these metrics against SPICE and WMD are not that high. Moreover, the pairwise correlations between SPICE and WMD are relatively low as well. All these findings suggest that these three groups of metrics, the  $n$ -gram based metrics, the scene-graph based SPICE and the word embedding

<sup>5</sup>Here, we only report Spearman’s correlation since, compared to Pearson’s, it provides a more consistent ranking of the metrics across the two datasets, and is similar to Kendall’s correlation.

based WMD, can be complementary to each other.

Finally, in Figure 4(b), we provide the results of Williams significance test, which compares two different metrics with respect to their correlations against human judgements. Our results show that all the metric pairs have a significant difference in correlation with human judgement at  $p < 0.05$ . This reveals that the pair of metrics which has close correlation scores with human judgements (e.g. SPICE and WMD in FLICKR-8K dataset) are found to be statistically different than each other. These findings collectively support our previous conclusion that all metrics considered here can complement each other in evaluating the quality of the generated captions.

### 3.2 Accuracy

In this section, following the methodology introduced in (Vedantam et al., 2015), we analyze the ability of each metric to discriminate certain pair of captions from one another in reference to

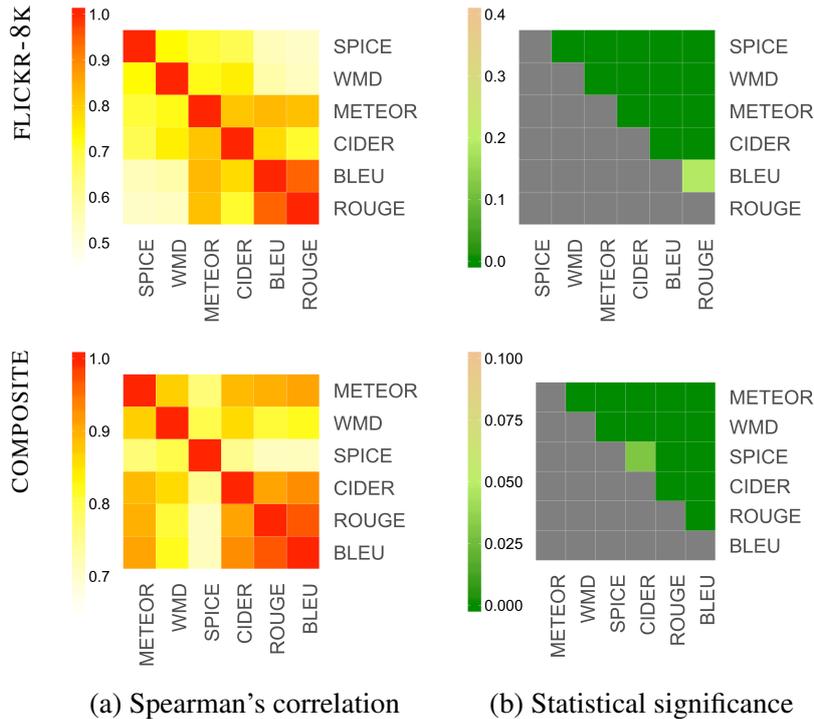

Figure 4: Significance test results for pairs of automatic metrics on FLICKR-8K and COMPOSITE datasets. (a) Spearman correlation between pairs of metrics; and (b)  $p$ -value of Williams significance tests, green cells indicate a significant win for metric in row  $i$  over metric in column  $j$ .

a groundtruth caption. We employ the human consensus scores while evaluating the accuracies. In particular, for evaluation, a triplet of descriptions, one reference and two candidate descriptions, is shown to human subjects and they are asked to determine the candidate description that is more similar to the reference. A metric is accurate if it provides a higher score to the description chosen by the human subject as being more similar to the reference caption. For this analysis, we carry out our experiments on PASCAL-50S and ABSTRACT-50S datasets<sup>6</sup>. We consider different kinds of pairs such as (human-human correct) HC, (human-human incorrect) HI, (human-machine) HM, and (machine-machine) MM. As the candidate sentences are generated by both humans and machines, each test scenario has a different level of difficulty.

ABSTRACT-50S (Vedantam et al., 2015) dataset is a subset of the Abstract Scenes Dataset (Zitnick and Parikh, 2013), which includes 500 images containing clipart objects in everyday scenes. Each image is annotated with 50 different descriptions. For evaluation, 48 of these 50 descriptions are used as reference descriptions and the remain-

ing 2 descriptions are employed as candidate descriptions. For 400 pairs of these descriptions, human consensus scores are available, with the first 200 are for HC and the remaining 200 are for HI.

PASCAL-50S (Vedantam et al., 2015) dataset is an extended version of the Pascal Sentences (Farhadi et al., 2010) dataset that contains 1000 images from PASCAL Object Detection challenge (Everingham et al., 2010) of 20 different object classes like person, car, horse, etc. This version includes 50 captions per image and human judgements for 4000 candidate pairs for the aforementioned binary-forced choice task, which are all collected through Amazon Mechanical Turk (AMT). For this dataset, all four different categories are available, having 1000 pairs for each category.

In Table 4, we present caption-level classification accuracy scores of automatic evaluation metrics at matching human consensus scores. On ABSTRACT-50S dataset, the CIDER metric outperforms all other metrics in both HC and HI cases. On the other hand, on PASCAL-50S dataset, the WMD metric gives the best scores in three out of four cases. Especially, it is the most accurate metric at matching human judgements on the chal-

lenging MM and HC cases, which require distinguishing fine-grained differences between descriptions. On average, the performances of all the other metrics are very similar to each other.

### 3.3 Robustness

In this section, we evaluate the robustness of the automatic image captioning metrics. For this purpose, we employ the binary (two-alternative) forced choice task introduced in (Hodosh and Hockenmaier, 2016) to compare the existing image captioning models. For a given image, this task involves distinguishing a correct description from its slightly distracted incorrect versions. In our case, a robust image captioning metric should always choose the correct caption over the distracted ones.

In our experiments, we use the data<sup>7</sup> provided

<sup>7</sup>[http://nlp.cs.illinois.edu/HockenmaierGroup/Papers/VL2016/HodoshHockenmaier16\\_BinaryTasks\\_Data.tar](http://nlp.cs.illinois.edu/HockenmaierGroup/Papers/VL2016/HodoshHockenmaier16_BinaryTasks_Data.tar)

by the authors for a subset of FLICKR-30K (Hodosh et al., 2013). Specifically, we consider four different types of distractions for the image descriptions, namely 1) Replace-Scene, 2) Replace-Person, 3) Share-Scene, and 4) Share-Person, which results 15548 correct and distracted caption pairs in total. For Replace-Scene and Replace-Person tasks, the distracted descriptions were artificially constructed by replacing the main actor (first person) and the scene in the original caption by random person and scene elements, respectively. For Share-Scene and Share-Person tasks, the distracted captions were selected from the sentences from the training part of FLICKR-30K (Young et al., 2014) dataset whose actor or scene chunks share the similar main actor or scene elements with the correct description. Figure 5 presents an example image together with the original description and its distracted versions.

We compare each correct caption available for an image with the remaining correct and distracted

captions for that image by considering tested evaluation metrics, and then estimate an average accuracy score. In Table 5, we present the classification accuracies of the evaluation metrics for each distraction type. As can be seen, the WMD metric gives the best results for three out of four categories, and provides the second best result for the Replace-Scene case. Overall, METEOR and CIDER metrics seem to be also robust to these distractions. The very recently proposed SPICE metric performs the worst for this task. This is somewhat expected as it is even affected by the use of synonyms of the words as we have previously shown in Table 2.

### 3.4 Discussion

As the experiments on quality, accuracy and robustness tests demonstrate in Sections 3.1-3.3, existing automatic image captioning metrics all have some strengths and weaknesses due to their design choices. For example, while SPICE, METEOR and WMD give the best performances in terms of our correlation analysis against human judgments, CIDER and WMD provide the best classification scores for our accuracy experiments. Moreover, CIDER, METEOR and WMD are found to be less affected by the distractors. Overall, our analysis suggests that the recently proposed WMD document metric is also quite effective for image captioning since it has high correlations with the human scores, is much less sensitive to synonym swapping and additionally performs well at the accuracy and distraction tasks.

Our analysis also shows that the existing metrics both theoretically and empirically differ from each other with significant differences. Compared to the recent results of significance testing of machine translation and summarization metrics (Graham and Baldwin, 2014; Graham et al., 2015; Graham and Liu, 2016; Graham, 2015), our results suggest that there remains much room for improvement in developing more effective image captioning evaluation metrics. We leave this for future work, but a very naive idea would be combining different metrics into a unified metric and we simply test this idea using score combination, after normalizing the score of each metric to the range  $[0, 1]$ . Among all possible combinations, we find that the combination of WMD+SPICE+METEOR performs the best with a Spearman’s correlation of 0.66 for FLICKR-8K and

0.45 for COMPOSITE dataset, yielding an improvement from SPICE (0.64 and 0.42). In addition, we should add that this unified metric significantly outperforms the individual metrics according to Williams test ( $p < 0.01$ ).

## 4 Conclusion

In this paper, we provide a careful evaluation of the automatic image captioning metrics, and propose to use WMD, which utilizes *word2vec* embeddings of the words to compute a semantic similarity of sentences. We highlight the drawbacks of the existing metrics, and we empirically show that they are significantly different than each other. We hope that this work motivates further research into developing better evaluation metrics, probably learning based ones, as previously studied in machine translation literature (Kotani and Yoshimi, 2010; Guzmán et al., 2015). We also observe that incorporating visual information (via Scene-graph used by SPICE) and semantic information (via WMD) is useful for the caption evaluation task, which motivates the use of multimodal embeddings (Kottur et al., 2015).

# Integrating Meaning into Quality Evaluation of Machine Translation

Osman Başkaya<sup>1</sup>, Eray Yıldız<sup>1</sup>, Doruk Tunaoglu<sup>1</sup>, M. Tolga Eren<sup>1</sup>, and A. Seza Doğruöz<sup>2</sup>

<sup>1</sup>Huawei Turkey Research and Development Center, Istanbul, Turkey

## Abstract

Machine translation (MT) quality is evaluated through comparisons between MT outputs and the human translations (HT). Traditionally, this evaluation relies on form related features (e.g. lexicon and syntax) and ignores the transfer of meaning reflected in HT outputs. Instead, we evaluate the quality of MT outputs through meaning related features (e.g. polarity, subjectivity) with two experiments. In the first experiment, the meaning related features are compared to human rankings individually. In the second experiment, combinations of meaning related features and other quality metrics are utilized to predict the same human rankings. The results of our experiments confirm the benefit of these features in predicting human evaluation of translation quality in addition to traditional metrics which focus mainly on form.

## 1 Introduction

Machine translation (MT) systems translate large chunks of data automatically across languages. Although these systems may achieve high level accuracies using form related features (e.g. lexical and syntactic), they often fail to carry over the meaning embracing the form. Example (1) highlights the meaning difference between a Human Translation (HT) and an MT output for the same source sentence:

## Example (1)

HT: “*Your feet’s too big.*”<sup>1</sup>

MT: “*Your feet is too great.*”<sup>2</sup>

Although the form is often preserved, MT outputs may sound “strange” or “different” in comparison to HT ones due to the loss of meaning. Therefore, human translators generally enrich the text with the appropriate tone, style and sentiments during translation. Current quality evaluation metrics like BLEU (Papineni et al., 2002) and METEOR (Lavie and Agarwal, 2007) are based on form related features and do not directly consider the transfer of meaning (e.g. sentiment and style) in MT. Some of these metrics check for synonyms and paraphrases but this approach is still limited to the coverage of the corresponding pair tables. In other words, these metrics do not explicitly evaluate the transfer of meaning in MT. Our main goals are:

- to find out whether the transfer of meaning related features (e.g. sentiment and style) in MT influences the human judgment of translation quality.
- to compare meaning and form related features for quality evaluation of MT.
- to measure whether meaning and form related features can be combined to improve the performance of existing MT quality evaluation metrics.

<sup>1</sup>WMT’15 Finnish to English test set, reference translation, segment id:440

<sup>2</sup>WMT’15 Finnish to English test set, translated by system: UoS.4059, segment id:440

By using publicly available parallel corpora (Tenth Workshop on Statistical Machine Translation (WMT15)), we achieve our goals with two experiments described in Section 5. Our results indicate that combining meaning related features with form related ones approximates to the human judged rankings better than the BLEU metric. These combined features also improve the performance of other MT quality evaluation metrics by 0.5-2 percentage points.

## 2 Related Work

So far, MT studies have focused mostly on features related to form (e.g., lexical and syntactic features) for the automatic evaluation of MT quality (e.g., BLEU (Papineni et al., 2002) and METEOR (Lavie and Agarwal, 2007)). BLEU metric is based on n-gram matching of the HT and MT texts and used widely in the MT community to evaluate the MT quality. METEOR employs both word matching scores and the linguistic information (e.g., synonyms and stemming) in contrast to BLEU. Following studies have evaluated MT quality with various features: POS tags (Dahlmeier et al., 2011), morphemes (Tantuĝ et al., 2008), sentence structure (Li et al., 2012), named entities (Buck, 2012), semantic textual similarity (Castillo and Estrella, 2012), paraphrasing (Snover et al., 2006), semantic roles (Lo and Wu, 2011) and language models (Stanojevic and Simaan, 2014). Recently, Yu et al. (2015) proposed another metric (i.e. DPMFComb) which is a combination of a syntax-based metric and some other evaluation metrics in Asiya<sup>3</sup>. At WMT15, DPMFComb obtained the best results at the metrics task for system-level evaluation of translation into English tasks.

Although previous methods require human reference translation, recent methods (e.g. *quality estimation metrics*), aim to eliminate the necessity of human translation. These methods apply Machine Learning (ML) techniques using lexical (e.g. average source/target token length), syntactic (e.g. ratio of percentage of POS tags in the source/target sentences), and statistical features (e.g. source/target sentence LM probability, word alignment probabilities, etc.) (Stymne et al., 2014; Langlois, 2015; Shah et al., 2015). Interested reader may also benefit from the survey on MT evaluation metrics by Han and Wong (2016).

Table 1: WMT15 Test Data Statistics grouped by source languages. The domain of source text, the number of sentences and the number of human judgments are presented for each source language.

Chen and Zhu (2014) explore sentiment consistency between MT and HT texts to improve the MT quality by incorporating sentiment related features (e.g. subjectivity, polarity, intensity and negation). By using these features in their MT system, they improved the BLEU score by 1.1 point on NIST Chinese-to-English translation dataset<sup>4</sup>. Mohammad et al. (2015) also investigate the sentiment consistency between MT and HT texts with a different motivation. They improve sentiment analysis performance for Arabic by translating available resources (e.g., sentiment lexicon, sentiment annotated data) from English to Arabic. Although sentiment analysis of English translations of Arabic texts obtain competitive results to current state-of-the-art Arabic sentiment analysis systems, they did not evaluate the MT output quality.

There are also studies using MT systems to enrich labeled data for sentiment analysis by translating between languages and leveraging sentiment scores (Wan, 2009; Demirtaş and Pechenizkiy, 2013; Hiroshi et al., 2004). However, none of these studies employ meaning related features to evaluate the MT quality.

## 3 Data Description

### 3.1 2015 Workshop on Statistical Machine Translation

We utilized WMT15<sup>5</sup> parallel corpora (Bojar et al., 2015) which include several tasks (e.g., standard news translation task, a metrics task, a tuning task, a task for run-time estimation of machine translation quality, and an automatic post-editing task). 24 institutions participated in the translation task with a total of 68 machine translation systems. The WMT15 data includes:

<sup>4</sup><http://www.nist.gov/speech/tests/mt>

<sup>5</sup><http://www.statmt.org/wmt15/>

	Human Translation (HT) Output	Machine Translation (MT) Output
1.	<i>Adam, you see badly what you are looking at.</i>	<i>Adam, you see what you look at.</i>
2.	<i>Of course I don't hate you.</i>	<i>Of course I hate you.</i>
3.	<i>This is business news</i>	<i>This is supposed to be of business news</i>
4.	<i>The views of Chinese towards white people is similar!</i>	<i>The Chinese think like white people!</i>

Table 2: Examples of MT Errors in WMT15 Dataset

- Source sentences
- Reference human translations (HT)
- Machine translations (MT)
- Human judgments (e.g. from 1 (*best*) to 5 (*worst*)) for each MT text.

The data is available for five language pairs: Czech (ces)-English, French (fre)-English, German (deu)-English, Finnish (fin)-English, and Russian (rus)-English. Domains of the test data are the same for all languages except for French. The test data for the French-English language pair was fetched from a news discussion forum instead of news texts. Table 1 shows the statistics for the test data. The target language is English for all source languages. The domain of source text, the number of sentences and the number of human judgments are presented. All data was based on the news text corpora except for French-English pair.

In order to evaluate the quality of each MT system, Bojar et al. (2015) conducted a human evaluation using Appraise<sup>6</sup> (Federmann, 2012) which is an open source toolkit (similar to Amazon Mechanical Turk<sup>7</sup>). Each segment consists of a source sentence in the original language (e.g. Czech), its corresponding human translation (English), and 5 anonymous MT system translations (English).

To make the task more consistent and to increase the number of data points, the organizers treated almost identical system translations as one. Even though exactly 5 translations are presented to each judge in a segment, there may be more than 5 MT systems that are ranked. Judges rate the segments from 1 (best) to 5 (worst) by the quality of translated sentences (allowing ties).

<sup>6</sup><https://github.com/cfedermann/Appraise>

<sup>7</sup><https://www.mturk.com/mturk/>

In total, there were 29,007 segments, each of which would have produced at least 10 individual system comparisons (e.g.,  $A > B$ ,  $B > C$ ,  $A = C$ ,  $C > B$ , etc.). To map these individual comparisons to system scores, the organizers used TrueSkill<sup>8</sup> (Herbrich et al., 2006), a Bayesian skill ranking algorithm (similar to Elo used in Chess (Elo, 1978)) and fed these individual bilateral comparisons to TrueSkill. A score is produced for each participated system. In this study, we utilized the HT texts, MT system translations and human judgments in our experiments.

### 3.2 Features

Table 2 provides examples of MT errors in comparison to HT. All example translations (MT vs. HT texts) are selected from the WMT15 dataset based on the lowest (5) rankings by human judges. Although translations overlap at the word level, they convey quite different meanings. In example (1), the word '*badly*' has disappeared in MT output and led to a loss of information. In example (2), a negated sentence is translated as an affirmative sentence by the MT system. Example (3) illustrates how the MT system generates a more speculative sentence than HT sentence. The pair in example (4) differs in terms of formality between MT vs HT output. MT evaluation metrics may attribute high scores for these pairs since they mainly focus on lexical and syntactic matching. However, as our examples demonstrate, meaning could easily be lost if we rely only on form related MT system evaluation metrics.

To investigate the consistency between MT and HT texts for sentiment and stylistic features, we make use of *sentiment polarity*, *subjectivity*, *connotation*, *negation*, *speculation*, *readability* and *formality* to measure how these features influence the quality of translation with respect to human rankings.

<sup>8</sup><http://research.microsoft.com/en-us/projects/trueskill/>

**Sentiment Polarity** indicates whether the designated sentence has an affirmative or negative sentiment. To measure the impact of this feature, we use *Vader*, a rule based sentiment analysis tool (Hutto and Gilbert, 2014). It utilizes grammatical and syntactical rules. In the experiments performed by Hutto and Gilbert (2014), *Vader* outperforms several competing sentiment analysis approaches.

Additionally, we trained a machine learning (ML) based sentiment analyzer using a deep learning approach described by Yildiz et al. (2016). Their architecture is a Convolutional Neural Network (CNN) which takes pre-trained word vectors<sup>9</sup> as input and applies interleaved convolution and pooling operations. The top layer in the network is Softmax layer which computes the probability of assigning a class (positive, negative).

We adopted this architecture and trained a network using Stanford Twitter Sentiment Corpus<sup>10</sup>. The training set contains 1.6 million tweets automatically labeled as positive or negative from various domains while the test set is labeled manually. This ML based sentiment analyzer achieves 90.1% accuracy and outperforms the SVM classifier reported by Go et al. (2009).

**Subjectivity** indicates whether a text expresses an opinion. In order to compute the subjectivity scores, we trained our architecture using the *sentiment polarity and subjectivity dataset*<sup>11</sup> (Pang and Lee, 2004) which includes 5000 subjective and 5000 objective sentences. We applied 10-fold cross validation to the data and obtained 91.50% average accuracy.

**Connotation** indicates cultural or emotional association carried by words that appear in sentences (Feng et al., 2013). In contrast to the sentiment polarity, connotation polarity indicates subtle shades of sentiment beyond denotative or surface meaning of text. The words which do not express sentiment can carry a positive or negative connotation.

For instance, “life” and “home” are considered neutral with regard to the sentiment analysis. However, they convey a positive connotation

(Carpuat, 2015). We use the connotation polarity of each word in a sentence to compute connotation score using a normalized version of the formulation proposed by Carpuat (2015). The connotation polarities of the words are obtained by looking up a lexicon which is constructed by Feng et al. (2013). We used the following formula to compute the connotation score:

$$CS = \frac{\#positive - \#negative}{\#total} \quad (1)$$

where  $CS$  is the connotation score,  $\#positive$  indicates the number of the words with positive connotation and  $\#negative$  indicates the number of the words with negative connotation.

This formula assigns a continuous value between 1 and  $-1$  to the sentence as a connotation score. The values close to 1 indicate that a given sentence carries a positive connotation while the values close to  $-1$  indicate a negative connotation.

**Negation** turns an affirmative statement into a negative one. We also detect the effects of negation feature in our experiments. Konstantinova et al. (2012) present a freely available dataset which contains 400 reviews (50 each from 8 domains such as movies and consumer products) annotated by linguists for negation and speculation. We train our deep learning model with these datasets and obtain 96.65% accuracy for negation.

**Speculation** is used to express levels of certainty. We obtain 95.55% accuracy using the same dataset and method for negation.

**Readability** measures the ease of reading and comprehending a text (Dale and Chall, 1948). For readability measurement we use Flesch reading-ease test in which higher scores indicate that the text is easier to read. The Flesch readability score (Kincaid et al., 1975) is calculated using the sentence length and the number of syllables per word as presented in the formula below.

$$Flesch = 206.835 - 1.015 \frac{A}{B} - 84.6 \frac{C}{A} \quad (2)$$

where  $A$  is the number of words,  $B$  is the number of sentences and  $C$  is the number of syllables in a given text.

In addition to the rule based readability measurement, we use an ML based readability metric “*simplicity*” as described by Vajjala and Meurers (2016). They extract various syntactic, psycholinguistic and lexical features from text and

<sup>9</sup><https://code.google.com/archive/p/word2vec/>

<sup>10</sup><http://help.sentiment140.com/for-students>

<sup>11</sup>[http://www.cs.cornell.edu/people/pabo/movie-review-data/rotten\\_imdb.tar.gz](http://www.cs.cornell.edu/people/pabo/movie-review-data/rotten_imdb.tar.gz)

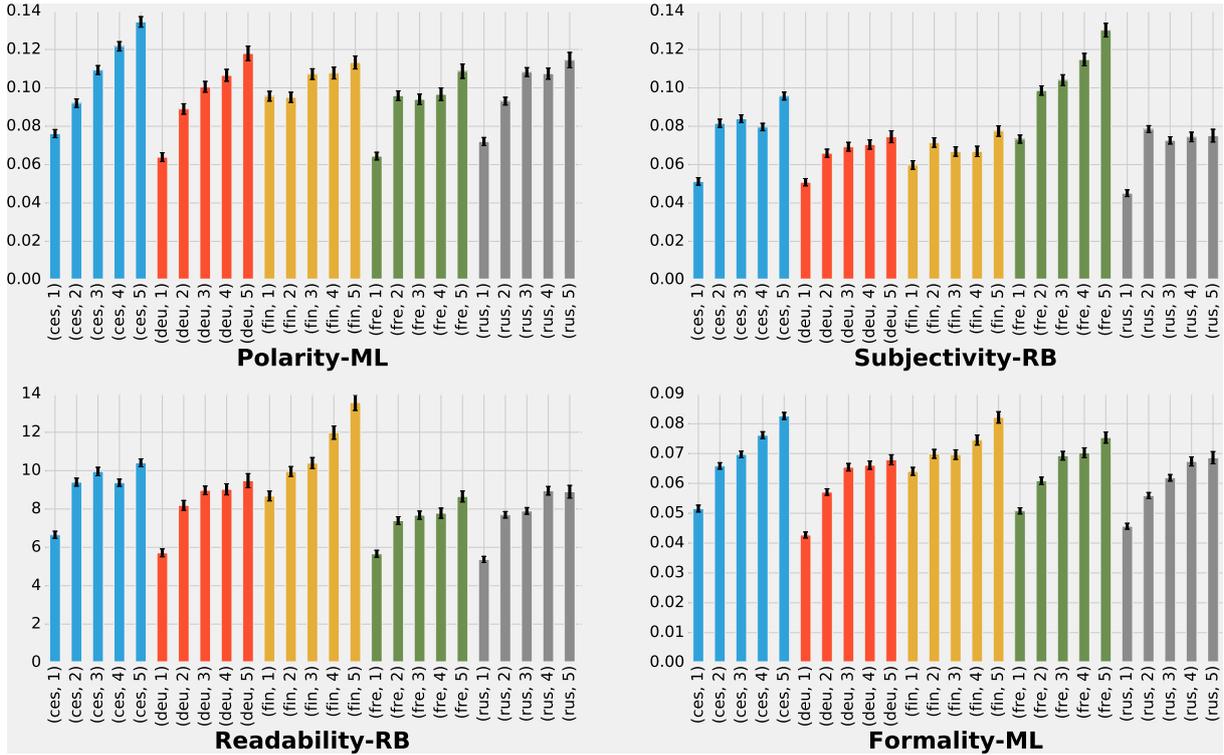

Figure 1: Means of absolute differences between the feature scores of MT and HT outputs. x-axis denotes the language and human rank pairs. Error bars indicate 95% confidence intervals.

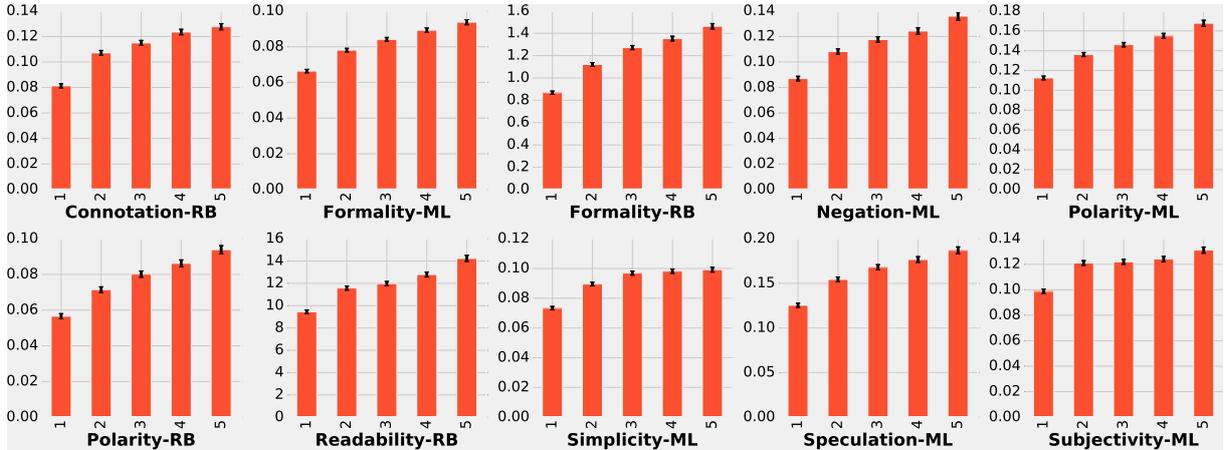

Figure 2: Means of absolute differences between the features scores of MT outputs and the corresponding HT outputs for all features. x-axis denotes the human rankings. Error bars indicate 95% confidence intervals.

train a pair-wise classifier using them. The training data is a sentence-aligned corpus constructed from news articles and Wikipedia pages and their simplified versions. The method correctly classifies the simplified and complex sentences in terms of their reading level with an accuracy of over 80%.

**Formality** Heylighen and Dewaele (1999) state formality as the most important dimension of vari-

ation between styles. They define the formality score as a function of POS tag frequencies. The formality score is given in Equation 3 where NF is the frequency of nouns, AdjF is the adjective frequency, PF is the preposition frequency, ArtF is the article frequency, PrpF is the proper noun frequency, VF is the verb frequency, AdvF is the adverb frequency and IF is the interjection frequency.

$$F = \frac{NF + AdjF + PF + ArtF}{2} - \frac{PrpF + VF + AdvF + IF}{2} + 50 \quad (3)$$

Additionally, we use an ML based formality score obtained by training the mentioned architecture on the dataset introduced by Pavlick and Tetreault (2016). We have observed 80.71% accuracy through 10-fold cross validation.

All metrics were normalized between (0, 1) except the Readability and Formality. Since these two metrics are formula-based, we avoided interfering with their original scales.

## 4 Method

In the WMT15 task, the language pairs are divided into two groups depending on whether English is the source or the target language. We only utilize the pairs where English is the target language due to the richness in resources. For each feature, MT texts are ranked using the following approach:

1. Compute the score for HT text (e.g., 0.65).
2. Compute the scores for MT texts (e.g. A=.79, B=.25, C=.20, D=.95, E=.30).
3. Compute the absolute difference between MT scores and the HT score (e.g.,  $\hat{A} = .14$ ,  $\hat{B} = .40$ ,  $\hat{C} = .45$ ,  $\hat{D} = .30$ ,  $\hat{E} = .35$ ).
4. Rank the systems according to these differences where a smaller value corresponds to a better ranking (e.g. 1=A, 2=D, 3=E, 4=B, 5=C).

Figure 1 shows absolute differences for four features with respect to language and human rankings of MT system output. For instance, *Subjectivity-RB* feature captures the differences between ranks when the source language is French but cannot achieve the same performance for Finnish and Russian translations. Moreover, *Readability-RuleBased (RB)* and *Formality-MachineLearning (ML)* seem to perform well for all languages whereas *Polarity-ML* falls short for French.

Figure 2 illustrates the trend for all features in which absolute score difference between MT system outputs and HT text is low for high rankings (e.g., 1) and high for the low (e.g., 5) ones. Therefore, high ranked translations preserve the meaning better than the low ranked ones. Note that both

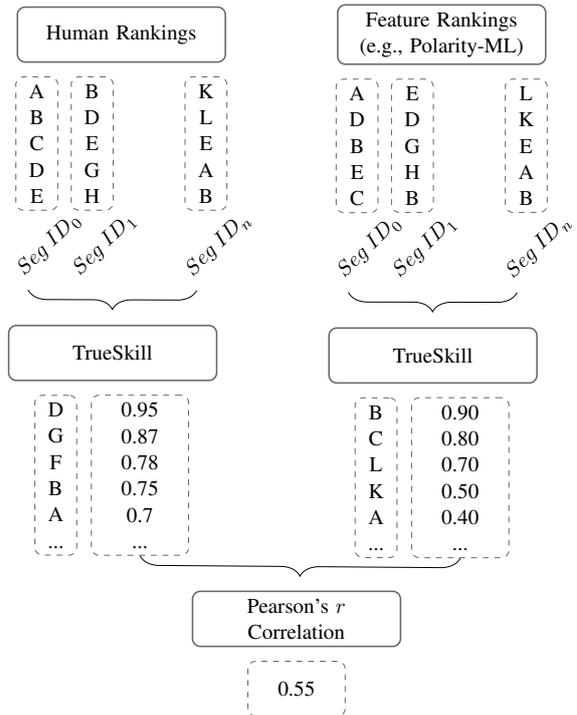

Figure 3: Steps to map human rankings and feature rankings (for example, *Polarity-ML*) to system-wide scores.  $A$  to  $L$  denotes individual rankings and  $SegID_i$  denotes the  $i^{th}$  segment in the WMT15 test set.

figures are descriptive and do not correspond to an objective evaluation directly.

## 5 Experiments

### 5.1 Experiment #1: Impact of Individual Features on Translation Quality

This experiment investigates the correlation between each feature and MT translation quality evaluated by rankings of human judges. Using the rankings described in Section 4, we followed the “System-Based Evaluation Methodology” by Stanojević et al. (2015). After obtaining the rankings for each feature as described in the previous section, we used TrueSkill to map segment rankings to system-wide scores (see Figure 3). Next, we compared TrueSkill scores obtained per feature and human judgments with Pearson’s  $r$  correlation using the scripts provided by the WMT15 Metrics Task<sup>12</sup>. As stated in (Stanojević et al., 2015) the script performs bootstrap resampling of 1000 samples while calculating the correlation scores and the 95% confidence intervals.

Subjectivity-ML	61.1 ± 2.6	56.3 ± 1.3	66.4 ± 2.9	42.5 ± 3.2	75.9 ± 2.6	64.3 ± 2.9
BLEU	91.6 ± 1.4	95.8 ± 0.6	86.5 ± 2.0	92.9 ± 1.4	97.5 ± 0.9	85.1 ± 2.2
DPMFComb	96.2 ± 0.9	96.0 ± 0.5	97.0 ± 0.9	95.1 ± 1.2	98.0 ± 0.8	95.0 ± 1.1
Meteor	94.9 ± 1.0	94.8 ± 0.5	95.5 ± 1.0	96.3 ± 1.0	95.1 ± 1.2	92.7 ± 1.4
Random-Baseline	0.0 ± 2.9	-28.4 ± 1.5	47.6 ± 3.2	-65.9 ± 2.8	-3.6 ± 3.6	50.4 ± 3.4

Table 3: Pearson’s  $r$  correlation between Trueskill scores of a metric and human judgments with the corresponding 95% confidence intervals are shown. Each row represent either a meaning related feature (top) or a selected metric from WMT15 (bottom). ML stands for machine learning and RB stands for rule based method.

We have used three metrics from WMT15 Metrics Task for comparison, BLEU and METEOR and DPMFComb. DPMFComb was selected since it was the best system in overall score in system-based evaluation of WMT15 Metrics Shared Task and the best performing evaluation metric for three out of five languages.

**Results** Table 3 shows all the Pearson’s correlations. Overall, *Formality-RB* obtains the highest correlation score (80.7%) among all features. However, DPMFComb (96.2%), BLEU and METEOR are better than the rest. The exceptions are German for BLEU and French for METEOR. For German, *Formality-RB* (92.5%) outperforms BLEU (86.5%). For French, *Formality-RB* (97.4%) beats the METEOR score (95.1%). In addition, Rule-Based (RB) systems perform better than Machine Learning (ML) ones. For example, *Formality-RB* and *Polarity-RB* outperform *Formality-ML* and *Polarity-ML* respectively.

Meaning related features outperform *Random* baseline as expected. The random baseline is computed by assigning random ranks (1-5) to each translation in each segment. We assigned uniformly random ranks to all sentences without considering the language. Although its performance may vary per language, its overall performance is 0.0 ( $\pm 2.9$ ).

## 5.2 Experiment #2: Impact of Combined Features on Translation Quality

As discussed in Section 4, our approach is fundamentally different than MT evaluation metrics such as BLEU. Results of our first experiment indicated strong correlations between quality scores of the features and human rankings. Therefore, we also investigate whether we can predict human rankings of MT translated text by combining these features since they capture different aspects of translation.

In contrast with Experiment 1, this experiment focuses on training systems that combine several features to predict human rankings. As input, BLEU, METEOR and DPMFComb metrics are utilized in combination with the feature scores. We experimented with several classifiers from RankLib<sup>13</sup> to train the ensemble systems and opted to utilize a Random Forest (Liaw and Wiener, 2002) based approach which produced the best 5-fold cross validation score.

First, we obtained scores and rankings for each translation using the Random Forest classifiers for the following combinations:

1. All meaning related features
2. All meaning related features + BLEU

<sup>13</sup><https://sourceforge.net/p/lemur/wiki/RankLib/>

	All	Ces	Deu	Fin	Fre	Rus
ALL+DPMFComb	<b>96.8 ± 0.8</b>	95.9 ± 0.4	<b>97.5 ± 0.8</b>	<b>97.9 ± 0.8</b>	<b>98.6 ± 0.6</b>	94.3 ± 1.3
DPMFComb	96.2 ± 0.9	<b>96.0 ± 0.5</b>	97.0 ± 0.9	95.1 ± 1.2	98.0 ± 0.8	<b>95.0 ± 1.1</b>
ALL+Meteor	95.8 ± 0.9	95.4 ± 0.5	96.6 ± 1.0	97.7 ± 0.8	98.0 ± 0.8	91.2 ± 1.6

ALL+BLEU	93.5 ± 1.2	93.4 ± 0.6	92.3 ± 1.5	96.8 ± 0.9	97.6 ± 0.9	87.3 ± 1.9
ALL	92.0 ± 1.2	87.5 ± 0.7	93.4 ± 1.3	94.5 ± 1.2	97.8 ± 0.8	86.8 ± 1.8
BLEU	91.6 ± 1.4	95.8 ± 0.6	86.5 ± 2.0	92.9 ± 1.4	97.5 ± 0.9	85.1 ± 2.2

Table 4: Pearson’s  $r$  correlation between Trueskill scores of a metric and human judgments with the corresponding 95% confidence intervals are shown. ALL represents the combination of all meaning related features.

3. All meaning related features + Meteor
4. All meaning related features + DPMFComb

evaluation of MT system quality can be predicted with a higher accuracy. (See Table 4).

Then, we calculated the Trueskill scores for translation systems and finally fed them into WMT15 scripts to obtain Pearson’s  $r$  correlation similar to the first experiment.

**Results** Combined meaning related features outperform the BLEU score (Table 4). Even though the margin is relatively low, it is a promising indication. Moreover, combining them with a metric increases the performance of the metric: 1.9pp for BLEU, 0.9pp for METEOR and 0.6pp for DPMFComb. In other words, these features can utilize some meaning or style related information which is not captured by the conventional MT evaluation metrics.

## 6 Discussion & Conclusion

In this paper, we investigate how meaning related features influence the automatic evaluation of MT systems. Our experiments prove the additional benefit of these features in predicting human evaluation of translation quality. More specifically, we find that:

- MT systems that are ranked higher by human judges preserve the meaning (features such as polarity, formality and readability) better than the low ranked ones.
- Rankings of MT output generated according to meaning based features correlate highly with human rankings on translation quality (See Figure 2).
- When meaning related features are combined with form related lexical features, human

Extracting meaning related features from text and using form related features for MT evaluation have been studied separately. However, integrating meaning related features into MT quality evaluation can capture the meaning preservation from source to target languages. Our experiments prove that this integrated approach achieves a only slightly better performance than the form based metrics (e.g. BLEU). Moreover, our experiments indicate that the meaning related features can boost the performance of BLEU, METEOR and DPMFComb metrics without even specific optimization. Therefore, our method of integrating meaning related features to MT systems with ranking components can also improve the performances of other metrics instead of only relying on form based features.

Commonly used evaluation metrics (e.g. BLEU and METEOR) require a reference human translation to assess the quality of MT. We also use human translation as a reference since most meaning related feature extraction tools are only available for English and limited for other languages. Although there are studies assessing the quality of MT systems without human translation, meaning related features are still not integrated to MT systems yet. As new tools for other languages become available, we plan to extend our work to implement MT quality estimation for these languages as well. As future work, we will investigate the ways to develop more "human-like" MT systems by employing these meaning related and stylistic features in the training of MT systems or in post-processing steps such as parameter tuning.

# Cross-Lingual Dependency Parsing with Late Decoding for Truly Low-Resource Languages

Michael Sejr Schlichtkrull

University of Amsterdam\*  
m.s.schlichtkrull@uva.nl

Anders Søgaard

University of Copenhagen  
soegaard@di.ku.dk

## Abstract

In cross-lingual dependency annotation projection, information is often lost during transfer because of early decoding. We present an end-to-end graph-based neural network dependency parser that can be trained to reproduce matrices of edge scores, which can be directly projected across word alignments. We show that our approach to cross-lingual dependency parsing is not only simpler, but also achieves an absolute improvement of 2.25% averaged across 10 languages compared to the previous state of the art.

## 1 Introduction

Dependency parsing is an integral part of many natural language processing systems. However, most research into dependency parsing has focused on learning from treebanks, i.e. collections of manually annotated, well-formed syntactic trees. In this paper, we develop and evaluate a graph-based parser which does not require the training data to be well-formed trees. We show that such a parser has an important application in cross-lingual learning.

Annotation projection is a method for developing parsers for low-resource languages, relying on aligned translations from resource-rich source languages into the target language, rather than linguistic resources such as treebanks or dictionaries. The Bible has been translated completely into 542 languages, and partially translated into a further 2344 languages. As such, the assumption that we have access to parallel Bible data is much less constraining than the assumption of access to linguistic resources. Furthermore, for truly low-resource languages, relying upon the Bible scales

better than relying on less biased data such as the EuroParl corpus.

In Agić et al. (2016), a projection scheme is proposed wherein labels are collected from many sources, projected into a target language, and then averaged. Crucially, the paper demonstrates how projecting and averaging edge scores from a graph-based parser *before* decoding improves performance. Even so, decoding is still a requirement between projecting labels and retraining from the projected data, since their parser (TurboParser) requires well-formed input trees. This introduces a potential source of noise and loss of information that may be important for finding the best target sentence parse.

Our approach circumvents the need for decoding prior to training, thereby surpassing a state-of-the-art dependency parser trained on decoded multi-source annotation projections as done by Agić et al. We first evaluate the model across several languages, demonstrating results comparable to the state of the art on the Universal Dependencies (McDonald et al., 2013) dataset. Then, we evaluate the same model by inducing labels from cross-lingual multi-source annotation projection, comparing the performance of a model with early decoding to a model with late decoding.

**Contributions** We present a novel end-to-end neural graph-based dependency parser and apply it in a cross-lingual setting where the task is to induce models for truly low-resource languages, assuming only parallel Bible text. Our parser is more flexible than similar parsers, and accepts any weighted or non-weighted graph over a token sequence as input. In our setting, the input is a dense weighted graph, and we show that our parser is superior to previous best approaches to cross-lingual parsing. The code is made available on GitHub.<sup>1</sup>

## 2 Model

The goal of this section is to construct a first-order graph-based dependency parser capable of learning *directly* from potentially incomplete matrices of edge scores produced by another first-order graph-based parser. Our approach is to treat the encoding stage of the parser as a tensor transformation problem, wherein tensors of edge features are mapped to matrices of edge scores. This allows our model to approximate sets of scoring matrices generated by another parser directly through non-linear regression. The core component of the model is a layered sequence of recurrent neural network transformations applied to the axes of an input tensor.

More formally, any digraph  $G = (V, E)$  can be expressed as a binary  $|V| \times |V|$ -matrix  $M$ , where  $M_{ij} = 1$  if and only if  $(j, i) \in E$  – that is, if  $i$  has an ingoing edge from  $j$ . If  $G$  is a tree rooted at  $v_0$ ,  $v_0$  has no ingoing edges. Hence, it suffices to use a  $(|V| - 1) \times |V|$ -matrix. In dependency parsing, every sentence is expressed as a matrix  $S \in \mathbb{R}^{w \times f}$ , where  $w$  is the number of words in the sentence and  $f$  is the width of a feature vector corresponding to each word. The goal is to learn a function  $P : \mathbb{R}^{w \times f} \rightarrow \mathbb{Z}_2^{w \times (w+1)}$ , such that  $P(S)$  corresponds to the matrix representation of the correct parse tree for that sentence – see Figure 1 for an example.

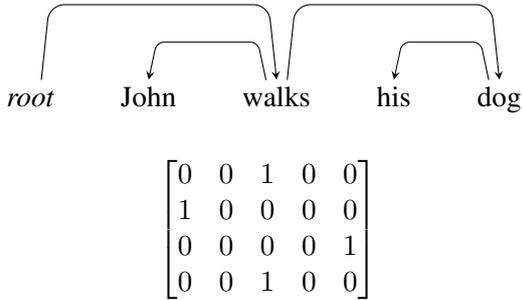

Figure 1: An example dependency tree and the corresponding parse matrix.

In the arc-factored (first-order), graph-based model,  $P$  is a composite function  $P = D \circ E$  where the encoder  $E : \mathbb{R}^{w \times f} \rightarrow \mathbb{R}^{w \times (w+1)}$  is a real-valued scoring function and the decoder  $D : \mathbb{R}^{w \times (w+1)} \rightarrow \mathbb{Z}_2^{w \times (w+1)}$  is a minimum spanning tree algorithm (McDonald et al., 2005). Commonly, the encoder includes only *local* information – that is,  $E_{ij}$  is only dependent on  $S_i$  and

$S_j$ , where  $S_i$  and  $S_j$  are feature vectors corresponding to dependent and head. Our contribution is the introduction of an LSTM-based *global* encoder where the entirety of  $S$  is represented in the calculation of  $E_{ij}$ .

We begin by extending  $S$  to a  $(w+1) \times (f+1)$ -matrix  $S^*$  with an additional row corresponding to the root node and a single binary feature denoting whether a node is the root. We now compute a 3-tensor  $F = S \boxplus S^*$  of dimension  $w \times (w+1) \times (2f+1)$  consisting of concatenations of all combinations of rows in  $S$  and  $S^*$ . This tensor effectively contains a featurization of every edge  $(u, v)$  in the complete digraph over the sentence, consisting of the features of the parent word  $u$  and child word  $v$ . These edge-wise feature vectors are organized in the tensor exactly as the dependency arcs in a parse matrix such as the one shown in the example in Figure 1.

The edges represented by elements  $F_{ij}$  can as such easily be interpreted in the context of related edges represented by the row  $i$  and the column  $j$  in which that edge occurs. The classical arc-factored parsing algorithm of McDonald et al. (2005) corresponds to applying a function  $O : \mathbb{R}^{2f+1} \rightarrow \mathbb{R}$  pointwise to  $S \boxplus S^*$ , then decoding the resulting  $w \times (w+1)$ -matrix. Our model diverges by applying an LSTM-based transformation  $Q : \mathbb{R}^{w \times (w+1) \times (2f+1)} \rightarrow \mathbb{R}^{w \times (w+1) \times d}$  to  $S \boxplus S^*$  before applying an analogous transformation  $O : \mathbb{R}_d \rightarrow \mathbb{R}$ .

The Long Short-Term Memory (LSTM) unit is a function  $LSTM(x, h_{t-1}, c_{t-1}) = (h_t, c_t)$  defined through the use of several intermediary steps, following Hochreiter et al. (2001). A concatenated input vector  $I = x \oplus h_{prev}$  is constructed, where  $\oplus$  represents vector concatenation. Then, functions corresponding to input, forget, and output gates are defined following the form  $g_{input} = \sigma(W_{input}I + b_{input})$ . Finally, the internal cell state  $c_t$  and the output vector  $h_t$  at time  $t$  are defined using the Hadamard (pointwise) product  $\bullet$ :

$$\begin{aligned} c_t &= g_{forget} \bullet c_{prev} + g_{input} \bullet \tanh(W_{cell}I + b_{cell}) \\ h_t &= g_{output} \bullet \tanh(c_t) \end{aligned}$$

We define a function Matrix-LSTM inductively, that applies an LSTM to the rows of a matrix  $X$ . Formally, Matrix-LSTM is a function  $\mathcal{M} : \mathbb{R}^{a \times b} \rightarrow \mathbb{R}^{a \times c}$  such that  $(h_1, c_1) = LSTM(X_1, 0, 0)$ ,  $\forall 1 < i \leq n$   $(h_i, c_i) = LSTM(X_i, h_{i-1}, c_{i-1})$ , and  $\mathcal{M}(X)_i = h_i$ .

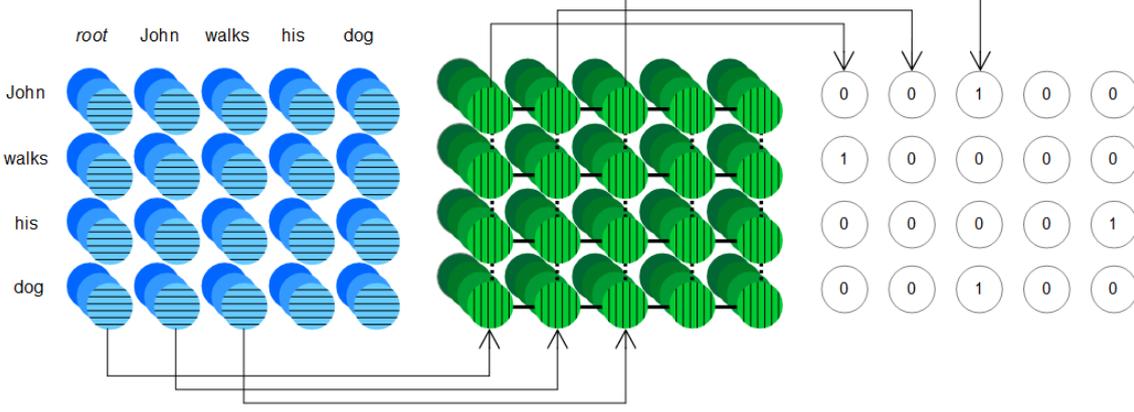

Figure 2: Four-directional Tensor-LSTM applied to the example sentence seen in Figure 1. The word-pair tensor  $S \boxplus S^*$  is represented with blue units (horizontal lines), a hidden Tensor-LSTM layer  $H$  with green units (vertical lines), and the output layer with white units. The recurrent connections in the hidden layer along  $H$  and  $H^{T(2,1,3)}$  are illustrated respectively with dotted and fully drawn lines.

An effective extension is the *bidirectional* LSTM, wherein the LSTM-function is applied to the sequence both in the forward and in the backward direction, and the results are concatenated. In the matrix formulation, reversing a sequence corresponds to inverting the order of the rows. This is most naturally accomplished through left-multiplication with an exchange matrix  $J_m \in \mathbb{R}^{m \times m}$  such that:

$$J_m = \begin{bmatrix} 0 & \cdots & 1 \\ \vdots & \ddots & \vdots \\ 1 & \cdots & 0 \end{bmatrix}$$

Bidirectional Matrix-LSTM is therefore defined as a function  $\mathcal{M}_{2d} : \mathbb{R}^{a \times b} \rightarrow \mathbb{R}^{a \times 2c}$  such that:

$$\mathcal{M}_{2d}(S) = \mathcal{M}(S) \oplus_2 J_a \mathcal{M}(J_a S)$$

Here,  $\oplus_2$  refers to concatenation along the second axis of the matrix.

Keeping in mind the goal of constructing a tensor transformation  $Q$  capable of propagating information in an LSTM-like manner between any two elements of the input tensor, we are interested in constructing an equivalent of the Matrix-LSTM-model operating on 3-tensors rather than matrices. This construct, when applied to the edge tensor  $F = S \boxplus S^*$ , can then provide a means of interpreting edges in the context of related edges.

A very simple variant of such an LSTM-function operating on 3-tensors can be constructed by applying a bidirectional Matrix-LSTM to every matrix along the first axis of the tensor. This forms

the center of our approach. Formally, bidirectional Tensor-LSTM is a function  $\mathcal{T}_{2d} : \mathbb{R}^{a \times b \times c} \rightarrow \mathbb{R}^{a \times b \times 2h}$  such that:

$$\mathcal{T}_{2d}(T)_i = \mathcal{M}_{2d}(T_i)$$

This definition allows information to flow *within* the matrices of the first axis of the tensor, but not *between* them – corresponding in Figure 2 to horizontal connection along the rows, but no vertical connections along the columns. To fully cover the tensor structure, we must extend this model to include connections along columns.

This is accomplished through tensor transposition. Formally, tensor transposition is an operator  $T^{T\sigma}$  where  $\sigma$  is a permutation on the set  $\{1, \dots, \text{rank}(T)\}$ . The last axis of the tensor contains the feature representations, which we are not interested in scrambling. For the Matrix-LSTM, this leaves only one option –  $M^{T(1,2)}$ . When the LSTM is operating on a 3-tensor, we have two options –  $T^{T(2,1,3)}$  and  $T^{T(1,2,3)}$ . This leads to the following definition of four-directional Tensor-LSTM as a function  $\mathcal{T}_{4d} : \mathbb{R}^{a \times b \times c} \rightarrow \mathbb{R}^{a \times b \times 4h}$  analogous to bidirectional Sequence-LSTM:

$$\mathcal{T}_{4d}(T) = \mathcal{T}_{2d}(T) \oplus_3 \mathcal{T}_{2d}(T^{T(2,1,3)})^{T(2,1,3)}$$

Calculating the LSTM-function on  $T^{T(1,2,3)}$  and  $T^{T(2,1,3)}$  can be thought of as constructing the recurrent links either "side-wards" or "down-wards" in the tensor – or, equivalently, constructing recurrent links either between the outgoing or between the in-going edges of every vertex in

the dependency graph. In Figure 2, we illustrate the two directions respectively with full or dotted edges in the hidden layer.

The output of Tensor-LSTM is itself a tensor. In our experiments, we use a multi-layered variation implemented by stacking layers of models:  $\mathcal{T}_{4d,stack}(T) = \mathcal{T}_{4d}(\mathcal{T}_{4d}(\dots\mathcal{T}_{4d}(T)\dots))$ . We do not share parameters between stacked layers. Training the model is done by minimizing the value  $\mathcal{E}(G, O(Q(S \boxplus S^*)))$  of some loss function  $\mathcal{E}$  for each sentence  $S$  with gold tensor  $G$ . We experiment with two loss functions.

In our monolingual set-up, we exploit the fact that parse matrices by virtue of depicting trees are right stochastic matrices. Following this observation, we constrain each row of  $O(Q(S \boxplus S^*))$  under a softmax-function and use as loss the row-wise cross entropy. In our cross-lingual set-up, we use mean squared error. In both cases, prediction-time decoding is done with Chu-Liu-Edmonds algorithm (Edmonds, 1968) following McDonald et al. (2005).

### 3 Cross-lingual parsing

Hwa et al. (2005) is a seminal paper for cross-lingual dependency parsing, but they use very detailed heuristics to ensure that the projected syntactic structures are well-formed. Agić et al. (2016) is the latest continuation of their work, presenting a new approach to cross-lingual projection, projecting edge scores rather than subtrees. Agić et al. (2016) construct target-language treebanks by aggregating scores from multiple source languages, before decoding. Averaging before decoding is especially beneficial when the parallel data is of low quality, as the decoder introduces errors, when edge scores are missing. Despite averaging, there will still be scores missing from the input weight matrices, especially when the source and target languages are very distant. Below, we show that we can circumvent error-inducing early decoding by training directly on the projected edge scores.

We assume source language datasets  $\mathcal{L}_1, \dots, \mathcal{L}_n$ , parsed by monolingual arc-factored parsers. In our case, this data comes from the Bible. We assume access to a set of sentence alignment functions  $A_s : \mathcal{L}_s \times \mathcal{L}_t \rightarrow \mathbb{R}_{0,1}$  where  $A_s(S_s, S_t)$  is the confidence that  $S_t$  is the translation of  $S_s$ . Similarly, we have access to a set of word alignment functions  $W_{\mathcal{L}_s, S_s, S_t} : S_s \times S_t \rightarrow \mathbb{R}_{0,1}$  such that

$S_s \in \mathcal{L}_s$ ,  $S_t \in \mathcal{L}_t$ , and  $W(w_s, w_t)$  represents the confidence that  $w_s$  aligns to  $w_t$  given that  $S_t$  is the translation of  $S_s$

For each source language  $\mathcal{L}_s$  with a scoring function  $score_{\mathcal{L}_s}$ , we define a local edge-wise voting function  $vote_{S_s}((u_s, v_s), (u_t, v_t))$  operating on a source language edge  $(u_s, v_s) \in S_s$  and a target language edge  $(u_t, v_t) \in S_t$ . Intuitively, every source language edge votes for every target language edge with a score proportional to the confidence of the edges aligning and the score given in the source language. For every target language edge  $(u_t, v_t) \in S_t$ :

$$\begin{aligned} vote_{S_s}((u_s, v_s), (u_t, v_t)) &= W_{\mathcal{L}_s, S_s, S_t}(u_s, u_t) \\ &\quad \cdot W_{\mathcal{L}_s, S_s, S_t}(v_s, v_t) \\ &\quad \cdot score_{\mathcal{L}_s}(u_s, v_s) \end{aligned}$$

Following Agić et al. (2016), a sentence-wise voting function is then constructed as the highest contribution from a source-language edge:

$$vote_{S_s}(u_t, v_t) = \max_{u_s, v_s \in S_s} vote_{S_s}((u_s, v_s), (u_t, v_t))$$

The final contribution of each source language dataset  $\mathcal{L}_s$  to a target language edge  $(u_t, v_t)$  is then calculated as the sum for all sentences  $S_s \in \mathcal{L}_s$  over  $vote_{S_s}(u_t, v_t)$  multiplied by the confidence that the source language sentence aligns with the target language sentence. For an edge  $(u_t, v_t)$  in a target language sentence  $S_t \in \mathcal{L}_t$ :

$$vote_{\mathcal{L}_s}(u_t, v_t) = \sum_{S_s \in \mathcal{L}_s} A_s(S_s, S_t) vote_{S_s}(u_t, v_t)$$

Finally, we can compute a target language scoring function by summing over the votes for every source language:

$$score(u_t, v_t) = \frac{\sum_{i=1}^n vote_{\mathcal{L}_i}(u_t, v_t)}{Z_{S_t}}$$

Here,  $Z_{S_t}$  is a normalization constant ensuring that the target-language scores are proportional to those created by the source-language scoring functions. As such,  $Z_{S_t}$  should consist of the sum over the weights for each sentence contributing to the scoring function. We can compute this as:

$$Z_{S_t} = \sum_{i=1}^n \sum_{S_s \in \mathcal{L}_i} A_s(S_s, S_t)$$

The sentence alignment function is not a probability distribution; it may be the case that no source-language sentences contribute to a target language sentence, causing the sum of the weights *and* the sum of the votes to approach zero. In this case, we define  $score(u_t, v_t) = 0$ . Before projection, the source language scores are all standardized to have 0 as the mean and 1 as the standard deviation. Hence, this corresponds to assuming neither positive nor negative evidence concerning the edge.

We experiment with two methods of learning from the projected data – decoding with Chu-Liu-Edmonds algorithm and then training as proposed in Agić et al. (2016), or directly learning to reproduce the matrices of edge scores. For alignment, we use the sentence-level *hunalign* algorithm introduced in Varga et al. (2005) and the token-level model presented in Östling (2015).

## 4 Experiments

We conduct two sets of experiments. First, we evaluate the Tensor-LSTM-parser in the monolingual setting. We compare Tensor-LSTM to the TurboParser (Martins et al., 2010) on several languages from the Universal Dependencies dataset. In the second experiment, we evaluate Tensor-LSTM in the cross-lingual setting. We include as baselines the delexicalized parser of McDonald et al. (2011), and the approach of Agić et al. (2016) using TurboParser. To demonstrate the effectiveness of circumventing the decoding step, we conduct the cross-lingual evaluation of Tensor-LSTM using cross entropy loss with *early* decoding, and using mean squared loss with *late* decoding.

### 4.1 Model selection and training

Our features consist of 500-dimensional word embeddings trained on translations of the Bible. The word embeddings were trained using skipgram with negative sampling on a word-by-sentence PMI matrix induced from the Edinburgh Bible Corpus, following (Levy et al., 2017). Our embeddings are not trainable, but fixed representations throughout the learning process. Unknown tokens were represented by zero-vectors.

We combined the word embeddings with one-hot-encodings of POS-tags, projected across word alignments following the method of Agić et al. (2016). To verify the value of the POS-features, we conducted preliminary experiments on English development data. When including POS-

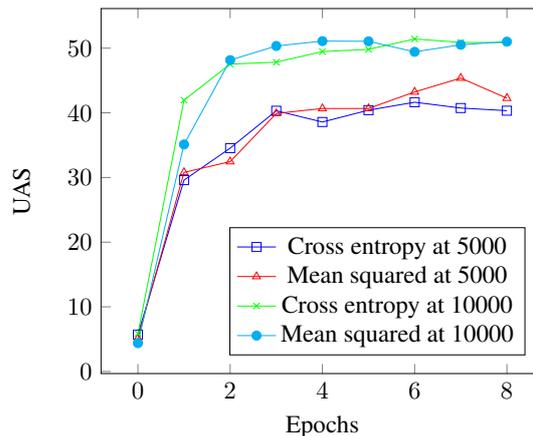

Figure 3: UAS per epoch on German development data training from 5000 or 10000 randomly sampled sentences with projected annotations.

tags, we found small, non-significant improvements for monolingual parsing, but significant improvements for cross-lingual parsing.

The weights were initialized using the normalized values suggested in Glorot and Bengio (2010). Following Jozefowicz et al. (2015), we add 1 to the initial forget gate bias. We trained the network using RMSprop (Tieleman and Hinton, 2012) with hyperparameters  $\alpha = 0.1$  and  $\gamma = 0.9$ , using minibatches of 64 sentences. Following Neelakantan et al. (2015), we added a noise factor  $n \sim \mathcal{N}(0, \frac{1}{(1+t)^{0.55}})$  to the gradient in each update. We applied dropouts after each LSTM-layer with a dropout probability  $p = 0.5$ , and between the input layer and the first LSTM-layer with a dropout probability of  $p = 0.2$  (Bluche et al., 2015). As proposed in Pascanu et al. (2012), we employed a gradient clipping factor of 15. In the monolingual setting, we used early stopping on the development set.

We experimented with 10, 50, 100, and 200 hidden units per layer, and with up to 6 layers. Using greedy search on monolingual parsing and evaluating on the English development data, we determined the optimal network shape to contain 100 units per direction per hidden layer, and a total of 4 layers.

For the cross-lingual setting, we used two additional hyper-parameters. We used the development data from one of our target languages (German) to determine the optimal number of epochs before stopping. Furthermore, we trained only on a subset of the projected sentences, choosing the size of the subset using the development data.

We experimented with either 5000 or 10000 randomly sampled sentences. There are two motivating factors behind this subsampling. First, while the Bible in general consists of about 30000 sentences, for many low-resource languages we do not have access to annotation projections for the full Bible, because parts were never translated, and because of varying projection quality. Second, subsampling speeds up the training, which was necessary to make our experiments practical: At 10000 sentences and on a single GPU, each epoch takes approximately 2.5 hours. As such, training for a single language could be completed in less than a day. We plot the results in Figure 3. We see that the best performance is achieved at 10000 sentences, and with respectively 6 and 5 epochs for cross entropy and mean squared loss.

## 4.2 Results

In the monolingual setting, we compare our parser to TurboParser (Martins et al., 2010) – a fast, capable graph-based parser used as a component in many larger systems. TurboParser is also the system of choice for the cross-lingual pipeline of Agić et al. (2016). It is therefore interesting to make a direct comparison between the two. The results can be seen in Table 1.

Language	TurboParser	Tensor-LSTM
English*	83.84	<b>85.81</b>
German	81.45	<b>82.64</b>
Danish	81.82	<b>82.24</b>
Finnish	77.74	<b>78.83</b>
Spanish	83.19	<b>86.69</b>
French	81.17	<b>84.63</b>
Czech	81.32	<b>85.04</b>
Average	81.50	<b>83.70</b>

Table 1: Unlabeled Attachment Score on the UD test data for TurboParser and Tensor-LSTM with cross entropy loss. English development data was used for model selection (marked \*).

Note that in order for a parser to be directly applicable to the annotation projection setup explored in the secondary experiment, it must be a *first-order graph-based* parser. In the monolingual setting, the best results reported so far (84.74, on average) for the above selection of treebanks were by the Parsito system (Straka et al., 2015), a transition-based parser using a dynamic oracle.

For the cross-lingual annotation projection experiments, we use the delexicalized system suggested by McDonald et al. (2011) as a baseline. We also compare against the annotation projection scheme using TurboParser suggested in Agić et al. (2016), representing the previous state of the art for truly low-resource cross-lingual dependency parsing. Note that while our results for the TurboParser-based system use the same training data, test data, and model as in Agić et al., our results differ due to the use of the Bible corpus rather than a Watchtower publications corpus as parallel data. The authors made results available using the Edinburgh Bible Corpus for unlabeled data. The two tested conditions of Tensor-LSTM are the mean squared loss model *without* intermediary decoding, and the cross entropy model *with* intermediary decoding. The results of the cross-lingual experiment can be seen in Table 2.

## 5 Discussion

As is evident from Table 2, the variation in performance across different languages is large for all systems. This is to be expected, as the quality of the projected label sets vary widely due to linguistic differences. On average, Tensor-LSTM with mean squared loss outperforms all other systems. In Section 1, we hypothesized that incomplete projected scorings would have a larger impact upon systems reliant on an intermediary decoding step. To investigate this claim, we plot in Figure 4 the performance difference with mean squared loss and cross entropy loss for each language versus the percentage of missing edge scores.

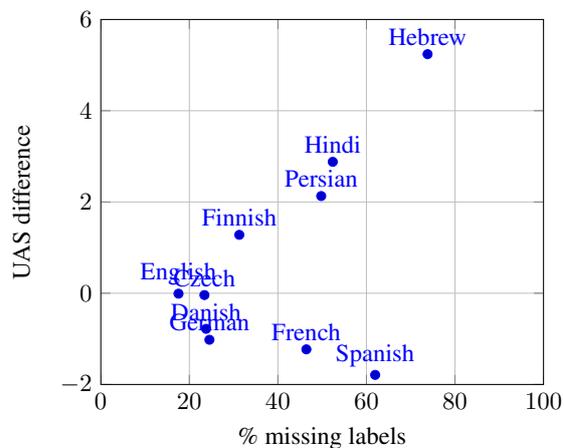

Figure 4: Percentage of missing edge scores versus performance difference for Tensor-LSTM with mean squared loss and cross entropy loss.

Language	Delexicalized	TurboParser	Tensor-LSTM (Decoding)	Tensor-LSTM (No decoding)
Czech (cs)	40.99	<b>43.81</b>	42.58	41.54
Danish (da)	49.65	54.87	<b>54.93</b>	54.15
English* (en)	48.08	52.52	<b>52.91</b>	52.90
Finnish (fi)	41.18	<b>46.08</b>	43.98	45.26
French (fr)	48.97	45.83	<b>55.06</b>	53.83
German* (de)	49.36	51.79	<b>54.87</b>	53.85
Spanish (es)	47.60	58.90	<b>59.60</b>	57.81
Persian (fa)	28.93	14.88	46.47	<b>48.60</b>
Hebrew (he)	19.06	<b>52.89</b>	26.17	31.41
Hindi (hi)	21.03	43.31	43.21	<b>46.09</b>
Average	39.49	46.29	47.98	<b>48.54</b>

Table 2: Unlabeled attachment scores for the various systems. Tensor-LSTM is evaluated using cross entropy and mean squared loss. We include the results of two baselines – the delexicalized system of McDonald et al. (2011) and the Turbo-based projection scheme of Agić et al. (2016). English and German development data was used for hyperparameter tuning (marked \*).

For languages outside the Germanic and Latin families, our claim holds – the performance of the cross entropy loss system decreases faster with the percentage of missing labels than the performance of the mean squared loss system. To an extent, this confirms our hypothesis, as we for the average language observe an improvement by circumventing the decoding step. French and Spanish, however, do not follow the same trend, with cross entropy loss outperforming mean squared loss despite the high number of missing labels.

In Table 2, performance on French and Spanish for both systems can be seen to be very high. It may be the case that Indo-European target languages are not as affected by missing labels as most of the *source* languages are themselves Indo-European. Another explanation could be that some feature of the cross entropy loss function makes it especially well suited for Latin languages – as seen in Table 1, French and Spanish are also two of the languages for which Tensor-LSTM yields the highest performance improvement.

To compare the effect of missing edge scores upon performance without influence from linguistic factors such as language similarity, we repeat the cross-lingual experiment on one language with respectively 10%, 20%, 30%, and 40% of the projected and averaged edge scores artificially set to 0, simulating missing data. We choose the English data for this experiment, as the English projected data has the lowest percentage of missing labels

across any of the languages. In Figure 5, we plot the performance for each of the two systems versus the percentage of deleted values.

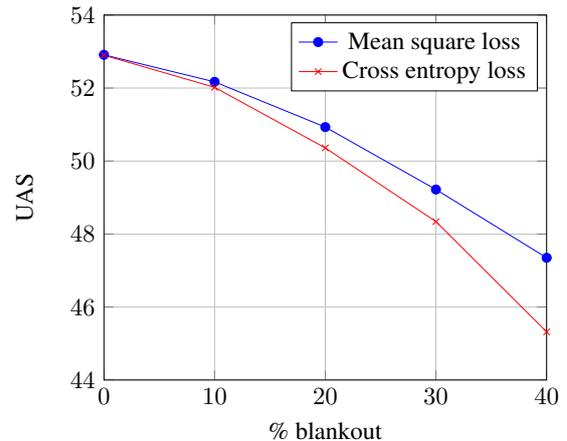

Figure 5: Performance for Tensor-LSTM on English test data with 0-40% of the edge scores artificially maintained at 0.

As can be clearly seen, performance drops faster with the percentage of deleted labels for the cross entropy model. This confirms our intuition that the initially lower performance using mean squared loss compared to cross entropy loss is mitigated by a greater robustness towards missing labels, gained by circumventing the decoding step in the training process. In Table 2, this is reflected as dramatic performance increases using mean squared error for Finnish, Persian, Hindi, and Hebrew – the four languages furthest

removed from the predominantly Indo-European source languages and therefore the four languages with the poorest projected label quality.

Several possible avenues for future work on this project are available. In this paper, we used an extremely simple feature function. More complex feature functions is one potential source of improvement. Another interesting direction for future work would be to include POS-tagging directly as a component of Tensor-LSTM prior to the construction of  $S \boxplus S^*$  in a multi-task learning framework. Similarly, incorporating semantic tasks on top of dependency parsing could lead to interesting results. Finally, extensions of the Tensor-LSTM function to deeper models, wider models, or more connected models as seen in e.g. Kalchbrenner et al. (2015) may yield further performance gains.

## 6 Related Work

Experiments with neural networks for dependency parsing have focused mostly on learning higher-order scoring functions and creating efficient feature representations, with the notable exception of Fonseca et al. (2015). In their paper, a convolutional neural network is used to evaluate local edge scores based on global information. In Zhang and Zhao (2015) and Pei et al. (2015), neural networks are used to simultaneously evaluate first-order and higher-order scores for graph-based parsing, demonstrating good results. Bidirectional LSTM-models have been successfully applied to feature generation (Kiperwasser and Goldberg, 2016). Such LSTM-based features could in future work be employed and trained in conjunction with Tensor-LSTM, incorporating global information both in parsing and in featurization.

An extension of LSTM to tensor-structured data has been explored in Graves et al. (2007), and further improved upon in Kalchbrenner et al. (2015) in the form of GridLSTM. Our approach is similar, but simpler and computationally more efficient as no within-layer connections between the first and the second axes of the tensor are required.

Annotation projection for dependency parsing has been explored in a number of papers, starting with Hwa et al. (2005). In Tiedemann (2014) and Tiedemann (2015) the process is extended and evaluated across many languages. Li et al. (2014) follows the method of Hwa et al. (2005) and adds a probabilistic target-language classifier to deter-

mine and filter out high-uncertainty trees. In Ma and Xia (2014), performance on projected data is used as an additional objective for unsupervised learning through a combined loss function.

A common thread in these papers is the use of high-quality parallel data such as the EuroParl corpus. For truly low-resource target languages, this setting is unrealistic as parallel resources may be restricted to biased data such as the Bible. In Agić et al. (2016) this problem is addressed, and a parser is constructed which utilizes averaging over edge posteriors for many source languages to compensate for low-quality projected data. Our work builds upon their contribution by constructing a more flexible parser which can bypass a source of bias in their projected labels, and we therefore compared our results directly to theirs.

Annotation projection procedures for cross-lingual dependency parsing has been the focus of several other recent papers (Guo et al., 2015; Zhang and Barzilay, 2015; Duong et al., 2015; Rasooli and Collins, 2015). In Guo et al. (2015), distributed, language-independent feature representations are used to train shared parsers. Zhang and Barzilay (2015) introduce a tensor-based feature representation capable of incorporating prior knowledge about feature interactions learned from source languages. In Duong et al. (2015), a neural network parser is built wherein higher-level layers are shared between languages.

Finally, Rasooli and Collins (2015) leverage dense information in high-quality sentence translations to improve performance. Their work can be seen as opposite to ours – whereas Rasooli and Collins leverage high-quality translations to improve performance when such are available, we focus on improving performance in the *absence* of high-quality translations.

## 7 Conclusion

We have introduced a novel algorithm for graph-based dependency parsing based on an extension of sequence-LSTM to the more general Tensor-LSTM. We have shown how the parser with a cross entropy loss function performs comparably to state of the art for monolingual parsing. Furthermore, we have demonstrated that the flexibility of our parser enables learning from non well-formed data and from the output of other parsers. Using this property, we have applied our parser to a cross-lingual annotation projection problem

for truly low-resource languages, demonstrating an average target-language unlabeled attachment score of 48.54, which to the best of our knowledge are the best results yet for the task.

## Abstract

We propose UDP, the first training-free parser for Universal Dependencies (UD). Our algorithm is based on PageRank and a small set of head attachment rules. It features two-step decoding to guarantee that function words are attached as leaf nodes. The parser requires no training, and it is competitive with a delexicalized transfer system. UDP offers a linguistically sound unsupervised alternative to cross-lingual parsing for UD, which can be used as a baseline for such systems. The parser has very few parameters and is distinctly robust to domain change across languages.

## 1 Introduction

Grammar induction and unsupervised dependency parsing are active fields of research in natural language processing (Klein and Manning, 2004; Gelling et al., 2012). However, many data-driven approaches struggle with learning relations that match the conventions of the test data, e.g., Klein and Manning reported the tendency of their DMV parser to make determiners the heads of German nouns, which would not be an error if the test data used a DP analysis (Abney, 1987). Even supervised transfer approaches (McDonald et al., 2011) suffer from target adaptation problems when facing word order differences.

The Universal Dependencies (UD) project (Nivre et al., 2015; Nivre et al., 2016) offers a dependency formalism that aims at providing a consistent representation across languages, while enforcing a few hard constraints. The arrival of such treebanks, expanded and improved on a regular basis, provides a new milestone for cross-lingual dependency parsing research (McDonald et al., 2013).

Furthermore, given that UD rests on a series of simple principles like the primacy of lexical heads, cf. Johannsen et al. (2015) for more details, we expect that such a formalism lends itself more naturally to a simple and linguistically sound rule-based approach to cross-lingual parsing. In this paper we present such an approach.

Our system is a dependency parser that requires no training, and relies solely on explicit part-of-speech (POS) constraints that UD imposes. In particular, UD prescribes that trees are single-rooted, and that function words like adpositions, auxiliaries, and determiners are always dependents of content words, while other formalisms might treat them as heads (De Marneffe et al., 2014). We ascribe our work to the viewpoints of Bender (2009) about the incorporation of linguistic knowledge in language-independent systems.

**Contributions** We introduce, to the best of our knowledge, the first unsupervised rule-based dependency parser for Universal Dependencies.

Our method goes substantially beyond the existing work on *rule-aided* unsupervised dependency parsing, specifically by:

- i) adapting the dependency head rules to UD-compliant POS relations,
- ii) incorporating the UD restriction of function words being leaves,
- iii) applying personalized PageRank to improve main predicate identification, and by
- iv) making the parsing entirely free of language-specific parameters by estimating adposition attachment direction at runtime.

We evaluate our system on 32 languages<sup>1</sup> in three setups, depending on the reliability of available POS tags, and compare to a multi-source delexi-

<sup>1</sup>Out of 33 languages in UD v1.2. We exclude Japanese because the treebank is distributed without word forms and hence we can not provide results on predicted POS.

calized transfer system. In addition, we evaluate the systems’ sensitivity to domain change for a subset of UD languages for which domain information was retrievable. The results expose a solid and competitive system for all UD languages. Our unsupervised parser compares favorably to delexicalized parsing, while being more robust to domain change.

## 2 Related work

**Cross-lingual learning** Recent years have seen exciting developments in cross-lingual linguistic structure prediction based on transfer or projection of POS and dependencies (Das and Petrov, 2011; McDonald et al., 2011). These works mainly use supervised learning and domain adaptation techniques for the target language.

The first group of approaches deals with annotation projection (Yarowsky et al., 2001), whereby parallel corpora are used to transfer annotations between resource-rich source languages and low-resource target languages. Projection relies on the availability and quality of parallel corpora, source-side taggers and parsers, but also tokenizers, sentence aligners, and word aligners for sources and targets. Hwa et al. (2005) were the first to project syntactic dependencies, and Tiedemann et al. (2014; 2016) improved on their projection algorithm. Current state of the art in cross-lingual dependency parsing involves leveraging parallel corpora for annotation projection (Ma and Xia, 2014; Rasooli and Collins, 2015).

The second group of approaches deals with transferring source parsing models to target languages. Zeman and Resnik (2008) were the first to introduce the idea of delexicalization: removing lexical features by training and cross-lingually applying parsers solely on POS sequences. Sjøgaard (2011) and McDonald et al. (2011) independently extended the approach by using multiple sources, requiring uniform POS and dependency representations (McDonald et al., 2013).

Both model transfer and annotation projection rely on a large number of presumptions to derive their competitive parsing models. By and large, these presumptions are unrealistic and exclusive to a group of very closely related, resource-rich Indo-European languages. Agić et al. (2015; 2016) exposed some of these biases in their proposal for realistic cross-lingual tagging and parsing, as they emphasized the lack of perfect sentence- and

word-splitting for truly low-resource languages. Further, Johannsen et al. (2016) introduced joint projection of POS and dependencies from multiple sources while sharing the outlook on bias removal in real-world multilingual processing.

**Rule-based parsing** Cross-lingual methods, realistic or not, depend entirely on the availability of data: for the sources, for the targets, or most often for both sets of languages. Moreover, they typically do not exploit constraints placed on linguistic structures through a formalism, and they do so *by design*.

With the emergence of UD as the practical standard for multilingual POS and syntactic dependency annotation, we argue for an approach that takes a fresh angle on both aspects. Specifically, we propose a parser that i) requires *no* training data, and in contrast ii) critically *relies* on exploiting the UD constraints.

These two characteristics make our parser unsupervised. Data-driven unsupervised dependency parsing is now a well-established discipline (Klein and Manning, 2004; Spitzkovsky et al., 2010a; Spitzkovsky et al., 2010b). Still, the performance of these parsers falls far behind the approaches involving any sort of supervision.

Our work builds on the line of research on rule-aided unsupervised dependency parsing by Gillenwater et al. (2010) and Naseem et al. (2010), and also relates to Sjøgaard’s (2012a; 2012b) work. Our parser, however, features two key differences:

- i) the usage of PageRank personalization (Lofgren, 2015), and of
- ii) two-step decoding to treat content and function words differently according to the UD formalism.

Through these differences, even without any training data, we parse nearly as well as a delexicalized transfer parser, and with increased stability to domain change.

## 3 Method

Our approach does not use any training or unlabeled data. We have used the English treebank during development to assess the contribution of individual head rules, and to tune PageRank parameters (Sec. 3.1) and function-word directionality (Sec. 3.2). Adposition direction is calculated on the fly at runtime. We refer henceforth to our UD parser as UDP.

### 3.1 PageRank setup

Our system uses the PageRank (PR) algorithm (Page et al., 1999) to estimate the relevance of the content words of a sentence. PR uses a random walk to estimate which nodes in the graph are more likely to be visited often, and thus, it gives higher rank to nodes with more incoming edges, as well as to nodes connected to those. Using PR to score word relevance requires an effective graph-building strategy. We have experimented with the strategies by Søgaard (2012b), such as words being connected to adjacent words, but our system fares best strictly using the dependency rules in Table 1 to build the graph. UD trees are often very flat, and a highly connected graph yields a PR distribution that is closer to uniform, thereby removing some of the difference of word relevance.

We build a multigraph of all words in the sentence covered by the head-dependent rules in Table 1, giving each word an incoming edge for each eligible dependent, i.e., ADV depends on ADJ and VERB. This strategy does not always yield connected graphs, and we use a teleport probability of 0.05 to ensure PR convergence.

*Teleport probability* is the probability that, in any iteration of the PR calculation, the next active node is randomly chosen, instead of being one of the adjacent nodes of the current active node. See Brin and Page (1998) for more details on teleport probability, where the authors refer to one minus teleport probability as *damping factor*.

We chose this value incrementally in intervals of 0.01 during development until we found the smallest value that guaranteed PR convergence. A high teleport probability is undesirable, because the resulting stationary distribution can be almost uniform. We did not have to re-adjust this value when running on the actual test data.

The main idea behind our personalized PR approach is the observation that ranking is only relevant for content words.<sup>2</sup> PR can incorporate a priori knowledge of the relevance of nodes by means of *personalization*, namely giving more weight to certain nodes.

Intuitively, the higher the rank of a word, the closer it should be to the root node, i.e., the main predicate of the sentence is the node that should have the highest PR, making it the dependent of the root node (Fig. 1, lines 4-5). We use PR personalization to give 5 times more weight (over an

otherwise uniform distribution) to the node that is estimated to be main predicate, i.e., the first verb or the first content word if there are no verbs.

### 3.2 Head direction

Head direction is an important trait in dependency syntax (Tesnière, 1959). Indeed, the UD feature inventory contains a trait to distinguish the general adposition tag ADP in pre- and post-positions.

Instead of relying on this feature from the treebanks, which is not always provided, we estimate the frequency of ADP-NOMINAL vs. NOMINAL-ADP bigrams.<sup>3</sup> We calculate this estimation directly on input data at runtime to keep the system training-free. Moreover, it requires very few examples to converge (10-15 sentences). If a language has more ADP-NOMINAL bigrams, we consider all its ADP to be prepositions (and thus dependent of elements at their right). Otherwise, we consider them postpositions.

For other function words, we have determined on the English dev data whether to make them strictly right- or left-attaching, or to allow either direction. There, AUX, DET, and SCONJ are right-attaching, while CONJ and PUNCT are left-attaching. There are no direction constraints for the rest. Punctuation is a common source of parsing errors that has very little interest in this setup. While we do evaluate on all tokens including punctuation, we also apply a heuristic for the last token in a sentence; if it is a punctuation, we make it a dependent of the main predicate.

<sup>2</sup>ADJ, NOUN, PROPN, and VERB mark content words.

<sup>3</sup>NOMINAL = {NOUN, PROPN, PRON}

ADJ	→	ADV
NOUN	→	ADJ, NOUN, PROPN
NOUN	→	ADP, DET, NUM
PROPN	→	ADJ, NOUN, PROPN
PROPN	→	ADP, DET, NUM
VERB	→	ADV, AUX, NOUN
VERB	→	PROPN, PRON, SCONJ

Table 1: UD dependency rules.

### 3.3 Decoding

Fig. 1 shows the tree-decoding algorithm. It has two blocks, namely a first block (3-11) where we assign the head of content words according to their PageRank and the constraints of the dependency rules, and a second block (12-15) where we assign the head of function words according to their proximity, direction of attachment, and dependency rules. The algorithm requires:

1. The PR-sorted list of content words  $C$ .
2. The set of function words  $F$ , sorting is irrelevant because function-head assignments are inter-independent.
3. A set  $H$  for the current possible heads, and a set  $D$  for the dependencies assigned at each iteration, which we represent as head-dependent tuples  $(h, d)$ .
4. A symbol  $root$  for the root node.
5. A function  $\gamma(n, m)$  that gives the linear distance between two nodes.
6. A function  $\kappa(h, d)$  that returns whether the dependency  $(h, d)$  has a valid attachment direction given the POS of the  $d$  (cf. Sec. 3.2).
7. A function  $\delta(h, d)$  that determines whether  $(h, d)$  is licensed by the rules in Table 1.

The head assignments in lines 7 and 13 read as follow: the head  $h$  of a word (either  $c$  or  $f$ ) is the closest element of the current list of heads ( $H$ ) that has the right direction ( $\kappa$ ) and respects the POS-dependency rules ( $\delta$ ). These assignments have a back-off option to ensure the final  $D$  is a tree. If the conditions determined by  $\kappa$  and  $\delta$  are too strict, i.e., if the set of possible heads is empty, we drop the  $\delta$  head-rule constraint and recalculate the closest possible head that respects the directionality imposed by  $\kappa$ . If the set is empty again, we drop both constraints and assign the closest head.

Lines 4 and 5 enforce the single-root constraint. To enforce the leaf status of function nodes, the algorithm first attaches all content words ( $C$ ), and

then all function words ( $F$ ) in the second block where  $H$  is not updated, thereby ensuring leafness for all  $f \in F$ . The order of head attachment is not monotonic wrt. PR between the first and second block, and can yield non-projectivities. Nevertheless, it still is a one-pass algorithm. Decoding runs in less than  $O(n^2)$ , namely  $O(n \times |C|)$ . However, running PR incurs the main computation cost.

## 4 Parser run example

This section exemplifies a full run of UDP for the example sentence from the English test data: “They also had a special connection to some extremists”.

### 4.1 PageRank

Given an input sentence and its POS tags, we obtain rank of each word by building a graph using head rules and running PR on it. Table 2 provides the sentence, the POS of each word, the number of incoming edges for each word after building the graph with the head rules from Sec. 3.1, and the personalization vector for PR on this sentence. Note that all nodes have the same personalization weight, except the estimated main predicate, the verb “had”.

Word:	They	also	had	a	special	connection	to	some	extremists
POS:	PRON	ADV	VERB	DET	ADJ	NOUN	ADP	DET	NOUN
Personalization:	1	1	5	1	1	1	1	1	1
Incoming edges:	0	0	4	0	1	5	0	0	5

Table 2: Words, POS, personalization, and incoming edges for the example sentence.

Table 4 shows the directed multigraph used for PR in detail. We can see, e.g., that the four incoming edges for the verb “had” from the two nouns, plus from the adverb “also” and the pronoun “They”.

After running PR, we obtain the following ranking for content words:

$$C = \langle \text{had}, \text{connection}, \text{extremists}, \text{special} \rangle$$

Even though the verb has four incoming edges and the nouns have five each, the personalization makes the verb the highest-ranked word.

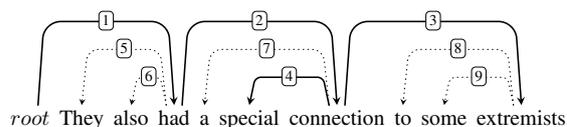

Figure 2: Example dependency tree predicted by the algorithm.

## 4.2 Decoding

Once  $C$  is calculated, we can follow the algorithm in Fig. 1 to obtain a dependency parse. Table 3 shows a trace of the algorithm, with  $C = \langle \text{had,connection,extremists,special} \rangle$  and  $F = \{\text{They,also,a,to,some}\}$ .

$it$	$word$	$h$	$H$
1	had	root	$\emptyset$
2	connection	had	$\{\text{had}\}$
3	extremists	had	$\{\text{had,connection}\}$
4	special	connection	$\{\text{had,connection,extremists}\}$
5	They	had	$\{\text{had,connection,extremists,special}\}$
6	also	had	...
7	a	connection	...
8	to	extremists	...
9	some	extremists	...

Table 3: Algorithm trace for example sentence.  $it$ : iteration number,  $word$ : current word,  $H$ : set of possible heads.

The first four iterations calculate the head of content words following their PR, and the following iterations attach the function words in  $F$ . Finally, Fig. 2 shows the resulting dependency tree. Full lines are assigned in the first block (content dependents), dotted lines are assigned in the second block (function dependents). The edge labels indicate in which iteration the algorithm has assigned each dependency. Note that the algorithm is deterministic for a certain input POS sequence. Any 10-token sentence with the POS labels shown in Table 2 would yield the same dependency tree.<sup>4</sup>

## 5 Experiments

This section describes the data, metrics and comparison systems used to assess the performance of UDP. We evaluate on the test sections of the UD1.2 treebanks (Nivre et al., 2015) that contain word forms. If there is more than one treebank per language, we use the treebank that has the

<sup>4</sup>The resulting trees always pass the validation script in [github.com/UniversalDependencies/tools](https://github.com/UniversalDependencies/tools).

Table 4: Matrix representation of the directed graph for the words in the sentence.

canonical language name (e.g., *Finnish* instead of *Finnish-FTB*). We use standard unlabeled attachment score (UAS) and evaluate on all sentences of the canonical UD test sets.

## 5.1 Baseline

We compare our UDP system with the performance of a rule-based baseline that uses the head rules in Table 5. The baseline identifies the first verb (or first content word if there are no verbs) as the main predicate, and assigns heads to all words according to the rules in Table 1. We have selected the set of head rules to maximize precision on the development set, and they do not provide full coverage. The system makes any word not covered by the rules (e.g., a word with a POS such as X or SYM) either dependent of their left or right neighbor, according to the estimated runtime parameter.

We report the best head direction and its score for each language in Table 5. This baseline finds the head of each token based on its closest possible head, or on its immediate left or right neighbor if there is no head rule for the POS at hand, which means that this system does not necessarily yield well-formed trees. Each token receives a head, and while the structures are single-rooted, they are not necessarily connected. Note that we do not include results for the DMV model by Klein and Manning (2004), as it has been outperformed by a system similar to ours (Søgaard, 2012b). The usual adjacency baseline for unsupervised dependency parsing, where all words depend on their left or right neighbor, fares much worse than our baseline (20% UAS below on average) even with an oracle pick for the best per-language direction, and we do not report those scores.

## 5.2 Evaluation setup

Our system relies solely on POS tags. To estimate the quality degradation of our system under non-gold POS scenarios, we evaluate UDP on two alternative scenarios. The first is predicted POS (UDP<sub>P</sub>), where we tag the respective test set with TnT (Brants, 2000) trained on each language’s training set. The second is a naive type-constrained two-POS tag scenario (UDP<sub>N</sub>), and approximates a lower bound. We give each word either CONTENT or FUNCTION tag, depending on the word’s frequency. The 100 most frequent words of the input test section receive the FUNCTION tag.

Finally, we compare our parser UDP to a supervised cross-lingual system (MSD). It is a multi-source delexicalized transfer parser, referred to as *multi-dir* in the original paper by McDonald et al. (2011). For this baseline we train TurboParser (Martins et al., 2013) on a delexicalized training set of 20k sentences, sampled uniformly from the UD training data excluding the target language. MSD is a competitive and realistic baseline in cross-lingual transfer parsing work. This gives us an indication how our system compares to standard cross-lingual parsers.

### 5.3 Results

Table 5 shows that UDP is a competitive system; because  $UDP_G$  is remarkably close to the supervised  $MSD_G$  system, with an average difference of 6.4%. Notably, UDP even outperforms MSD on one language (Hindi).

More interestingly, on the evaluation scenario with predicted POS we observe that our system drops only marginally (2.2%) compared to MSD (2.7%). In the least robust rule-based setup, the error propagation rate from POS to dependency would be doubled, as either a wrongly tagged head or dependent would break the dependency rules. However, with an average POS accuracy by TnT of 94.1%, the error propagation is 0.37, i.e., each POS error causes 0.37 additional dependency errors. In contrast, for MSD this error propagation is 0.46, thus higher.<sup>5</sup>

For the extreme POS scenario, content vs. function POS (CF), the drop in performance for UDP is very large, but this might be too crude an evaluation setup. Nevertheless, UDP, the simple unsupervised system with PageRank, outperforms the adjacency baselines (BL) by  $\sim 4\%$  on average on the two type-based naive POS tag scenario. This difference indicates that even with very deficient POS tags, UDP can provide better structures.

## 6 Discussion

In this section we provide a further error analysis of the UDP parser. We examine the contribution to the overall results of using PageRank to score content words, the behavior of the system across different parts of speech, and we assess the robustness of UDP on text from different domains.

<sup>5</sup>Err. prop. =  $(E(Parse_P) - E(Parse_G)) / E(POS_P)$ , where  $E(x) = 1 - Accuracy(x)$ .

Table 5: UAS for baseline with gold POS (BL<sub>G</sub>) with direction (L/R) for backoff attachments, UDP with gold POS (UDP<sub>G</sub>) and predicted POS (UDP<sub>P</sub>), PR with naive content-function POS (UDP<sub>N</sub>), and multi-source delexicalized with gold and predicted POS (MSD<sub>G</sub> and MSD<sub>P</sub>, respectively). BL values higher than UDP<sub>G</sub> are underlined, and UDP<sub>G</sub> values higher than MSD<sub>G</sub> are in boldface.

### 6.1 PageRank contribution

UDP depends on PageRank to score content words, and on two-step decoding to ensure the leaf status of function words. In this section we isolate the contribution of both parts. We do so by comparing the performance of BL, UDP, and UDP<sub>NoPR</sub>, a version of UDP where we disable PR and rank content words according to their reading order, i.e., the first word in the ranking is the first word to be read, regardless of the specific language’s script direction. The baseline BL described in 5.1 already ensures function words are leaf nodes, because they have no listed dependent POS in the head rules. The task of the decoding steps is mainly to ensure the resulting structures are well-formed dependency trees.

If we measure the difference between  $UDP_{NoPR}$  and BL, we see that  $UDP_{NoPR}$  contributes with 4 UAS points on average over the baseline. Nevertheless, the baseline is oracle-informed about the language’s best branching direction, a property that UDP does not have. Instead, the decoding step determines head direction as described in Section 3.2. Complementarily, we can measure the contribution of PR by observing the difference between regular UDP and  $UDP_{NoPR}$ . The latter scores on average 9 UAS points lower than UDP. These 9 points are caused by the difference attachment of content words in the first decoding step.

## 6.2 Breakdown by POS

UD is a constantly improving effort, and not all v1.2 treebanks have the same level of formalism compliance. Thus, the interpretation of, e.g., the AUX-VERB or DET-PRON distinctions might differ across treebanks. However, we ignore these differences in our analysis and consider all treebanks to be equally compliant.

The root accuracy scores oscillate around an average of 69%, with Arabic and Tamil (26%) and Estonian (93%) as outliers. Given the PR personalization (Sec. 3.1), UDP has a strong bias for choosing the first verb as main predicate. Without personalization, performance drops 2% on average. This difference is consistent even for verb-final languages like Hindi, given that the main verb of a simple clause will be its only verb, regardless of where it appears. Moreover, using PR personalization makes the ranking calculations converge a whole order of magnitude faster.

The bigram heuristic to determine adposition direction succeeds at identifying the predominant pre- or postposition preference for all languages (average ADP UAS of 75%). The fixed direction for the other functional POS is largely effective, with few exceptions, e.g., DET is consistently right-attaching on all treebanks except Basque (average overall DET UAS of 84%, 32% for Basque). These alternations could also be estimated from the data in a manner similar to ADP. Our rules do not make nouns eligible heads for verbs. As a result, the system cannot infer relative clauses. We have excluded the NOUN  $\rightarrow$  VERB rule during development because it makes the hierarchy between verbs and nouns less conclusive.

We have not excluded punctuation from the evaluation. Indeed, the UAS for the PUNCT is low

(an average of 21%, standard deviation of 9.6), even lower than the otherwise problematic CONJ. Even though conjunctions are pervasive and identifying their scope is one of the usual challenges for parsers, the average UAS for CONJ is much larger (an average of 38%, standard deviation of 13.5) than for PUNCT. Both POS show large standard deviations, which indicates great variability. This variability can be caused by linguistic properties of the languages or evaluation datasets, but also by differences in annotation convention.

## 6.3 Cross-domain consistency

Models with fewer parameters are less likely to overfit for a certain dataset. In our case, a system with few, general rules is less likely to make attachment decisions that are very particular of a certain language or dataset. Plank and van Noord (2010) have shown that rule-based parsers can be more stable to domain shift. We explore if their finding holds for UDP as well, by testing on i) the UD development data as a readily available proxy for domain shift, and ii) manually curated domain splits of select UD test sets.

Table 6: Evaluation across domains. UAS for baseline with gold POS ( $BL_G$ ), UDP with gold POS ( $UDP_G$ ) and predicted POS ( $UDP_P$ ), and multi-source delexicalized with gold and predicted POS ( $MSD_G$  and  $MSD_P$ ). English datasets marked with † are in-house annotated. Lowest results per language underlined. Bold: UDP outperforms MSD.

**Development sets** We have used the English development data to choose which relations would be included as head rules in the final system (Table 1). It would be possible that some of the rules are indeed more befitting for the English data or for that particular section.

However, if we regard the results for  $UDP_G$  in Table 5, we can see that there are 24 languages (out of 32) for which the parser performs better than for English. This result indicates that the head rules are general enough to provide reasonable parses for languages other than the one chosen for development. If we run  $UDP_G$  on the development sections for the other languages, we find the results are very consistent. Any language scores on average  $\pm 1$  UAS with regards to the test section. There is no clear tendency for either section being easier to parse with UDP.

**Cross-domain test sets** To further assess the cross-domain robustness, we retrieved the domain (genre) splits from the test sections of the UD treebanks where the domain information is available as sentence metadata: from Bulgarian, Croatian, and Italian. We also include a UD-compliant Serbian dataset which is not included in the UD release but which is based on the same parallel corpus as Croatian and has the same domain splits (Agić and Ljubešić, 2015). When averaging we pool Croatian and Serbian together as they come from the same dataset.

For English, we have obtained the test data splits matching the sentences from the original distribution of the English Web Treebank. In addition to these already available datasets, we have annotated three different datasets to assess domain variation more extensively, namely the first 50 verses of the King James Bible, 50 sentences from a magazine, and 75 sentences from the test split in QuestionBank (Judge et al., 2006). We include the third dataset to evaluate strictly on questions, which we could do already in Italian. While the `answers` domain in English is made up of text from the Yahoo! Answers forum, only one fourth of the sentences are questions. Note these three small datasets are not included in the results on the canonical test sections in Table 5.

Table 7 summarizes the per-language average score and standard deviation, as well as the macro-averaged standard deviation across languages. UDP has a much lower standard deviation across domains compared to MSD. This holds across lan-

Language	$BL_G$	$MSD_G$	$UDP_G$	$MSD_P$	$UDP_P$
Bulgarian	50.1 $\pm$ 2.4	73.5 $\pm$ 3.5	69.7 $\pm$ 1.8	71.3 $\pm$ 3.3	66.9 $\pm$ 3.2
Croatian+Serbian	42.1 $\pm$ 0.7	66.0 $\pm$ 3.0	57.8 $\pm$ 1.4	62.1 $\pm$ 3.0	54.4 $\pm$ 2.0

<i>Average Std.</i>	1.8	4.5	2.5	4.2	3.1

Table 7: Average language-wise domain evaluation. We report average UAS and standard deviation per language. The bottom row provides the average standard deviation for each system.

guages. We attribute this higher stability to UDP being developed to satisfy a set of general properties of the UD syntactic formalism, instead of being a data-driven method more sensitive to sampling bias. This holds for both the gold-POS and predicted-POS setup. The differences in standard deviation are unsurprisingly smaller in the predicted POS setup. In general, the rule-based UDP is less sensitive to domain shifts than the data-driven MSD counterpart, confirming earlier findings (Plank and van Noord, 2010).

Table 6 gives the detailed scores per language and domain. From the scores we can see that `presidential bulletin`, `legal` and `weblogs` are amongst the hardest domains to parse. However, the systems often do not agree on which domain is hardest, with the exception of `Bulgarian bulletin`. Interestingly, for the Italian data and some of the hardest domains UDP outperforms MSD, confirming that it is a robust baseline.

## 6.4 Comparison to full supervision

In order to assess how much information the simple principles in UDP provide, we measure how many gold-annotated sentences are necessary to reach its performance, that is, after which size the treebank provides enough information for training that goes beyond the simple linguistic principles outlined in Section 3.

For this comparison we use a first-order non-projective TurboParser (Martins et al., 2013) following the setup of Agić et al. (2016). The supervised parsers require around 100 sentences to reach UDP-comparable performance, namely a mean of 300 sentences and a median of 100 sentences, with Bulgarian (3k), Czech (1k), and German (1.5k) as outliers. The difference between mean and median shows there is great variance, while UDP provides very constant results, also in terms of POS and domain variation.

## 7 Conclusion

We have presented UDP, an unsupervised dependency parser for Universal Dependencies (UD) that makes use of personalized PageRank and a small set of head-dependent rules. The parser requires no training data and estimates adposition direction directly from the input.

We achieve competitive performance on all but two UD languages, and even beat a multi-source delexicalized parser (MSD) on Hindi. We evaluated the parser on three POS setups and across domains. Our results show that UDP is less affected by deteriorating POS tags than MSD, and is more resilient to domain changes. Given how much of the overall dependency structure can be explained by this fairly system, we propose UDP as an additional UD parsing baseline. The parser, the in-house annotated test sets, and the domain data splits are made freely available.<sup>6</sup>

UD is a running project, and the guidelines are bound to evolve overtime. Indeed, the UD 2.0 guidelines have been recently released. UDP can be augmented with edge labeling for some deterministic labels like `case` or `det`. Some further constraints can be incorporated in UDP. Moreover, the parser makes no special treatment of multiword expression that would require a lexicon, coordinations or proper names. All these three kinds of structures have a flat tree where all words depend on the leftmost one. While coordination attachment is a classical problem in parsing and out of the scope of our work, a proper name sequence can be straightforwardly identified from the part-of-speech tags, and it falls thus in the area of structures predictable using simple heuristics. Moreover, our use of PageRank could be expanded to directly score the potential dependency edges instead of words, e.g., by means of edge reification.

## Abstract

This paper presents a new approach to the problem of cross-lingual dependency parsing, aiming at leveraging training data from different source languages to learn a parser in a target language. Specifically, this approach first constructs word vector representations that exploit structural (i.e., dependency-based) contexts but only considering the morpho-syntactic information associated with each word and its contexts. These delexicalized word embeddings, which can be trained on any set of languages and capture features shared across languages, are then used in combination with standard language-specific features to train a lexicalized parser in the target language. We evaluate our approach through experiments on a set of eight different languages that are part the Universal Dependencies Project. Our main results show that using such delexicalized embeddings, either trained in a monolingual or multilingual fashion, achieves significant improvements over monolingual baselines.

## 1 Introduction

Over the recent years, distributional and distributed representations of words have become a critical component of many NLP systems (Turian et al., 2010; Collobert et al., 2011). The reason for this success is that these low-dimensional, dense word vectors address two major problems that appear in many NLP applications, namely data sparsity and the inherent lack of expressivity of one-hot representations, and they can also be trained on large unannotated corpora which are cheap to produce and easily available. While they have proven

useful in a number of tasks, and especially in dependency parsing (Koo et al., 2008), these word vectors are often learned in a generic manner, only using linear bag-of-word contexts (F. Brown et al., 1992; Mikolov et al., 2013), without paying much attention to the specifics of the task to be solved. Only very recently, people have tried to learn dependency-based embeddings (Bansal et al., 2014; Levy and Goldberg, 2014; Madhyastha et al., 2014; Bansal, 2015), and these new structure-aware representations have been shown to improve parsing performance in a monolingual setting.

We would like to generalize this idea to a multilingual setting in a way that allows the transfer of structural information associated with words from one (or several) languages to others. While previous work have attempted to learn multilingual word clusters or embeddings (Guo et al., 2015) and use these for cross-lingual transfer, this paper explores a different research direction. Specifically, we investigate the use of vectorial representations in which lemma information have been abstracted away from both words and contexts, hence reduced to their morpho-syntactic attributes. The appeal of these de facto *delexicalized* word representations is that they further increase the coverage over the available training data, potentially allowing for better generalization. Furthermore, while words tend to be hard to align in a cross-lingual setting due to homonymy and polysemy, morpho-syntactic information tends to be much more robust to language barrier (depending on typological closeness), which make them particularly relevant for cross-lingual transfer. In contrast with delexicalized parsing approaches (McDonald et al., 2011), the proposed method uses delexicalization during word embedding learning, not during parsing. Once induced over different source language datasets, these language-shared

representations are used as additional features, in combination with standard language-specific features, in a standard lexicalized monolingual graph-based dependency parser for the target language. As far as we know, this is the first attempt at constructing delexicalized word embeddings for cross-lingual dependency parsing.

Through the use of these delexicalized word embeddings, we wish to explore two main hypotheses. First and foremost, we want to assess to what extent a parser for a particular language can benefit from using morpho-syntactic regularities extracted from other languages. By comparing the performance of embeddings learned on different sets of source languages in parsing a specific target language, we also hope to assess whether and which typological similarities impact the learning of “good” embeddings. The second hypothesis looks at the choice of context types (sequential vs structural) used for learning these embeddings. That is, we wish to see if the use of syntactic structure delivers better parsing improvements, again in relation to typological similarities or differences. These hypotheses will be tested on treebanks from the recent Universal Dependencies Project (Nivre et al., 2016), which provides us with homogeneous syntactic dependency annotations in many languages.

In section 2, we provide some background and review previous work on graph-based dependency parsing for mono- and cross-lingual settings and on word embeddings. Section 3 details our approach for learning delexicalized word embeddings and using them in dependency parsing. In section 4, we present some experimental results that show the importance of grammatical embeddings for the task at hand. And finally in section 5, we draw some conclusions and present future perspectives.

## 2 Preliminaries and Related Work

The approach proposed in this paper draws on three different lines of work in dependency parsing.

### 2.1 Graph-based Dependency Parsing

A dependency tree is a graphical representation of the syntactic structure of a sentence. The task of dependency parsing is to predict the dependency tree of a given sentence  $x$ ,  $\mathcal{T}_x$  being the set of all its possible trees. Assuming we have access to a

scoring function  $Score(\bullet, \bullet)$  that tells how well a dependency tree fits the syntactic structure of a sentence, the goal of dependency parsing is to find the tree  $\hat{y}$  such that:

$$\hat{y} = \operatorname{argmax}_{t \in \mathcal{T}_x} Score(x, t).$$

The size of  $\mathcal{T}_x$  grows exponentially with the length of  $x$ ,  $|\mathcal{T}_x| = |x|^{|x|-2}$ , making an exhaustive search for the best tree impractical in most cases. Thus in practice, some simplifying assumptions are made. Here we use the graph-based, edge-factored approach based on the assumption that the score of a tree can be computed as the sum of its edges scores (McDonald et al., 2005a). Let  $score(\bullet, \bullet)$  be a scoring function for edges.

$$Score(x, t) = \sum_{e \in t} score(x, e).$$

In this case, finding the best parse tree for  $x$  boils down to finding the maximum spanning tree in the complete graph whose vertices are the words of  $x$ . The score of an edge  $e$  is here defined as the dot product between a model  $w$  (a weight vector) and the feature vector  $\phi(x, e)$  of this edge.

$$score(x, e) = w \cdot \phi(x, e).$$

In this paper, we learn the model  $w$  in an online manner with the Passive-Aggressive (PA) algorithm described in (Crammer et al., 2006). Specifically, we use the PA-II that uses a squared hinge loss in its predicted-loss cost-sensitive version, in which the cost is computed in terms of the symmetric difference on the edges with respect to the target tree.

### 2.2 Word Vectors for Dependency Parsing

Distributional and distributed word representations are dense vectorial representations of words that live in a multi-dimensional integer or real space whose size is much smaller than the size of the original language vocabulary. There are now a large variety of spectral and neural approaches for learning these representations, including several variants of Principal Component Analysis (Jolliffe, 2002) and several deep neural net approaches. Most of these approaches have in common that they solely exploit linear, bag-of-word co-occurrence between words to derive these low-dimensional representations (Mikolov et al., 2013; Lebrecht and Collobert, 2014).

Starting with the work of Koo (2008), the inclusion of this type of low-dimensional word representations as features has been shown to be a

simple yet very effective way of improving dependency parsing performance. The main appeal of these low-dimensional dense representations is that they mitigate major shortcomings of standard one-hot encoding representations which are very sparse and live in very high dimensional spaces, thus lacking in expressivity and hindering generalization. While it is still unclear whether pre-trained embeddings (Andreas and Klein, 2014) indeed capture interesting syntactic information, more recent work have concentrated on learning dependency-based word embeddings (Bansal et al., 2014; Levy and Goldberg, 2014; Madhyastha et al., 2014; Bansal, 2015). In these approaches, word co-occurrences are defined in terms of dependency contexts ( $x$  is the governor of word  $w$ ), instead of linear contexts ( $x$  appears within a range of  $s$  around word  $w$ ). Embedding techniques have also started to be applied to objects other than words, namely on dependency relations (Bansal, 2015; Kiperwasser and Goldberg, 2015).

In this paper, we depart from these approaches by learning a low-dimensional word vector representation that is based only on the morpho-syntactic information associated with that word, and learning is performed with simple PCA. Furthermore, we do not use any auto-parsed data in order to avoid errors from spreading into the embedding. Another point is that even if we use a first order parsing model, we use higher-order contexts for learning the embeddings. Bansal (2015) also uses higher-order contexts but combines them with a second-order dependency model.

### 2.3 Cross-lingual Dependency Parsing

Cross-lingual dependency parsing encompasses several problems ranging from learning a parser for a target language relying solely on annotated data from a source language (Lynn et al., 2014) to learning a unique parser that can handle various languages (Ammar et al., 2016). Delexicalized parsers (McDonald et al., 2011) have been used to avoid the problems that arise from lexical translation. More recently, cross-lingual parsers have been trained using cross-lingual word clusters as well as multilingual word embeddings (Guo et al., 2015) to alleviate the lack of lexical information.

Our work differs from previous studies in that it assumes the availability of annotated data from the target language for training the parser, but uses multilingual embeddings to benefit from annotated

data in other languages. Another important difference is that while multilingual word embeddings are usually used to replace lexical items, we use morpho-syntactic embeddings that are less language dependent.

## 3 Dependency Parsing with Delexicalized Word Embeddings

Standard word embeddings have two major drawbacks for our purposes: they represent word forms which are not easy to transfer from one language to another, and they rely on sequential contexts which are not grammatically motivated for languages with free word order.

To circumvent these problems, we propose to create embeddings for morpho-syntactic attribute sets using structural information from dependency trees. As we abstract away the lexical form of words we call our embeddings *delexicalized word embeddings*. The advantage of embedding sets of morpho-syntactic attributes over word forms is that morpho-syntactic attributes are shared across languages much more frequently than lexical features, and they also tend to be more stable through translation. This allows a more reliable transfer of linguistic knowledge from one language to another. This also increases the vocabulary coverage as the number of morpho-syntactic attributes is far smaller than the number of word forms. Here, we choose to learn representations for *full* attribute sets (i.e., the set containing all the morpho-syntactic attributes associated with a word form) instead of learning representations for single attributes and then composing those for each word. This is in line with standard word embedding approaches which implicitly do the same in learning a different representation for each distinct word form of a lemma (e.g., *be*, *am*, *is*, *were*) without any further analysis. We discuss this issue in more detail in the experiment section.

### 3.1 Delexicalized Words

Let us briefly illustrate the kinds of morpho-syntactic attributes we want to embed with some examples. For these examples, we are using the notation of the Universal Dependencies project.

The English word *a* is a *determiner* (its part-of-speech or POS is DET), its number is *singular* and its definiteness is *indefinite*. As a determiner, it does not have tense or mood, and as most English words, it does not have gen-

der. We would thus embed the feature set  $DET:Definite=Ind|Number=Sing$ .

Looking at an example from a morphologically richer language, we have Finnish verb form *oli* (meaning *was*) which we encode as  $VERB:Mood=Ind|Number=Sing|Person=3|Tense=Past|VerbForm=Fin|Voice=Act$ . This means that *oli* is a finite verb form (not a participle) in the indicative past, its voice is active and its agreement is third person, singular.

This gives vocabulary sizes ranging from a hundred or less for analytic languages (English has about 120 such combinations) to several thousands for synthetic ones (the Finnish part of the UD Project has about 4000 such combinations).

### 3.2 Structural Contexts

Having decided to embed morpho-syntactic attribute sets rather than words, we need to map these new objects to dense vectors in  $\mathbb{R}^d$ . To this end, we apply principal component analysis (PCA) to a co-occurrence matrix (possibly re-weighted) whose lines represent our new attribute sets (i.e., our delexicalized words) and whose columns are their contexts, which are also expressed in terms of morpho-syntactic attributes. We describe those contexts later on, but it is worth noting that as we allow them to diverge from the morpho-syntactic features sets, not including every features for example, the number of context can potentially reach a few tens of thousands.

As we want to learn embeddings specifically tailored to dependency parsing, we use not only sequential (i.e. linear) contexts but also structural contexts based on dependency trees. Sequential contexts are of the kind: “word  $x$  appears in a window of size  $l$  centered on word  $y$ ”. Structural contexts are instead defined on the dependency tree: “word  $x$  is the governor of word  $y$ ”, or “ $x$  is a dependent of  $y$ ” or again “ $x$  is a sibling of  $y$ ”.

The new structural contexts can be seen as following a certain path in the dependency tree linking two words. Let  $up(x, t)$  be the function that maps a word  $x$  to its governor (following the *upgoing* edge) in tree  $t$ . As the root of a tree has no governor we add a dummy token called *nil* for that purpose. Then  $down(x, t)$  is the function that maps  $x$  to the set of its dependents in  $t$ .

$$down(x, t) = \{y \in t \mid up(y, t) = x\}$$

Then we can define our new contexts as combinations of *up* and *down*, for example the governor

of  $x$  is  $up(x, t)$ , its dependents are  $down(x, t)$  and its siblings are  $down(up(x, t), t) \setminus \{x\}$ .

We can also define similar functions over sequences. Let  $right(x, s)$  (respectively  $left(x, s)$ ) be the word in sequence  $s$  standing just at the right (respectively at the left) of  $x$ , then we can also express the sequential contexts in the same framework. We also add two new dummy tokens *begin* and *end* to avoid ill definition at the borders of  $s$ . Using the notation  $f^n(\bullet)$  for  $f \circ f \circ \dots \circ f(\bullet)$  where  $f$  is applied  $n$  times, we have that the window of size  $l$  centered on  $x$  is  $\{right^i(x, s) \mid i \in [i..l]\} \cup \{left^i(x, s) \mid i \in [i..l]\}$ . We can also define new contexts such as left or right siblings.

Let us now turn to an example to make our approach more concrete. Figure 1 shows a dependency tree for a Gothic sentence<sup>1</sup> from the Universal Dependencies Project. Each word is accompanied with its part-of-speech and the corresponding morpho-syntactic attributes. Colored links represent examples of contexts, orange links standing for contexts of length 1 and blue links standing for contexts of length 2.

#### Embedding Delexicalized Words With Structural Contexts

Given the above definition of structural contexts, there are still several design parameters to set in order to construct embeddings. First, we distinguish different *types of contexts*, depending on whether the contexts are sequential (with a distinction between left and right), governor, dependents and siblings (with a distinction between first left sibling, first right sibling and others). Second, there are different *context spans*, where the span is the maximum length (in term of function applications) of a context. It is equivalent to the window size for sequential context. For example, the sibling context has a fixed span of 2, but the governor of span 2 means the governor of the governor (if it exists, *nil* otherwise). Third, we distinguish different *granularity levels* of contexts, corresponding to the maximum number of morpho-syntactic attributes used to model contexts. Like words, contexts are also defined in terms of morpho-syntactic attributes, but we do not require complete sets for them, hence allowing for different granularity

<sup>1</sup>The reader may notice that there is no punctuation in that sentence, it is because there is originally no punctuation in Ulfila’s Bible from which the sentence comes, but if there were some (as in modern texts) we would use them just as usual, treating any token as a word.

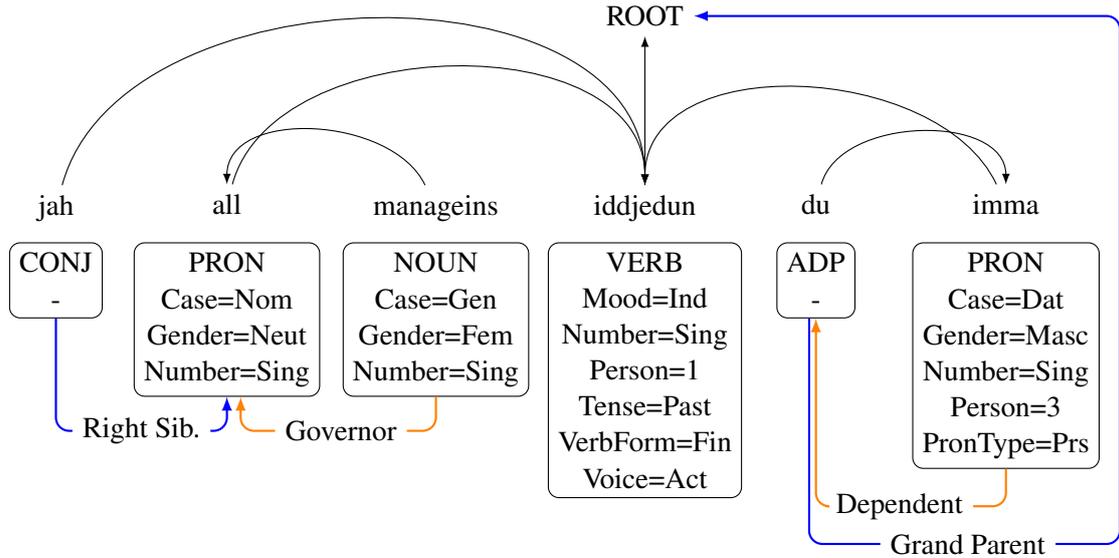

Figure 1: Dependency tree of sentence *jah all manageins iddjedun du imma* (and all of the crowd went to him) from Ulfila’s Bible, from the Gothic part of the Universal Dependencies Project. Under the words are their morpho-syntactic analysis and the colored links represent some possible structural contexts.

levels. Taking an example from the sentence of Figure 1, with a granularity of 0, the word *manageins* triggers the context *NOUN* only (i.e., the POS tag alone). With a granularity of 1, it triggers *NOUN:Case=Gen*, *NOUN:Gender=Fem* and *NOUN:Number=Sing* (i.e., the word POS tag is crossed with each of the other attributes). And with *full* granularity, the union over all subsets of attributes (of size 0 to 3) is combined with the POS tag. This gives  $2^a$  possible contexts for a morpho-syntactic attributes set with  $a$  attributes.

Finally, other parameters are the embedding algorithm (here we use PCA), the matrix normalization method (here we use a simple L2-norm row normalization), the size of the embedding space and the number of contexts used. We can keep all the contexts as their numbers range from 36 (each part-of-speech counted twice for before and after a word and two extra context representing the beginning and the end of the sentence) to a few tens of thousands.

### 3.3 From Word Embeddings to Edge Embeddings to Parsing Features

As the dependency model factors on edges, we need to turn the word embeddings into edge embeddings. We want an aggregating function that preserves edge orientation and the dependency between the edge endpoints. So we chose to use the

outer product of the two original embeddings because it is not commutative and each output dimension depends on the two inputs. Let  $\otimes$  denote the outer product and let  $u$  and  $v$  be two vectors of  $\mathbb{R}^d$ , then:

$$u \otimes v = uv^\top$$

This operation yields a matrix in  $\mathbb{R}^{d \times d}$  but we need a vector, so we take the vector  $vec(uv^\top)$ . In the following, whenever we use a matrix where a vector is expected, we implicitly assume the presence of a  $vec(\bullet)$ <sup>2</sup>. There is a slight scalability problem as the output size grows quadratically with the size of the inputs. But in the case of dependency parsing, where feature vectors are commonly a few millions dimensions long, for typical embeddings size (between 100 and 500) an increase of a few tens of thousands dimensions is acceptable.

We would like to use more context than just the two nodes of the edge to represent it. In order to define higher-order contexts, we use triplets of delexicalized words centered on each side of the edge. Specifically, we concatenate the representations associated with the triplets to keep a tractable model of size  $9d^2$ . Note that applying an outer product across each word of the triplet would be

<sup>2</sup>In this case, it does not matter if a matrix is vectorized by the columns or by the rows, as soon as the same convention is used consistently throughout the algorithm.

prohibitive, leading to vectors of the order of  $10^{12}$  dimensions which would not even fit in memory.

More formally, let  $\oplus$  denote the concatenation operator,  $Dep(e)$  (respectively  $Gov(e)$ ) be the dependent (respectively the governor) of an edge  $e$  and let  $emb(\bullet)$  be the embedding function.  $\phi_{emb}(\bullet, \bullet)$  being the embedding part of the feature vector. Using the notation of section 2.1, we have:

$$\begin{aligned} \phi_{emb}(x, e) = & \bigoplus_{i \in \{-1, 0, +1\}} emb(Gov(e)_i) \\ & \otimes \bigoplus_{i \in \{-1, 0, +1\}} emb(Dep(e)_i). \end{aligned}$$

$$score(x, e) = \mathbf{w} \cdot (\phi(x, e) \oplus \alpha \phi_{emb}(x, e)).$$

Where  $\alpha$  is a scalar allowing to tune the relative importance of each part of the feature vector, and  $\phi(\bullet, \bullet)$  is the traditional dependency feature vector. This follows the same approach as Kiperwasser and Goldberg (2015) and Chen et al.(2014). As mentioned previously, we have special tokens such as *begin* and *end* to represent the word before the beginning and the end of a sentence. We also have a *root* token that stands for the extra root node added by the graphical dependency model. And we also have a back-off embedding of raw part-of-speech to handle unseen delexicalized words in the test set.

## 4 Experiments

### 4.1 Data set

We have tested our parsing models based on delexicalized word embeddings on eight languages using the data of the Universal Dependencies (UD) v1.3 (Nivre et al., 2016). We have chosen to work on English (en), Basque (eu), Finnish (fi), French (fr), Gothic (got), Hebrew (he), Hungarian (hu) and Romanian (ro). These languages belong to four different families, which are Indo-European (en, fr, got, ro), Finno-Ugric (fi, hu), Semitic (he), and Basque which forms a separate group. They also display various levels of morphological complexity not correlated with the families (en, fr and he do not have case marking while the other five do to various degrees) as well as different grammatical typologies (eu is an ergative language, while the other seven are accusative ones). When several corpora are available for a language, we picked the standard one. Table 1 provides some basic statistics on the language datasets. Also note that our experiments follow the train/dev/test split as pro-

vided by the UD Project.

### 4.2 Features

#### Dependency Features

For parsing, we use standard graphical dependency parsing features that include word forms and POS-tags of edge nodes and surrounding words, edge length and direction and conjunction of those basic features. The main difference with the original MSTparser features of McDonald et al.(2005b) is that instead of using truncated words of length 5 as back-off features, we use the lemmas that are provided in the UD Project.

#### Embedding Contexts

For the embedding contexts, we consider four parameters, namely the type and span of contexts, the granularity of the morpho-syntactic attributes used in those contexts and the dimension of the embedding space. Regarding the type of contexts we have experiments with three settings: (i) strictly sequential contexts (*Seq*), (ii) strictly structural contexts that use governor, dependents and siblings information (*Struct*) and (iii) mixed contexts using both dependency-based and sequential contexts (*Mix*). Regarding the span, we have tried 1 and 2. Siblings are only used in structural and mixed contexts of span 2 because that is the length of the path between a vertex and its siblings in a tree. We have tried granularity of 0 and full granularity. For the embedding space dimension we have tried 50, 150 and 500 dimensions, or the maximum possible size<sup>3</sup> if smaller than 500. For better readability, we will use shortcuts to refer to the different parameter settings: 1 = (span 1, granularity 0), 2 = (span 2, granularity 0) and 3 = (span 2, full granularity for contexts span 1, granularity 0 for context span 2).

### 4.3 Experimental Settings

We have carried out two sets of experiments: monolingual and cross-lingual. In the first set, embeddings are learned on a single language training set and then used to parse that same language. In the second set, we have defined several clusters of languages based on their phylogenetic relationship and typological similarities. For a given cluster, embeddings are learned on the training sets of

<sup>3</sup>Spectral-based dimension reduction such as PCA are limited by the number of eigenvectors of the matrix to be reduced. For example a matrix of size  $200 \times 500$  can at most be reduced into a  $200 \times 200$  matrix via PCA. When the number of eigenvectors is smaller than 500, we use that value instead.

	Train		Test		morpho-syntactic tokens	POS
	sentences	words	sentences	words		
English	12 543	204 586	2 077	25 096	118	17
Basque	5 396	72 974	1 799	24 374	845	16
Finnish	12 217	162 721	648	9 140	1 592	15
French	14 557	356 216	298	7 018	195	17
Gothic	4 360	44 722	485	5 158	662	13
Hebrew	5 142	15 558	491	12 125	480	16
Hungarian	1 433	23 020	188	4 235	651	16
Romanian	4 759	108 618	794	18 375	412	17

Table 1: Number of sentences and words in the training and test sets, number of delexicalized word and of POS-tags for each language. The total number of embedded tokens is  $|\text{morpho-syntactic feature set}| + |\text{POS}| + 3$  because of the POS back-offs and the special *begin*, *end* and *root* tokens.

each language in that cluster, and in turn used to parse each language in that cluster. It is possible not to use any data from the target language when learning the embeddings, but in this study we stick to using target language data.

Besides embeddings, there are three additional hyper-parameters that need to be tuned: the  $C$  aggressiveness parameter of the PA-II algorithm, the scaling factor  $\alpha$  that controls the relative weight of the embedding features in the edge scores, and the number  $i$  of training iterations of the PA-II algorithm. We have tuned these hyper-parameters through a grid search on the development sets and picked the values that were behaving best on average, giving  $C = 0.001$ ,  $\alpha = 0.001$ ,  $i = 5$ .

All the scores reported below are Unlabeled Attachment Scores (UAS) measured on the test sets ignoring the punctuation marks. As a baseline comparison we use our implementation of the MSTparser without morpho-syntactic attributes representation of any kind. We computed the significance of the scores using the McNemar’s test.

#### 4.4 Monolingual Experiments

Table 2 displays UAS scores for the monolingual setting. Except for French and Romanian that do not show real improvement, the six other languages show substantial performance increases with the embeddings. These improvements are statistically significant for all languages, except for Basque and Hebrew. One of our hypotheses was that structure is important when learning an embedding for dependency parsing and indeed our results support it. The largest improvements appear with structural or mixed embeddings which rely on syntactic structures.

The results for English are significant and close to each other for all types of embeddings, this tends to show that in English, sentence structure and word order are very correlated and both contribute information. Indeed that is what one expects for English which has a rigid syntax and a poor morphology.

On the other side of the picture, Basque and Gothic display the largest improvements with structural morpho-syntactic embeddings. This is also expected as those are both morphologically rich languages with more flexible word order. Even though the argument is less clear for Hungarian and Finnish, they both show that structure is important for learning informative dependency embeddings.

#### 4.5 Cross-lingual Experiments

Table 3 summarizes the UAS scores achieved using delexicalized embeddings learned on several languages. Parsing accuracy improves for four languages (en, eu, hu, ro) in the cross-lingual setting compared to the best monolingual setting. While the multilingual embeddings do not outperform the monolingual ones for the other four languages, they still deliver parsing performance that are better than with the baseline MST parser for all languages (but Gothic). That shows that indeed using data from other languages is beneficial for learning good embeddings for dependency parsing, which was the second hypothesis we wanted to evaluate. We also notice that the largest gains are achieved with structural (or mixed) embeddings, giving more evidence to the importance of structure for learning embeddings for dependency parsing.

Language	Baseline	Seq 1	Seq 2	Seq 3	Struct 1	Struct 2	Struct 3	Mix 1	Mix 2	Mix 3

Table 2: Best UAS scores for each embedding type in monolingual setting. The best score for each language are in bold and in gray are the results above the baseline. The statistical significance (using McNemar’s test) of an improvement over the baseline is indicated with a superscript mark: \* stands for a significance with a p-value inferior than 0.05,  $\diamond$  stands for  $p \leq 0.01$  and  $\diamond^*$  for  $p \leq 0.001$ . The length of the embeddings is reported as a subscript.

Language	Baseline	Best Mono	Best All	Best Multilingual
English	85.62	86.19 <sup>*</sup>	86.18 <sup>*</sup> <sub>seq3,50</sub>	<b>86.32</b> <sup>*</sup> <sub>en,got,mix3,50</sub>
Basque	76.65	76.90	<b>76.97</b> <sup>*</sup> <sub>struct3,50</sub>	76.68 <sub>decl,seq2,50</sub>
Finnish	79.97	<b>80.92</b> <sup>*</sup>	80.89 <sup>*</sup> <sub>struct2,50</sub>	80.81 <sup>◇</sup> <sub>decl,seq2,50</sub>
French	<b>83.99</b>	83.89	83.87 <sub>struct1,37</sub>	83.89 <sub>en,fr,ro,mix1,77</sub>
Gothic	79.16	<b>80.09</b> <sup>◇</sup>	79.80 <sub>struct2,50</sub>	79.99 <sup>*</sup> <sub>got,ro,mix3,500</sub>
Hebrew	84.05	<b>84.36</b>	84.32 <sub>seq3,150</sub>	84.13 <sub>en,fr,he,mix1,77</sub>
Hungarian	79.15	80.13 <sup>*</sup>	80.05 <sup>*</sup> <sub>mix2,150</sub>	<b>80.30</b> <sup>◇</sup> <sub>decl,struct1,37</sub>
Romanian	81.35	81.38	81.31 <sub>seq3,150</sub>	<b>81.52</b> <sub>hu,ro,mix3,50</sub>

Table 3: Best UAS scores in cross-lingual setting. Under *Best All* are the results using the embeddings learned on the set of all languages, while under *Best Multilingual* are given the best results for each language using only a subset of the languages for learning the embedding. The subscript represents the context types and the number of dimensions of the embedding. The baselines and best monolingual scores are also reported. Significance of scores uses the same conventions as in Table 2.

Let us now look more closely at which groups of source languages are most helpful for specific target languages. First, note in general the best performing embeddings are never those obtained by using the full set of languages (this is only the case for Basque). This is expected since we have picked languages with very different grammars thus the full embeddings can be very noisy with regard to a single language. In fact, the Basque results are rather surprising since this language differs the most from the others in terms of morphology, but also one for which we had rather small training data.

The best parsing performance for English are achieved when using additional data from Gothic. As both are Germanic languages, this tends to show that data from genetically related languages

can help in learning a better representation. Even though they do not achieve the best results, similar patterns occur for French (French and Romanian are Romance languages and English has been heavily influenced by Romance languages) and for Gothic (Gothic and Romanian are both Indo-European languages). Similarly, Hungarian and Romanian reach their best scores when parsed with typologically close languages that have case marking. And again, Basque, Finnish and Gothic display similar patterns. Hebrew performs reasonably well with French and English which are two languages with fairly restricted word orders.

As to why some languages have better monolingual parsing results than multilingual results, we think this is at least partly due to the lack of flexibility of our model. That is, morpho-syntactic

attributes sets are treated independently from one another making some of them hard to use in the cross-lingual setting. For example, Hebrew verbs display ‘binyanim’ (internal flection classes) that do not appear in any other language, similarly Finnish has a lot of cases that are not found in other languages. Those are indeed two languages that do not perform well with other languages. We thus believe that introducing compositionality in our embedding model should help in solving those problems and enhance the results further.

## 5 Conclusion

In this paper, we have described a new way to induce multilingual embeddings, namely delexicalized word embeddings, that solely rely on the morpho-syntactic attributes of words which can easily be transferred across languages. This new approach to multilingual embeddings allows one to use annotated data from other languages to further improve the resulting embeddings and parsers, avoiding the problems that arise from lexicon alignment or cross-lingual word clustering.

In line with previous recent work, we have shown that the syntactic structure is crucial when it comes to learning embeddings for dependency parsing. In addition, we have seen that the impact of the structure on the quality of an embedding depends on language typology.

In future work, we should see how those morpho-syntactic embeddings can help in labeled dependency parsing, as edge types and word morpho-syntactic attributes are related. We would like to investigate the impact of the embedding algorithms (here we use PCA) on the final embeddings. We would also like to try other ways to turn word embeddings into edge embeddings in order to benefit more from the local neighborhoods. Finally, we would like to work on the embedding of clusters of morpho-syntactic attributes to induce higher-order embeddings for noun-phrases or verb-phrases and to deal with agreement and morpho-syntactic attributes hierarchy.

## Abstract

Recent work has addressed the problem of detecting relevant claims for a given controversial topic. We introduce the complementary task of *claim stance classification*, along with the first benchmark dataset for this task. We decompose this problem into: (a) open-domain target identification for topic and claim (b) sentiment classification for each target, and (c) open-domain contrast detection between the topic and the claim targets. Manual annotation of the dataset confirms the applicability and validity of our model. We describe an implementation of our model, focusing on a novel algorithm for contrast detection. Our approach achieves promising results, and is shown to outperform several baselines, which represent the common practice of applying a single, monolithic classifier for stance classification.

## 1 Introduction

The need for making persuasive arguments arises in many domains, including politics, law, marketing, and financial and business advising. On-demand generation of pro and con arguments for a given controversial topic would therefore be of great practical value. Natural use cases include *debating support*, where the user is presented with persuasive arguments for a topic of interest, and *decision support*, where the pros and cons of a given proposal are presented to the user.

A notable research effort in this area is the IBM Debater® project whose goal is “to develop technologies that can assist humans to debate and

reason”<sup>1</sup>. As part of this research, Levy et al. (2014) have developed *context-dependent claim detection*. Given a controversial *topic*, such as

- (1) *The sale of violent video games to minors should be banned*,

their system extracts, from corpora such as Wikipedia, *Context-Dependent Claims (CDCs)*, defined as “general, concise statements that directly support or contest the given Topic”. A claim forms the basis of an argument, being the assertion that the argument aims to establish, and therefore claim detection may be viewed as a first step in automated argument construction. Recent research on claim detection (Levy et al., 2014; Lippi and Torroni, 2015) was facilitated by the IBM argumentative structure dataset (Aharoni et al., 2014), which contains manually collected claims for a variety of topics, as well as supporting evidence.

In this work we introduce the related task of *Claim Stance Classification*: given a topic, and a set of claims extracted for it, determine for each claim whether it supports or contests the topic. Sorting extracted claims into *Pro* and *Con* would clearly improve the usability of both debating and decision support systems. We introduce the first benchmark for this task, by adding Pro/Con annotations to the claims in the IBM dataset.

Based on the analysis of this dataset, we propose a semantic model for predicting claim stance. We observed that both the debate topic and a supporting/contesting claim often contain a *target* phrase, about which they make a positive or a negative statement. The pro/con relation can then be determined by the sentiments of the topic and the claim towards their targets, as well as the semantic relation between these targets. For example, suppose that a topic expresses support for *freedom of*

<sup>1</sup>[http://researcher.ibm.com/researcher/view\\_group.php?id=5443](http://researcher.ibm.com/researcher/view_group.php?id=5443)

\*Present affiliation - Amazon.

*speech*. A *Pro* claim may support it by arguing in favor of *free discussion*, or alternatively by criticizing *censorship*. We say that *freedom of speech* and *free discussion* are *consistent* targets, while *freedom of speech* and *censorship* are *contrastive*. Accordingly, we suggest that claim stance classification can be reduced to simpler, more tractable sub-problems:

1. Identify the targets of the given topic and claim.
2. Identify the polarity (*sentiment*) towards each of the targets.
3. Determine whether the targets are consistent or contrastive.

While our model seems intuitive, it was not clear a priori how well it captures the semantics of claims in practice. Some types of claims do not fit into this decomposition. Consider the following *Con* claim for the topic given in (1):

- (2) *Parents, not government bureaucrats, have the right to decide what is appropriate for their children.*

In this example, there is no clear sentiment target in the claim that is either consistent or contrastive with *the sale of violent video games to minors*. Nevertheless, extensive data annotation confirmed that our model is applicable to about 95% of the claims in the dataset, and for these claims, Pro/Con relations can be accurately predicted by solving the above sub-problems. Furthermore, our analysis reveals that *contrastive targets* are quite common, and thus must be accounted for. Our model highlights intriguing sub-problems such as *open-domain target identification* and *open-domain contrast detection* between a given pair of phrases, which have received relatively little attention in previous stance classification work. We hope that the annotated data collected in this work will facilitate further research on these important subtasks.

We developed a classifier for each of the above subtasks. Most notably, we present a novel method for the challenging task of contrast detection. Empirical evaluation confirms that our modular approach outperforms several strong baselines that employ a single, monolithic classifier.

## 2 Related Work

Previous work on *stance classification* focused on analyzing debating forums (Somasundaran and

Wiebe, 2009; Somasundaran and Wiebe, 2010; Walker et al., 2012b; Hasan and Ng, 2013; Walker et al., 2012a; Sridhar et al., 2014), congressional floor debates (Thomas et al., 2006; Yessenalina et al., 2010; Burfoot et al., 2011), public comments on proposed regulations (Kwon et al., 2007), and student essays (Faulkner, 2014). Most of these works relied on both generic features such as sentiment, and topic-specific features learned from labeled data for a closed set of topics. Simple classifiers with unigram or ngram features are known to be hard to beat for these tasks (Somasundaran and Wiebe, 2010; Hasan and Ng, 2013; Mohammad et al., 2016).

In addition to content-based features, previous work also made use of various types of contextual information, such as agreement/disagreement between posts or speeches, author identity, conversation structure in debating forums, and discourse structure. Collective classification has been shown to improve performance (Thomas et al., 2006; Yessenalina et al., 2010; Burfoot et al., 2011; Hasan and Ng, 2013; Walker et al., 2012a; Sridhar et al., 2014).

The setting of ad-hoc claim retrieval, which we address in this work, is different in several respects. First, topics are not known in advance. They may be arbitrarily complex, and belong to any domain. Second, much of the contextual information that was exploited in previous work is not available in this setting. In addition, claims are short sentences, while previous work typically addressed text spanning one or more paragraphs. Moreover, since we may want to present to the user only claims for which we are confident about stance, reliable confidence ranking of our predictions is important. We explore this aspect in our evaluation.

Consequently, our approach relies on generic sentiment analysis, rather than on topic or domain-specific features. We focus on precise semantic analysis of the debate topic and the claim, including target identification, and contrast detection between the claim and the topic targets. While sentiment analysis is a well-studied task, open-domain target identification and open-domain contrast detection between two given phrases have received little attention in previous work.

*Consistent/contrastive* targets were previously discussed by Somasundaran et al. (2009)<sup>2</sup>, who

<sup>2</sup>Termed *same/alternative* in their paper.

used them in conjunction with discourse relations to improve the prediction of opinion polarity. However, these targets and relations were not automatically identified, but rather taken from a labeled dataset. Somasundaran and Wiebe (2009) considered debates comparing two products, such as *Windows* and *Mac*. In comparison, topics in our setting are not limited to product names, and the scope of contrast we address is far more general.

Cabrio and Villata (2013) employ textual entailment to detect *support/attack* relations between arguments. However, as illustrated in Table 1, claims typically refer to the pros and cons of the topic target, but do not entail or contradict the topic.

A recent related task is the SemEval 2016 tweets stance classification (Mohammad et al., 2016). In particular, in its weakly supervised subtask (Task B), no labeled training data was provided for the single assessed topic (*Donald Trump*). Beyond the obvious differences in language and content between claims and tweets, the setting of this task is rather different from ours: the topic was known in advance to the participants, and an unlabeled corpus of related tweets was provided. Top performing systems took advantage of this setting, and developed offline rules for automatically labeling the domain corpus. In our setting, the topic is not known in advance, and obtaining a large collection of claims for a given topic does not seem feasible.

### 3 The Claim Polarity Dataset

The IBM argumentative structure dataset published by Aharoni et al. (2014) contains claims and evidence for 33 controversial topics. In this work we used an updated version of this dataset, which includes 55 topics. Topics were selected at random from the debate motions database at the International Debate Education Association (IDEA) website<sup>3</sup>. Motions are worded as “This house ...”, in the tradition of British Parliamentary debates. Claims and evidence were manually collected from hundreds of Wikipedia articles. The dataset contains 2,394 claims.

By definition, all claims in the dataset either support or contest the topic, and Aharoni et al. give a few examples for *Pro* and *Con* claims in their paper. However, the dataset itself does not include stance annotations. We enhanced the dataset

<sup>3</sup><http://idebate.org/>

with polarity annotations as follows. The polarity of each claim with respect to the motion (*Pro/Con*) was assessed by five annotators, and the final label was determined by the majority annotation.<sup>4</sup> Table 1 shows examples of motions, claims and their pro/con labeling.

### 4 Semantic Model for Claim Stance Classification

In this section we propose a model for predicting the stance of a claim  $c$  towards a topic sentence  $t$ .

We assume that  $c$  includes a *claim target*  $x_c$ , defined as a phrase about which  $c$  makes a positive or a negative assertion. Specifically, it is defined as the most explicit and direct sentiment target in the claim. The *claim sentiment*  $s_c \in \{-1, 1\}$  is the sentiment of the claim towards its target, where 1 denotes positive sentiment and  $-1$  denotes negative sentiment. Similarly, we define for a topic  $t$  the *topic target*  $x_t$  and *topic sentiment*  $s_t$ .

We say that the claim target  $x_c$  is *consistent* with the topic target  $x_t$  if the stance towards  $x_c$  implies the *same* stance towards  $x_t$ . Similarly,  $x_c$  and  $x_t$  are *contrastive* if the stance towards  $x_c$  implies the *opposite* stance towards  $x_t$ . The *contrast relation* between  $x_c$  and  $x_t$ , denoted  $\mathcal{R}(x_c, x_t) \in \{-1, 1\}$  is 1 if  $x_c$  and  $x_t$  are consistent, and  $-1$  if they are contrastive. Using the above definitions, we define the stance relation between  $c$  and  $t$  as

$$Stance(c, t) = s_c \times \mathcal{R}(x_c, x_t) \times s_t \quad (1)$$

where  $Stance(c, t) \in \{-1, 1\}$ , 1 indicates *Pro* and  $-1$  indicates *Con*. Rows 1-8 in Table 1 show examples for  $x_c$ ,  $s_c$ ,  $x_t$ ,  $s_t$  and  $\mathcal{R}(x_c, x_t)$ . It is easy to verify that the model correctly predicts the claim polarity for these examples. For instance, row 3 has  $x_c$ =“Unity”,  $x_t$ =“Multiculturalism”,  $s_c = 1$ ,  $\mathcal{R}(x_c, x_t) = -1$ ,  $s_t = 1$ , and the resulting stance is  $1 \times (-1) \times 1 = -1$  (*Con*).

**Continuous model:** The above model produces binary output (+1/-1). In practice, it would be desirable to obtain confidence ranking of the model predictions, which would allow presenting to the user only the top  $k$  predictions, or predictions whose confidence is above some threshold. We therefore implemented a continuous variant of the model, where  $s_c$ ,  $s_t$ ,  $\mathcal{R}(x_c, x_t)$  and the resulting stance score are all real-valued numbers in  $[-1, 1]$ .

<sup>4</sup>Note that while we considered the original motion phrasing for Pro/Con labeling, the original dataset only contains motion themes as the topics, e.g. *boxing* for “This house would ban boxing”.

#	Debate Topic (Motion)		Claim	
1	This house believes that <b>advertising</b> is harmful. $\ominus$	$\Leftrightarrow$	<b>Marketing</b> promotes consumerism and waste. $\ominus$	Pro
2	This house would ban <b>boxing</b> . $\ominus$	$\Leftrightarrow$	<b>Boxing</b> remains the 8th most deadly sport. $\ominus$	Pro
3	This house would embrace <b>multiculturalism</b> . $\oplus$	$\nrightarrow$	<b>Unity</b> is seen as an essential feature of the nation and the nation-state. $\oplus$	Con
4	This house supports <b>the one-child policy of the republic of China</b> . $\oplus$	$\nrightarrow$	<b>Children with many siblings</b> receive fewer resources. $\ominus$	Pro
5	This house would <b>build hydroelectric dams</b> . $\oplus$	$\Leftrightarrow$	As an alternative energy source, <b>a hydroelectric power source</b> is cheaper than both nuclear and wind power. $\oplus$	Pro
6	This house believes that it is sometimes right for the government to restrict <b>freedom of speech</b> . $\ominus$	$\Leftrightarrow$	<b>Human rights</b> can be limited or even pushed aside during times of national emergency. $\ominus$	Pro
7	This house would abolish <b>the monarchy</b> . $\ominus$	$\Leftrightarrow$	<b>Hereditary succession</b> is outdated. $\ominus$	Pro
8	This house would <b>unleash the free market</b> $\oplus$	$\nrightarrow$	Virtually all developed countries today successfully promoted their national industries through <b>protectionism</b> . $\oplus$	Con
9	This house supports <b>the one-child policy of the republic of China</b> . $\oplus$		If, for any reason, the single child is unable to care for their older adult relatives, the oldest generations would face a lack of resources and necessities.	Con

Table 1: Sample topic and claim annotations. Targets are marked in bold.  $\oplus/\ominus$  denote positive/negative sentiment towards the target, and  $\Leftrightarrow/\nrightarrow$  denote consistent/contrastive targets.

For each real-valued prediction, the class is given by its sign, and the confidence is given by its absolute value.

## 5 Model Assessment via Manual Data Annotation

We assessed the validity and applicability of the proposed model through manual annotation of the IBM dataset.<sup>5</sup> The labeled data was also used to train and assess sub-components in the model implementation. This section describes the annotation process and the analysis of the annotation results.

**Annotation Process:** Each of the 55 topics was annotated by one of the authors for its target  $x_t$  and sentiment  $s_t$ .  $x_t$  was used as an input for the claim annotation task. Each claim was labeled independently by five annotators who were given the definitions for claim target  $x_c$ , claim sentiment  $s_c$  and the contrast relation  $\mathcal{R}(x_c, x_t)$  (cf. Section 4). The annotators were first asked to identify  $x_c$  and  $s_c$ . If successful, they proceeded to determine  $\mathcal{R}(x_c, x_t)$ .

The final claim labels were derived from the five individual annotations as follows. First, overlapping claim targets were clustered together. If no cluster contained the majority of the annotations

( $\geq 3$ ), then the claim was labeled as incompatible with our model. If a majority cluster was found, we discarded annotations where the target was not in this cluster, and selected  $x_c$ ,  $s_c$  and  $\mathcal{R}(x_c, x_t)$  based on the majority of the remaining annotations. We required absolute majority agreement ( $\geq 3$ ) for  $s_c$  and  $\mathcal{R}(x_c, x_t)$ , otherwise the claim was labeled as incompatible with our model.

Rows 1-8 in Table 1 show some examples of annotated claims in our dataset. Row 9 is an example of a claim that was found incompatible with our model.

**Data Annotation Results:** Majority cluster was found for 98.5% of the claims, and for 92.5% of the claims, the majority of the annotators agreed on the exact boundaries of the target. 94.4% of the claims were found to be compatible with our model. Furthermore, combining the labels for  $s_c$ ,  $\mathcal{R}(x_c, x_t)$  and  $s_t$  as in Equation (1) correctly predicted the Pro/Con labels in the dataset (which were collected independently and were not presented to the annotators) for 99.6% of the compatible claims. Given that the pro/con labels are approximately balanced (55.3% are Pro, 44.7% are Con), this result provides a clear and strong evidence for the applicability and validity of the proposed model. This near-perfect correspondence also indicates the high quality of both *Pro/Con* labels and the model-based annotations.

Similar to pro/con labels, claim sentiment is approximately balanced between positive and negative (55% negative vs. 45% positive). Interestingly, 20% of the compatible claims have a con-

<sup>5</sup>The IBM Debating Technologies group in IBM Research has already released several data resources, found here: [https://www.research.ibm.com/haifa/dept/vst/mlta\\_data.shtml](https://www.research.ibm.com/haifa/dept/vst/mlta_data.shtml). We aim to release the resource presented in this paper as well, as soon as we obtain the required licenses.

trastive relation with the topic target. Since contrastive targets flip polarity, stance classification would fail in these cases, unless these cases are correctly identified and accounted for. This highlights the importance of contrast classification for claim pro/con analysis. We discuss contrast detection in Section 7.

## 6 Target Extraction and Targeted Sentiment Analysis

Next, we describe an implementation of the stance classification model. This section provides a concise description of target identification and targeted sentiment analysis. The next section presents in more detail our novel contrast detection algorithm. We assume that for the user, directly specifying the topic target  $x_t$  and the topic sentiment  $s_t$  (e.g.,  $\langle \textit{boxing}, \textit{Con} \rangle$ ) is as easy as phrasing the topic as a short sentence (“*This house would ban boxing*”), in terms of supervision effort. Therefore, we focus on finding  $x_c$  and  $s_c$ , the claim target and sentiment, and assume that  $x_t$  and  $s_t$  are given.

### 6.1 Claim Target Identification

Previous work on *targeted/aspect-based* sentiment analysis focused on detecting in user reviews sentiment towards products and their components (Popescu and Etzioni, 2005; Hu and Liu, 2004b), or considered only named entities as targets (Mitchell et al., 2013). Here we address a more general problem of open domain, generic target identification. Table 1 illustrates the diversity and complexity of claim targets.

We set up the problem of claim target identification as a supervised learning problem, using an  $L2$ -regularized logistic regression classifier. Target candidates are the noun phrases in the claim, obtained from its syntactic parse<sup>6</sup>. We create one training example from each such candidate phrase  $x$  and claim  $c$  in our training set. The feature set is summarized in Table 2. Candidate phrases that exactly match the true target or overlap significantly with it are considered positive training examples, while the other candidates are considered negative examples. We measured overlap using the Jaccard similarity coefficient, defined as the ratio between the number of tokens in the intersection and the union of the two phrases, and considered an over-

<sup>6</sup>We used the ESG parser (McCord, 1990; McCord et al., 2012).

<b>Syntactic and Positional:</b> The dependency relation of $x$ in $c$ ; whether $x$ is a direct child of the root in the dependency parse tree for $c$ ; the minimum distance of $x$ from the start or the end of the chunk containing it.
---

<b>Wikipedia:</b> whether $x$ is a Wikipedia title, (e.g. <i>human rights</i> )
---

<b>Sentiment:</b> The dependency relation connecting $x$ to any sentiment phrase in the rest of $c$ . The (Hu and Liu, 2004a) sentiment lexicon was used. For example, <i>Hereditary succession</i> is the sentiment target of <i>outdated</i> , indicated by the subject-predicate relation connecting them (Table 1, row 7).
--

<b>Topic relatedness:</b> Semantic similarity between $x$ and the topic target, e.g. <i>Marketing</i> and <i>advertising</i> (Table 1, row 1). We consider morphological similarity, paths in WordNet (Miller, 1995; Fellbaum, 1998), and cosine similarity of word2vec embeddings (Mikolov et al., 2013).
--

Table 2: Features extracted for a target candidate  $x$  in a claim  $c$ . Examples are taken from Table 1.

lap of 0.6 or higher as significant overlap<sup>7</sup>. The candidate with the highest classifier confidence is predicted to be the target.

### 6.2 Claim Sentiment Classification

This component determines the sentiment of the claim towards its target. Given our open-domain setting, and the relatively small amount of training data available, we followed the common practice of lexicon-based sentiment analysis (Liu, 2012, pp. 50–53)<sup>8</sup>. Our method is similar to the one described by Ding et al. (2008), and comprises the following steps:

**Sentiment matching:** Positive and negative terms from the sentiment lexicon of Hu and Liu (2004a) are matched in the claim.

**Sentiment shifters application:** Sentiment shifters (Polanyi and Zaenen, 2004) reverse the polarity of sentiment words, and may belong to various parts of speech, e.g. “*not successful*+”, “*prevented success*+”, and “*lack of success*+”. We manually composed a small lexicon of about 160 sentiment shifters. The scope was defined as the  $k$  tokens following the shifter word.<sup>9</sup>

**Sentiment weighting and score computation:** Following Ding et al., sentiment term weight decays based on its distance from the claim target. We used a weight of  $d^{-0.5}$ , where  $d$  is the distance in tokens between the sentiment term and the target. Let  $p$  and  $n$  be the weighted sums of positive

<sup>7</sup>Determined empirically based on the training set.

<sup>8</sup>Our sentiment analyzer was found to outperform the Stanford sentiment analyzer (Socher et al., 2013) on claims.

<sup>9</sup>We experimentally set  $k = 8$  based on the training data.

and negative sentiments detected in the claim, respectively. The final sentiment score is then given by  $\frac{p-n}{p+n+1}$ , following Feldman et al. (2011).

## 7 Contrast Classification

The most challenging subtask in our model implementation is determining the contrast relation between the topic target  $x_t$ , and the claim target  $x_c$ . Previous work has focused on word-level contrast and synonym-antonym distinction (Mohammad et al., 2013; Yih et al., 2012; Scheible et al., 2013). The algorithm presented in this section addresses complex phrases, as well as consistent/contrastive semantic relations that go beyond synonyms/antonyms.

### 7.1 Algorithm

Consider the targets *atheism* and *denying the existence of God*. The relation between these targets is determined based on the contrastive relation between *God* and *atheism*, which is flipped by the negative polarity towards *God*, resulting in a consistent relation between the targets. We call the pair (*God*, *atheism*) the *anchor pair*, defined as the pair of core phrases that establishes the semantic link between the targets.

The following algorithm generalizes this notion, analogously to our claim-level model. The input for the algorithm includes  $x_c$ ,  $x_t$  and a relatedness measure  $r(u, v) \in [-1, +1]$  over pairs of phrases  $u$  and  $v$ . Positive/negative values of  $r$  indicate a consistent/contrastive relation, respectively, and the absolute value indicates confidence.

First, anchor candidates are extracted from  $x_c$  and  $x_t$ , as detailed in the next subsection. The anchor pair is selected based on the association strength of each anchor with the debate topic domain, as well as the strength of the semantic relation between the anchors. Term association with the domain is given by a TF-IDF measure  $w(x) = tf(x)/df(x)$ , where  $tf(x)$  is the frequency of  $x$  in articles that were identified as relevant to the topic in the labeled dataset, and  $df(x)$  is its overall frequency in Wikipedia. We choose in  $(x_c, x_t)$  the anchor pair  $(a_c, a_t)$  that maximizes  $w(u) \times |r(u, v)| \times w(v)$ .

The contrast score is then predicted as  $p(x_c, a_c) \times r(a_c, a_t) \times p(x_t, a_t)$ , where  $p(u, v) \in [-1, +1]$  is the polarity towards  $v$  in  $u$ . Negative polarity is determined by the presence of words such as *limit*, *ban*, *restrict*, *deny* etc. We manu-

ally developed a small lexicon of stance flipping words, which largely overlaps with our sentiment shifters lexicon. We employ several relatedness measures, described in the next subsection, and the contrast scores obtained for these measures are used as features in the contrast classifier, implemented as a random forest classifier.

The above approach can be extended to find the top-K anchor pairs for complex targets. We use  $K = 3$  in our experiments. When considering additional anchor pairs beyond the top-ranked pair  $(a_c, a_t)$ , we multiply the above contrast score by  $sgn(r(b_c, b_t))$  for each such additional pair  $(b_c, b_t)$ . Thus, these pairs may affect the sign of the contrast score but not its magnitude. Anchor pair assignment is computed using the Hungarian Method (Kuhn, 1955).

### 7.2 Contrast Relations

We initially implemented the following known relatedness measures: (i) morphological similarity, (ii) cosine similarity using word2vec embeddings (Mikolov et al., 2013), (iii) reachability in WordNet via synonym-antonym chains (Harabagiu et al., 2006) and (iv) thesaurus-based synonym-antonym relations using polarity-inducing LSA (Yih et al., 2012). Note that the measures (i) and (ii) above take values only in  $[0, 1]$ , and thus are indicative of similarity but not of contrast. All these measures suffer from two limitations: (a) They only operate at the token level, while our anchors are often phrases (b) Their coverage on our data is insufficient, in particular for contrastive anchors.

We developed a novel relatedness measure that addresses these limitations, and is used in conjunction with the other measures. Our method is based on co-occurrence of the anchor pair with consistent and contrastive cue-phrases. For example, “*vs*”, “*or*” and “*against*” are contrastive cue phrases, while “*and*”, “*like*” and “*same as*” are consistent cue phrases. We compiled a list of 25 cue phrases.

The anchors are matched in a corpus we composed from the union of two complementary sources, which were found particularly effective for this task:

**Query logs:** We obtained 2.2 billion queries (450 million distinct queries) from the Blekko® search engine. With over a million distinct queries containing the words *vs*, *vs.*, or *versus*, it is an abundant resource for detecting contrast. Some

examples are: “*God or atheism*”, “*political correctness vs freedom of speech*”, “*free trade vs protectionism*” and “*advertising and marketing*”.

**Wikipedia headers:** We considered article titles, and section and subsection headers in Wikipedia (3 million in total). For example, “*Military intervention vs diplomatic solution*”.

Compared to full sentences, both queries and headers are short, concise texts, and therefore are less likely to suffer from contextual errors (in which the context alters the meaning of the matched pattern).

The score returned by our method is calculated as follows. Let  $Lex^+$  and  $Lex^-$  be the lexicons of consistent and contrastive cue phrases, respectively. Let  $Freq(u, v)$  be the number of documents (queries or headers), which contain  $u$  and  $v$  separated by at most 3 tokens, and  $Freq(u, Lex^+, v)$  is the size of the subset of these documents, which also contain a consistent cue phrase between  $u$  and  $v$ . We then define the probability  $P(Lex^+|u, v)$  as  $\frac{Freq(u, Lex^+, v)}{Freq(u, v)}$ .  $P(Lex^-|u, v)$  is defined analogously for the contrastive lexicon. The returned score is  $P(Lex^+|u, v)$  if  $P(Lex^+|u, v) > P(Lex^-|u, v)$ , and  $-P(Lex^-|u, v)$  otherwise. We also experimented with other scoring methods, based on pointwise mutual information between the concurrences of the the pair  $(u, v)$  and the lexicon cue phrase, as well as statistical significance tests for their co-occurrence. However, the above method was found to perform best on our data.

**Generating anchor candidates:** Candidate anchors for measures (i)-(iv) are all single tokens. For our method, we additionally considered phrases as anchors. Candidates were generated from diverse sources, including the output of the ESG syntactic parser (McCord, 1990; McCord et al., 2012), the TagMe Wikifier (Ferragina and Scaiella, 2010), named entities recognized with the Stanford NER (Finkel et al., 2005) and multiword expressions in WordNet. Candidates subsumed by larger candidates were discarded. Following Levy et al. (2015), we kept only dominant terms with respect to the topic, by applying a statistical significance test (Hyper-geometric test with Bonferroni correction).

Overall, our method detects many consistent and contrastive pairs missed by previous methods.

### 7.3 Classification Output

The contrast classifier outputs a score in the  $[0, 1]$  interval indicating the likelihood of  $x_t$  and  $x_c$  being consistent. We found that while it still cannot predict reliably contrastive targets, this consistency confidence score performs well on ranking the targets according to their likelihood of being consistent. We therefore use this score to re-rank our predictions, so that claims that are likely to have consistent targets would rank higher.

## 8 Evaluation

### 8.1 Experimental Setup

We evaluated the overall performance of the system, as well as the performance of individual components. The dataset was randomly split into a training set, comprising 25 topics (1,039 claims), and a test set, comprising 30 topics (1,355 claims). The training set was used to train the target identification classifier and the contrast classifier in our system, as well as the baselines described below.

We explore the trade-off between presenting high-accuracy predictions to the user, and making predictions for a large portion of the claims. This tradeoff is controlled by setting a threshold on the prediction confidence, and discarding predictions below that threshold. Let  $\#claims$  be the total number of claims. Given some threshold  $\alpha$ , we define  $\#predicted(\alpha)$  as the number of corresponding predictions, and  $\#correct(\alpha)$  as the number of correct predictions. We then define:  $coverage(\alpha) = \frac{\#predicted(\alpha)}{\#claims}$ , and  $accuracy(\alpha) = \frac{\#correct(\alpha)}{\#predicted(\alpha)}$ .

We consider the macro averaged  $accuracy(\alpha)$  and  $coverage(\alpha)$  over the test topics. Our evaluation focuses on the following question: suppose that we require a minimum coverage level, what is the highest accuracy we can obtain? The result is determined by an exhaustive search over threshold values. This assessment was performed for varying coverage levels.

The following configurations were evaluated. The first two configurations represent known strong baselines in stance classification (cf. Section 2).

**Unigrams SVM:** SVM with unigram features. The SVM classifier gets the claim as an input, and aims to predict the claim sentiment  $s_c$ . Assuming consistent targets ( $\mathcal{R}(x_c, x_t) = 1$ ), stance is then predicted as  $s_c \times s_t$ , where  $s_t$  is the given topic

Configuration	Accuracy@Coverage									
	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0
Baselines										
Unigrams SVM	0.688	0.688	0.659	0.612	0.587	0.563	0.560	0.554	0.554	0.547
Unigrams+Sentiment SVM	0.717	0.717	0.717	0.709	0.693	0.691	0.687	0.668	0.655	0.632

Sentiment Score	0.752	0.720	0.720	0.720	0.720	0.720	0.636	0.636	0.636	0.636
+Targeted Sentiment	0.770	0.770	0.770	0.749	0.734	0.734	<b>0.706</b>	0.632	0.632	0.632
+Contrast Detection	<b>0.849</b>	<b>0.847</b>	<b>0.836</b>	<b>0.793</b>	<b>0.767</b>	<b>0.740</b>	0.704	0.632	0.632	0.632
Our System+Unigrams SVM	0.784	0.758	0.749	0.743	0.730	0.711	0.682	<b>0.671</b>	<b>0.658</b>	<b>0.645</b>

Table 3: Stance classification results. Majority baseline accuracy: 51.9%

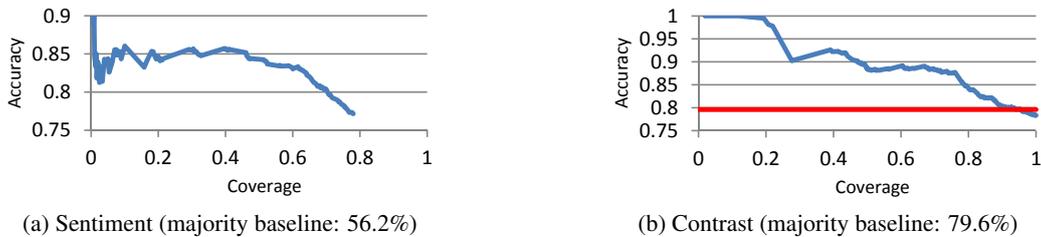

Figure 1: Performance of Sub-Components

sentiment.

**Unigrams+Sentiment SVM:** The unigram SVM with additional sentiment features. We employed here a simplified version of the sentiment analyzer (cf. Section 6.2), in which target identification is not performed, and sentiment terms are weighted uniformly. The following three features were used: the sums of positive and negative sentiments ( $p$  and  $n$ ), and the final sentiment score.

The next three configurations are incremental implementations of our system. For each configuration, only the difference from the previous configuration is specified.

**Sentiment Score:** Predicts  $s_c$  as the sentiment score of the simplified sentiment analyzer. Stance is predicted as  $s_c \times s_t$ , similar to the SVM baselines.

**+Targeted Sentiment:** Employs the targeted sentiment analyzer described in Section 6.2.

**+Contrast Detection:** Full implementation of our model. Stance score is further multiplied by the output of the contrast classifier,  $\mathcal{R}(x_c, x_t)$ , predicted for the extracted claim target  $x_c$  and the topic target  $x_t$ . As discussed in the previous section, this aims to rank higher claims with consistent targets.

Lastly, we tested a combination of our system with the unigrams SVM baseline.

**Our System+Unigrams SVM:** Adding the targeted sentiment score as a feature to the unigrams SVM. The SVM output is multiplied by the contrast classifier score.

For each configuration, if the classifier outputs zero<sup>10</sup>, we predict the majority class in the train set with a constant, very low confidence.

## 8.2 Results, Analysis and Discussion

The results are shown in Table 3. Comparing the two baselines highlights the importance of sentiment in our open-domain setting, in which no topic-specific training data is available.

Using only the simple sentiment score outperforms the baselines for coverage rates  $\leq 0.6$ . For higher coverage rates the performance drops from 72% to 63.6%. This happens since the sentiment analyzer makes predictions for 69.4% of the claims, and the remaining claims are given the majority class with a fixed low confidence, as described above. For coverage rates  $\geq 0.7$ , these claims are added together (since they all match the same threshold), and thus accuracy is actually computed over the whole test set.

Targeted sentiment analysis improves over the non-weighted *Sentiment Score* baseline. It makes predictions for 77.4% of the claims<sup>11</sup>, and similar to the previous configuration, accuracy drops accordingly from 70.6% to 63.2% for higher coverage rates ( $\geq 0.8$ ).

Re-ranking based on target consistency confi-

<sup>10</sup>This can happen, for example, if the sentiment analyzer does not match any sentiment term in the claim.

<sup>11</sup>Coverage is improved since sentiment weighting breaks ties between positive and negative sentiments, which result in zero predictions of the simple analyzer.

dence substantially improves accuracy for lower coverage rates ( $\leq 0.6$ ). For instance, the classifier achieves accuracy of 79.3% over 40% the claims, and 83.6% for 30% of the claims.

Finally, combining our system with the uni-grams SVM allows the classifier to make predictions for claims that are not covered by the targeted sentiment analyzer, and consequently this configuration achieves the best accuracy for high coverage rates ( $\geq 0.8$ ). It outperforms the SVM baselines for both low and high coverage rates.

Overall, the results confirm that our modular approach outperforms the common practice of monolithic classifiers for stance classification, in particular for making high-accuracy stance predictions for a large portion of the claims. Each component was shown to contribute to the overall performance.

We also assessed the performance for each sub-task on the test set. Claim target identification achieves accuracy of 0.752 for exact matching, and 0.813 for relaxed matching (using the Jaccard measure, as in Section 6.1). Figure 1 shows accuracy vs. coverage curves for targeted claim sentiment analysis and contrast detection. Both components achieve higher accuracy for lower coverage rates, illustrating the effectiveness of their confidence score. As mentioned above, the sentiment analyzer makes a prediction for nearly 80% of the claims, and is shown to perform well. The contrast classifier, while not outperforming the majority baseline over the whole dataset, achieves accuracy that is much higher than the baseline for lower coverage rates.

## 9 Conclusion

This work is the first to address claim stance classification with respect to a given topic. We proposed a model that breaks down this complex task into simpler, well defined subtasks. Extensive data annotation and analysis has confirmed the applicability and accuracy of this reduction. The annotated dataset, which we plan to share with the community, is another contribution of this work.

The work also presented a concrete implementation of our model, using the collected labeled data to train each component, and demonstrated its effectiveness empirically. We plan to improve each of these components in future work.

## Acknowledgments

We would like to thank Yonatan Bilu, Ido Dagan, and Charles Jochim for their helpful feedback on this work.

## Abstract

This paper provides a linguistic and pragmatic analysis of the phenomenon of irony in order to represent how Twitter's users exploit irony devices within their communication strategies for generating textual contents. We aim to measure the impact of a wide-range of pragmatic phenomena in the interpretation of irony, and to investigate how these phenomena interact with contexts local to the tweet. Informed by linguistic theories, we propose for the first time a multi-layered annotation schema for irony and its application to a corpus of French, English and Italian tweets. We detail each layer, explore their interactions, and discuss our results according to a qualitative and quantitative perspective.

## 1 Introduction

Irony is a complex linguistic phenomenon widely studied in philosophy and linguistics (Grice et al., 1975; Sperber and Wilson, 1981; Utsumi, 1996). Glossing over differences across approaches, irony can be defined as an incongruity between the literal meaning of an utterance and its intended meaning. For many researchers, irony overlaps with a variety of other figurative devices such as satire, parody, and sarcasm (Clark and Gerrig, 1984; Gibbs, 2000). In this paper, we use irony as an umbrella term that includes sarcasm, although some researchers make a distinction between them, considering that sarcasm tends to be more aggressive (Lee and Katz, 1998; Clift, 1999).

Different categories of irony have been studied in the linguistic literature such as hyperbole, exaggeration, repetition or change of register (see section 3 for a detailed description). These categories were mainly identified in literary texts (books, po-

ems, etc.), and as far as we know, no one explored them in the context of social media. The goal of the paper is thus four folds: (1) analyse if these categories are also valid in social media contents, focusing on tweets which are short messages (140 characters) where the context may not be explicitly represented; (2) examine whether these categories are linguistically marked; (3) test if there is a correlation between the categories and markers; and finally (4) see if different languages have a preference for different categories.

This analysis can be exploited in a purpose of automatic irony detection, which is progressively gaining relevance within sentiment analysis (Maynard and Greenwood, 2014; Ghosh et al., 2015). In particular, it will bring out the most discriminant pragmatic features that need to be taken into account for an accurate irony detection, therefore helping systems improve beyond standard approaches that still heavily rely on features gleaned from the utterance-internal context (Davidov et al., 2010; Gonzalez-Ibanez et al., 2011; Liebrecht et al., 2013; Buschmeier et al., 2014; Hernández Farías et al., 2016).

To this end, informed by well-established linguistic theories of irony, we propose for the first time:

- A multi-layered annotation schema in order to measure the impact of a wide-range of pragmatic phenomena in the interpretation of irony, and to investigate how these phenomena interact with context local to the tweet. The schema includes three layers: (1) *irony activation types* according to a new perspective of how irony activation happens—explicit vs. implicit, (2) *irony categories* as defined in previous linguistic studies, and (3) *irony markers*.
- A multilingual corpus annotated according

to this schema. As the expression of irony is very dependent on culture, we chose, for this first study, three Indo-European languages whose speakers share quite the same cultural background: French, English and Italian. The corpus is freely available for research purposes and can be downloaded here <http://github.com/IronyAndTweets/>.

- A qualitative and quantitative study, focusing in particular on the interactions between irony activation types and markers, irony categories and markers, and the impact of external knowledge on irony detection. Our results demonstrate that implicit activation of irony is a major challenge for future systems.

The paper is organised as follows. We first present our data. Sections 3 and 4 respectively detail the annotation scheme and the annotation procedure. Section 5 discusses the reliability study whereas Section 6 the quantitative results. In Section 7, we compare our scheme to already existing schemes for irony stressing the originality of our approach and the importance of the reported results for automatic irony detection. Finally we end the paper by showing how the annotated corpora are actually exploited in automatic irony detection shared tasks.

## 2 Data

The datasets used in this study are tweets about hot topics discussed in the media. Our intuition behind choosing such topics is that the pragmatic context needed to infer irony is more likely to be understood by annotators compared to tweets that relate personal content. We relied on three corpora in French, English and Italian, referred to as  $F$ ,  $E$  and  $I$  respectively. Table 1 shows the distribution of ironic vs. non ironic tweets in the data.

Corpus	<i>Ironic</i>	<i>Not Ironic</i>
F	2,073	16,179
E	5,173	6,116
I	806 (Sentipolc) + 2,273 (TW-SPINO)	5,642 (Sentipolc)

Table 1: Distribution of tweets in each corpus.

The selection of ironic vs non-ironic tweets has been based on partly different criteria for the three

addressed languages in order to tackle their features.

In English and French, users employ specific hashtags (*#irony*, *#sarcasm*, *#sarcastic*) to mark their intention to be ironic. These hashtags have been often used as gold labels to detect irony in a supervised learning setting. Although this approach cannot be generalized well since not all ironic tweets contain hashtags, it has however shown to be quite reliable as good inter-annotator agreements (kappa around 0.75) between annotators' irony label and the reference irony hashtags have been reported (Karoui et al., 2015). Nevertheless, irony corpus construction through hashtag filtering is not always possible for all languages. For instance, both in Czech and Italian, Twitter users generally do not use the sarcasm (i.e. ‘#sarkasmus’, in Czech; ‘#sarcasmo’ in Italian) or irony (‘#ironie’ in Czech or ‘#ironia’ in Italian) hashtag variants to mark their intention to be ironic, thus in such cases relying on simple self-tagging for collecting ironic samples is not an option (Ptáček et al., 2014; Bosco et al., 2013). Similar considerations hold for Chinese (Tang and Chen, 2014). For what concerns Italian, we observe that even if occasionally Italian tweeters do use creative hashtags to explicitly mark the presence of irony, no generic shared hashtags have been used for long-time which can be considered as firmly established indicators of irony like those used for English.

The corpora built for English and French are new datasets built using the Twitter API as follows. We first selected 9 topics (politics, sport, artists, locations, Arab Spring, environment, racism, health, social media) discussed in the French media from Spring 2014 until Autumn 2015 and in the American media from Spring 2014 until Spring 2016. For each topic, we selected a set of keywords with and without hashtag: politics (e.g. Hollande, Obama), sport (e.g. #Zlatan, #FIFAworldcup), etc. Then, we selected ironic tweets containing the topic keywords and the French (English) ironic hashtags. Finally, we selected non ironic tweets that contained only the topic keywords without the ironic hashtag. We removed duplicates, retweets and tweets containing pictures which would need to be interpreted to understand the ironic content. For English, since we were interested in ironic tweets for our annotation purpose, we stopped collecting messages when the number of ironic tweets was sufficient; this ex-

plains the fact that classes of Ironic and Not Ironic tweets in the English dataset are pretty balanced, i.e. the amount of ironic tweets is not very low compared with the amount of not ironic ones.

Italian data are instead extracted from two existing annotated data: the Sentipolc corpus, released for the shared task on sentiment analysis and irony detection in Twitter at Evalita 2014 (Basile et al., 2014), and TW-SPINO which extends the Spinoza section of the Senti-TUT corpus (Bosco et al., 2013). The Sentipolc dataset is a collection of Italian tweets derived from two existing corpora Senti-TUT and TWITA (Basile and Nissim, 2013). It includes Twitter data exploiting specific keywords and hashtags marking political topics. In Sentipolc, each tweet has an annotation label among five mutually exclusive labels: positive opinion, negative opinion, irony, both positive and negative, and objective. TW-SPINO instead is from the Twitter section of Spinoza<sup>1</sup>, a popular collective Italian blog that publishes posts with sharp satire on politics. Since there is a collective agreement about the fact that these posts include irony mostly about politics, they represent a natural way to extend the sampling of ironic expressions. Moreover, while Sentipolc collects tweets spontaneously posted by Italian Twitter users, Spinoza’s posts are selected and revised by an editorial staff, which explicitly characterize the blog as satiric. Such difference will possibly have a reflection on the types and variety of irony we detect in the tweets.

### 3 A multi-layered annotation schema for irony in social media

To define our annotation schema, we analyzed the different categories of irony studied in the linguistic literature. Several categories have been proposed, as shown in the first column of Table 2. Since all these categories have been found in a specific genre (literary texts), the first step was to check their presence on a small subset of 150 ironic tweets from our corpus. Three observations resulted from this first step, regarding irony activation, irony categories, and irony markers.

#### 3.1 Irony activation

We observed that incongruity in ironic tweets often consists of at least two propositions (or words)  $P_1$  and  $P_2$  which are in contradiction to each other

(i.e.  $P_2 = \text{Contradiction}(P_1)$ ). It is the presence of this contradiction that activates irony. This contradiction can be at a semantic, veracity or intention level.  $P_1$  and  $P_2$  can be both part of the internal context of an utterance (that is explicitly lexicalized), or one is present and the other one implied. We thus defined two types of irony activation: EXPLICIT and IMPLICIT.

In EXPLICIT activation, one needs to rely exclusively on the lexical clues internal to the utterance, like in (1) where there is a contrast between  $P_1$  that contains no opinion word, and  $P_2$  which refers to a situation which is commonly judged as being negative, but in a communicative context which is clearly unsuitable w.r.t. to the one expressed in  $P_1$ .

(1) *L’Italia [attende spiegazioni] $_{P_1}$  da così tanti paesi che comincio a pensare che le nostre richieste [finiscano nello spam] $_{P_2}$ .*  
(Italy is [waiting for explanations] $_{P_1}$  from so many countries that I suspect our requests are being [labeled as spam] $_{P_2}$ .)

Example (2) shows another example of explicit semantic contradiction between  $P_1$  and  $P_2$ .

(2) *Ben non ! [Matraquer et crever des yeux] $_{P_1}$ , [ce n’est pas violent et ça respecte les droits] $_{P_2}$  !!! #ironie*  
(Well, no ! [Clubbing and putting up eyes] $_{P_1}$ , [it is not violent and it does respect human rights] $_{P_2}$  !!! #irony)

On the other hand, IMPLICIT activation arises from a contradiction between a lexicalized proposition  $P_1$  describing an event or state and a pragmatic context  $P_2$  external to the utterance in which  $P_1$  is false, not likely to happen or contrary to the writer’s intention. The irony occurs because the writer believes that his audience can detect the disparity between  $P_1$  and  $P_2$  on the basis of contextual knowledge or common background shared with the writer. For example, in (3), the negated fact in  $P_1$  helps to recognize that the tweet is ironic.

(3) *La #NSA a mis sur écoute un pays entier. Pas d’inquiétude pour la #Belgique: [ce n’est pas un pays entier.] $_{P_1}$  #ironie*  
(The #NSA wiretapped a whole country. No worries for #Belgium: [it is not a whole country.] $_{P_1}$  #irony)  
→  $P_2$ : Belgium is a country.

<sup>1</sup><http://www.spinoza.it/>

State of the art irony categories	Our categories	Usage
<i>Metaphor</i> (Ritchie, 2005; Burgers, 2010)	Analogy <sup>Both</sup> : Metaphor and Comparison	Covers analogy, simile, and metaphor. Involves similarity between two things that have different ontological concepts or domains, on which a comparison may be based
<i>Hyperbole</i> (Berntsen and Kennedy, 1996; Mercier-Leca, 2003; Didio, 2007)	Hyperbole/ Exaggeration <sup>Both</sup>	Make a strong impression or emphasize a point
<i>Exaggeration</i> (Didio, 2007)		
<i>Euphemism</i> (Muecke, 1978; Seto, 1998)	Euphemism <sup>Both</sup>	Reduce the facts of an expression or an idea considered unpleasant in order to soften the reality
<i>Rhetorical question</i> (Barbe, 1995; Berntsen and Kennedy, 1996)	Rhetorical question <sup>Both</sup>	Ask a question in order to make a point rather than to elicit an answer ( $P_1$ : asking a question to have an answer, $P_2$ : no intention to have an answer because it is already known)
<i>Context shift</i> (Haiman, 2001; Leech, 2016)	Context Shift <sup>Exp</sup>	A sudden change of the topic/frame, use of exaggerated politeness in a situation where this is inappropriate, etc.
<i>False logic or misunderstanding</i> (Didio, 2007)	False assertion <sup>Imp</sup>	A proposition, fact or an assertion fails to make sense against the reality
<i>Oxymoron</i> (Gibbs, 1994; Mercier-Leca, 2003)	Oxymoron/ paradox <sup>Exp</sup>	Equivalent to “False assertion” except that the contradiction is explicit
<i>Paradox</i> (Tayot, 1984; Barbe, 1995)		
<i>Situational irony</i> (Shelley, 2001; Niogret, 2004)	Other <sup>Both</sup>	Humor or situational irony (irony where the incongruity is not due to the use of words but to a non intentional contradiction between two facts or events)
Surprise effect, repetition, quotation marks, emoticons, exclamation, capital letter, crossed-out text, special signs (Haiman, 2001; Burgers, 2010)	Markers	Words, expressions or symbols used to make a statement ironic

Table 2: Irony categories in our annotation schema.

Note that inferring irony in both types of activation requires some pragmatic knowledge. However, in case of IMPLICIT, the activation of irony happens *only* if the reader knows the context. To help annotators identify irony activation type, we apply the following rule: if  $P_1$  and  $P_2$  can be found in the tweet, then EXPLICIT, otherwise IMPLICIT.

### 3.2 Irony categories

Both explicit and implicit activation types can be expressed in different ways which we call irony categories. After a thorough inspection of how categories have been defined in linguistic literature, some of them were grouped, like *hyperbole* and *exaggeration*, as we observed that it is very difficult to distinguish them in short messages. We also discarded others, since we considered them as markers rather than irony categories (see the last row in Table 2). We finally retain eight categories, as shown in Table 2: Five are more likely to be found in both types of activation (marked *Both*) while three may occur exclusively in a specific type (marked *Exp* for explicit or *Imp* for implicit).

Categories are not mutually exclusive. Example (5) shows a case of implicit irony activation where the user uses a false assertion  $P_1$  and two rhetorical questions.

(5) @infos140 @mediapart Serge Dassault ?

*Corruption ? Non ! Il doit y avoir une erreur. [C'est l'image même de la probité en politique] $_{P_1}$  #ironie.*

*(@infos140 @mediapart Serge Dassault? Corruption? No ! There must be an error. [He is the perfect image of probity in politics] $_{P_1}$  #irony) →  $P_2$ : Serge Dassault is involved and has been sentenced in many court cases.*

### 3.3 Irony markers

As shown in Table 2, linguistic literature considers other forms of irony categories, such as surprise effect, repetition, etc. Having a computational perspective in mind, we preferred to clearly distinguish between *categories of irony* which are pragmatic devices of irony as defined in the previous section, and *irony markers* which are a set of tokens (words, symbols, propositions) that may activate irony on the basis of the linguistic content of the tweet only. This distinction is also motivated by the fact that markers can either be present in distinct irony categories, not present at all, or present in non ironic tweets as well.

Eighteen markers have been selected for our study. Some of them have shown their effectiveness when used as surface features in irony detection such as punctuation marks, capital letters, reporting speech verbs, emoticons, interjections,

negations, opinion and emotion words (Davidov et al., 2010; Gonzalez-Ibanez et al., 2011; Reyes et al., 2013; Karoui et al., 2015). We investigate in addition novel markers (cf. Table 5): **discourse connectives** as they usually mark oppositions, argumentation chains and consequences; **named entities** and **personal pronouns**, as we assume they can be an indicator of the topic discussed in the tweet (media topic vs. a more personal tweet); **URLs** as they give contextual information that may help the reader to detect irony; and finally **false propositions**. These last four markers might be good features for an automatic detection of implicit irony, for example by detecting that an external context is needed. For example, in (2) markers are negations (*no, not*), punctuation (*!, !!!*), opinion word (*violent*) whereas in (3) markers are named entities (*NSA, Belgium*), negation (*no, not*) and false proposition (*it is not a whole country*).

#### 4 Annotation procedure

For each tweet  $t$ , the annotation works as follows<sup>2</sup>:

- (a) Classify  $t$  into *Ironic/Not ironic*. In case annotators do not understand the tweet because of cultural references or lack of background knowledge,  $t$  can be classified into the *No decision* class. Note that this third class concerns only French and English corpora since the Italian corpus already has annotations for irony (cf. Section 2).
- (b) If  $t$  is ironic, define its activation type: Can  $P_1$  and  $P_2$  be found in the tweet? If *yes* then *explicit*, otherwise *implicit*. Then specify the pragmatic devices used to express irony by selecting one or several categories.
- (c) Identify text spans within the tweet that correspond to a pre-defined list of linguistic markers. Markers are annotated whatever the class of  $t$ . This is very important for analyzing the correlation between ironic (vs. non ironic) readings and the presence (vs. absence) of these markers.

Linguistic markers were automatically identified relying on dedicated resources for each language (opinion and emotion lexicons, intensifiers, interjections, syntactic parsers for named entities, etc.).

<sup>2</sup>The annotation manual is available at: [github.com/IronyAndTweets/Scheme](https://github.com/IronyAndTweets/Scheme)

In case of missing markers or erroneous annotations, automatic annotations were manually corrected. Also, to ensure that the annotations were consistent with the instructions given in the manual, common errors are automatically detected: ironic tweets without activation type or irony category, absence of markers, etc. Annotators were asked to correct their errors before continuing to annotate new tweets.

In order to evaluate the stability of the schema regarding language variations, we considered first the French set with a total of 2,000 tweets. Such tweets have been randomly selected from the ones collected as described in Section 2. In order to be sure to have a significant amount of ironic samples, 80% of the total tweets to be manually annotated were selected from the ironic set (i.e. tweets explicitly marked with hashtags like #ironie and #sarcasme)<sup>3</sup>. Three French native speakers were involved. The annotation of the French corpus followed a three-step procedure where an intermediate analysis of agreement and disagreement between the annotators was carried out. Annotators were first trained on 100 tweets, then were asked to annotate separately 300 tweets (this step allows to compute inter-annotator agreements, cf. next section), to finally annotate 1,700 tweets. In the last step, a revised version of the schema was provided. The adjudicated annotations performed in the second step are part of the corpus.

Then we annotated the English and Italian sets in two steps. First, a training phase (100 tweets each) and then the effective annotation, with respectively 550 and 500 tweets. Four native speakers were involved: two for English and two for Italian. All annotators are skilled in linguistics, researchers and PhD students in computational linguistics.

#### 5 Qualitative results

We report on the reliability of the annotation schema on the French data. Among 300 tweets, annotators agreed on 255 tweets (174 ironic and 63 not ironic), among which 18 have been classified as *No decision*. We get a Cohen's Kappa of 0.69 for *Ironic/Not ironic* classification which is a

<sup>3</sup>Notice that at this stage such hashtags have been removed, and manual annotation have been applied to 2,000 tweets for all the layers foreseen by our schema. In this way, the reliability of self-tagging has been confirmed, and it was possible to identify the presence of irony also in tweets where it was not explicitly marked by hashtags.

very good score. When compared to gold standard labels, we also obtained a good Kappa measure (0.62), which shows that French irony hashtags are quite reliable. We also noticed that more than 90% of the tweets annotated as *No decision* due to the lack of external context, are in fact ironic according to gold labels. We however decided to keep them for the experiments.

For EXPLICIT vs. IMPLICIT, agreement on activation type knowing the tweet ironic obtained a Kappa of 0.65. It was interesting to note that implicit activation is the majority (76.42%). We observed the same tendency in the other languages too (cf. next section). This is an important result that shows that annotators are able to identify which are the textual spans that activate the incongruity in ironic tweets, whether explicit or implicit, and we expect automatic systems to do as good as humans, at best.

Finally, for irony category identification, since the same ironic tweet can belong to several irony categories, we computed agreements by counting, for each tweet, the number of common categories and then dividing by the total number of annotated categories. We obtained 0.56 which is moderate. This score reflects the complexity of the identification of pragmatic devices. When similar devices are grouped together (mainly hyperbole/exaggeration and euphemism, as they are used to make the intended meaning either stronger or weaker), the score increases to 0.60.

## 6 Quantitative results

The main aim of our corpus-based study is to verify if the different linguistic theories and definitions made on irony can be applied to social media, especially to tweets, and to study its portability to several languages. Besides standard frequencies, we provide the correlations between irony activation types and markers and between categories and markers in order to bring out features that could be used in a perspective of automatic irony detection. In each corpus, all the frequencies presented here are statistically significant from what would be expected by chance using the  $\chi^2$  test ( $p < 0.05$ ).

Table 3 gives the total number of annotated tweets and the activation type for ironic tweets. We observe that most irony activation types in the French and English corpora are implicit with respectively 73.01% and 66.28% while in the Italian corpus, explicit activation is the majority. Notice

that the fact the analysis of the Italian dataset results in a different tendency on this respect can be possibly related to the absence of user-generated ironic hashtags, while user explicitly mark the intention to be ironic (see Section 2).

	Ironic		Non Ironic	No decision	Total
	explicit	implicit			
F	394	1066	380	160	2000
E	144	283	99	24	550
I	260	140	100	–	500

Table 3: Number of tweets in annotated corpora in French (F), English (E) and Italian (I).

Table 4 gives the percentage of tweets belonging to each category of irony split according to explicit vs. implicit activation, when applicable. Higher frequencies are in bold font. We note that *oxymoron/paradox* is the most frequent category for explicit irony in French, English and Italian. Concerning implicit irony, *false assertion* and *other* are the most frequent categories in French and English (*other* is the most frequent one in English because a majority of implicit ironic tweets use situational irony, e.g. *Libertarian Ron Paul condemns Bill Clinton for taking advantage of 20y/o but would not support any law to protect her. #Monica*). In Italian, *false assertion*, *analogy* and *other* are the most frequent categories. As classes are not mutually exclusive, there are 64/38 tweets (resp. in French and English) that belong to more than one category for explicit contradiction. The most frequent combinations are *oxymoron/rhetorical question* and *oxymoron/other* for both English and French; *oxymoron/hyperbole* for French and *oxymoron/analogy* for English. Concerning implicit activation, there are 134/62 tweets (resp. in French and English) that belong to more than one category. The most frequent combinations are *false assertion/other* and *false assertion/hyperbole* for both English and French; and *analogy/other* for English<sup>4</sup>.

Table 5 provides the percentage of tweets containing markers for ironic (explicit or implicit) and non ironic tweets (row in gray). In French, intensifiers, punctuation marks and interjections are more frequent in ironic tweets whereas quotations are more frequent in non ironic tweets. In English, discourse connectors, quotations, comparison words and reporting speech verbs are twice as

<sup>4</sup>For what concerns Italian, at the current stage, only the category considered prevalent for implicit/explicit irony activation was annotated.

	Analogy			Context shift			Euphemism			Hyperbole			Rhetorical question			Oxymoron			False assertion			Other		
	F	E	I	F	E	I	F	E	I	F	E	I	F	E	I	F	E	I	F	E	I	F	E	I
<b>Ex</b>	12	17	21	1	6	19	1	1	5	8	2	9	10	15	10	<b>66</b>	<b>81</b>	<b>28</b>	-	-	-	21	6	7
<b>Im</b>	2	13	<b>26</b>	-	-	-	1	1	4	10	7	5	14	1	12	-	-	-	<b>56</b>	20	<b>34</b>	<b>32</b>	<b>65</b>	<b>19</b>

Table 4: Categories in explicit (*Ex*) or implicit (*Im*) activation in French, English and Italian (in %).

frequent in ironic tweets as in non ironic tweets whereas is it the opposite for personal pronouns. Note that there is no English ironic tweet containing URL since they were all annotated as *no decision* because of a lack of knowledge from the annotators who did not understand the tweet and the Web page pointed by the URL. In Italian, most of markers are more frequent in ironic tweets, while some, like quotations and URL, are more frequent in non ironic tweets<sup>5</sup>.

Our study of negation as an irony marker actually considers negation words like *no* and *not* as well as periphrastic forms of negation such as *ne ... pas* in French. We however excluded lexical negations such as *unreliable*, *unhappy*, *etc.* We will further refine our analysis by considering more words that introduce negation. Also, regarding personal pronouns, they are more common in French and English than in Italian. Italian being a pro-drop language can in part motivate the difference detected with respect to pronouns.

Then, we investigated the correlation between irony markers and irony activation types (resp. between irony markers and irony categories). Our aim is to analyze to what extent these markers can be indicators for irony prediction. Using the Cramer’s V test (Cohen, 1988) on the number of occurrences of each marker, we found a statistically significant ( $p < 0.05$ ) large correlation between markers and ironic/not ironic class for French ( $V = 0.156$ ,  $df = 14$ ) and Italian ( $V = 0.31$ ,  $df = 6$ ); between medium and large for English ( $V = 0.132$ ,  $df = 9$ ). We also found a large correlation between markers and irony activation types for French ( $V = 0.196$ ,  $df = 16$ ), between medium and large for Italian ( $V = 0.138$ ,  $df = 5$ ) and medium for English ( $V = 0.083$ ,  $df = 12$ ).<sup>6</sup>

We also analyzed the correlations per marker ( $df=1$ ). The markers which are the most corre-

<sup>5</sup>For Italian, only values for markers automatically identified reliably, without need of manual correction, are reported (e.g. emoticons, negations). Values for other markers are currently missing since they require a manual check, for instance the case of capital letters, because of the presence in the Italian corpus where all the letters are capital.

<sup>6</sup>For both settings, frequencies  $< 5$  were removed.

lated to ironic/non ironic class are: negations, interjections, named entities and URL for French ( $0.140 < V < 0.410$ ); negations, discourse connectors and personal pronouns for English ( $0.120 < V < 0.170$ ); and quotations, named entities and URL for Italian ( $0.310 < V < 0.416$ ). The markers which are the most correlated to explicit/implicit activation are: opposition markers, comparison words and false assertion for French ( $0.140 < V < 0.190$ ); opposition markers and discourse connectors for English ( $0.110 < V < 0.120$ ); and discourse connectors, punctuation and named entities for Italian ( $0.136 < V < 0.213$ ). Note that even if opinion words are very frequent in ironic tweets, they are however not correlated with either irony/non irony classification or explicit/implicit activation ( $V < 0.06$ ), as many non ironic tweets also contain sentiment words.

Finally, when analyzing which markers are correlated to irony categories, the more discriminant markers are: intensifiers, punctuation, false assertion and opinion words for French (large Cramer’s V); negations, discourse connectors and personal pronouns for English (medium Cramer’s V); and punctuation, interjections and named entities for Italian (medium Cramer’s V).

## 7 Related work

Most state of the art approaches rely on automatically built social media data collections to detect irony using a variety of features gleaned from the utterance-internal context going from n-gram models, stylistic, to dictionary-based features (Burfoot and Baldwin, 2009; Davidov et al., 2010; Tsur et al., 2010; Gonzalez-Ibanez et al., 2011; Liebrecht et al., 2013; Joshi et al., 2015; Hernández Farías et al., 2015). In addition to the above more lexical features, many authors point out the contribution of pragmatic features, such as the use of common vs. rare words or synonyms (Barbieri and Saggion, 2014). Recent work explores other kinds of contextual information like author profiles, conversational threads, or querying external sources of information (Bamman and Smith, 2015; Wallace et al., 2015; Karoui et al.,

Table 6: Percentage of tweets in each ironic category containing markers in French, English and Italian.

2015).

Compared to automatic irony detection, little efforts have been done on corpus-based linguistic study of irony. Most of these efforts focus on analyzing the impact of irony in feeling expressions and emotions, by manually annotating tweets at both sentiment polarity and irony levels. E.g. Van Hee et al. (2016) distinguish between ironic, possibly ironic, and non-ironic tweets in English and Dutch. For ironic statements, polarity change that causes irony was annotated to specify whether the change comes from an opposition explicitly marked by a contrast between a positive situation and a negative one, an hyperbole, or an understatement. Stranisci et al. (2016) recently extend the Italian Senti-TUT schema (cf. Section 2) to mark the aspects of the topic being discussed in the tweet, as well as the sentiment expressed towards each aspect. Bosco et al. (2016) propose a second extension with the annotation of French tweets using three labels: positive irony, negative irony, and metaphorical expression.

Current state of the art corpus-based studies are mainly oriented to a sentiment analysis perspective on irony, focusing almost exclusively on cap-

turing tweet’s overall sentiment, explicit polarity change, or syntactic irony patterns. We argue in this paper that irony should instead be an object of study by its own by proposing a more linguistic perspective in order to provide a deeper inspection of what are the inferential mechanisms that activate irony, either explicit or implicit, and the correlations between irony types and irony markers. As far as we know, this is the first study that investigates the portability of a wide-range of pragmatic devices in the interpretation of irony to social media data from a multilingual perspective.

## 8 Exploiting the annotated corpus for automatic irony detection

The French and Italian parts of the annotated corpus have been respectively exploited as datasets for the first irony detection shared tasks DEFT@TALN2017<sup>7</sup> and for the SENTIPOLC@Evalita shared task on irony detection<sup>8</sup> in both 2014 and 2016 editions (Basile et al., 2014; Barbieri et al., 2016). In particular, currently only the first layer of the annotation scheme has been

<sup>7</sup><https://deft.limsi.fr/2017/>

<sup>8</sup><http://di.unito.it/sentipolc16>

exploited aiming at detecting if a given tweet is ironic or not. The French task is ongoing. For what concerns Italian, in Sentipolc the irony detection task is one three related but independent sub-tasks focusing on subjectivity, polarity and irony detection, respectively. All tweets of the campaign are, therefore, annotated by a multi-layered annotation scheme including tags for all the three dimensions and available on the Task's website. In 2016 SENTIPOLC has been the most participated EVALITA task with a total of 57 submitted runs from 13 different teams. Not surprisingly, results of the 12 systems evaluated for irony detection seem to suggest that the task appears truly challenging. However, organizers observe that its complexity does not depend (only) on the inner structure of irony, but on unbalanced data distribution in Sentipolc (1 out of 7 examples is ironic in the training set, as they reflect the distribution in a realistic scenario) and on the overall availability of a limited amount of examples (probably not sufficient to generalise over the structure of ironic tweets). The plan is to organize an irony detection dedicated task including a larger and more balanced dataset of ironic tweets in future campaigns. In this perspective, it will be also interesting to investigate if the finer-grained annotation layers for irony proposed here can have a role in the annotation scheme proposed for the new task data.

## 9 Conclusion and future work

In this paper, we proposed a multi-layered annotation schema for irony in tweets and a multilingual corpus-based study for measuring the impact of pragmatic phenomena in the interpretation of irony. The results show that our schema is reliable for French and that it is portable to English and Italian, observing relatively the same tendencies in terms of irony categories and markers. We observed correlations between markers and ironic/non ironic classes, between markers and irony activation types (explicit or implicit) and between markers and irony categories.

These observations are interesting in a perspective of pragmatically and linguistically informed automatic irony detection, since it brings out the most discriminant features. On this line, we plan to accomplish a validation of the schema based on the definition of an automatic classification model built upon such annotated features. Moreover, an interesting challenge could be to apply the annota-

tion schema to a new language also less culturally close to those addressed in this work.

Finally, another perspective is to investigate how the application of our schema can contribute to shed light on the issue of distinguishing between irony and sarcasm. This issue is challenging, and only recently addressed from computational linguistics. In particular, new data-driven arguments for a possible separation between irony and sarcasm emerged from recent work on Twitter data (Sulis et al., 2016). It could be interesting to see the relation between the finer-grained and pragmatic phenomena related to irony investigated in the present study and the higher-level distinction between irony and sarcasm.

## Abstract

Sentiment Analysis is a broad task that involves the analysis of various aspect of the natural language text. However, most of the approaches in the state of the art usually investigate independently each aspect, i.e. Subjectivity Classification, Sentiment Polarity Classification, Emotion Recognition, Irony Detection. In this paper we present a Multi-View Sentiment Corpus (MVSC), which comprises 3000 English microblog posts related the *movie domain*. Three independent annotators manually labelled MVSC, following a broad annotation schema about different aspects that can be grasped from natural language text coming from social networks. The contribution is therefore a corpus that comprises five different views for each message, i.e. *subjective/objective*, *sentiment polarity*, *implicit/explicit*, *irony*, *emotion*. In order to allow a more detailed investigation on the human labelling behaviour, we provide the annotations of each human annotator involved.

## 1 Introduction

The exploitation of user-generated content on the Web, and in particular on the social media platforms, has brought to a huge interest on Opinion Mining and Sentiment Analysis. Both Natural Language Processing (NLP) communities and corporations are continuously investigating on more accurate automatic approaches that can manage large quantity of noisy natural language texts, in order to extract opinions and emotions towards a topic. The data are usually collected from Twitter, the most popular microblogging platform. In this particular environment, the posts, called tweets,

are constrained to a maximum number of characters. This constraint, in addition to the social media context, leads to a specific language rich of synthetic expressions that allow the users to express their ideas or what happens to them in a short but intense way.

However, the application of automatic sentiment classification approaches, in particular when dealing with noisy texts, is subjected to the presence of sufficiently manually annotated dataset to perform the training. The majority of the corpora available in the literature are focused on only one (or at most two) aspects related to Sentiment Analysis, i.e. Subjectivity, Polarity, Emotion, Irony.

In this paper we propose a Multi-View Sentiment Corpus<sup>1</sup>, manually labelled by three independent annotators, that makes possible to study Sentiment Analysis by considering several aspects of the natural language text: *subjective/objective*, *sentiment polarity*, *implicit/explicit*, *irony* and *emotion*.

## 2 State of the Art

The work of Go et al. (2009) was the first attempt to address the creation of a sentiment corpus in a microblog environment. Their approach, introduced in (Read, 2005), consisted to filter all the posts containing emoticons and subsequently label each post with the polarity class provided by them. For example, :) in a tweet indicates that the tweet contains positive sentiment and :( indicates that the tweet contains negative sentiment. The same procedure was also applied in (Pak and Paroubek, 2010), differently from the aforementioned works they introduced the class of objective posts, retrieved from Twitter accounts of popular newspapers and magazines. Davidov et

<sup>1</sup>The proposed corpus is available at [www.mind.disco.unimib.it](http://www.mind.disco.unimib.it)

al. (2010) maintained the idea of distant supervision by combining 15 common emoticons and 50 sentiment-driven hashtags for automatic labelling. However, an intervention of human experts was needed to annotate the sentiment of frequent tags. Kouloumpis et al. (2011) extended their work in order to perform a 3-way polarity classification (positive, negative and neutral) on the Edinburgh Twitter corpus (Petrović et al., 2010).

Mohammad (2012) and Wang et al. (2012) applied the same distant supervision approach for the construction of a large corpus for emotion classification. They collect the data retrieving tweets by considering as keywords a predefined list of emotion hashtags. In (Mohammad, 2012), the authors used the Ekman's six basic emotions (#anger, #disgust, #fear, #joy, #sadness, and #surprise), while in (Wang et al., 2012) the authors expanded this list by including both basic and secondary emotions and their lexical variants, for a total of 131 keywords.

Hashtags have also been used to create datasets for irony detection purposes. The work of Reyes et al. (2013) proposed a corpus of 40000 tweets, 10000 ironic and 30000 non ironic tweets respectively retrieved with the hashtags #irony for the former and #education, #humor, #politics for the latter.

However, each of these resources have been created either fully automatically or in a semi-supervised way based on the assumption that single words and symbols are representative of the whole document. Moreover, the use of hashtags and emoticons for exploiting distant-supervision approaches can definitely create a bias towards posts that do not use these forms of expression to communicate opinions and emotions. Adopting a manual annotation approach is crucial for dealing with these issues and obtaining high quality labelling. In this direction the SemEval corpora (Nakov et al., 2013; Rosenthal et al., 2014; Nakov et al., 2016) have provided a fundamental contribution. These datasets have been labelled by taking advantage of crowdsourcing platforms, such as Amazon Mechanical Turk and CrowdFlower. Although the size of these corpora is very high (around 15-20K posts), Mozetič et al. (2016) overly exceeded these dimensions proposing a set of over 1.6 million sentiment labelled tweets. This corpus, that is the largest manually-labelled dataset reported in the literature, was an-

notated in 13 European languages.

Regarding emotion classification, Roberts et al. (2012) introduced a corpus of tweets manually labelled with the Ekman's six basic emotions and love. In (Liew et al., 2016), the authors extended their work by considering a fine-grained set of emotion categories to better capture the richness of expressed emotions.

The only manually-annotated corpus on irony detection was proposed by (Gianti et al., 2012). They studied the use of this particular device on Italian tweets, focusing on the political domain.

In this paper, we present a Multi-View Sentiment Corpus (MSVC) on English microblog posts that differs from the state of the art corpora for several reasons:

- The proposed corpus is the first benchmark that collects implicit or explicit opinions. This contribution will allow researchers to develop sentiment analysis approaches able to model opinions not directly expressed.
- The corpus provides different annotations simultaneously: subjectivity/objectivity, polarity, implicitness/explicitness, emotion, irony. This characteristic allows researchers to perform wide-ranging studies on the users' opinions, instead of considering each of this view as independent from the others.
- The corpus will show the label provided by each annotator, instead of producing a final label obtained by a majority voting rule. Given the different expertise of the annotators involved, a detailed investigation on single behaviours can be performed to improve the knowledge about the annotation procedures.
- This is the first corpus that explicitly labels emojis. We aim to prove that the role of the emojis is strictly related to the context where they appear: their contribution in terms of conveyed sentiment (or conveyed topic) strictly depends on the domain where they are used.

### 3 Annotation Procedure

The corpus has been annotated by considering different views related to the same post: subjectivity/objectivity, polarity, implicitness/explicitness, presence of irony and emotion. In this section, we provide a definition and examples for each of these

views. Moreover, we present the characteristics of the annotators in order to have more insights on their behaviour.

### 3.1 Annotation of Subjectivity/Objectivity

Given a post  $p$  about a given topic  $t$ , its subjectivity or objectivity can be defined as follows (Liu, 2012):

**Definition 1.** An *objective* post  $p_o$  presents some factual information about the world, while a *subjective* post  $p_s$  expresses some personal feelings, views, or beliefs.

In microblogs contexts the recognition of objective posts can be easily misled by the presence of hashtags and other linguistic artefacts that aim to show the post as more appealing. The reported examples are very similar, despite they belong to different classes:

[Objective] “Tonight @CinemaX #SuicideSquad!! Come to see #HarleyQuinn :)”

[Subjective] “-1 to #Deadpool...that’s tomorrow!!!! I can’t wait!”

### 3.2 Annotation of polarity

Given a subjective post  $p_s$  that expresses an opinion about a topic  $t$ , we want to determine its polarity between positive, negative and neutral classes. While the definition of positive and negative classes is commonly clear, the neutral label is differently treated in the state of the art. As in Pang and Lee (2008), we use neutral only in the sense of a sentiment that lies between positive and negative.

Posts that express a sentiment about specific aspects of a given topic  $t$ , such as actors, scenes, commercials for a film are considered part of the topic. Moreover, it is important to understand what is the target of the opinion, because it can lead to completely different interpretations.

[Positive] “Best Joker EVER!! #suicidesquad”

[Negative] “Deadpool is so childish! I slept during the movie”

[Neutral] “Good movie, @VancityReynolds worst actor ever #deadpool” (neutral - mixed sentiment)

[Neutral] “I love my boyfriend! We are watching deadpool tonight” (positive about the boyfriend - neutral about the film)

### 3.3 Annotation of explicit/implicit opinion

Given a subjective post  $p_s$  that expresses an opinion about a topic  $t$ , we can define its implicitness or explicitness as follows (Liu, 2012):

**Definition 2.** An *explicit opinion* is a subjective statement that gives an opinion.

**Definition 3.** An *implicit (or implied) opinion* is an objective statement that implies an opinion. Such an objective statement usually expresses a desirable or undesirable fact.

The detection of an implicit opinion can be complex because it does not rely on specific words (e.g. amazing, awful), as in the following examples:

[Explicit - Positive] “Suicide Squad is a great movie and an awesome cast”

[Implicit - Positive] “I’ve already watched Deadpool three times this month”

[Implicit - Negative] “I went out the cinema after 15 minutes #suicidesquad”

### 3.4 Annotation of Irony

Given a subjective post  $p_s$  that expresses an opinion about a topic  $t$ , the presence of irony can be detected focusing on the definition given by Wilson and Sperber (2007):

**Definition 4.** *Irony* is basically a communicative act that expresses the opposite of what is literally said.

Irony is one of the most difficult figurative language to comprehend, and a person can perceive it differently depending on several factors (e.g. culture, language).

[Ironic] “Hey @20thcenturyfox remember when you didn’t want anything to do with #Deadpool and now it’s your biggest opening weekend ever?”

### 3.5 Annotation of Emotion

A post  $p$  about the topic  $t$  can be associated to an emotion  $e$  corresponding to the eight Plutchik primary emotions (shown in Figure 1): anger, anticipation, joy, trust, fear, surprise, sadness and disgust. We provide an example for each emotion.

[Anger] “#Deadpool I wasted time and money grrrrrrrr”

[Anticipation] “Can’t wait to see Deadpool”

[Joy] “Deadpool was A-M- A-Z- I-N- G”

[Trust] “Best movie ever #Deadpool! Trust me!”

[Fear] “Saw #Deadpool last night. I was frightened during some crude scenes!”

[Surprise] “Much to my surprise, I actually liked *Deadpool*.”

[Sadness] “i finally got to watch *deadpool* and im so sad this is so boring”

[Disgust] “*Deadpool* is everything I hate about our century combined in the trashiest movie possible.”

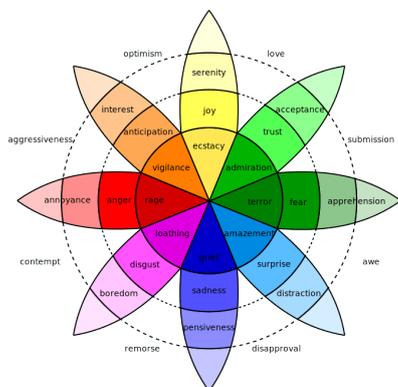

Figure 1: Plutchik’s wheel of emotions.

### 3.6 Annotation of Emojis

Given a post  $p$  related to a specific topic  $t$ , each emoji (if present) has been labelled as *positive*, *negative*, *neutral* or *topic-related* according to the context where it has been used. We provide an example for each label.

[Positive] “Love Jared Leto 🤩❤️”

[Negative] “*SuicideSquad* was awful 🤮”

[Neutral] “#*SuicideSquad*...Still thinking 🤔”

[Topic] “*Deadpool* today !! 🍷👤🎥”

### 3.7 Annotators

The complete set of posts has been labelled by three different annotators. Each annotator is a very proficient English speaker and he/she has a different level of NLP background and topic knowledge from the others. We distinguish these two types of knowledge because they are equally important and necessary for annotating a dataset, especially in a movie domain. A topic expert can be very confident on understanding the meaning of the text, but without any NLP knowledge he/she would not be able to perform a confident annotation, especially when dealing with the implicitness/explicitness and subjectivity/objectivity labels. On the other hand, being only a NLP expert

is not sufficient when in the text subtle and sophisticated references to the topic are present, resulting in an incorrect annotation because of an improper understanding.

The first annotator  $A_1$  is a NLP expert while he/she is not very confident on the topic selected, the second annotator  $A_2$  has a good expertise in NLP and a good knowledge about the topic, the third annotator  $A_3$  is a beginner in the field of NLP but he/she is competent on the topic.

## 4 Dataset

The data has been retrieved by monitoring different keywords on the Twitter microblogging platform related to two popular movies: *Deadpool* and *Suicide Squad*. This choice was motivated by the intention to increase the number of opinionated posts and therefore to have a variety of aspects to be analysed. Also, both the movies were massive blockbuster successes with popular actors and this led to a very wide and diverse audience.

This case study is experimentally convenient for our purposes because it represents a domain where people are more willing to express opinions, so that the final corpus will have a variety of opinionated tweets expressed in diverse ways. The collection of the data has been performed in the narrow days of the release date, *Deadpool* 18<sup>th</sup> February 2016 and *Suicide Squad* 1<sup>th</sup> August 2016.

After the streaming collection phase, we filter out the non-English tweets, duplicates and retweets resulting in a dataset of millions of posts. Then, we randomly sampled 3000 tweets equally distributed between the topics, maintaining the original daily distribution. This sample has been manually annotated, obtaining a final corpus composed of 1500 posts about *Deadpool* and 1500 posts about *Suicide Squad*.

On average, a tweet is composed of about 14 words of which one is a hashtag. Although this number can lead to conclude that hashtags are an important language expression and therefore they can be used for automatically collecting opinions and emotions, we found that most of them are strongly related only to the topic, e.g. #ShowTimeAtGC, #Joker, #HarleyQuinn, #DC. A preliminary analysis of the user mentions has shown that users are inclined to directly mention the actors or the entertainment companies for complaining or complimenting, and this, together with hashtags, can be particularly helpful when per-

forming aspect-based sentiment analysis.

Regarding emojis, the most frequent ones are (as expected) sentiment-driven, i.e. joy, heart eyes, sob.

## 5 Annotation Evaluations

The annotation of emotions, sentiment and other emotional aspects in a microblog message is not an easy task, and strongly depends on subjective judgement of human annotators. Annotators can disagree between themselves, and sometimes an individual cannot be consistent with her/himself. The disagreement depends on the complexity of the annotation task, the use of complex language (e.g., slang), or simply on the poor annotator work.

Table 1: Label distribution per annotator

	A <sub>1</sub>	A <sub>2</sub>	A <sub>3</sub>
<b>Subjective</b>	0.671	0.748	0.657
<b>Objective</b>	0.330	0.252	0.343
<b>None</b>	0.330	0.252	0.343
<b>Positive</b>	0.509	0.476	0.426
<b>Neutral</b>	0.038	0.146	0.131
<b>Negative</b>	0.123	0.126	0.100
<b>None</b>	0.330	0.252	0.343
<b>Explicit</b>	0.254	0.512	0.416
<b>Implicit</b>	0.416	0.236	0.242
<b>Not Ironic</b>	0.980	0.988	0.971
<b>Ironic</b>	0.020	0.012	0.029
<b>None</b>	0.374	0.355	0.507
<b>Joy</b>	0.317	0.328	0.243
<b>Anticipation</b>	0.144	0.108	0.078
<b>Disgust</b>	0.070	0.071	0.047
<b>Surprise</b>	0.038	0.024	0.038
<b>Sadness</b>	0.035	0.044	0.036
<b>Anger</b>	0.014	0.034	0.028
<b>Trust</b>	0.008	0.034	0.022
<b>Fear</b>	0.001	0.001	0.002

In Table 1, we report some statistics that summarize behaviours of the involved annotators. By analysing the distributions, we can observe different attitudes: A<sub>1</sub> is inclined to label more posts as positive against the neutral ones; A<sub>2</sub> shows a predisposition to identify a high number of explicit expressions; A<sub>3</sub> has a low sensibility to capture the emotions behind the text. Moreover, we can highlight a balanced distribution for implicit/explicit opinions.

For those tweets encoding one of the eight emotions, there is a predominance of the joy label. Concerning the remaining classes the distributions are skewed towards a specific label, i.e. Subjective, Positive and Not Ironic.

An analogous consideration can be drawn for the emoji distribution (see Table 2). It turns out that most of the emojis are positive, especially the most popular ones and their presence provide an insight of the human emotional perceptions.

Table 2: Emojii distribution

	A <sub>1</sub>	A <sub>2</sub>	A <sub>3</sub>
<b>Topic</b>	0.141	0.129	0.095
<b>Positive</b>	0.559	0.601	0.593
<b>Negative</b>	0.141	0.187	0.173
<b>Neutral</b>	0.160	0.083	0.139

By a detailed analysis of the emoji annotations, it emerges that the role of the emojis is closely related to the context where they appear: their contribution in terms of conveyed sentiment (or conveyed topic) strictly depends on the domain where they are used. In Table 3, we report a comparison between the label distribution of two emojis in our corpus and the corresponding distribution in a state of the art emoji sentiment lexicon (Novak et al., 2015).

In the proposed corpus, the *fire* emoji has been mainly labelled as positive because it represents the word “hot”, whose meaning is intended as something beautiful and trendy. However, in the emoji sentiment lexicon the same emoji primarily corresponds to a neutral sentiment. Similar considerations can be drawn for the *pistol* emoji: in our corpus it represents the topic underlying the two movies, while in the state of the art lexicon it is frequently used to denote a negative sentiment orientation. As conclusion, any emoji should be not considered as independent on the context and therefore evaluated according to its semantic.

### 5.1 Agreement Measures

The kappa coefficient (Cohen, 1960) is the most used statistic for measuring the degree of reliability between annotators. The need for consistency among annotators immediately arises due to the

Table 3: Emoji label distribution

			
Multi-View Sentiment Corpus	Topic	0.127	<b>0.476</b>
	Negative	0.079	0.143
	Neutral	0.111	0.190
	Positive	<b>0.683</b>	0.190
Emoji Sentiment Ranking (Novak et al., 2015)	Negative	0.124	<b>0.493</b>
	Neutral	<b>0.613</b>	0.209
	Positive	0.263	0.298

Table 4: Inter-agreement (PABAK-OS)

	Subjective/Objective	Sentiment Polarity	Implicit/Explicit	Irony	Emotion
$\mathbf{A}_1$ vs $\mathbf{A}_2$	0.606	0.598	0.354	0.949	0.590
$\mathbf{A}_2$ vs $\mathbf{A}_3$	0.670	0.596	0.476	0.923	0.601
$\mathbf{A}_1$ vs $\mathbf{A}_3$	0.592	0.585	0.416	0.912	0.551

Table 5: Self-agreement (PABAK-OS)

	Subjective/Objective	Sentiment Polarity	Implicit/Explicit	Irony	Emotion
$\mathbf{A}_1$	0.920	0.920	0.640	1.000	0.820
$\mathbf{A}_2$	0.878	0.867	0.670	0.960	0.865
$\mathbf{A}_3$	1.000	0.920	0.850	0.878	0.820

variability among human perceptions. This **inter-agreement** measure can be summarized as:

$$k = \frac{\text{observed agreement} - \text{chance agreement}}{1 - \text{chance agreement}} \quad (1)$$

However, considering only this statistic is not appropriate when the prevalence of a given response is very high or very low in a specific class. In this case, the value of kappa may indicate a low level of reliability even with a high observed proportion of agreement. In order to address these imbalances caused by differences in prevalence and bias, Byrt et al. (1993) introduced a different version of the kappa coefficient called prevalence-adjusted bias-adjusted kappa (PABAK). The estimation of PABAK depends solely on the observed proportion of agreement between annotators:

$$PABAK = 2 \cdot \text{observed agreement} - 1 \quad (2)$$

A more reliable measure for estimating the agreement among annotators is PABAK-OS (Parker et al., 2011), which controls for chance agreement. PABAK-OS aims to avoid the peculiar, unintuitive results sometimes obtained from Cohen’s Kappa, especially related to skewed annotations (prevalence of a given label).

We report in Table 4, the inter-agreement between couples of annotators distinguished for each label. We can easily note that the highest agreement is related to the irony/not-irony labelling. This is due to the predominance of non-ironic messages identified by all the annotators. Thus, we perform a detailed analysis on the disagreement between each couple of annotators regarding only the ironic messages. From the results, reported in Table 6, we can confirm that  $\mathbf{A}_1$  and  $\mathbf{A}_2$  annotators are more willing to interpret irony similarly (as already stated in Table 4).

Concerning the implicit/explicit labels, the inter-agreement measure highlights the difficulties

Table 6: Count of disagreement on the irony label

	Disagreement ( <i>irony</i> )
$\mathbf{A}_1$ vs $\mathbf{A}_2$	76
$\mathbf{A}_2$ vs $\mathbf{A}_3$	114
$\mathbf{A}_1$ vs $\mathbf{A}_3$	132

encountered by the annotators to distinguish “objective statements” (see Definition 1) from “objective statements that imply an opinion” (see Definition 3). Regarding the remaining labels, we can assert that there is a moderate agreement between the labellers. An analogous conclusion can be derived for the consensus about the emoji annotation, where the inter-agreement is 0.731 for  $\mathbf{A}_1$  vs  $\mathbf{A}_2$ , 0.771 for  $\mathbf{A}_2$  vs  $\mathbf{A}_3$ , and 0.647 for  $\mathbf{A}_1$  vs  $\mathbf{A}_3$ .

When dealing with complex annotations, the perception of the same annotator on the same post can change over time, resulting in inconsistent labelling. In order to estimate the uncertainty of the annotation of each labeller, we sampled a portion of tweets to be annotated twice by the same annotator. We report in Table 5 the **self-agreement** measure, that is a valid index to quantify the quality of the labelling procedure. The resulting statistics show that there is a high self-agreement for almost all the labels. The annotators can be considered moderately reliable for implicit/explicit annotations and very accurate for the remaining labels.

## 6 Conclusion

In this paper we presented a Multi-View Sentiment Corpus (MVSC), which simultaneously considers different aspects related to sentiment analysis, i.e. *subjectivity*, *polarity*, *implicitness*, *irony*, *emotion*. We described the construction of the corpus, together with annotation schema, statistics and some interesting remarks. The proposed corpus is aimed at providing a benchmark to develop sentiment analysis approaches able to model opinions not directly expressed. Researchers can also take advan-

tage of the complete label set given by the annotators to investigate their behaviours and the underlying annotation procedures. We finally provided some interesting conclusions related to the use of emojis, highlighting that their role is strictly related to the context where they appear. As future work, we aim at defining novel machine learning models able to simultaneously take advantage of the multiple views available. Moreover, an annotation scheme at a fine-grained level will be investigated.

## Abstract

Inferring implicit discourse relations in natural language text is the most difficult subtask in discourse parsing. Many neural network models have been proposed to tackle this problem. However, the comparison for this task is not unified, so we could hardly draw clear conclusions about the effectiveness of various architectures. Here, we propose neural network models that are based on feedforward and long-short term memory architecture and systematically study the effects of varying structures. To our surprise, the best-configured feedforward architecture outperforms LSTM-based model in most cases despite thorough tuning. Further, we compare our best feedforward system with competitive convolutional and recurrent networks and find that feedforward can actually be more effective. For the first time for this task, we compile and publish outputs from previous neural and non-neural systems to establish the standard for further comparison.

## 1 Introduction

The discourse structure of a natural language text has been analyzed and conceptualized under various frameworks (Mann and Thompson, 1988; Lascarides and Asher, 2007; Prasad et al., 2008). The Penn Discourse TreeBank (PDTB) and the Chinese Discourse Treebank (CDTB), currently the largest corpora annotated with discourse structures in English and Chinese respectively, view the discourse structure of a text as a set of discourse relations (Prasad et al., 2008; Zhou and Xue, 2012). Each discourse relation (e.g. causal or temporal) is grounded by a discourse connective (e.g. *because* or *meanwhile*) taking two text segments as argu-

ments (Prasad et al., 2008). Implicit discourse relations are those where discourse connectives are omitted from the text and yet the discourse relations still hold.

While classifying explicit discourse relations is relatively easy, as the discourse connective itself provides a strong cue for the discourse relation (Pitler et al., 2008), the classification of implicit discourse relations has proved to be notoriously hard and remained one of the last missing pieces in an end-to-end discourse parser (Xue et al., 2015). In the absence of explicit discourse connectives, implicit discourse relations have to be inferred from their two arguments. Previous approaches on inferring implicit discourse relations have typically relied on features extracted from their two arguments. These features include the Cartesian products of the word tokens in the two arguments as well as features manually crafted from various lexicons such as verb classes and sentiment lexicons (Pitler et al., 2009; Rutherford and Xue, 2014). These lexicons are used mainly to offset the data sparsity problem created by pairs of word tokens used directly as features.

Neural network models are an attractive alternative for this task, but it is not clear how well they will fare with a small dataset, typically found in discourse annotation projects. Many neural approaches have been proposed. However, we lack a unified standard comparison to really learn whether we make any progress at all because not all past studies agree on the same experimental settings such as label sets to use. Previous work used four binary classification (Pitler et al., 2008; Rutherford and Xue, 2014), 4-way coarse sense classification (Rutherford and Xue, 2015), and intermediate sense classification (Lin et al., 2009). CoNLL Shared Task introduces a unified scheme for evaluation along with a new unseen test set in English in 2015 (Xue et al., 2015) and in Chinese in 2016 (Xue et al., 2016). We want to corrob-

rate this new evaluation scheme by running more benchmark results and providing the output under this evaluation scheme. We systematically compare the relative advantages of different neural architectures and publish the outputs from the systems for the research community to conduct further analysis.

In this work, we explore multiple neural architectures in an attempt to find the best distributed representation and neural network architecture suitable for this task in both English and Chinese. We do this by probing the different points on the spectrum of structurality from structureless bag-of-words models to sequential and tree-structured models. We use feedforward, sequential long short-term memory (LSTM), and tree-structured LSTM models to represent these three points on the spectrum. To the best of our knowledge, there is no prior study that investigates the contribution of the different architectures in neural discourse analysis.

Our main contributions and findings from this work can be summarized as follows:

- We establish that the simplest feedforward discourse model outperforms systems with surface features and perform comparably with or even outperforms recurrent and convolutional architectures. This holds across different label sets in English and in Chinese.
- We investigate the contribution of the linguistic structures in neural discourse modeling and found that high-dimensional word vectors trained on a large corpus can compensate for the lack of structures in the model, given the small amount of annotated data.
- We collect and publish the system outputs from many neural architectures on the standard experimental settings for the community to conduct more error analysis. These are made available on the author’s website.

## 2 Model Architectures

Following previous work, we assume that the two arguments of an implicit discourse relation are given so that we can focus on predicting the senses of the implicit discourse relations. The input to our model is a pair of text segments called Arg1 and Arg2, and the label is one of the senses defined in the Penn

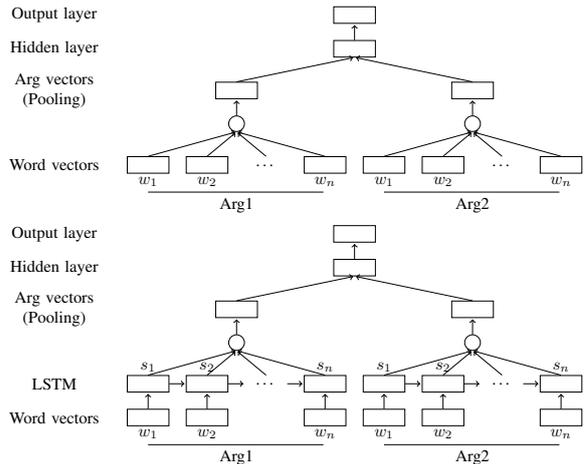

Figure 1: (Top) Feedforward architecture. (Bottom) Sequential Long Short-Term Memory architecture.

Discourse Treebank as in the example below:

**Input:**

Arg1 Senator Pete Domenici calls this effort “the first gift of democracy”

Arg2 The Poles might do better to view it as a Trojan Horse.

**Output:**

Sense Comparison.Contrast

In all architectures, each word in the argument is represented as a  $k$ -dimensional word vector trained on an unannotated data set. We use various model architectures to transform the semantics represented by the word vectors into distributed continuous-valued features. In the rest of the section, we explain the details of the neural network architectures that we design for the implicit discourse relations classification task. The models are summarized schematically in Figure 1.

### 2.1 Bag-of-words Feedforward Model

This model does not model the structure or word order of a sentence. The features are simply obtained through element-wise pooling functions. Pooling is one of the key techniques in neural network modeling of computer vision (Krizhevsky et al., 2012; LeCun et al., 2010). Max pooling is known to be very effective in vision, but it is unclear what pooling function works well when it comes to pooling word vectors. Summation pooling and mean pooling have been claimed to perform well at composing meaning of a short phrase from individual word vectors (Le and Mikolov,

2014; Blacoe and Lapata, 2012; Mikolov et al., 2013b; Braud and Denis, 2015). The Arg1 vector  $a^1$  and Arg2 vector  $a^2$  are computed by applying element-wise pooling function  $f$  on all of the  $N_1$  word vectors in Arg1  $w_{1:N_1}^1$  and all of the  $N_2$  word vectors in Arg2  $w_{1:N_2}^2$  respectively:

$$\begin{aligned} a_i^1 &= f(w_{1:N_1,i}^1) \\ a_i^2 &= f(w_{1:N_2,i}^2) \end{aligned} \qquad \begin{aligned} a_i^1 &= f(s_{1:N_1,i}^1) \\ a_i^2 &= f(s_{1:N_2,i}^2) \end{aligned}$$

We consider three different pooling functions namely max, summation, and mean pooling functions:

$$\begin{aligned} f_{max}(w_{1:N}, i) &= \max_{j=1}^N w_{j,i} \\ f_{sum}(w_{1:N}, i) &= \sum_{j=1}^N w_{j,i} \\ f_{mean}(w_{1:N}, i) &= \sum_{j=1}^N w_{j,i}/N \end{aligned}$$

Inter-argument interaction is modeled directly by the hidden layers that take argument vectors as features. Discourse relations cannot be determined based on the two arguments individually. Instead, the sense of the relation can only be determined when the arguments in a discourse relation are analyzed jointly. The first hidden layer  $h_1$  is the non-linear transformation of the weighted linear combination of the argument vectors:

$$h_1 = \tanh(W_1 \cdot a^1 + W_2 \cdot a^2 + b_{h_1})$$

where  $W_1$  and  $W_2$  are  $d \times k$  weight matrices and  $b_{h_1}$  is a  $d$ -dimensional bias vector. Further hidden layers  $h_t$  and the output layer  $o$  follow the standard feedforward neural network model.

$$\begin{aligned} h_t &= \tanh(W_{h_t} \cdot h_{t-1} + b_{h_t}) \\ o &= \text{softmax}(W_o \cdot h_T + b_o) \end{aligned}$$

where  $W_{h_t}$  is a  $d \times d$  weight matrix,  $b_{h_t}$  is a  $d$ -dimensional bias vector, and  $T$  is the number of hidden layers in the network.

## 2.2 Sequential Long Short-Term Memory (LSTM)

A sequential Long Short-Term Memory Recurrent Neural Network (LSTM-RNN) models the semantics of a sequence of words through the use of hidden state vectors. Therefore, the word ordering does affect the resulting hidden state vectors, unlike the bag-of-word model. For each word vector

at word position  $t$ , we compute the corresponding hidden state vector  $s_t$  and the memory cell vector from the previous step, using standard formula for LSTM. The argument vectors are the results of applying a pooling function over the hidden state vectors.

In addition to the three pooling functions that we describe in the previous subsection, we also consider using only the last hidden state vector, which should theoretically be able to encode the semantics of the entire word sequence.

$$f_{last}(s_{1:N}, i) = s_{N,i}$$

Inter-argument interaction and the output layer are modeled in the same fashion as the bag-of-words model once the argument vector is computed.

## 2.3 Tree LSTM

The principle of compositionality leads us to believe that the semantics of the argument vector should be determined by the syntactic structures and the meanings of the constituents. For a fair comparison with the sequential model, we apply the same formulation of LSTM on the binarized constituent parse tree. The hidden state vector now corresponds to a constituent in the tree. These hidden state vectors are then used in the same fashion as the sequential LSTM. The mathematical formulation is the same as Tai et al. (2015).

This model is similar to the recursive neural networks proposed by Ji and Eisenstein (2015). Our model differs from their model in several ways. We use the LSTM networks instead of the ‘‘vanilla’’ RNN formula and expect better results due to less complication with vanishing and exploding gradients during training. Furthermore, our purpose is to compare the influence of the model structures. Therefore, we must use LSTM cells in both sequential and tree LSTM models for a fair and meaningful comparison. The more in-depth comparison of our work and recursive neural network model by Ji and Eisenstein (2015) is provided in the discussion section.

## 3 Corpora and Implementation

**The Penn Discourse Treebank (PDTB)** We use the PDTB due to its theoretical simplicity in discourse analysis and its reasonably large size. The

Table 1: The distribution of the level 2 sense labels in the Penn Discourse Treebank. The instances annotated with two labels are not double-counted, and partial labels are excluded.

annotation is done as another layer on the Penn Treebank on Wall Street Journal sections. Each relation consists of two spans of text that are minimally required to infer the relation, and the sense is organized hierarchically. The classification problem can be formulated in various ways based on the hierarchy. Previous work in this task has been done over three schemes of evaluation: top-level 4-way classification (Pitler et al., 2009), second-level 11-way classification (Lin et al., 2009; Ji and Eisenstein, 2015), and modified second-level classification introduced in the CoNLL 2015 Shared Task (Xue et al., 2015). We focus on the second-level 11-way classification because the labels are fine-grained enough to be useful for downstream tasks and also because the strongest neural network systems are tuned to this formulation. If an instance is annotated with two labels ( $\sim 3\%$  of the data), we only use the first label. Partial labels, which constitute  $\sim 2\%$  of the data, are excluded. Table 3 shows the distribution of labels in the training set (sections 2-21), development set (section 22), and test set (section 23).

**Training** Weight initialization is uniform random, following the formula recommended by Bengio (2012). The cost function is the standard cross-entropy loss function, as the hinge loss function (large-margin framework) yields consistently inferior results. We use Adagrad as the optimization algorithm of choice. The learning rates are tuned over a grid search. We monitor the accuracy on the development set to determine convergence and prevent overfitting. L2 regularization and/or dropout do not make a big impact on performance in our case, so we do not use them in the final re-

sults.

**Implementation** All of the models are implemented in Theano (Bergstra et al., 2010; Bastien et al., 2012). The gradient computation is done with symbolic differentiation, a functionality provided by Theano. Feedforward models and sequential LSTM models are trained on CPUs on Intel Xeon X5690 3.47GHz, using only a single core per model. A tree LSTM model is trained on a GPU on Intel Xeon CPU E5-2660. All models converge within hours.

## 4 Experiment on the Second-level Sense in the PDTB

We want to test the effectiveness of the inter-argument interaction and the three models described above on the fine-grained discourse relations in English. The data split and the label set are exactly the same as previous works that use this label set (Lin et al., 2009; Ji and Eisenstein, 2015).

**Preprocessing** All tokenization is taken from the gold standard tokenization in the PTB (Marcus et al., 1993). We use the Berkeley parser to parse all of the data (Petrov et al., 2006). We test the effects of word vector sizes. 50-dimensional and 100-dimensional word vectors are trained on the training sections of WSJ data, which is the same text as the PDTB annotation. Although this seems like too little data, 50-dimensional WSJ-trained word vectors have previously been shown to be the most effective in this task (Ji and Eisenstein, 2015). Additionally, we also test the off-the-shelf word vectors trained on billions of tokens from Google News data freely available with the `word2vec` tool. All word vectors are trained on the Skip-gram architecture (Mikolov et al., 2013b; Mikolov et al., 2013a). Other models such as GloVe and continuous bag-of-words seem to yield broadly similar results (Pennington et al., 2014). We keep the word vectors fixed, instead of fine-tuning during training.

### 4.1 Results

The feedforward model performs best overall among all of the neural architectures we explore (Table 2). It outperforms the recursive neural network with bilinear output layer introduced by Ji and Eisenstein (2015) ( $p < 0.05$ ; bootstrap test) and performs comparably with the surface feature baseline (Lin et al., 2009), which uses var-

Architecture	$k$	No hidden layer				1 hidden layer				2 hidden layers

ious lexical and syntactic features and extensive feature selection. Tree LSTM achieves inferior accuracy than our best feedforward model. The best configuration of the feedforward model uses 300-dimensional word vectors, one hidden layer, and the summation pooling function to derive argument feature vectors. The model behaves well during training and converges in less than an hour on a CPU.

The sequential LSTM model outperforms the feedforward model when word vectors are not high-dimensional and not trained on a large cor-

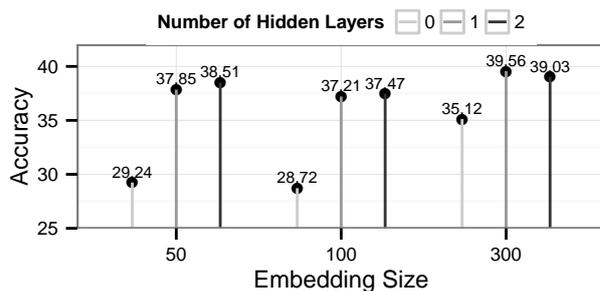

Figure 3: Inter-argument interaction can be modeled effectively with hidden layers. The results are shown for the feedforward models with summation pooling, but this effect can be observed robustly in all architectures we consider.

pus (Figure 4). Moving from 50 units to 100 units trained on the same dataset, we do not observe much of a difference in performance in both architectures, but the sequential LSTM model beats the feedforward model in both settings (Table 3). This suggests that only 50 dimensions are needed for the WSJ corpus. However, the trend reverses when we move to 300-dimensional word vectors trained on a much larger corpus. These results suggest an interaction between the lexical information encoded by word vectors and the structural information encoded by the model itself.

Hidden layers, especially the first one, make a substantial impact on performance. This effect is observed across all architectures (Figure 3). Strikingly, the improvement can be as high as 8% absolute when used with the feedforward model with small word vectors. We tried up to four hidden layers and found that the additional hidden layers yield diminishing—if not negative—returns. These effects are not an artifact of the training process as we have tuned the models quite extensively, although it might be the case that we do not

Figure 4: Comparison between feedforward and sequential LSTM when using summation pooling function.

have sufficient data to fit those extra parameters.

Summation pooling is effective for both feedforward and LSTM models (Figure 2). The word vectors we use have been claimed to have some additive properties (Mikolov et al., 2013b), so summation pooling in this experiment supports this claim. Max pooling is only effective for LSTM, probably because the values in the word vector encode the abstract features of each word relative to each other. It can be trivially shown that if all of the vectors are multiplied by -1, then the results from max pooling will be totally different, but the word similarities remain the same. The memory cells and the state vectors in the LSTM models transform the original word vectors to work well the max pooling operation, but the feedforward net cannot transform the word vectors to work well with max pooling as it is not allowed to change the word vectors themselves.

#### 4.2 Why does the feedforward model outperform the LSTM models?

Summing up vectors indeed works better than recurrent models. We provide further evidence for this claim in Section 5. Sequential and tree LSTM models might work better if we are given larger amount of data. We observe that LSTM models outperform the feedforward model when word vectors are smaller, so it is unlikely that we train the LSTMs incorrectly. It is more likely that we do not have enough annotated data to train a more powerful model such as LSTM. In previous work, LSTMs are applied to tasks with a lot of labeled data compared to mere 12,930 instances that we have (Vinyals et al., 2015; Chiu and Nichols, 2015; Írsoy and Cardie, 2014). Another explanation comes from the fact that the contextual information encoded in the word vectors can compen-

sate for the lack of structure in the model in this task. Word vectors are already trained to encode the words in their linguistic context especially information from word order.

Our discussion would not be complete without explaining our results in relation to the recursive neural network model proposed by Ji and Eisenstein (2015). Why do sequential LSTM models outperform recursive neural networks or tree LSTM models? Although this first comes as a surprise to us, the results are consistent with recent works that use sequential LSTM to encode syntactic information. For example, Vinyals et al. (2015) use sequential LSTM to encode the features for syntactic parse output. Tree LSTM seems to show improvement when there is a need to model long-distance dependency in the data (Tai et al., 2015; Li et al., 2015). Furthermore, the benefits of tree LSTM are not readily apparent for a model that discards the syntactic categories in the intermediate nodes and makes no distinction between heads and their dependents, which are at the core of syntactic representations.

Another point of contrast between our work and Ji and Eisenstein’s (2015) is the modeling choice for inter-argument interaction. Our experimental results show that the hidden layers are an important contributor to the performance for all of our models. We choose linear inter-argument interaction instead of bilinear interaction, and this decision gives us at least two advantages. Linear interaction allows us to stack up hidden layers without the exponential growth in the number of parameters. Secondly, using linear interaction allows us to use high dimensional word vectors, which we found to be another important component for the performance. The recursive model by Ji and Eisenstein (2015) is limited to 50 units due to the bilinear layer. Our choice of linear inter-argument interaction and high-dimensional word vectors turns out to be crucial to building a competitive neural network model for classifying implicit discourse relations.

### 5 Extending the results across neural architectures, label sets, and languages

We want to provide further evidence that feedforward models perform well without surface features or without sophisticated recurrent or convolutional structures across different label sets and languages as well. Toward that goal, we evaluate

our models on non-explicit discourse relation data used in English and Chinese CoNLL 2016 Shared Task.

### 5.1 English discourse relations

We follow the experimental setting used in CoNLL 2015-2016 Shared Task. To compare our results against previous systems, we compile all of the official system outputs, and make them publicly available. The label set is modified by the shared task organizers into 15 different senses including EntRel as another sense (Xue et al., 2015; Xue et al., 2016). We use the 300-dimensional word vector used in the previous experiment and tune the number of hidden layers and hidden units on the development set. We consider the following models: Bidirectional-LSTM (Akanksha and Eisenstein, 2016), two flavors of convolutional networks (Qin et al., 2016; Wang and Lan, 2016), two variations of simple argument pooling (Mihaylov and Frank, 2016; Schenk et al., 2016), and the best system using surface features alone (Wang and Lan, 2015). The comparison results and brief system descriptions are shown in Table 4.

Our model presents the state-of-the-art system on the blind test set in English. We once again confirm that manual features are not necessary for this task and that our feedforward network outperforms the best available LSTM and convolutional networks in many settings despite its simplicity. While performing well in-domain, convolutional networks degrade sharply when tested on the blind slightly out-of-domain dataset.

### 5.2 Chinese discourse relations

We evaluate our model on the Chinese Discourse Treebank (CDTB) because its annotation is the most comparable to the PDTB (Zhou and Xue, 2015). The sense set consists of 10 different senses, which are not organized in a hierarchy, unlike the PDTB. We use the version of the data provided to the CoNLL 2016 Shared Task participants. This version has 16,946 instances of discourse relations total in the combined training and development sets. The test set is not yet available at the time of submission, so the system is evaluated based on the average accuracy over 7-fold cross-validation on the combined set of training and development sets.

To establish baseline comparison, we use MaxEnt models loaded with the feature sets previously shown to be effective for English, namely

Model	Acc.
<i>CoNLL-ST 2015-2016 English (WSJ Test set)</i>	
Most frequent tag baseline	21.36
Our best LSTM variant	31.76
Wang and Lan (2015) - winning team	34.45

ME + Word pairs	83.13
ME + All feature sets	84.16
Our best feedforward variant	<b>85.45</b>

Table 5: Our best feedforward variant significantly outperforms the systems with surface features ( $p < 0.05$ ). ME=Maximum Entropy model

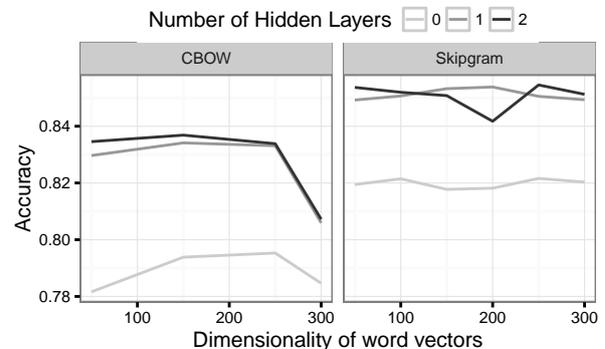

Figure 5: Comparing the accuracies across Chinese word vectors for feedforward model.

dependency rule pairs, production rule pairs (Lin et al., 2009), Brown cluster pairs (Rutherford and Xue, 2014), and word pairs (Marcu and Echihabi, 2002). We use information gain criteria to select the best subset of each feature set, which is crucial in feature-based discourse parsing.

Chinese word vectors are induced through CBOW and Skipgram architecture in `word2vec` (Mikolov et al., 2013a) on Chinese Gigaword corpus (Graff and Chen, 2005) using default settings. The number of dimensions that we try are 50, 100, 150, 200, 250, and 300. We induce 1,000 and 3,000 Brown clusters on the Gigaword corpus.

Table 5 shows the results for the models which are best tuned on the number of hidden units, hidden layers, and the types of word vectors. The feedforward variant of our model significantly outperforms the strong baselines in both English and Chinese ( $p < 0.05$  bootstrap test). This suggests that our approach is robust against different label

Systems	Arg vector	Features?	Blind set	WSJ Test	WSJ Dev

sets, and our findings are valid across languages. Our Chinese model outperforms all of the feature sets known to work well in English despite using only word vectors. The choice of neural architecture used for inducing Chinese word vectors turns out to be crucial. Chinese word vectors from Skip-gram model perform consistently better than the ones from CBOW model (Figure 5). These two types of word vectors do not show much difference in the English tasks.

## 6 Related Work

The prevailing approach for this task is to use surface features derived from various semantic lexicons (Pitler et al., 2009), reducing the number of parameters by mapping raw word tokens in the arguments of discourse relations to a limited number of entries in a semantic lexicon such as polarity and verb classes. Along the same vein, Brown cluster assignments have also been used as a general purpose lexicon that requires no human manual annotation (Rutherford and Xue, 2014). However, these solutions still suffer from the data sparsity problem and almost always require extensive feature selection to work well (Park and Cardie, 2012; Lin et al., 2009; Ji and Eisenstein, 2015). The work we report here explores the use of the expressive power of distributed representations to overcome the data sparsity problem found in the traditional feature engineering paradigm.

Neural network modeling has been explored to some extent in the context of this task. Recently, Braud and Denis (2015) tested various word vectors as features for implicit discourse relation classification and show that distributed features achieve the same level of accuracy as one-hot representations in some experimental settings. Ji et al. (2015; 2016) advance the state of the art for this task by using recursive and recurrent neural networks. In the work we report here, we

systematically explore the use of different neural network architectures and show that when high-dimensional word vectors are used as input, a simple feed-forward architecture can outperform more sophisticated architectures such as sequential and tree-based LSTM networks, given the small amount of data.

Recurrent neural networks, especially LSTM networks, have changed the paradigm of deriving distributed features from a sentence (Hochreiter and Schmidhuber, 1997), but they have not been much explored in the realm of discourse parsing. LSTM models have been notably used to encode the meaning of source language sentence in neural machine translation (Cho et al., 2014; Devlin et al., 2014) and recently used to encode the meaning of an entire sentence to be used as features (Kiros et al., 2015). Many neural architectures have been explored and evaluated, but there is no single technique that is decidedly better across all tasks. The LSTM-based models such as Kiros et al. (2015) perform well across tasks but do not outperform some other strong neural baselines. Ji et al. (2016) uses a joint discourse language model to improve the performance on the coarse-grained label in the PDTB, but in our case, we would like to deduce how well LSTM fares in fine-grained implicit discourse relation classification, which is more practical for application.

## 7 Conclusions and future work

We report a series of experiments that systematically probe the effectiveness of various neural network architectures for the task of implicit discourse relation classification. We found that a feedforward variant of our model combined with hidden layers and high dimensional word vectors outperforms more complicated LSTM and convolutional models. We also establish that manually crafted surface features are not necessary for

this task. These results hold for different settings and different languages. In addition, we collect and compile the system outputs from all competitive systems and make it available for the research community to conduct further analysis. We encourage that researchers who work on this task to evaluate their systems under the CoNLL Shared Task 2015-2016 scheme to allow for easy comparison and progress tracking.

## Abstract

Discourse parsing is an integral part of understanding information flow and argumentative structure in documents. Most previous research has focused on inducing and evaluating models from the English RST Discourse Treebank. However, discourse treebanks for other languages exist, including Spanish, German, Basque, Dutch and Brazilian Portuguese. The treebanks share the same underlying linguistic theory, but differ slightly in the way documents are annotated. In this paper, we present (a) a new discourse parser which is simpler, yet competitive (significantly better on 2/3 metrics) to state of the art for English, (b) a harmonization of discourse treebanks across languages, enabling us to present (c) what to the best of our knowledge are the first experiments on cross-lingual discourse parsing.

## 1 Introduction

Documents can be analyzed as sequences of hierarchical discourse structures. Discourse structures describe the organization of documents in terms of discourse or rhetorical relations. For instance, the three discourse units below can be represented by the tree in Figure 1, where a relation COMPARISON holds between the segments 1 and 2, and a relation CONTRIBUTION links the segment covering the units 1 and 2, and the segment 3.<sup>1</sup>

- 1 Consumer spending in Britain rose 0.1% in the third quarter from the second quarter
- 2 and was up 3.8% from a year ago,
- 3 the Central Statistical Office estimated.

<sup>1</sup>“NS” and “NN” in Figure 1 describe the nuclearity of the segments, see Section 3.

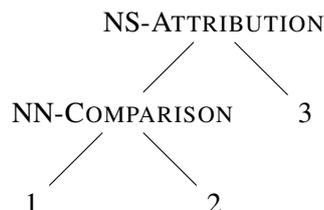

Figure 1: Tree for the structure covering the segments 1 to 3 in document 1384 in the English RST Discourse Treebank.

Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) is a prominent linguistic theory of discourse structures, in which texts are analyzed as constituency trees, such as the one in Figure 1. This theory guided the annotation of the RST Discourse Treebank (RST-DT) (Carlson et al., 2001) for English, from which several text-level discourse parsers have been induced (Hernault et al., 2010; Joty et al., 2012; Feng and Hirst, 2014; Li et al., 2014; Ji and Eisenstein, 2014). Such parsers have proven to be useful for various downstream applications (Daumé III and Marcu, 2009; Burstein et al., 2003; Higgins et al., 2004; Thione et al., 2004; Sporleder and Lapata, 2005; Taboada and Mann, 2006; Louis et al., 2010; Bhattia et al., 2015).

There are discourse treebanks for other languages than English, including Spanish, German, Basque, Dutch, and Brazilian Portuguese. However, most research experimenting with these languages has focused on rule-based systems (Pardo and Nunes, 2008; Maziero et al., 2011) or has been limited to intra-sentential relations (Maziero et al., 2015).

Moreover, all discourse corpora are limited in size, since annotation is complex and time consuming. This data sparsity makes learning hard, especially considering that discourse parsing involves several complex and interacting factors, ranging from syntax and semantics, to pragmat-

ics. We thus propose to harmonize existing corpora in order to leverage information by combining datasets in different languages.

**Contributions** In this paper, we propose a new discourse parser that is significantly better than existing parsers for English on 2/3 standard metrics. Our parser relies on fewer features than previous work and is arguably algorithmically simpler. Moreover, we present the first end-to-end statistical discourse parsers for other languages than English (6 languages, in total). We also present the first experiments in cross-lingual discourse parsers, showing that discourse parsing is possible even when no or very little labeled data is available for the language of interest. We do so by harmonizing available discourse treebanks, enabling us to apply models across languages. We make the code and preprocessing scripts available for download at <https://bitbucket.org/chloeht/discourse>.

## 2 Related Work

The first text-level discourse parsers were developed for English, relying mainly on hand-crafted rules and heuristics (Marcu, 2000a; Carlson et al., 2001). Hernault et al. (2010, HILDA) greedily use SVM classifiers to make attachment and labeling decisions, building up a discourse tree. Joty et al. (2012, TSP) build a two-stage parsing system, training separate sequential models (CRF) for the intra- and the inter-sentential levels. These models jointly learn the relation and the structure, and a CKY-like algorithm is used to find the optimal tree. Feng and Hirst (2014) use CRFs only as local models for the inter- and intra-sententials levels. For Brazilian Portuguese, for example, the first system, called DiZer (Pardo and Nunes, 2008; Maziero et al., 2011), was also rule-based, but there has been some work on using classification of intra-sentential relations (Maziero et al., 2015).

Recently studies have focused on building good representations of the data. Feng and Hirst (2012) introduced linguistic features, mostly syntactic and contextual ones. Li et al. (2014) used a recursive neural network that builds a representation for each clause based on the syntactic tree, and then apply two classifiers as in Hernault et al. (2010). This leads to the best performing system for unlabeled structure (85.0 in  $F_1$ ). The system presented by Ji and Eisenstein (2014, DPLP) jointly learns the representation and the task: a large mar-

gin classifier is used to learn the actions of a shift-reduce parser, optimizing at the same time the loss of the parser and a projection matrix that maps the bag-of-words representation of the discourse units into a new vector space. This system, however, only slightly outperforms the original bag-of-words representation. DPLP is the best performing discourse parser for labeled structure, 71.13 in  $F_1$  for nuclearity and 61.63% for relation.

Our system is similar to these last approaches in learning a representation using a neural network. However, we found that good performance can already be obtained without using all the words in the discourse units, resulting in a parser that is faster and easier to adapt, as demonstrated in our multilingual experiments, see Section 7.

## 3 RST framework

**Discourse analysis** In building a discourse structure, the text is first segmented into elementary discourse units (EDU), mostly clauses. EDUs are the smallest discourse units (DUs). Discourse relations are then used to build DUs, recursively. A non-elementary DU is called a complex discourse unit (CDU). The structure of a document is the set of linked DUs. In this paper, we focus on the Rhetorical Structure Theory (RST), a theoretical framework proposed by Mann and Thompson (1988).

**Nuclearity** A DU is either a *nucleus* or a *satellite*, the nucleus being the most important part of the relation (i.e. of the text), while the satellite contains additional, less important information. In general, this feature depends on the relation: a relation can be either mono-nuclear (with a scheme nucleus-satellite or satellite-nucleus depending on the relative order of the spans), or multi-nuclear. Some relations can be either mono- or multi-nuclear, such as *consequence* or *evaluation* in the RST-DT.

**Binary trees** In the original RST framework, each relation is associated with an application scheme that defines the nuclearity of the DUs (mono- or multi-nuclear relation), and the number of DUs linked. Among the six schemes, two correspond to a link between more than two DUs, either a nucleus shared between two mono-nuclear relations (e.g. *motivation* and *enablement*) or a relation linking several nuclei (e.g. *list*). Marcu (1997) proposed to simplify the representation to

Corpus	#Doc	#Trees	#Words	#Rel	#Lab	#EDU	max/min/avg	#CDU
En-DT	385	<b>385</b>	206,300	56	110	21,789	304/2/56.6	21,404
Pt-DT	330	<b>329</b>	135,820	32	58	12,573	187/3/38.2	12,244
Es-DT <sup>a</sup>	266	<b>266</b>	69,787	29	43	4,019	77/2/11.5	3,671

<sup>a</sup>The test set contains 84 documents doubly annotated, we report figures for annotator A.

binary trees, and all discourse parsers are built on a binary representation.

## 4 Data

We test our discourse parser on six languages, using available RST corpora harmonized as described in Section 4.2. Information about the datasets are summarized in Table 1.

### 4.1 RST corpora

**English** The RST Discourse Treebank (Carlson and Marcu, 2001), from now on En-DT, is the most widely used corpus to build discourse parsers. It contains 385 documents in English from the Wall Street Journal. The relation set contains 56 relations (ignoring nuclearity and embedding information<sup>2</sup>). The inter-annotator agreement scores are 88.70 for the unlabeled structure (score “Span”), 77.72 for the structure with nuclearity (“Nuclearity”) and 65.75 with relations (“Relation”).<sup>3</sup>

**Brazilian Portuguese** We merged all the corpora annotated for Brazilian Portuguese, as in (Maziero et al., 2015), to form the Pt-DT. The largest corpus is CST-News<sup>4</sup> (Cardoso et al., 2011), it is composed of 140 documents from the news domain annotated with 31 relations. Authors report agreement scores corresponding to nuclearity (0.78 in  $F_1$ ) and relations (0.66).

The other corpora are: Summ-it<sup>5</sup> (Collovini et al., 2007) – 50 texts from science articles

<sup>2</sup>In this corpus, the embedded relations are annotated with a specific label (suffix “-e”) that we removed.

<sup>3</sup>See Section 6 for a description of these metrics.

<sup>4</sup><http://nilc.icmc.usp.br/CSTNews/login/?next=/CSTNews/>

<sup>5</sup><http://www.inf.pucrs.br/ontolp/downloads-ontolpplogin.php>

in a newspaper, annotated with 29 relations; Rhetalho<sup>6</sup> (Pardo and Seno, 2005) – 40 texts from the computer science and news domains, annotated with 23 relations; and CorpusTCC<sup>6</sup> (Pardo and Nunes, 2003; Pardo and Nunes, 2004) – 100 introductions of scientific texts in computer science, annotated with 31 relations.

**Spanish** The Spanish RST DT<sup>7</sup> (da Cunha et al., 2011), from now on Es-DT, contains 267 texts written by specialists on different topics (e.g. astrophysics, economy, law, linguistics) The relation set contains 29 relations. The authors report inter-annotator agreement of 86% in precision for the unlabeled structure, 82.46% for the structure with nuclearity and 76.81% with relations.

**German** The Postdam Commentary Corpus 2.0<sup>8</sup> (Stede, 2004; Stede and Neumann, 2014), from now on De-DT, contains newspaper commentaries annotated at several levels. A part of this corpus (MAZ) contains 175 documents annotated within the RST framework using 30 relations.<sup>9</sup>

**Dutch** The corpus for Dutch (Vliet et al., 2011; Redeker et al., 2012), from now on Nl-DT, contains 80 documents from expository (encyclopedias and science news website) and persuasive (fund-raising letters and commercial advertisements) genres, annotated with 31 relations. The authors report an agreement of 0.83 for discourse spans, 0.77 for nuclearity and 0.70 for relations.

<sup>6</sup><http://conteudo.icmc.usp.br/pessoas/taspardo/Projects.htm>

<sup>7</sup>[http://corpus.iingen.unam.mx/rst/index\\_en.html](http://corpus.iingen.unam.mx/rst/index_en.html)

<sup>8</sup><http://angcl.ling.uni-potsdam.de/resources/pcc.html>

<sup>9</sup>We systematically ignore the first segment of each document, the title, that is not linked to the rest of the text.

**Basque** The Basque RST DT<sup>10</sup> (Iruskieta et al., 2013), from now on Eu-DT, contains 88 abstracts from three specialized domains – medicine, terminology and science –, annotated with 31 relations. The inter-annotator agreement is 81.67% for the identification of the CDU (Iruskieta et al., 2015), and 61.47% for the identification of the relations.

**Other corpora** To the best of our knowledge, the only two non English corpora not included are the one annotated for Tamil (Subalalitha and Parthasarathi, 2012) that we were unable to find, and the (intra-sentential) one developed for Chinese (Wu et al., 2016), for which we were unable to produce RST trees since annotation does not contain nuclearity indications.

For English, there are corpora annotated for other domains than the one covered by the En-DT. We however leave out-of-domain evaluation for future work: it requires to decide how to use a corpus annotated only at the sentence level (SFU review corpus)<sup>11</sup>, or a corpus annotated with genre specific relations (Subba and Di Eugenio, 2009).

## 4.2 Harmonization of the datasets

Recent discourse parsers built on the En-DT are based on pre-processed data: the corpus contains only binary trees, with the large label set mapped to 18 coarse-grained classes. In this section, we describe this pre-processing step for all corpora used. Discourse corpora have been released under three different file formats: `dis` (En-DT), `lisp` (Rhetalho and CorpusTCC) and `rs3` (all remaining corpora). The first two ones are bracketed format, the third one is an XML encoding. In all cases, the trees encoded do not look like the one in Figure 1: the relations are annotated on the daughter nodes, on the satellite for mono-nuclear relations, or on all the nuclei for multi-nuclear relations. Moreover, in the `rs3` format, the nuclearity of the segments is not directly annotated, it has to be retrieved using the type of the relation (indicated at the beginning of each file) and the previous principle. Our pre-processing step leads to corpora with bracketed files representing directly the RST trees (as in Figure 1) with stand-off annotation of the text of the EDUs.

Note that, even if harmonized, the corpora are not parallel, making it hard to use them to study

language variations for the discourse level. Some preliminary work exists on this question (Iruskieta et al., 2015).

**Pre-processing** Some documents (format `rs3`) contain several roots or empty segments. We were generally able to remove useless units, that is units that are not linked to other ones within the tree, except for one document in the CST corpus (two roots, both linked to other units).

Another issue concerns unordered EDUs: the structure annotated contains nodes spanning non adjacent EDUs. In general, we were able to correct these cases, but we failed to automatically produce trees spanning only adjacent EDUs for three documents in the Eu-DT, and one document in the De-DT.

**Binarization** All the corpora contain non-binary trees that we map to binary ones. In the En-DT, common cases of non-binarity are nodes whose daughters all hold the same multi-nuclear relation – indicating that this relation spans multiple DUs, e.g. *list*.<sup>12</sup> In rare cases, the children are two satellites and a nucleus – indicating that the nucleus is shared by the satellites. These configurations are the ones described in (Marcu, 1997) (see Section 3), and choosing right or left-branching leads to a similar interpretation. For the En-DT, right-branching is the chosen strategy since (Soricut and Marcu, 2003).

We found more diverse cases in the other corpora, and, for some of them, right-branching is impossible. It is the case when the daughters are one nucleus (annotated with “Span”, only indicating that this node spans several EDUs) and more than two satellites holding different relations – i.e. the nucleus is shared by all the relations. More precisely, the issue arises when the last two children are satellites. Using right-branching, we end with a node with two satellites as daughters, and thus a ill-formed tree. In order to keep as often as possible the “right-branching by default” strategy, we first do a right-branching and then a left-branching: beginning with four children –  $S_1-R_i$ ,  $N_2$ -Span,  $S_3-R_j$  and  $S_4-R_k$ , indicating the relations  $R_i(S_1, N_2)$ ,  $R_j(N_2, S_3)$  and  $R_k(N_2, S_4)$ <sup>13</sup> –, we end up with the tree in Figure 2. Finally, we used a right-branching in all cases, except when the two last children are satellites.

<sup>10</sup><http://ixa2.si.ehu.es/diskurtsosa/en/>

<sup>11</sup>[https://www.sfu.ca/~mtaboada/research/SFU\\_Review\\_Corpus.html](https://www.sfu.ca/~mtaboada/research/SFU_Review_Corpus.html)

<sup>12</sup>Recall that in the original format, the relation is not annotated on the parent node but on the children.

<sup>13</sup> $S$  being a satellite,  $N$  a nucleus and  $R$  a relation.

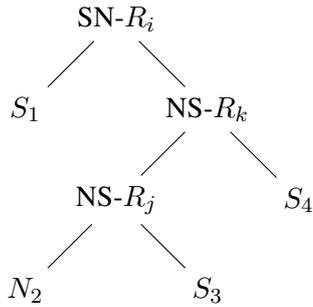

Figure 2: Binary tree for a node  $X$  with 4 children:  $S_1-R_i$ ,  $N_2$ -Span,  $S_3-R_j$  and  $S_4-R_k$ .

**Label set harmonization** We map all the relations used in the corpora to the 18 coarse grained classes (Carlson and Marcu, 2001) used to build the most recent discourse parsers on the En-DT.<sup>14</sup>

The mapping for the En-DT is given in (Carlson and Marcu, 2001). For all the other corpora, we first map all the relations that exist in this mapping (i.e. used in the En-DT annotation scheme) to their corresponding classes. We end with 18 problematic relations, that is relations that were not used when annotating the En-DT.

Among them, 10 can be mapped easily, because they directly correspond to a class – *explanation* is mapped to the class EXPLANATION, *elaboration* to ELABORATION, *joint* to JOINT –, because they were just renamed – *reformulation* is mapped to the class RESTATEMENT and *solutionhood* (same as *problem-solution*) to TOPIC-COMMENT –, or because they correspond to a more-fine grained formulation of existing relations – *entity-elaboration* is mapped to ELABORATION and the 4 *volitional/non-volitional cause* and *result* are mapped to the class CAUSE, corresponding to the relations *cause* and *result* in the En-DT.

For the remaining relations, we looked at the definition of the relations<sup>15</sup> to decide on a mapping. Note that this label mapping is made quite easy by the fact that all the corpora were annotated following the same underlying theory – they thus use relations defined using similar criteria –, and that we are using a coarse-grained classification – we thus do not need to decide whether a relation is equivalent to another one, but rather whether it fits the properties of the other relations within a specific class. Label mappings for corpora annotated following different frameworks are still

<sup>14</sup>The full mapping is provided in Appendix A.

<sup>15</sup><http://www.sfu.ca/rst/01intro/definitions.html>

discussed (Roze, 2013; Benamara and Taboada, 2015).

We decided on the following mapping, considering the properties of the relations and the classes: *parenthetical* – used to give “additional details” – is mapped to ELABORATION, *conjunction* – similar to a *list* with only two elements – to JOINT, *justify* – similar to *Explanation-argumentative* – and *motivation* – quite similar to *reason* and grouped with *evidence* in (Benamara and Taboada, 2015) – to EXPLANATION, *preparation* – presenting preliminary information, increasing the readiness to read the nucleus – to BACKGROUND, and *unconditional* and *unless* – linked to *condition* – to CONDITION.

Finally, note that this mapping does not lead to having the same relation set for all the corpora, and that the relation distribution could vary among the datasets.

## 5 Discourse Parser

Our discourse parser builds discourse structures from segmented texts, we did not implement discourse segmenters for each language. Discourse segmenters only exist for English (Hernault et al., 2010) (95, 0% in  $F_1$ ), Brazilian Portuguese (Pardo and Nunes, 2008) (56.8%) and Spanish (da Cunha et al., 2010; da Cunha et al., 2012) (80%). Discourse segmenters can be built quite easily relying only on manual rules as it is the case for the Spanish and Portuguese ones, especially considering that segmentation has generally been made coarser in the corpora built after the En-DT (Vliet et al., 2011). While improving this first step is crucial, we focus on the harder step of tree building.

### 5.1 Description of the Parser

We used the syntactic parser described in Coavoux and Crabbé (2016), in the static oracle setting. We chose this parser because it can take pre-trained embeddings as input and, more importantly, because it was designed for morphologically rich languages and thus takes as input not only tokens and POS tags, but any token attribute that is then mapped to a real-valued vector, which allows the use of complex features.

The parser is a transition-based constituent parser that uses a lexicalized shift-reduce transition system (Sagae and Lavie, 2005). The transition system is based on two data structures – a *stack* ( $S$ ) stores partial trees and a *queue* ( $B$ ) con-

tains the unparsed DUs. A parsing *configuration* is a couple  $\langle S, B \rangle$ . In the initial configuration,  $S$  is empty and  $B$  contains the whole document. The parser iteratively applies actions to the current configuration, in order to derive new configurations until it reaches a final state, i.e. a parsing configuration where  $B$  is empty and  $S$  contains a single element (the root of the tree).

The actions are defined as follows:

- SHIFT pops an EDU from  $B$  and pushes it onto  $S$ .
- REDUCE-R-X and REDUCE-L-X pop two DUs from  $S$ , push a new CDU with the label X on  $S$  and assign its nucleus (Left or Right).

**Scoring System** As in Chen and Manning (2014), at each parsing step, the parser scores actions with a feed-forward neural network. The input of the network is a sequence of typed symbols extracted from the top elements of  $S$  and  $B$ . The symbols are typically discourse relations or attributes of their nucleus EDU (e.g. first word of EDU, see Section 5.3).

The first layer of the network projects these symbols onto an embedding space (each type of symbol has its own embedding matrix). The following two layers are non-linear layers with a ReLU activation. The output of the network is a probability distribution over possible actions computed by a softmax layer.

To generate a set of training examples  $\{a^{(i)}, c^{(i)}\}_{i=1}^N$ , we used the static oracle to extract the gold sequence of actions and configurations for each tree in the corpus. The objective function of the parser is the negative log-likelihood of gold actions given corresponding configurations:

$$\mathcal{L}(\theta) = - \sum_{i=1}^N \log P(a^{(i)} | c^{(i)}; \theta)$$

where  $\theta$  is the set of all parameters, including embedding matrices.

We optimized this objective with the averaged stochastic gradient descent algorithm (Polyak and Juditsky, 1992). At inference time, we used beam-search to find the best-scoring tree.

## 5.2 Cross-lingual Discourse Parsing

Our first experiments are strictly monolingual, and they are intended to give state-of-the-art performance in a fully supervised setting. We consider

that we need at least 100 documents to build a monolingual model, since we already keep around 65 documents for test and development.

We then evaluate multi-source transfer methods, considering one language as the target and the others as sources. More precisely, we will evaluate two settings: (1) training and optimizing only on the available source data; (2) training on all available data, including target ones if any, and optimizing on the development set of the target language. Setting (1) provides performance when no data are available at all in the target language, while (2) aims at evaluating if one can expect improvements by simply combining all the available data.

When combining the corpora, we cannot ignore lexical information as it has been done for syntactic parsing with delexicalized models (McDonald et al., 2011). Discourse parsing is a semantic task, at least when it comes to predict a rhetorical relation between two spans of text, and information from words have proven to be crucial (Rutherford and Xue, 2014; Braud and Denis, 2015). We thus include word features using bilingual dictionaries – i.e. translating the words used as features into a single language (English) –, or through cross-lingual word embeddings as proposed in (Guo et al., 2015) for dependency parsing. More precisely, we used the cross-lingual word representations presented in (Levy et al., 2017) that allow multi-source learning and have proven useful for POS tagging but also more semantic-oriented tasks, such as dependency parsing and document classification.

## 5.3 Features

As in previous studies, we used features representing the two EDUs on the top of the stack and the EDU on the queue. If the stack contains CDUs, we use the nuclearity principle to choose the head EDU, converting multi-nuclear relations into nucleus-satellite ones as done since (Sagae, 2009). However, we found that using these information also for the left and right children of the two CDUs on the top of the stack, and adding as a feature the representation built for these two CDUs lead to important improvements.

**Lexical features** We use the first three words and the last word along with their POS, features that have proven useful for discourse (Pitler et al., 2009), and the words in the *head set* (Sagae, 2009)

– i.e. words whose head in the dependency graph is not in the EDU –, here limited to the first three.<sup>16</sup> This head set contains the head of the sentence (in general, the main event), or words linked to the main clause when the segment does not contain the head (especially, discourse connectives that are subordinating or coordinating conjunctions could be found there). The words at the boundaries could also contain discourse connectives, adverbs or temporal expressions that could be relevant for discourse structure. Note however that these features have been built for English, and they could be less useful for other languages. We leave the question of investigating their utility linked to word order differences for future work.

Note that we do not use all the words in the EDUs as features, contrary to (Li et al., 2014; Ji and Eisenstein, 2014). Our only word features are the words in the head set and at the boundaries, thus 7 words per EDU. When using word embeddings, we concatenate the vectors for each word, each of  $d$  dimensions, keeping the same order to build a vector of  $7d$  dimensions (e.g., the first word of the EDU corresponds to the first  $d$  dimensions, the second has values between  $d$  and  $2d$ ).

**Position and length** Other features are used to represent the position of the EDU in the document and its length in tokens. We use thresholds to distinguish between very long (length  $l > 25$  tokens), long ( $l > 15$ ), short ( $l > 5$ ) and very short ( $l \leq 5$ ) EDUs. We also distinguish between the “first” and the “last” EDU in the document, and use also a threshold on the ratio  $s = (\text{position of the EDU} / \text{total number of EDUs})$  to separate EDUs at the beginning ( $s < 0.25$ ), in the first middle ( $0.25 \leq s < 0.5$ ), in the second middle ( $0.5 \leq s < 0.75$ ) or in the end ( $s \geq 0.75$ ).

**Position of the head** We add a boolean feature indicating if the head of the sentence is in the current EDU or outside.

**Number/date/percent/money** We also use 4 indicators of the presence of a date, a number, an amount of money and a percentage, features that have proven to be useful for discourse (Pitler et al., 2009). We build these features using simple regular expressions.

Corpus	Size dict.	# words	# unk. words
Pt-DT	18,049	13,417	6,929
Es-DT	22,815	6,961	3,231
De-DT	31,900	5,856	1,762
Nl-DT	19,012	3,316	1,428
Eu-DT	1,092	6,553	5,446

Table 2: Dictionary coverage for each dataset on the train set when available, on the dev set else.

## 6 Experiment settings

**Data** For the En-DT, we follow previous works in using the official test set of 38 documents. For the Es-DT, we report results on the test set A.<sup>17</sup> For all the other corpora, we randomly choose 38 documents to make a test set, and either use the remaining documents as development set (Nl-DT and Eu-DT), or split them into a development set of 25 documents, the remaining being used as training set (En-DT, Es-DT, Pt-DT and De-DT).

All the results given are based on a gold segmentation of the documents.

Each dataset is parsed using UDPipe,<sup>18</sup> thus tokenizing, splitting into sentences and annotating each document based on the Universal Dependency scheme (Nivre et al., 2016).

The word features for the non-English datasets are translated using available bilingual Wiktionaries<sup>19</sup> without disambiguation, the coverage of each dictionary is given in Table 2. We also look for a translation of the lemma (and of the stems for the languages for which a stemmer<sup>20</sup> was available) as a backup strategy. When no translation is found, we keep the original token.

The word embeddings used were built on the EuroParl corpus (Levy et al., 2017). We keep only the 50 first dimensions of the vectors representing the words, our preliminary experiments suggesting no significant differences against keeping the whole 200 dimensions. Unknown words are represented by the average vector of all word vectors. For Basque, we had no access to these embeddings, we thus only report results using bilingual Wiktionaries.

<sup>16</sup>Having more than three tokens in the head set is rare.

<sup>17</sup>We found similar performance on the other test set.

<sup>18</sup><http://ufal.mff.cuni.cz/udpipe>

<sup>19</sup>[https://en.wiktionary.org/wiki/User:Matthias\\_Buchmeier](https://en.wiktionary.org/wiki/User:Matthias_Buchmeier)

<sup>20</sup><https://pypi.python.org/pypi/snowballstemmer>

**Parameter tuning** In our experiments we optimized on the development set the following parameters: the learning rate  $\in \{0.01, 0.02, 0.03\}$ , the learning rate decay constant  $\in \{10^{-5}, 10^{-6}, 10^{-7}, 0\}$ , the number of iterations  $\in [1 - 20]$ , and the size of the beam  $\in \{1, 2, 4, 8, 16, 32\}$ . We fixed the number  $N$  of hidden layers to 2 and the size of the hidden layers  $H$  to 128 after experimenting on the En-DT (with  $N \in \{1, 2, 3\}$  and  $H \in \{64, 128\}$ ).

We fixed the size of the vectors for each feature to 50 for word features,<sup>21</sup> 16 for POS, 6 for position, 4 for length, and 2 for other features.

**Metrics** Following (Marcu, 2000b) and most subsequent work, output trees are evaluated against gold trees in terms of how similar they bracket the EDUs (Span), how often they agree about nuclei when predicting a true bracket (Nuclearity), and in terms of the relation label, i.e., the overlap between the shared brackets between predicted and gold trees (Relation).<sup>22</sup> These scores are analogous to labeled and unlabeled syntactic parser evaluation metrics.

**Baseline** Since we do not have state-of-the-art results for most of the languages, we provide results for a simple most frequent baseline (System MFS) that labels all nodes with the most frequent relation in the training or development set – that is NN-JOINT for De-DT and Es-DT, and NS-ELABORATION for the others –, and build the structure by right-branching.

## 7 Results

**Monolingual experiments** Monolingual experiments are aimed at evaluating performance for languages having a large annotated corpus (at least 100 documents). Our results are summarized in Table 3. Our parser is competitive with state-of-the-art systems for English (first line in Table 3), with even better performance for unlabeled structure (85.04%) and structure labeled with nuclearity (72.29%). These results show that using all the words in the units (Ji and Eisenstein, 2014; Li et al., 2014), is not as useful as using more contextual information, that is taking more DUs into account (left and right children of the CDUs in the stack). However, the slight drop for Relation shows that

<sup>21</sup>When using embeddings, the final vector is of size 350.

<sup>22</sup>We use the evaluation script provided at <https://github.com/jiyfeng/DPLP>.

we probably miss some lexical information, or that we need to choose a more effective combination scheme than concatenation. We plan to use bi-LSTM encoders (Hochreiter and Schmidhuber, 1997) to construct fixed-length representations of EDUs.

For the other languages, performance are still high for unlabeled structure, but far lower for labeled structure except for Spanish. For this language, the quite high performance obtained were unexpected, since the corpus is far much smaller than the Portuguese one. One possible explanation is that the Portuguese corpus is in fact a mix of different corpora, with varied domains, and possibly changes in annotation choices. On the other hand, the low results for German show the sparsity issue since it is the language for which we have the fewest annotations (“#CDU”, see Table 1).

**Cross-lingual experiments** When only relying on data from different languages (“Cross” in Table 3), we observe a large drop in performance compared to monolingual systems. The source-only discourse parsers still have fairly high performance for unlabeled structure (around 70% or higher), the scores being especially low for relation identification. This could indicate that our representation does not generalize well. But it also comes from differences among the corpora. For example, only the En-DT and the Pt-DT use the relation `ATtribution`. This leads to a large drop in performance associated with this relation, when one of these corpora is not in the training data, especially for the source-only system for the En-DT (from 93% in  $F_1$  to 30%). On the other hand, on the En-DT, we observe improvement for other relations either largely represented in all the corpora (e.g. `JOINT` +3%), or under-represented in the En-DT (e.g. `CONDITION` +3%).

When combining corpora for source and target languages (“+ dev.” in Table 3), we obtain our best performing system for English, with all scores improved compared to our best monolingual system (+0.8 for Nuclearity and +1.3 for Relation). Otherwise scores are similar to the monolingual case.

Finally, for languages without training set (NI-DT and Eu-DT), this strategy allows us to build parsers outperforming our simple baseline (MFS) by around 11–13% for Span, 8–15% for Nuclearity and 6–11% for Relation. Having at least some annotated data to make a development set allows improvements against only using corpora in other

System	En-DT			Pt-DT			Es-DT			De-DT			NI-DT			Eu-DT

+ dev.	<b>85.1</b>	<b>73.1</b>	61.4	81.9	65.1	49.8	88.8	68.0	50.4	79.6	53.6	34.1	<b>69.2</b>	<b>43.4</b>	<b>28.3</b>	76.7	50.5	<b>29.5</b>
Human <sup>b</sup>	88.7	77.7	65.8	-	78	66	86	82.5	76.8	-	-	-	83	77	70	81.7	-	61.5

Table 3: Performance of our monolingual and cross-lingual systems for Span (Sp), Nuclearity (Nuc) and Relation (Rel). “MFS” corresponds to the baseline system described in Section 6; “+ emb.” is the monolingual system using word embeddings; “+dev.” means that the system is optimized on the development set of the target language (vs the union of the source development sets). For cross-lingual systems, we only report our best results using either word embeddings or bilingual dictionaries.

<sup>a</sup>Scores reported from (Li et al., 2014), and DPLP (Ji and Eisenstein, 2014).

<sup>b</sup>For Brazilian Portuguese, inter-annotator agreement scores are only available for the CST-news corpus ; For Spanish, only precision scores are reported ; For Basque, the scores reported are different (Iruskieta et al., 2015).

languages (around +3% for the NI-DT and the Eu-DT for Relation). On the other hand, we probably overfit our development data for the Eu-DT, since better results were obtained for unlabeled structure (+2%) and structure with nuclearity (+2.5%) using only data in other languages.

**Word embeddings** Using word embeddings (“+emb” in Table 3) for monolingual systems often leads to an important drop in performance, especially for Relation (from  $-1.1$  to  $-4.2\%$ ). This demonstrates that these embeddings do not provide the large range of information needed for relation identification, a task inherently semantic. We believe however that the results are not too low to prevent for interesting applications. It is noteworthy that the English parser with embeddings is still better than the systems proposed in (Hernault et al., 2010; Joty et al., 2013).

For cross-lingual experiments, the bilingual dictionaries perform generally better than embeddings (except for Pt-DT and De-DT for source-only systems), demonstrating again that we need representations more tailored to the task to leverage all relevant lexical information.

## 8 Conclusion

We introduced a new discourse parser that obtains state-of-the-art performance for English. We harmonized discourse treebanks for several languages, enabling us to present results for five other languages for which available corpora are smaller, including the first cross-lingual discourse parsing

results in the literature.

## Abstract

In an end-to-end dialog system, the aim of dialog state tracking is to accurately estimate a compact representation of the current dialog status from a sequence of noisy observations produced by the speech recognition and the natural language understanding modules. This paper introduces a novel method of dialog state tracking based on the general paradigm of machine reading and proposes to solve it using an End-to-End Memory Network, MemN2N, a memory-enhanced neural network architecture. We evaluate the proposed approach on the second Dialog State Tracking Challenge (DSTC-2) dataset. The corpus has been converted for the occasion in order to frame the hidden state variable inference as a question-answering task based on a sequence of utterances extracted from a dialog. We show that the proposed tracker gives encouraging results. Then, we propose to extend the DSTC-2 dataset and the definition of this dialog state task with specific reasoning capabilities like counting, list maintenance, yes-no question answering and indefinite knowledge management. Finally, we present encouraging results using our proposed MemN2N based tracking model.

## 1 Introduction

One of the core components of state-of-the-art and industrially deployed dialog systems is a dialog state tracker. Its purpose is to provide a compact representation of a dialog produced from past user inputs and system outputs which is called the dialog state. The dialog state summarizes the infor-

mation needed to successfully maintain and finish a dialog, such as users' goals or requests. In the simplest case of a so-called *slot-filling schema*, the state is composed of a predefined set of variables with a predefined domain of expression for each of them. As a matter of fact, in the recent context of end-to-end trainable machine learnt dialog systems, state tracking remains a central element of such architectures (Wen et al., 2016). Current models, mainly based on the principle of discriminative learning, tend to share three common limitations. First, the tracking task is performed using a fixed window of the past dialog utterances as support for decision. Second, the possible correlations between the set of tracked variables are not leveraged and individual trackers tend to be learnt independently. Third, the tracking task is summarized as the capability of inferring values for a predefined set of latent variables. Starting from these observations, we propose to formalize the task of state tracking as a particular instance of machine reading problem. Indeed, these formalization and the proposed resolution model called MemN2N (Weston et al., 2015) allow to define a tracker that is able to decide at the utterance level on the basis of the current entire dialog. Indeed, the model learns to focus its attention on the meaningful parts of the dialog regarding the currently asked slot and can eventually capture possible correlation between slots. As far as our knowledge goes, it is the first attempt to explicitly frame the task of dialog state tracking as a machine reading problem. Finally, such formalization allows for the implementation of approximate reasoning capability that has been shown to be crucial for any machine reading tasks (Weston et al., 2015) while extending the task from slot instantiation to question answering. This paper is structured as follows, Section 2 recalls the main definitions associated to transactional dialogs and describes

---

\*Work carried out as an intern at XRCE

the associated problem of statistical dialog state tracking with both the generative and discriminative approaches. At the end of this section, the limitations of the current models in terms of necessary annotations and reasoning capabilities are addressed. Then, Section 3 depicts the proposed machine reading model for dialog state tracking and proposes to extend a state of the art dialog state tracking dataset, *DSTC-2*, to several simple reasoning capabilities. Section 4 illustrates the approach with experimental results obtained using a state of the art benchmark for dialog state tracking.

## 2 Dialog state tracking

### 2.1 Main Definitions

A dialog state tracking task is formalized as follows: at each turn of a dyadic dialog, the dialog agent chooses a dialog act  $d$  to express and the user answers with an utterance  $u$ . In the simplest case, the dialog state at each turn is defined as a distribution over a set of predefined variables, which define the structure of the state (Williams et al., 2005). This classic state structure is commonly called *slot filling* or *semantic frame*. In this context, the state tracking task consists of estimating the value of a set of predefined variables in order to perform a procedure or transaction which is the purpose of the dialog. Typically, a natural language understanding module processes the user utterance and generates an N-best list  $o = \{(d_1, f_1), \dots, (d_n, f_n)\}$ , where  $d_i$  is the hypothesized user dialog act and  $f_i$  is its confidence score. Various approaches have been proposed to define dialog state trackers. The traditional methods used in most commercial implementations use hand-crafted rules that typically rely on the most likely result from an NLU module (Yeh et al., 2014) and hardly models uncertainty. However, these rule-based systems are prone to frequent errors as the most likely result is not always the correct one (Williams, 2014).

More recent methods employ statistical approaches to estimate the posterior distribution over the dialog states allowing them to leverage the uncertainty of the results of the NLU module. In the simplest case where no ASR and NLU modules are employed, as in a text based dialog system (Henderson et al., 2013), the utterance is taken as the observation using a so-called bag of words representation. If an NLU module is available, stan-

dardized dialog act schemes can be considered as observations (Bunt et al., 2010). Furthermore, if prosodic information is available from the ASR component of the dialog system (Milone and Rubio, 2003), it can also be considered as part of the observation definition. A statistical dialog state tracker maintains, at each discrete time step  $t$ , the probability distribution over states,  $b(s_t)$ , which is the system’s *belief* over the state. The actual slot filling process is composed of the cyclic tasks of *information gathering* and integration, in other words – *dialog state tracking*. In such framework, the purpose is to estimate as early as possible in the course of a given dialog the correct instantiation of each variable. In the following, we will assume the state is represented as a set of variables with a set of known possible values associated to each of them. Furthermore, in the context of this paper, only the bag of words has been considered as an observation at a given turn but dialog acts or detected named entity provided by an SLU module could have also been incorporated.

Two statistical approaches have been considered for maintaining the distribution over a state given sequential NLU output. First, the discriminative approach aims to model the posterior probability distribution of the state at time  $t + 1$  with regard to state at time  $t$  and observations  $z_{1:t}$ . Second, the generative approach attempts to model the transition probability and the observation probability in order to exploit possible interdependencies between hidden variables that comprise the dialog state.

### 2.2 Generative Dialog State Tracking

A generative approach to dialog state tracking computes the belief over the state using Bayes’ rule, using the belief from the last turn  $b(s_{t-1})$  as a prior and the likelihood given the user utterance hypotheses  $p(z_t|s_t)$ , with  $z_t$  the observation gathered at time  $t$ . In prior works (Williams et al., 2005), the likelihood is factored and some independence assumptions are made:  $b_t \propto \sum_{s_{t-1}, z_t} p(s_t|z_t, s_{t-1})p(z_t|s_{t-1})b(s_{t-1})$ . A typical generative model uses a factorial hidden Markov model (Ghahramani and Jordan, 1997). In this family of approaches, scalability is considered as one of the main issues. One way to reduce the amount of computation is to group the states into partitions, as proposed in the Hidden Information State (HIS) model (Gasic and Young, 2011). Other

approaches to cope with the scalability problem in dialog state tracking is to adopt a factored dynamic Bayesian network by making conditional independence assumptions among dialog state components, and then using approximate inference algorithms such as loopy belief propagation (Thomson and Young, 2010) or a blocked Gibbs sampling as (Raux and Ma, 2011). To cope with such limitations, discriminative methods of state tracking presented in the next part of this section aim at directly model the posterior distribution of the tracked state using a chosen parametric form.

### 2.3 Discriminative Dialog State Tracking

The discriminative approach of dialog state tracking computes the belief over a state via a parametric model that directly represents the belief  $b(s_{t+1}) = p(s_{t+1}|s_t, z_t)$ . For example, Maximum Entropy has been widely used in the discriminative approach (Metallinou et al., 2013). It formulates the belief as follows:  $b(s) = P(s|x) = \eta \cdot e^{w^T \phi(x,s)}$ , where  $\eta$  is the normalizing constant,  $x = (d_1^u, d_1^m, s_1, \dots, d_t^u, d_t^m, s_t)$  is the history of user dialog acts,  $d_i^u, i \in \{1, \dots, t\}$ , the system dialog acts,  $d_i^m, i \in \{1, \dots, t\}$ , and the sequence of states leading to the current dialog turn at time  $t$ . Then,  $\phi(\cdot)$  is a vector of feature functions on  $x$  and  $s$ . Finally,  $w$  is the set of model parameters to be learned from annotated dialog data. Finally, deep neural models, performing on a sliding window of features extracted from previous user turns, have also been proposed in (Henderson et al., 2014c; Mrksic et al., 2016). Of the current literature, this family of approaches have proven to be the most efficient for publicly available state tracking datasets. Recently, deep learning based models implementing this strategy (Mrksic et al., 2016; Henderson et al., 2014a; Williams et al., 2016) have shown state of the art results. This approaches tends to leverage unsupervised training word representation (Mikolov et al., 2013).

### 2.4 Current Limitations

Using error analysis (Henderson et al., 2014b), three limitations can be observed in the application of these inference approaches. First, current models tend to fail at considering long-tail dependencies that occurs on dialogs. For example, coreferences, inter-utterances informations and correlations between slots have been shown to be difficult to handle even with the usage of recurrent network models (Henderson et al., 2014a). To illustrate the

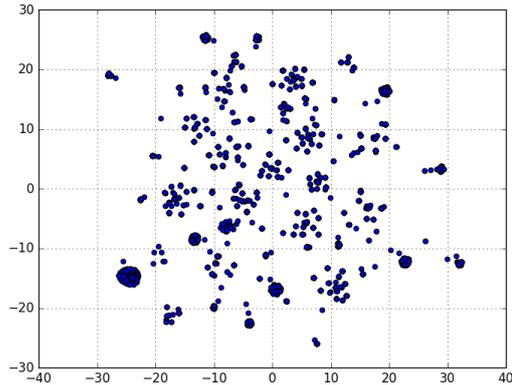

Figure 1: T-SNE transformation of the final state of DSTC-2 train set.

inter-slot correlation, Figure 1 depicted the t-SNE (van der Maaten and Hinton, 2008) projected final state of the dialog of the DSTC-2 training set. On the other hand, reasoning capabilities, as required in machine reading applications (Poon and Domingos, 2010; Etzioni et al., 2007; Berant et al., 2014; Weston et al., 2015) remain absent in these classic formalizations of dialog state tracking. Finally, tracking definition is limited to the capability to instantiate a predefined set of slots. In the next section, we present a model of dialog state tracking that aims at leveraging the current advances of MemN2N, a memory-enhanced neural networks and their approximate reasoning capabilities that seems particularly adapted to the sequential, long range dependency equipped and sparse nature of complex dialog state tracking tasks. Furthermore, this model allows to relax the hypothesis of strict utterance-level annotation that does not corresponds to common practices in industrial applications of transactional conversational user interfaces where annotations tend to be placed at a multi-utterance level or full-dialog level only.

## 3 Machine Reading Formulation of Dialog State Tracking

We propose to formalize the dialog state tracking task as a machine reading problem (Etzioni et al., 2007; Berant et al., 2014). In this section, we recall the main definitions of the task of machine reading, then describes the MemN2N, a memory-enhanced neural network architectures proposed to handle such tasks in the context of dialogs. Finally, we formalize the task of dialog state tracking as a machine reading problem and propose to

solve it using a memory-enhanced neural architecture of inference.

### 3.1 Machine Reading

The task of textual understanding has recently been formulated as a supervised learning problem (Kumar et al., 2015; Hermann et al., 2015). This task consists in estimating the conditional probability  $p(a|d, q)$  of an answer  $a$  to a question  $q$  where  $d$  is a document. Such an approach requires a large training corpus of {Document - Query - Answer} triples and until now such corpora have been limited to hundreds of examples (Richardson et al., 2013). In the context of dialog state tracking, it can be understood as the capability of inferring a set of latent values  $l$  associated with a set of variables  $v$  related to a given dyadic or multi-party conversation  $d$ , from direct correlation and/or reasoning, using the course of exchanges of utterances,  $p(l|d, v)$ .

State updates at an utterance-level are rarely provided off-the-shelf from a production environment. In these environments, annotation is often performed afterward for the purpose of logging, monitoring or quality assessment. In the limit cases, as in human-to-human dialog systems, dialog-level annotations remains a common practice of annotation especially in personal assistance, customer care dialogs and, in a more general sense, industrial application of transactional conversational user interfaces. Another frequent setting consist of informing the state after a given number of utterance exchange between the locutors. So an additional effort of specific annotation is often needed in order to train a state of the art statistical state tracking model (Henderson et al., 2014b). In that sense, formalizing dialog state tracking at a sub-dialog level in order to infer hidden state variables with respect to a list of utterances started from the first one to any given utterance of a given dialog seems particularly appropriate. In the context of dialog state tracking challenges, the *DSTC-4* dialog corpus have been designed in such purpose but only consists of 22 dialogs. Concerning the *DSTC-2* corpus, the training data contains 2207 dialogs (15611 turns) and the test set consists of 1117 dialogs (Williams et al., 2016). This dataset is more suitable for our experiments.

For these reasons, the machine reading paradigm becomes a promising formulation for

the general problem of dialog state tracking. Furthermore, current approaches and available datasets for state tracking do not explicitly cover reasoning capabilities such as temporal and spatial reasoning, counting, sorting and deduction. We suggest that in the future dataset dialogs expressing such specific abilities should be developed. In this last part, several reasoning enhancements are suggested to the *DSTC-2* dataset.

### 3.2 End-to-End Memory Networks

The MemN2N architecture, introduced by (Weston et al., 2015), consists of two main components: supporting memories and final answer prediction. Supporting memories are in turn comprised of a set of input and output memory representations with memory cells. The input and output memory cells, denoted by  $m_i$  and  $c_i$ , are obtained by transforming the input context  $x_1, \dots, x_n$  (i.e a set of utterances) using two embedding matrices  $A$  and  $C$  (both of size  $d \times |V|$  where  $d$  is the embedding size and  $|V|$  the vocabulary size) such that  $m_i = A\Phi(x_i)$  and  $c_i = C\Phi(x_i)$  where  $\Phi(\cdot)$  is a function that maps the input into a bag of dimension  $|V|$ .

Similarly, the question  $q$  is encoded using another embedding matrix  $B \in \mathbb{R}^{d \times |V|}$ , resulting in a question embedding  $u = B\Phi(q)$ . The input memories  $\{m_i\}$ , together with the embedding of the question  $u$ , are utilized to determine the relevance of each of the stories in the context, yielding in a vector of attention weights

$$p_i = \text{softmax}(u^\top m_i) \quad (1)$$

where  $\text{softmax}(a_i) = \frac{e^{a_i}}{\sum_i e^{a_i}}$ . Subsequently, the response  $o$  from the output memory is constructed by the weighted sum:

$$o = \sum_i p_i c_i \quad (2)$$

Other models of parametric encoding for the question and the document have been proposed in (Kumar et al., 2015). For the purpose of this presentation, we will keep with definition of  $\Phi$ .

For more difficult tasks requiring multiple supporting memories, the model can be extended to include more than one set of input/output memories by stacking a number of memory layers. In this setting, each memory layer is named a hop and the  $(k+1)^{\text{th}}$  hop takes as input the output of the  $k^{\text{th}}$  hop:

$$u^{k+1} = o^k + u^k \quad (3)$$

Lastly, the final step, the prediction of the answer to the question  $q$ , is performed by

$$\hat{a} = \text{softmax}(W(o^K + u^K)) \quad (4)$$

where  $\hat{a}$  is the predicted answer distribution,  $W \in \mathbb{R}^{|V| \times d}$  is a parameter matrix for the model to learn and  $K$  the total number of hops.

Two weight tying schemes of the embedding matrices have been introduced in (Weston et al., 2015):

1. **Adjacent:** the output embedding matrix in the  $k^{\text{th}}$  hop is shared with the input embedding matrix in the  $(k+1)^{\text{th}}$  hop, i.e.,  $A^{k+1} = C^k$  for  $k \in \{1, K-1\}$ . Also, the weight matrix  $W$  in Equation (4) is shared with the output embedding matrix in the last memory hop such that  $W^\top = C^K$ .
2. **Layer-wise:** all the weight matrices  $A^k$  and  $C^k$  are shared across different hops, i.e.,  $A^1 = A^2 = \dots = A^K$  and  $C^1 = C^2 = \dots = C^K$ .

In the next section, we show how the task of dialog state tracking can be formalized as machine reading task and solved using such memory enhanced model.

### 3.3 Dialog Reading Model for State Tracking

In this section, we formalize dialog state tracking using the paradigm of machine reading. As far as our knowledge goes, it is the first attempt to apply this approach and develop a specific dataset format, detailed in Section 4, from an existing and publicly available dialog state tracking challenge dataset to fulfill this task. Assuming (1) a dyadic dialog  $d$  composed of a list of utterances, (2) a state composed with (2a) a set of variables  $v_i$  with  $i = \{1, \dots, n\}$  and (2b) a set of corresponding assigned values  $l_i$ . One can define a question  $q_v$  that corresponds to the specific querying of a variable in the context of a dialog  $p(l_i|q_v, d)$ . In such context, a dialog state tracking task consists in determining for each variable  $v$ ,  $l^* = \arg \max_{l_i \in L} p(l_i|q_v, d)$ , with  $L$  the specific domain of expression of a variable  $v_i$ .

In addition to the actual dataset, we propose to investigate four general reasoning tasks using *DSTC-2* dataset as a starting point. In such way, we leverage the dataset of *DSTC-2* to create more complex reasoning task than the ones present in the original dialogs of the dataset by performing rule-based modification over the corpus. Obviously, the goal is to develop resolution algorithms

that are not dedicated to a specific reasoning task but inference models that will be as generic as possible. In the rest of the section, each of the reasoning tasks associated with dialog state tracking are described and the generation protocol is explained with examples.

**Factoid Questions :** This first task corresponds to the current formulation of dialog state tracking. It consists of questions where a previously given a set of supporting facts, potentially amongst a set of other irrelevant facts, provides the answer. This kind of task was already employed in (Weston et al., 2014) in the context of a virtual world. In that sense, the result obtained to such task are comparable with the state of the art approaches.

**Yes/No Questions :** This task tests the ability of a model to answer true/false type questions like “*Is the food italian ?*”. The conversion of a dialog to such format is deterministic regarding the fact that the utterances and corresponding true states are known at each utterance of a given dialog.

**Indefinite Knowledge :** This task tests a more complex natural language construction. It tests if statements can be models in order to describe possibilities rather than certainties, as proposed in (Weston et al., 2014). In our case, the answer will be “maybe” to the question “*Is the price-range required moderate ?*” if the slot hasn’t been mentioned yet throughout the current dialog. In the case of state tracking, it will allow to seamlessly deal with unknown information about the dialog state. Concretely, this set of questions and answers are generated has a super-set of the Yes-No Questions set. First, sub-dialog starting from the first utterance of a given dialog are extracted under the condition that a given slot is not informed in the corresponding annotation. Then, a question-answering question is generated.

**Counting and Lists/Sets :** This last task tests the capacity of the model to perform simple counting operations, by asking about the number of objects with a certain property, e.g. “*How many area are requested ?*”. Similarly, the ability to produce a set of single word answers in the form of a list, e.g. “*What are the area requested ?*” is investigated. Table 1 give an example of each of the question type presented below on a dialog sample of *DSTC-2* corpus.

**Inference procedure:** Concretely, the current set of utterances of a dialog will be placed into the memory using sentence based encoding and the

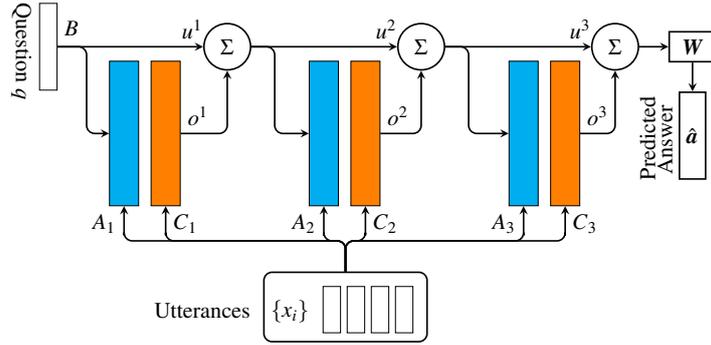

Figure 2: Illustration of the proposed MemN2N based state dialog tracker model with 3 hops.

question will be encoded as the controller state at  $t = 1$ . The answer will be produced using a softmax operation over the answer vocabulary that is supposed fixed. We consider this hypothesis valid in the case of factoid and list questions because the set of value for a given variable is often considered known. In the cases of Yes/No and Indefinite knowledge question, {Yes, No, Maybe} are added to the output vocabulary. Following (Weston et al., 2014), a list-task answer will be considered as a single element in the answer set and the count question. A possible alternative would be to change the activation function used at the output of the MemN2N from softmax activation function to a logistic one and to use a categorical cross entropy loss. A drawback of such alternative would be the necessity of cross-validating a decision threshold in order to select a eligible answers. Concerning the individual numbers for the count question set, the numbers founded on the training set are added into the vocabulary.

We believe more reasoning capabilities need to be explore in the future, like spacial and temporal reasoning or deduction as suggested in (Weston et al., 2015). However, it will probably need the development of a new dedicated resource. Another alternative could be to develop a question-answering annotation task based on a dialog corpus where reasoning task are present. The closest work to our proposal that can be cited is (Bordes and Weston, 2016). In this paper, the authors defines a so-called End-to-End learnable dialog system to infer an answer from a finite set of eligible answers w.r.t the current list of utterances of the dialog. The authors generate 5 artificial tasks of dialog. However the reasoning capabilities are not explicitly addressed and the author explicitly claim that the resulting dialog system is not satisfactory

yet. Indeed, we believe that having a proper dialog state tracker where a policy is built on top can guarantee dialog achievement by properly optimizing a reward function throughout a explicitly learnt dialog policy. In the case of proper end-to-end systems, the objective function is still not explicitly defined (Serban et al., 2015) and the resulting systems tend to be used in the context of chat-oriented and non-goal oriented dialog systems. In the next section, we present experimental details and results obtained on the basis of the *DSTC-2* dataset and its conversion to the four mentioned reasoning tasks.

## 4 Experiments

### 4.1 Dataset and Data Preprocessing

In the *DSTC-2* dialog corpus, a user queries a database of local restaurants by interacting with a dialog system. A dialog proceeds as follows: first, the user specifies constraints concerning the restaurant. Then, the system offers the name of a restaurant that satisfies the constraints. Finally, the user accepts the offer and requests additional information about the accepted restaurant. In this context, the dialog state tracker should be able to track several types of information that compose the state like the geographic area, the food type and the price range slots. In order to make comparable experiments, sub-dialogs generated from the first utterance to each utterance of each dialog of the corpus have been generated. The corresponding question-answer pairs have been generated using the annotated state for each of the sub-dialog. In the case of factoid question, this setting allows for fair comparison at the utterance-level state tracking gains with the prior art. The same protocol has been adopted for the generated reasoning task. In that sense, the tracker task consists

Index	Actor	Utterance
1	Cust	Im looking for a cheap restaurant in the west or east part of town.
2	Agent	Thanh Binh is a nice restaurant in the west of town in the cheap price range.
3	Cust	What is the address and post code.
4	Agent	Thanh Binh is on magdalene street city centre.
5	Cust	Thank you goodbye.
6		<b>Factoid Question</b> What is the pricerange ? Answer: {Cheap}
7		<b>Yes/No Question</b> Is the Pricerange Expensive ? Answer: {No}
8		<b>Indefinite Knowledge</b> Is the FoodType chinese ? Answer: {Maybe}
8		<b>Listing task</b> What are the areas ? Answer: {West,East}

Table 1: : Dialog state tracking question-answering examples from *DSTC2* dataset

in finding the value  $l^*$  as defined in Section 3.3. In the overall dialog corpus, Area slot counts 5 possible values, Food slot counts 91 possible values and Pricerange slot counts 3 possible values. In order to exhibit reasoning capability of the proposed model in the context of dialog state tracking, three other dataset have been automatically generated from the dialog corpus in order to support 3 capabilities of reasoning described in Section 3.3. Dialog modification has been required for two reasoning tasks, *List* and *Count*. Two types of rules have been developed to automatically produce modified dialogs. On a first hand, string matching has been performed to determine the position of a slot values in a given utterance and an alternative statement has been produced as a substitution. For example, the utterance “*I’m looking for a chinese restaurant in the north*” can be replaced by “*I’m looking for a chinese restaurant in the north or the west of town*”. A second type of modification has been performed in an inter-utterance fashion. For example, assuming a given value “north” has been informed in the current state of a given dialog, one can add lately in the dialog a remark like “I would also accept a place east side of town”. This kind of statement tends to not affect the overall flow of the dialog and allows to add richer semantic to the dialog. In the future, we plan to develop a richer set of generation procedures to augment the dataset. Nevertheless, we believe this simple dialog augmentation strategy allows to exhibit the competency of the proposed model beyond factoid questions.

## 4.2 Training Details

As suggested in (Sukhbaatar et al., 2015), 10% of the set was held-out to form a validation set for hyperparameter tuning. Concerning the utterance encoding, we use the so-called *Temporal Encoding* technique. In fact, reading tasks require some notion of temporal context. To enable the model

to address them, the memory vector is modified as such  $m_i = \sum_j Ax_{ij} + T_A(i)$ , where  $T_A(i)$  is the  $i^{th}$  row of a dedicated matrix  $T_A$  that encodes temporal information. The output embedding is augmented in the same way with a matrix  $T_c$  (e.g.  $c_i = \sum_j Cx_{ij} + T_C(i)$ ). Both  $T_A$  and  $T_C$  are learned during training in an end-to-end fashion. They are also subject to the same sharing constraints as  $A$  and  $C$ . The embedding matrix  $A$  and  $B$  are initialized using GoogleNews word2vec embedding model (Mikolov et al., 2013). Also suggested on (Sukhbaatar et al., 2015), utterances are indexed in reverse order, reflecting their relative distance from the question so that  $x_1$  is the last sentence of the dialog. Furthermore, adjacent weight tying schema has been adopted. Learning rate  $\eta$  is initially assigned a value of 0.005 with exponential decay applied every 25 epochs by  $\eta/2$  until 100 epochs are reached. Then, *linear start* is used in all our experiments as proposed by (Sukhbaatar et al., 2015). More precisely, the softmax function in each memory layer is removed and re-inserted after 20 epochs. Batch size is set to 16 and gradients with an  $L_2$  norm larger than 40 are divided by a scalar to have norm 40. All weights are initialized randomly from a Gaussian distribution with zero mean and  $\sigma = 0.1$ . In all our experiments, we have tested a set of the embedding size  $d \in \{20, 40, 60\}$ . After validation, each model uses a 5-hops depth configuration.

## 4.3 Experimental results

Table 3 presents tracking accuracy obtained for three variables of the *DSTC2* dataset formulated as *Factoid Question* task. We compare with two established utterance-level discriminative neural trackers, a Recurrent Neural Network (RNN) model (Henderson et al., 2014a) and the Neural Belief Tracker (Mrksic et al., 2016). As suggested in this last work, the first RNN baseline model uses no semantic (i.e. synonym) dictionary, while

<b>What is the area ? Answer: dontcare</b>						

Table 2: Attention shifting example for the *Area* slot from *DSTC2* dataset, the values corresponds the  $p_i$  values affected to each memory block  $m_i$  at each hop of the MemN2N

the improved baseline uses a hand-crafted semantic dictionary designed for the *DSTC2* ontology. In this context, a MemN2N model allows to obtain competitive results with the most close, non-memory enhanced, state of the art approach of recurrent neural network with word embedding as prior knowledge.

Model	Area	Food	Price	Joint
RNN - no dict.	0.92	0.86	0.86	0.69
RNN + sem. dict.	0.91	0.86	0.93	0.73
NBT-DNN	<b>0.90</b>	0.84	0.94	0.72
NBT-CNN	<b>0.90</b>	0.83	0.93	0.72
MemN2N( $d = 40$ )	0.89	<b>0.88</b>	<b>0.95</b>	<b>0.74</b>

Table 3: **One supporting fact task** : Acc. obtained on DSTC2 test set

As a second result, Table 4 presents the performance obtained for the four reasoning tasks. The obtained results lead us to think that MemN2N are a competitive alternative for the task dialog state tracking but also increase the spectrum of definition of the general dialog state tracking task to machine reading and reasoning. In the future, we believe new reasoning capabilities like spacial and temporal reasoning and deduction should be exploited on the basis of a specifically designed dataset.

## 5 Conclusion and Further Work

This paper describes a novel method of dialog state tracking based on the paradigm of machine reading and solved using MemN2N, a memory-enhanced neural network architecture. In this context, a dataset format inspired from the current datasets of machine reading tasks has been developed for this task. It is the first attempt to solve this classic sub-problem of dialog management in

Variable	d	Yes-No	I.K.	Count.	List.

Table 4: **Reasoning tasks** : Acc. on DSTC2 reasoning datasets

such way. Beyond the experimental results presented in the experimental section, the proposed approach offers several advantages compared to state of the art methods of tracking. First, the proposed method allows to perform tracking on the basis of segment-dialog-level annotation instead of utterance-level one that is commonly admitted in academic datasets but tedious to produce in a large scale industrial environment. Second, we propose to develop dialog corpus requiring reasoning capabilities to exhibit the potential of the proposed model. In future work, we plan to address more complex tasks like spatial and temporal reasoning, sorting or deduction and experiment with other memory enhanced inference models. Indeed, we plan to experiment and compare the same approach with Stacked-Augmented Recurrent Neural Network (Joulin and Mikolov, 2015) and Neural Turing Machine (Graves et al., 2014) that sounds also promising for these family of reasoning tasks.

## Abstract

Automated discourse analysis tools based on Natural Language Processing (NLP) aiming at the diagnosis of language-impairing dementias generally extract several textual metrics of narrative transcripts. However, the absence of sentence boundary segmentation in the transcripts prevents the direct application of NLP methods which rely on these marks to function properly, such as taggers and parsers. We present the first steps taken towards automatic neuropsychological evaluation based on narrative discourse analysis, presenting a new automatic sentence segmentation method for impaired speech. Our model uses recurrent convolutional neural networks with prosodic, Part of Speech (PoS) features, and word embeddings. It was evaluated intrinsically on impaired, spontaneous speech, as well as, normal, prepared speech, and presents better results for healthy elderly (CTL) ( $F_1 = 0.74$ ) and Mild Cognitive Impairment (MCI) patients ( $F_1 = 0.70$ ) than the Conditional Random Fields method ( $F_1 = 0.55$  and  $0.53$ , respectively) used in the same context of our study. The results suggest that our model is robust for impaired speech and can be used in automated discourse analysis tools to differentiate narratives produced by MCI and CTL.

## 1 Introduction

Mild Cognitive Impairment (MCI) has recently received much attention, as it may represent a pre-clinical state of Alzheimer’s disease (AD). MCI can affect one or multiple cognitive domains (e.g. memory, language, visuospatial skills and the ex-

ecutive function); the kind that affects memory, called amnesic MCI, is the most frequent and that which most often converts to AD (Janoutová et al., 2015). As dementias are chronic progressive diseases, it is important to identify them in the early stages, because early detection yields a greater chance of success for non-pharmacological treatment strategies such as cognitive training, physical activity and socialization (Teixeira et al., 2012). The definition of MCI diagnostic criteria is conducted mainly by the cognitive symptoms presented by patients in standardized tests and by functional impairments in daily life (McKhann et al., 2011). Difficulties related with narrative discourse deficits (e.g. repetitions or gaps during the narrative) may lead an elderly individual to look for a specialist. Narrative discourse is the reproduction of an experienced episode (necessarily evoking memory), respecting temporal and causal relations among events. Although MCI is clinically characterized by episodic memory deficits, language impairment may also occur.

Certain widely used neuropsychological tests require patients to retell or understand a story. This is the case of the logical memory test, where one reproduces a story after listening to it. The higher the number of recalled elements from the narrative, the higher the memory score (Wechsler, 1997; Bayles and Tomoeda, 1991; Morris et al., 2006). However, the main difficulties in applying these tests are: (i) time required, since it is a manual task; and (ii) the subjectivity of the clinician. Therefore, automatic analysis of discourse production is seen as a promising solution for MCI diagnosis, because its early detection ensures a greater chance of success in addressing potentially reversible factors (Muangpaisan et al., 2012). Since discourse is a natural form of communication, it favors the observation of the patient’s functionality in everyday life. Moreover, it

provides data for observing the language-cognitive skills interface, such as executive functions (planning, organizing, updating and monitoring data).

With regard to the Wechsler Logical Memory (WLM) test, the original narrative used is short, allowing for the use of Automatic Speech Recognition (ASR) output even without capitalization and sentence segmentation, as shown by Lehr et al. (2012) for English. They based their method on automatic alignment of the original and patient transcripts in order to calculate the number of recalled elements.

The evaluation of narrative discourse production from the standpoint of linguistic impairment is an attractive alternative as it allows for linguistic microstructure analysis, including phonetic-phonological, morphosyntactic and semantic-lexical components, as well as semantic-pragmatic macrostructures. Automated discourse analysis tools based on Natural Language Processing (NLP) resources and tools aiming at the diagnosis of language-impairing dementias via machine learning methods are already available for the English language (Fraser et al., 2015b; Yancheva et al., 2015; Roark et al., 2011) and also for Brazilian Portuguese (BP) (Aluísio et al., 2016). The latter study used a publicly available tool, Coh-Matrix-Dementia<sup>1</sup>, to extract 73 textual metrics of narrative transcripts, comprising several levels of linguistic analysis from word counts to semantics and discourse. However, the absence of sentence boundary segmentation in transcripts prevents the direct application of NLP methods that rely on these marks in order for the tools to function properly. To our knowledge, only one study evaluating automatic sentence segmentation in English transcripts of elderly aphasic exists (Fraser et al., 2015a).

The purpose of this paper is to present our method, DeepBond, for automatic sentence segmentation of spontaneous speech of healthy elderly (CTL) and MCI patients. Although it was evaluated for BP data, it can be adapted to other languages as well.

## 2 Related Work

The sentence boundary detection task has been treated by many researchers. Liu et al. (2006) investigated the imbalanced data problem, since there are more non-boundary words than not; their

study was carried out using two speech corpora: conversational telephone and broadcast news, both for English.

More recent studies have focused on Conditional Random Field (CRF) and Neural Network models. Wang et al. (2012) and Hasan et al. (2014) use CRF based methods to identify word boundaries in speech corpora datasets, more specifically on English broadcast news data and English conversational speech (lecture recordings), respectively. Khomitsevich et al. (2015), similar to our work, used a combination of two models, one based on Support Vector Machines to deal with prosodic information, and other based on CRF to deal with lexical information. They combine the two models using a logistic regression classifier.

Xu et al. (2014) uses a combination of CRF and a Deep neural network (DNN) to detect sentence boundaries on broadcast news data. Che et al. (2016) uses two different convolutional neural network (CNN), one which moves in only one dimension and another which moves in two. They achieved good results on a TED talks dataset. Tilk and Alumäe (2015) use a recurrent neural network (RNN) with long short-term memory units to restore punctuation in speech transcripts from broadcast news and conversations.

Although there are proposed methods for sentence segmentation of Portuguese datasets (Silla Jr. and Kaestner, 2004; Batista and Mamede, 2011; López and Pardo, 2015), none of them are used for transcriptions produced in a clinical setting for the elderly with dementia and related syndromes. The study most similar to our scenario is (Fraser et al., 2015a), which proposes a segmentation method for aphasic speech based on lexical, PoS and prosodic features using tools and a generic acoustic model trained for English. Their approach is based on a CRF model, and the best results for this study were obtained for non-spontaneous broadcast news data.

Our method uses recurrent convolutional neural networks with prosodic, PoS features, and also word embeddings and was evaluated intrinsically on impaired, spontaneous speech and normal, prepared speech. Although DNNs have already been used for this task, our work was the first, to the best of our knowledge, to evaluate them on impaired speech.

### 3 Datasets

A total of 60 participants from a research project on diagnostic tools for language impaired dementias produced narratives used to evaluate our method. Two datasets were used to train our model (Sections 3.1 and 3.2). As a preprocessing step we have removed capitalization information and in order to simulate high-quality ASR, we left all speech disfluences intact. Demographic information for participants in our study is presented in Table 1. A third dataset was used in robustness tests (Section 3.3).

Info	CTL	MCI	AD
Avg. Age	74.8	73.3	78.2
Avg. Education	11.4	10.8	8.6
No. of Male/Female	4/16	6/14	10/10

Table 1: Demographic information of participants in the Cinderella dataset. The Avg. Education is given in years.

#### 3.1 The Cinderella Dataset

The Cinderella dataset consists of spontaneous speech narratives produced during a test to elicit narrative discourse with visual stimuli, using a book consisting of sequenced pictures based on the Cinderella story. In the test, an individual verbally tells the story to the examiner based on the pictures. The narrative is manually transcribed by a trained annotator who scores the narrative by counting the number of recalled propositions.

This dataset consists of 60 narrative texts from BP speakers, 20 controls, 20 with AD, and 20 with MCI, diagnosed at the Medical School of University of São Paulo and also used in Aluísio et al. (2016). Counting all patient groups, this dataset has an audio duration of 4h and 11m, an average of  $1843/60 = 30.72$  sentences per narrative, and sentence averages of  $23807/1843 = 12.92$  words. AD narratives were only used for training the lexical model.

#### 3.2 The Brazilian Constitution Dataset

This dataset was made available by the LaPS (Signal Processing Laboratory) at the Federal University of Pará (Batista, 2013), and is composed of articles from Brazil’s 1988 constitution, in which the speech is prepared and read. Each file has an averages 30 seconds.

A preprocessing step removed lexical tips which indicate the beginning of the articles, sections and paragraphs. This removal was carried out on both the transcripts and audio. In addition, we separated the new dataset organized by articles, totaling 357 texts. Then, we marked the end of each article and paragraph and inserted punctuation at the end. Titles and chapters have been ignored during this process. We randomly selected 60 texts from this dataset, forcing only the condition that the number of sentences of each text sentence was greater than 12. We refer to the large dataset as Constitution L, and the dataset with the 60 texts as Constitution S.

The average number of sentences in each text of Constitution L is  $2698/357 = 7.56$ , and the average size of these sentences have  $63275/2698 = 23.45$  words while Constitution S has on average  $1409/60 = 23.48$  sentences, and these sentences average  $30521/1409 = 21.66$  words. The total audio duration of Constitution L is 7h 39m, and Constitution S is 3h 43m.

#### 3.3 The Dog Story Dataset

The Dog Story dataset is available from the BALE (Battery of Language Assessment in Aging, in English) instrument, described in (Jerônimo, 2016). It is composed of transcriptions from the narrative production test based on the presentation of a set of seven pictures telling a story of a boy who hides a dog that he found on the street (Le Boeuf, 1976). This battery was chosen because its aim is to allow for its administration to elderly people who are illiterate and/or of low educational level, who represent the majority of the aged sample assisted by the public health system in Brazil.

This dataset consists of 10 narratives transcripts (6 CTL and 4 MCI), where the average number of sentences and the average size of the sentences are 16.60 and 6.58, respectively. When compared with the Cinderella dataset, the dataset is composed of less sentences and the sentences have fewer words on average.

### 4 Features

#### 4.1 Lexical features

We divide our lexical features into two groups: PoS features and word embeddings, where every word is represented in a high dimensionality continuous vector.

The PoS features were extracted using a BP

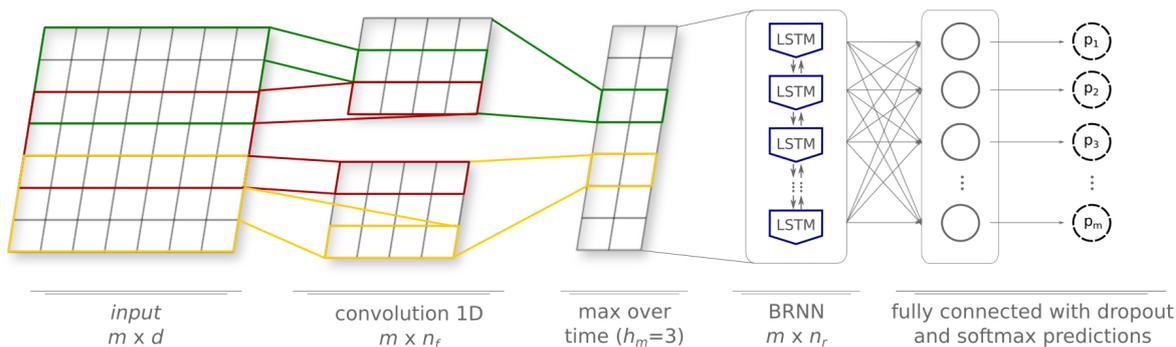

Figure 1: Architecture of the RCNN for both lexical and prosodic model.

morphosyntactic tagger called `nlpnet`<sup>2</sup> trained on a revised version of the Mac-Morpho corpus (Fonseca et al., 2015), which contains a set of 25 tags.

The word embeddings used in this work have 50 dimensions and were trained by Fonseca et al. (2015) with articles from the BP version of Wikipedia and a large journalistic corpus with articles from the news site G1<sup>3</sup>, totaling 240 million tokens and a vocabulary of 160,270 words. All of these tokens were made lowercase and trained with a neural language model described in (Collobert et al., 2011).

#### 4.2 Prosodic features

We used three prosodic features: F0, intensity and duration which were extracted at the phonetic level using PRAAT (Boersma and others, 2002) from forced alignment output. Alignment was done using the HTK toolkit (Young et al., 2002) with clean speech corpora and a pronunciation dictionary phonetically transcribed by Petrus (Serani, 2015) and augmented by our rule-based algorithm to insert multiple pronunciations, rendering a suitable model for ASR. The features were calculated for the first, last, penultimate and antepenultimate vowels of each word and pauses. These vowels were chosen based on knowledge of the BP which typically exhibits stress on the penultimate vowel, with notable patterns observed for final vowel stressing, for example words ending in “i” (“Barueri”) or a nasal consonant (“Renan”), and the antepenultimate vowel (usually indicated by a stress diacritic) like “helicóptero” (“helicopter”), “espírito” (“spirit”) and “árvore” (“tree”). Also, Portuguese, like most western languages, distinguishes sentence types by rising and falling pitch patterns, giving the listener a clue as

to whether the speaker has finished a sentence or not. Pause duration was also calculated since the length of a pause can be indicative of the presence of a punctuation mark (Beckman and Ayers Elam, 1997).

### 5 Model description

To automatically extract features from the input and also deal with the problem of long dependencies between words, we propose a model based on recurrent convolutional neural networks (RCNN), which was inspired by the work of Lai et al. (2015). The architecture of our model can be seen in Figure 1. First, we show how to prepare the input for the network, then we go through the networks layers and describe the training procedure, finally, we discuss the experimental settings.

#### 5.1 Input preparation

In our approach, the input to the network is a transcribed narrative which is categorized as CTL (healthy elderly individuals) and MCI (MCI patients). The narratives contain a sequence of words  $w_1, w_2, \dots, w_m$ . Each word is annotated with a label, to indicate whether it precedes a boundary ( $y = B$ ) or not ( $y = NB$ ). We do not make a distinction between punctuation marks, so a boundary is defined as a period, exclamation mark, question mark, colon or semicolon. With this approach, we can see this task as a binary classification problem.

#### 5.2 Representation

Our input contains transcribed narratives with  $m$  words in it. We represent the narrative  $i$  as  $X_i \in \mathbb{R}^{m \times n}$ ,  $X_i = \{x_1, x_2, \dots, x_{m \times n}\}$ , where  $n$  is the number of features. We represent the boundaries as  $Y_i \in \mathbb{R}^2$ ,  $Y_i = \{0, 1\}$ , where 0 stands for  $NB$  and 1 denotes  $B$ . Our final model consists of a

<sup>2</sup>[nilc.icmc.usp.br/nlpnet/](http://nilc.icmc.usp.br/nlpnet/)

<sup>3</sup>[g1.globo.com/](http://g1.globo.com/)

combination of two models. The first model is responsible for treating only lexical information, while the second treats only prosodic information. Both models have the same architecture shown in Figure 1. This strategy is based on the idea that we can train the lexical model with even more data, since textual information is easily found on the web. In order to obtain the most probable class  $y$  for the  $w_j$  word, a linear combination was created between these two models, where one receives the weighted complement of the other:

$$\alpha \cdot P_{lexical}(y | w_j) + (1 - \alpha) \cdot P_{prosodic}(y | w_j) \quad (1)$$

Then, the most probable class is the one that maximizes the linear combination from previous equation.

### 5.2.1 Embedding layer

The data input for the lexical model is divided into two features: word embeddings with dimensions  $|e_w|$ , and the PoS tags with dimensions  $|e_t|$ . Given a word  $w$ , the respective embedding  $e_w \in E_{word}$  is fetched and concatenated with the word's PoS vector  $e_t \in E_{tag}$ , thus obtaining a new vector size  $d = |e_w| + |e_t|$ . Out of vocabulary words share a single and randomly generated vector that represents an unknown word.

In the prosodic model we directly feed information about pitch, intensity and duration from the first, last, penultimate and ante-penultimate vowels of each word. Moreover, we feed the information about pause duration after each word, where duration of zero seconds denotes no pause. Therefore, for the prosodic model, we have a vector with dimensions  $d = 4 \cdot 3 + 1 = 13$ .

### 5.2.2 Convolutional and pooling layer

Once we have a matrix formed by the features of the words in the text, the convolutional layer receives it, which, in turn, is responsible for the automatic extraction of  $n_f$  new features depending on  $h_c$  neighboring words (Kim, 2014). The convolutional layer produces a new feature  $c_j$  by applying a filter  $W \in \mathbb{R}^{h_c \cdot d}$  to a window of  $h_c$  words  $x_{j-h_c+1:j}$  in a sentence with length  $m$ :

$$c_j = f(Wx_{(j-h_c+1):j} + b), \quad h_c \leq j \leq m \quad (2)$$

Where  $b \in \mathbb{R}$  represents a bias term and  $f$  is a non-linear function.

Our convolutional layer simply moves one dimension vertically, making one step at a time,

which gives us  $m - h_c + 1$  generated features. Since we want to classify exactly  $m$  elements, we add  $p = \lfloor h_c/2 \rfloor$  zero-padding on both sides of the text. Applying this strategy for each entry  $x_j$  yields the complete feature map  $c \in \mathbb{R}^{(m-h_c+1)+2p}$ .

In addition, we apply a max-pooling operation over time, looking at a region of  $h_m$  elements to find the most significant features:

$$\hat{c} = \max_{1 \leq j \leq m} \{c_{(j-h_m+1):j}\} \quad (3)$$

### 5.2.3 Recurrent layer

The new features extracted are fed into a recurrent bidirectional layer which has  $n_r$  units. A recurrent layer is able to store historic information by connecting the previous hidden state with the current hidden state at a time  $t$ . The values in the hidden and output layers are computed as follows:

$$h_t = f(W_x x_t + W_h h_{t-1} + b_h) \quad (4)$$

$$y_t = g(W_y h_t + b_y) \quad (5)$$

where  $W_x$ ,  $W_h$ , and  $W_y$  are the connection weights,  $b_y$  and  $b_h$  are bias vectors, and  $f$  and  $g$  are non-linear functions. Here, we use a special unit known as Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997), which is able to learn over long dependencies between words by a purpose-built memory cell. Figure 2 shows a single LSTM memory cell.

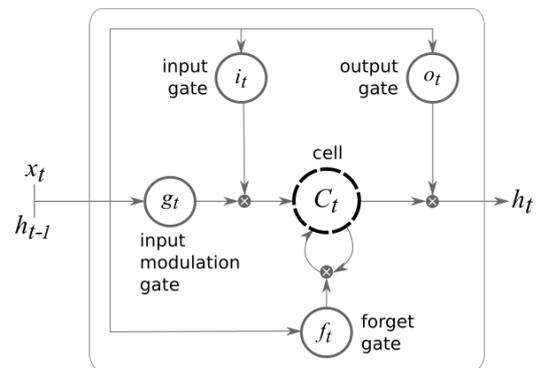

Figure 2: Diagram of a LSTM memory cell.

The LSTM updates for time steps  $t$  are done as described by Jozefowicz et al. (2015), which is a slight simplification of the one described by Graves and Jaitly (2014), where the memory cell is implemented as follows:

$$\begin{aligned}
i_t &= \sigma(W_{xi}x_t + W_{hi}h_{t-1} + b_i) \\
f_t &= \sigma(W_{xf}x_t + W_{hf}h_{t-1} + b_f) \\
o_t &= \sigma(W_{xo}x_t + W_{ho}h_{t-1} + b_o) \\
g_t &= \tanh(W_{xc}x_t + W_{hc}h_{t-1} + b_c) \\
c_t &= f_t \odot c_{t-1} + i_t \odot g_t \\
h_t &= o_t \odot \tanh(c_t)
\end{aligned}$$

where  $\sigma(z) = 1/(1 + e^{-z})$  is the sigmoid function,  $h_t \in \mathbb{R}^{n_r}$  is the hidden unit,  $i_t \in \mathbb{R}^{n_r}$  is the input gate,  $f_t \in \mathbb{R}^{n_r}$  is the forget gate,  $o_t \in \mathbb{R}^{n_r}$  is the output gate,  $g_t \in \mathbb{R}^{n_r}$  is the input modulation gate, and  $c_t \in \mathbb{R}^{n_r}$  is the memory cell unit, which is the summation of the previous memory cell modulated by the forget gate  $f_t$ , and a function of the current input with previous hidden state modulated by the input gate  $i_t$ .

As in Graves and Jaitly (2014), we used the features by looking at forward states and backward states. This kind of mechanism is known as a bidirectional neural network (BRNN), since it learns weights based on both past and future elements given a timestep  $t$ . In order to implement the BRNN, we reversed the sentences as a trick before we fed them to a regular LSTM layer, doubling the number of weights used in the recurrent layer. The output from this layer is the summation of the forward output with backward output:

$$y_t = \overleftarrow{y}_t + \overrightarrow{y}_t \quad (6)$$

With a bidirectional LSTM layer, we are able to explore the principle that words nearby have a greater influence in classification, while considering that words farther away can also have some impact. This often happens, for example, in the case of question words and conjunctions: por que (“why”); qual (“which”); quem (“who”); quando (“when”), etc.

#### 5.2.4 Fully connected layer

After the BRNN layer, dropout is used to prevent co-adaptation of hidden units during forward-backpropagation, where we ignore some neurons meaning to reduce the chance of overfitting the model (Srivastava et al., 2014).

The last layer receives the output from the BRNN in each timestep and passes them through a fully connected layer, where the softmax operation is calculated, giving us the probability of whether

or not the word precedes a boundary:

$$\hat{y}_t = \text{softmax}(W y_t + b) \quad (7)$$

Where  $W \in \mathbb{R}^{n_r \times 2}$  is a matrix of weights,  $b \in \mathbb{R}^{n_r}$  is a bias vector, and softmax is defined as:

$$s_j(z) = \frac{e^{z_j}}{\sum_{k=1}^K e^{z_k}}, \quad \text{for } j = 1, 2, \dots, K \quad (8)$$

### 5.3 Training

We define all of the parameters to be trained as  $\theta$ .

$$\begin{aligned}
\theta = \{ & E_{word}, E_{tag}, W^{(c)}, b^{(c)}, W^{(f)}, \\ & b^{(f)}, \overleftarrow{W}^{(r)}, \overleftarrow{b}^{(r)}, \overrightarrow{W}^{(r)}, \overrightarrow{b}^{(r)} \} \quad (9)
\end{aligned}$$

Where  $E_{word} \in \mathbb{R}^{|V| \times |e_w|}$  is the lookup table for the word embeddings,  $E_{tag} \in \mathbb{R}^{|V_{tag}| \times |e_t|}$  is the lookup table for PoS tags, and  $|V|, |V_{tag}|$  represents the size of the vocabulary for word embeddings and PoS tags, respectively.

For the convolutional layer: the weights  $W^{(c)} \in \mathbb{R}^{n_f \times h_c \times d}$  and the bias vector  $b^{(c)} \in \mathbb{R}^{n_f}$ .

For the fully connected layer: the weights matrix  $W^{(f)} \in \mathbb{R}^{n_r \times 2}$  and the bias vector  $b^{(f)} \in \mathbb{R}^{n_r}$ .

For the BRNN layer we divide the set of parameters from BRNN into two sets. Those from the forward pass and backward pass. Each set contains the weights for an input  $W_x^{(r)} \in \mathbb{R}^{n_r \times n_f}$ , the weights for previous hidden states  $W_h^{(r)} \in \mathbb{R}^{n_r \times n_r}$ , and the bias vectors  $b^{(r)} \in \mathbb{R}^{n_r}$  for all gates ( $i, f, o, g$ ). Additionally, we have the weights for an output in a timestep  $W_y^{(r)} \in \mathbb{R}^{n_r \times n_r}$  and a bias vector  $b_y \in \mathbb{R}^{n_r}$ .

We define the loss function  $\mathcal{L}$  as categorical cross-entropy (Murphy, 2012), shown in the equation below, which aims to minimize the negative log likelihood in relation to the weights. Since we have an unbalanced class problem, we give different weights for each class, where the weight of the minority class ( $B$ ) is greater than that of the majority ( $NB$ ).

$$\mathcal{L}(y, \hat{y}) = - \sum_i y_i \log(\hat{y}_i) c w_{y_i} \quad (10)$$

Where  $y$  are our real targets,  $\hat{y}$  are our predictions, and  $cw$  are the class weights for  $\ell = B$  and  $\ell = NB$ , calculated as follows:

$$c w_\ell = \frac{|y|}{2 \cdot |y = \ell|} \quad (11)$$

We minimize the loss function with respect to all weights  $\theta \mapsto \mathcal{L}$  by using RMSProp algorithm

(Tieleman and Hinton, 2012) with backpropagation to compute the gradients  $\nabla \mathcal{L}$ . The update step for a timestep  $t$  is made by normalizing the gradients by an exponent moving at an average  $r_t$ :

$$r_t = \gamma r_{t-1} + (1 - \gamma) \nabla \mathcal{L}(\theta_t)^2 \quad (12)$$

$$\theta_{t+1} = \theta_t - \eta \frac{\nabla \mathcal{L}(\theta_t)}{\sqrt{r_t} + \epsilon} \quad (13)$$

Where  $\eta$  is the learning rate and  $0 < \gamma < 1$  is the forgetting factor.

#### 5.4 Experiment settings

We break the text in tokens delimited by spaces. We do not remove stopwords from the texts, since they can be important features for our domain.

We ran a 5-fold cross-validation for the group being analyzed (CLT or MCI), which leaves about 10% of the data for testing, the rest for training.

The weight matrix for tag embeddings  $E_{tag}$  was generated randomly from a gaussian distribution scaled by fan in + fan out (Glorot and Bengio, 2010). Both embeddings matrix  $E_{word}$  and  $E_{tag}$  were adjusted during training. We follow previous studies on sentence boundary detection to set the network hyper-parameters (Tilk and Alumäe, 2015; Che et al., 2016). The values for each parameter are shown in Table 2.

Var.	Parameter	Lexical	Prosodic
$ e_w $	Word emb. size	50	-
$ e_t $	Tag emb. size	10	-
$n_f$	Conv. filters	100	8
$h_c$	Filter length	7	5
$h_m$	Max-pool size	3	3
$n_r$	Recurrent units	100	100
$\gamma$	Forget factor	0.9	0.9
$\eta$	Learning rate	0.001	0.001

Table 2: RCNN Hyper-parameters.

We tried three different learning rate values  $\eta \in \{0.01, 0.003, 0.001\}$  for both lexical and prosodic models, and found that 0.001 yielded best results. We trained our network over 20 epochs using a bucket strategy, which groups training examples in buckets of similar sentence size. Our implementation is based on Theano (Bergstra et al., 2010), a library that defines, optimizes and evaluates mathematical expressions in an effective way.

## 6 Evaluation

We evaluated our method intrinsically and also compared it with the method developed by Fraser et al. (2015a) for all of the datasets. We also performed robustness tests to indicate how well our method responds to both (i) test data that varies from Cinderella training data and (ii) train data that varies from Cinderella testing data.

If we classified all words as  $NB$ , our method would have an accuracy superior to 90%. For this reason, we use the  $F_1$  metric, which is defined as the harmonic mean between precision and recall. And since we are more interested in knowing whether our method correctly identifies the boundaries, we ignore the  $NBs$  and calculate  $F_1$  only for the positive class ( $B$ ).

### 6.1 Results

In this subsection, we evaluate the performance of our classifier (RCNN) for the Cinderella and Constitution datasets. Table 3 summarizes the results.

From Table 3 we can see that our approach presents better results for the Constitution dataset than Cinderella. This may be related to the text quality, as the Cinderella transcripts presents many disfluences, characteristic of spontaneous speech. As expected, results for CTL were higher than for MCI, since CTL narratives contain less disfluencies. Another important observation is that our method performs much better than the baseline. Where the baseline represents the results for a classifier that predicts all words as  $B$ . The Constitution results show us that traditional machine learning techniques used in NLP can be applied to this scenario, since the differences in the Cinderella data are few. Another reason that supports this statement is that  $F_1$  results from related studies on sentence boundary detection based on well-written texts are between 0.7 and 0.8 for two classes (Wang et al., 2012; Khomitsevich et al., 2015; Tilk and Alumäe, 2015; Che et al., 2016). When we compare the Constitution size relation we find out that corpus size is not greatly affected by the results, since the results for Constitution S were slightly better than for Constitution L. We think that, even with less data, our method performs better on Constitution S because of the distribution of sentence quantity in the dataset, where Constitution S has an average of 23.48 sentences per text, while Constitution L has an average of only 7.56 sentences per text.

Features	Cinderella						Constitution					
	CTL			MCI			L			S		
	<i>P</i>	<i>R</i>	<i>F</i> <sub>1</sub>	<i>P</i>	<i>R</i>	<i>F</i> <sub>1</sub>	<i>P</i>	<i>R</i>	<i>F</i> <sub>1</sub>	<i>P</i>	<i>R</i>	<i>F</i> <sub>1</sub>
Baseline	0.07	1.00	0.13	0.08	1.00	0.14	0.03	1.00	0.07	0.04	1.00	0.08
PoS	0.36	0.82	0.50	0.32	0.83	0.46	0.30	0.89	0.44	0.29	0.79	0.42
Prosody	0.20	0.59	0.30	0.19	0.58	0.29	0.54	0.84	0.66	0.48	0.85	0.61
Embeddings	0.70	0.70	0.70	0.63	0.77	0.69	0.60	0.63	0.63	0.60	0.64	0.62
PoS + Pros.	0.40	0.74	0.52	0.36	0.80	0.49	0.52	0.91	0.66	0.57	0.85	0.68

Emb. + Pros.	0.71	0.74	0.72	0.64	0.77	0.70	0.71	0.83	0.76	0.74	0.81	0.77
All	0.72	0.76	<b>0.74</b>	0.66	0.74	<b>0.70</b>	0.77	0.82	<b>0.79</b>	0.76	0.85	<b>0.80</b>

Table 3:  $F_1$  for boundary class for each feature set on Cinderella and Constitution data using our method.

We also evaluated the performance of different feature sets with our datasets. Embeddings have a great impact on both datasets. The PoS information was influential on both datasets, but by a small margin, since it has a small difference when used with embeddings (0.01) on the Cinderella, and (0.03) Constitution data. This tells us that embeddings already bring enough morphosyntactic information. It is evident that the weight of the prosodic features is higher on Constitution, which is based on prepared speech, than in Cinderella. This result is consistent with those found by Kolár et al. (2009) and Fraser et al. (2015a). We also believe that the quality of the audio recordings may have impacted the weight of the prosodic features, since the Constitution dataset was recorded by speech processing experts in a studio and the Cinderella dataset was recorded in a clinical setting. In light of this, we can see that our method performs better when all features are used. Furthermore, the best results were obtained by using  $\alpha = 0.6$ , from the linear combination in Equation 1, showing that our model lends more weight to the lexical model.

## 6.2 Comparison of methods

In order to compare our model with related work, we replicated the approach proposed by Fraser et al. (2015a), which uses a CRF model for sentence segmentation. To explain the choice for a recurrent convolutional model, we split our method in three: (i) Multilayer Perceptron (MLP): we removed the convolutional and the recurrent layer of our model, and added a hidden fully-connected layer with 100 units and sigmoid activation; (ii) CNN: we simply removed the recurrent layer from our model and passed the output from the convolutional to the fully-connected layer; (iii) Recurrent

Neural Network (RNN): analogous to the CNN model, we removed the convolutional layer and connected the embedding layer with the recurrent layer. The results for each method are presented in Table 4.

Our method achieved the best results in both datasets. We can see that the CRF method, used by Fraser et al. (2015a), obtained the worst results on Constitution, and was only better than RNN on the Cinderella data. These results were similar to those reported in their paper, which suggests that our replication was faithful. We believe that the RNN performed poorly because it has a large set of weights to be trained, and since we have relatively little data, it failed to achieve good results. This may be related to the fact that LSTM units are very complex and need more data to be able to converge. Looking at the Constitution results, which have about three times more words than the Cinderella data, we can note the difference ( $\sim 0.2$ ) with relation to corpus size.

MLP and CNN alone were able to achieve better results than CRF and RNN, but MLP results for the MCI subset were not as good as CNN, which indicates that MLP alone is not able to deal with narratives that are potentially impaired. However, for the Constitution data, MLP obtained results very close ( $\sim 0.02$ ) to our best method.

Our RCNN achieved the best results on both datasets, implying that a union of these models was a good choice in order to deal with impaired speech. We believe that the greatest influence was from the CNN, and the addition of a recurrent layer with LSTM was able to deal with some particular cases, likely over long dependencies similar to the findings in (Tilk and Alumäe, 2015), where the CNN was not able to do so due to the fixed filter length in the convolution process, a re-

Methods	Cinderella						Constitution					
	CTL			MCI			L			S		
	<i>P</i>	<i>R</i>	$F_1$	<i>P</i>	<i>R</i>	$F_1$	<i>P</i>	<i>R</i>	$F_1$	<i>P</i>	<i>R</i>	$F_1$
CRF	0.70	0.45	0.55	0.62	0.46	0.53	0.89	0.36	0.51	0.84	0.34	0.48
MLP	0.59	0.79	0.67	0.47	0.80	0.59	0.75	0.79	0.77	0.76	0.80	0.78
RNN	0.27	0.68	0.39	0.73	0.25	0.37	0.43	0.92	0.58	0.44	0.85	0.57
CNN	0.64	0.79	0.71	0.59	0.77	0.67	0.65	0.85	0.73	0.58	0.89	0.70
RCNN	0.72	0.76	<b>0.74</b>	0.66	0.74	<b>0.70</b>	0.77	0.82	<b>0.79</b>	0.76	0.85	<b>0.80</b>

Table 4: Best  $F_1$  results for each method.

sult which was also noted in (Che et al., 2016).

### 6.3 Robustness tests

Robustness was evaluated by measuring  $F_1$  on both out-of-genre and in-genre data. The results for each configuration are presented in Table 5.

Trained on	Tested on	<i>P</i>	<i>R</i>	$F_1$
Constitution	Cinderella CTL	0.19	0.29	0.23
Constitution	Cinderella MCI	0.20	0.25	0.22
Cinderella	Dog story CTL	0.72	0.62	0.66
Cinderella	Dog story MCI	0.65	0.64	0.64

Table 5: Results for robustness tests

We evaluated our method by changing the corpus genre: training with the Constitution and testing with the Cinderella dataset. This evaluation shows that our method performed poorly in this scenario, probably because the differences in the lexical clues between these datasets are high, since the Constitution is composed of prepared speech and Cinderella of spontaneous speech. When we maintain the corpus genre but change the story used in the neuropsychological test, our method can still achieve good results, yielding a small difference of 0.08 for CTL and 0.06 for MCI from our best results. We believe that these results are related with the linear combination weight from Equation 1, where the results were obtained by using  $\alpha = 0.8$ , lending less weight to the prosodic model when compared to our best results (where it has 40% of influence). Since the Dog Story and Cinderella datasets are composed of spontaneous speech, the lexical clues found in this kind of speech helped the method to achieve good performance.

## 7 Conclusions and Future Work

We have shown that our model, using a recurrent convolutional neural network, is benefited by

word embeddings and can achieve promising results even with a small amount of data. We found that our method is better for cases where speech is planned, since the prosodic features lend more weight to the classification. Our method achieved good results on impaired speech transcripts even with little data, with an  $F_1$  result of 0.74 on CTL patients, which is comparable with the results from other studies using broadcast news and conversational data (Wang et al., 2012; Khomitsevich et al., 2015; Tilk and Alumäe, 2015; Che et al., 2016). Moreover, our method achieved good results in robustness tests when we changed the story used in the neuropsychological test.

As for future work, we plan to evaluate our method on English data for comparison with related work. Also, we plan on using more text data to train the lexical model, as it is independent from the prosodic model and lends more weight in our evaluations. Moreover, we will evaluate our method with the output of an ASR system for BP, as a higher word recognition error rate can greatly affect our results. Lastly, we would like to evaluate our method with datasets with higher quality audio, more robust acoustic models and a manually aligned portion of the database as better audio segmentation would greatly improve the model and the usefulness of prosodic features.

With respect to improvements in the corpus, our dataset consists of spontaneous speech narratives and was annotated only with periods. Since there are initial conjunctions such as “and”, “moreover”, and “however”, we could include commas. This would turn our problem into a ternary problem. This could be done by increasing the number of neurons in the last layer of our architecture.

# Joint, Incremental Disfluency Detection and Utterance Segmentation from Speech

Julian Hough and David Schlangen

Dialogue Systems Group // CITEC // Faculty of Linguistics and Literature  
Bielefeld University

firstname.lastname@uni-bielefeld.de

## Abstract

We present the joint task of incremental disfluency detection and utterance segmentation and a simple deep learning system which performs it on transcripts and ASR results. We show how the constraints of the two tasks interact. Our joint-task system outperforms the equivalent individual task systems, provides competitive results and is suitable for future use in conversation agents in the psychiatric domain.

## 1 Introduction

Artificial conversational systems promise to be a valuable addition to the existing set of psychiatric health care delivery solutions. As artificial systems, they can ensure that interview protocols are followed, and, perhaps surprisingly, due to being “just a computer”, even seem to increase their interlocutors’ willingness to disclose (Lucas et al., 2014). Interactions with such conversational agents have been shown to contain interpretable markers of psychological distress, such as rate of filled pauses, speaking rate, and various temporal, utterance and turn-related interactional features (DeVault et al., 2013). Filled pauses and disfluencies in general have also been shown to predict outcomes to psychiatric treatment (Howes et al., 2012; McCabe et al., 2013).

Currently, these systems are only used to elicit material that is then analysed offline. For offline analysis of transcripts with gold standard utterance segmentation, much work exists on detecting disfluencies (Johnson and Charniak, 2004; Qian and Liu, 2013; Honnibal and Johnson, 2014). To enable more cost-effective analysis, however, and possibly even let the interaction script itself be dependent on an analysis hypothesis, it would be better to be able to work directly off the speech sig-

nal, and online (incrementally). This is what we explore in this paper, presenting and evaluating a model that works with online, incremental speech recognition output to detect disfluencies with various degrees of fine-grainedness.

As a second contribution, we combine incremental disfluency detection with another lower-level task that is important for responsive conversational systems, namely the detection of turn-taking opportunities through detection of utterance boundaries. (See for example (Schlangen and Skantze, 2011) for arguments for incremental processing and responsive turn-taking in conversational systems, and (Schlangen, 2006; Atterer et al., 2008; Raux, 2008; Manuvinakurike et al., 2016, *inter alia*) for examples of incremental utterance segmentation). Besides both being relevant for interactive health assessment systems, these tasks also have an immanent connection, as the approach typically used for turn-end detection is simply waiting for a silence of a certain duration, and hence is misled by intra-turn silent disfluencies. Similarly, without gold standard segmentation, disfluent restarts and repairs may be predicted at fluent utterance boundaries. We hence conjecture that the tasks can profitably be done jointly.

## 2 Related Work

As a separate task, there has been extensive work on utterance segmentation. Cuendet (2006) reports an NIST-SU utterance segmentation error rate result on the Switchboard corpus at 48.50, using a combination of lexical and acoustic features. Ang et al. (2005) report NIST-SU scores in the region of 34.35–45.92 on the ICSI Meeting Corpus. Martínez-Hinarejos et al. (2015) report state-of-the-art dialogue act segmentation results on Switchboard at 23.0 NIST-SU, however

this is not on the level of full dialogues, but on pre-segmented turn stretches. For the equivalent task of sentence boundary detection, Seeker et al. (2016) report an F-score of 0.7665 on Switchboard data, using a joint dependency parsing framework, and Xu et al. (2014) implement a deep learning architecture and report an 0.810 F-score and 35.9 NIST-SU error rate on broadcast news speech using prosodic and lexical features using a DNN for prosodic features, combined with a CRF classifier. However scaling this to spontaneous speech and the challenges of incrementality explained here, is yet to be tested.

Strongly incremental approaches to the task are rare, however (Atterer et al., 2008) achieve a word-by-word F-score of 0.511 on predicting whether the current word is the end of the utterance (dialogue act) on Switchboard, and using ground-truth syntactic information indicating sentence structure information achieve 0.559.

Disfluency detection on pre-segmented utterances in the Switchboard corpus has also had a lot of attention, and has also reached high performance (Johnson and Charniak, 2004; Georgila, 2009; Qian and Liu, 2013; Honnibal and Johnson, 2014). On detection on Switchboard transcripts, Honnibal and Johnson (2014) achieve 0.841 reparandum word accuracy using a joint dependency parsing approach, and Hough and Purver (2014) in a strongly incrementally operating system without look-ahead achieve 0.779, using a pipeline of classifiers and language model features. The potentially live approaches tend to use acoustic information (Moniz et al., 2015) and do not perform on a comparable level to their transcription-based task analogues, nor achieve the same fine-grained analysis of disfluency structure, which is often needed to identify the disfluency type and compute its meaning.

Live incremental approaches to both tasks have not been able to benefit from reliable ASR hypotheses arriving in a timely manner until recently. Now the arrival of improved performance, in terms of low Word Error Rate (WER) and better live performance properties is making this possible (Baumann et al., 2016). In this paper we define a joint task in a live setting. After defining the task we present a simple deep learning system which simultaneously detects disfluencies and predicts up-coming utterance boundaries from incremental word hypotheses and derived information.

### 3 The Tasks: Real-time disfluency prediction and utterance segmentation

#### 3.1 Incremental disfluency detection

Disfluencies, in their fullest form as speech repairs, are typically assumed to have a tripartite *reparandum-interregnum-repair* structure (terms originally proposed by Shriberg (1994)), as exhibited by the following example.

$$\text{John } \underbrace{[ \text{likes} + ]}_{\text{reparandum}} \underbrace{\{ \text{uh} \}}_{\text{interregnum}} \underbrace{\text{loves} ]}_{\text{repair}} \text{ Mary} \quad (1)$$

If reparandum and repair are absent, the disfluency reduces to an isolated *edit term*. In the example given here, the interregnum is filled by a marked, lexicalised edit term, but more phrasal terms such as *I mean* and *you know* can also occur.

The task of disfluency detection then is to recognise these elements and their structure, and the task of *incremental* disfluency detection adds the challenge of doing this in real-time, from “left-to-right”. In that latter setting, detection runs into the same problem as a human processor of such an utterance: Only by the time the interregnum is encountered, or possibly even only when the repair is seen, does it become clear that earlier material now is to be considered as “to be repaired” (reparandum).<sup>1</sup> Hence, the task cannot be set up as a straightforward sequence labelling task where the tags “reparandum”, “interregnum” and “repair” are distributed left-to-right over words as indicated in the example above; in this example, it would unfairly require the prediction that “likes” is *going to be* repaired, at a point when no evidence is available for making it.

We follow Hough and Schlangen (2015) and use a tag set that encodes the reparandum start only at a time when it can be guessed, namely at the onset of the actual repair. This is illustrated in Figure 1 in the “disfluency (complex)” row. Here, the word at the repair onset, “to”, gets tagged as repair onset (*rpS*) and, at the same time, as repairing material beginning 5 tokens in the past (-5, yielding the complex label *rpS-5*). Additionally, we annotate all repair words (as *rpMid*, if the word is neither first nor last word of the repair, and together with the disfluency type, if it is the final word; here, the

<sup>1</sup>Looking at it from a different perspective, this problem has been called the *continuation problem* by Levelt (1983): the repair material can only be integrated with the previous material, if it is identified as replacing the reparandum.

	A uh flight [ to Boston + { uh I mean } to Denver ] on Friday   Thank you

Figure 1: An utterance with the traditional repair disfluency and segmentation annotation in-line (Shriberg, 1994; Meteer et al., 1995) and our incrementally-oriented tag schemes

label is *rpESub* for substitution),<sup>2</sup> editing terms (*e*) and fluent material (*f*) as well. From the complex tag set, we can reconstruct the disfluency structure as in (1) in a strongly incremental fashion. We also define a reduced tag set (shown in Figure 1 as “disfluency (simple)”) that only tags fluent words, editing terms, and the repair onset.

### 3.2 Incremental utterance segmentation

We formulate incremental utterance segmentation as the judgement in real time as to when the current utterance is going to end, and so like (Schlangen, 2006; Atterer et al., 2008), we move from purely *reactive* approach, signalled by silence, to *prediction*. To allow prediction to be possible we use four tags for classifying stretches of acoustic data (which can be the time spans of forced aligned gold standard words, or the word hypotheses timings provided by an ASR), which are equivalent to a BIES (Beginning, Inside, End and Single) scheme for utterances— see Table 1.

The tag set allows evidence from the prior context of the word (the acoustic and linguistic information preceding the word) to be used to predict whether this word continues a current utterance (the *-* prefix) or starts anew (the *.* prefix), and also permits the online prediction of whether the next word (or segment) will continue the current utterance (the *-* suffix) or the current word ends the utterance (the *.* suffix). From these utterance boundary predictions can be derived when *-w.* or *.w.* is predicted (i.e. “will end utterance”). The tag set is summarized in Table 1 and an example is in Fig. 1, row “utterance segmentation”.

### 3.3 Defining the joint task

Studying the two phenomena in natural dialogue corpora, for example in terms of rich transcription mark-up in the SWBD annotation manual (Meteer et al., 1995), there are several constraints:

<sup>2</sup>The other repair type is delete *rpEDel*. Verbatim reparandum-repair repetitions are subsumed by *rpESub*.

	<i>-w-</i>	<i>-w.</i>	<i>.w-</i>	<i>.w.</i>
<i>f</i>	1	1	1	1
<i>e</i>	1	1	1	1
<i>rpS</i>	1	1	0	0

	<i>-w-</i>	<i>-w.</i>	<i>.w-</i>	<i>.w.</i>
<i>f</i>	1	1	1	1
<i>e</i>	1	1	1	1
<i>rpS-[1-8]</i>	1	0	0	0
<i>rpMid</i>	1	0	0	0
<i>rpESub</i>	1	1	0	0
<i>rpEDel</i>	1	1	0	0
<i>rpS-[1-8]ESub</i>	1	1	0	0
<i>rpS-[1-8]EDel</i>	1	1	0	0

Figure 2: The joint tag set for the task. 1= tag in set, simple (top) and complex (bottom).

- C1 Repair onsets cannot begin an utterance (by definition of first position repairs needing a preceding reparandum).
- C2 Repairs must be completed within the utterance in which they begin.
- C3 Utterances can be interrupted or abandoned, but these are different to within-dialogue-act repairs.

Given these constraints, we can generate a joint tag set as a subset of the cross product of both tag schemes. The utterance segmentation tags in Table 1 are combined with the simple strongly incremental disfluency tags described in §3.1. The joint set for both the simple and complex tasks is in Fig. 2, where 1 indicates the tag is in the set and 0 otherwise. In the simple task, there are 10 tags. The joint set for the full task including disfluency structure detection has 53 possible tags (rather than the full cross product, which would be 92). In reality, in the training corpus, only 43 of these possible combinations were found, so this constituted our tag set in practice. See Fig. 1 (bottom 2 rows) for example sequences.

### 3.4 Research questions

Given the formulation of the joint task, we would like to ask the following questions of scalable, automatic approaches to it:

-w-	a word which continues the current utterance and whose following word will continue it
-w.	a word which continues the current utterance and is the last word of it
.w-	a word which is the beginning of an utterance and whose following word will continue it
.w.	a word constituting an entire utterance

Table 1: The tag set for the continuity of each word within a dialogue act

- Q1 Given the interaction between the two tasks, can a system which performs both jointly help improve equivalent systems doing the individual tasks?
- Q2 Given the incremental availability of word timings from state-of-the-art ASR, to what extent can word timing data help performance of either task?
- Q3 To what extent is it possible to achieve a good online accuracy vs. final accuracy trade-off in a live, incremental, system?

To address these questions we use a combination of a deep learning architecture for sequence labelling and incremental decoding techniques which we will now explain.

#### 4 LSTMs and Incremental Decoding for Live Prediction

Our systems consist of deep learning sequence models which consume incoming words and use word embeddings in addition to other features to predict disfluency and utterance segmentation labels for each word, in a strictly left-to-right, word-by-word fashion. We also use word timings as input to a separate classifier whose output is combined with that of the deep learning architecture in an incremental decoder. See Fig. 3 for the overall architecture. We describe the elements of the system below.

##### 4.1 Input Features

In our systems we use the following input features:

- Words in a backwards window from the most recent word (transcribed or ASR)
- Durations of words in the current window (from transcription or ASR word timings)
- Part-Of-Speech (POS) tags for words in current window (either reference, or from an incremental CRF tagger)

For incremental ASR, we use the free trial version of IBM’s Watson Speech-To-Text service.<sup>3</sup> The service provides good quality ASR on noisy

<sup>3</sup><https://www.ibm.com/watson/developercloud/speech-to-text.html>

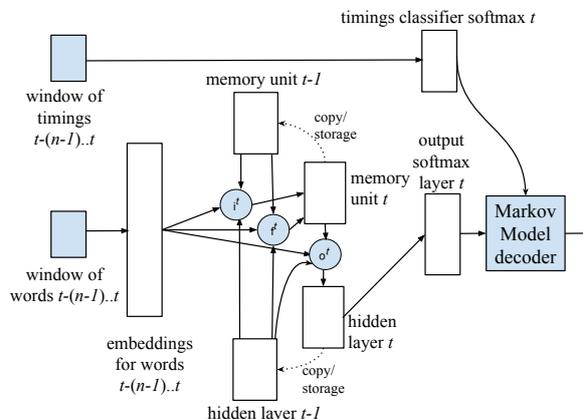

Figure 3: Schematic structure of the system.

data- on our selected heldout data on Switchboard, the average WER is 26.5%. The Watson service, crucially for our task, does not filter out hesitation markers or disfluencies, which is rare for current web-based services (Baumann et al., 2016). The service also outputs results incrementally, so silence-based end-pointing is not used. The service also returns word timings, which upon manual inspection were close enough to the reference timings to use as features in the live version of our system. In this paper, the durations are not features in the principal RNN but in an orthogonal logistic regression classifier- see §4.3.

For POS-tagging, we use the NLTK CRF tagger, which when trained on our training data and tested on our heldout data achieves 0.915 accuracy on all tags, which was sufficiently good for our purposes. Crucially, for the label  $UH$ , which is important evidence for an edit term, it achieves an F-score of 0.959.

##### 4.2 Architectures

We use two well-studied deep learning architectures for our sequence labelling task- the Elman Recurrent Neural Network (RNN) and the Long Short-Term Memory (LSTM) RNN. Architecturally the RNNs here reproduce approximately the identical set-up as described in (Mesnil et al., 2013; Hough and Schlangen, 2015).

**Input and word embeddings** Following (Mes-

nil et al., 2013), we use 1-of-N, or ‘one-hot’, vectors as our raw input to the network, which provide unique indices to dense vectors in a word embedding matrix. The initial word embeddings were obtained from Switchboard data using the python implementation of `word2vec` in `gensim`,<sup>4</sup> using a skip-gram context model. The training data for the initial embeddings was cleaned of disfluencies, effecting a ‘clean’ language model (Johnson and Charniak, 2004). These embeddings were then further updated as part of the objective function during the task-specific training itself. Instead of single word/POS inputs we use context windows which, like n-gram language models, are *backwards* from the current word. The internal representation of context windows of length  $n$  in the network is created through the ordered concatenation of the  $n$  corresponding word embedding vectors of size 50, resulting in an input to the network of dimension  $\mathbb{R}^{50n}$ . We use  $n = 2$  in our experiments here.

**RNN architecture and activation functions** In addition to the embedding layer, we use a (recurrent) hidden layer of 50 nodes and an output layer the size of our training tag sets (43 nodes for the complex task and 10 nodes for the simple task). The standard Elman RNN dynamics in the recurrent hidden layer at time  $t$  is as in (3), where the hidden layer  $h(t)$  is calculated as the Sigmoid function (2) of the addition of the weight matrix  $U'$  applied via dot product to the current input vector  $x(t)$  and the weight matrix  $V'$  applied via dot product to the stored previous value of the hidden layer at time  $t-1$ , i.e.  $h(t-1)$ .

$$s(x) = \frac{1}{1 + e^{-x}} \quad (2)$$

$$h(t) = s(U'x(t) + V'h(t-1)) \quad (3)$$

We use the standard softmax function for the node activation function of the output layer.

At decoding time, the compression of the context into the hidden layer allows us to save the current state of the decode live compactly from ASR results as they become available to the network. In order to integrate the new incoming words and POS tags with the history, it is only necessary to store the current hidden layer activation  $h(t)$  (and the output softmax layer too, if that is being used by another process), and wait for new information to the input layer.

<sup>4</sup><http://radimrehurek.com/gensim/>

**LSTM unit** In our LSTM, we include recurrent LSTM units that uses the input  $x(t)$ , the hidden state activation  $h(t-1)$ , and memory cell activation  $c(t-1)$  to compute the hidden state activation  $h(t)$  at time  $t$ . It uses a combination of a memory cell  $c$  and three types of gates: input gate  $i$ , forget gate  $f$ , and output gate  $o$  to decide if the input needs to be remembered (using the input gate), when the previous memory needs to be retained (forget gate), and when the memory content needs to be output (using the output gate). For each time step  $t$  the cell activations  $c(t)$  and  $h(t)$  are computed by the below steps, whereby the  $\odot$  is element-wise multiplication.

$$\begin{aligned} i(t) &= s(W'_i x(t) + U'_i h(t-1) + V'_i c(t-1)) \\ f(t) &= s(W'_f x(t) + U'_f h(t-1) + V'_f c(t-1)) \\ c(t) &= f(t) \odot c(t-1) + i(t) \odot \tanh(W'_c x(t) + U'_c h(t-1)) \\ o(t) &= s(W'_o x(t) + U'_o h(t-1) + V'_o c(t)) \\ h(t) &= o(t) \odot \tanh(c(t)) \end{aligned} \quad (4)$$

While many more weight matrices need to be learned (all the  $W'$ ,  $U'$  and  $V'$  subscripted matrices), as with the standard RNN, at decoding time it is efficient to store the current decoding state in a compact way, as it is only necessary to save the activation of the memory cell  $c(t)$  and the hidden layer  $h(t)$  to save the current state of the network. See Fig. 3 for the schematic overall disfluency detection architecture for the LSTM.

**Learning: error function and parameter update** As is common for RNNs (De Mulder et al., 2015) we use negative log likelihood loss (NLL) as a cost function and use stochastic gradient descent over the parameters, including the embedding vectors, to minimize it. We use a batch size of 9 words, consistent with our repair tag scheme. Both networks use a learning rate of 0.005 and L2 regularisation on the parameters to be learned with a weight of 0.0001.

### 4.3 Incremental decoding and timing driven classifier

**Markov model** For decoding optimization we use Viterbi decoding on the sequence of softmax output distributions from the network in the spirit of (Guo et al., 2014). We use a Markov model which is hand-crafted to ensure legal tag sequences are outputted for the given tag set. In our joint task, this permits ‘late’ detection of an utterance boundary if the probability for a  $-w.$  and following  $.w-$  or  $.w.$  tag on their own are not the arg max, but their combined probability permits the

best sequence. Similarly, in the complex task, repairs where evidence of a repair end tag is strong, but the repair onset tag was not the arg max can be detected at the repair end. From an incremental perspective, in Viterbi decoding there is the danger of output ‘jitter’. We investigate how different output representations have different effects on output prediction stability in our evaluation.

**Timing driven classifier** As an edition to the decoding step, we experimented with an independent timing driven classifier which consumes the durations of the last three words and outputs a probability that this is a fluent continuation or the beginning of a new utterance. We train a logistic regression classifier on our training data. Combining this two-class probability with the probability of the relevant utterance segmentation tags in decoding boosted performance considerably.

## 5 Evaluation Criteria

**Accuracy** On transcripts, we calculate repair onset detection accuracy  $F_{\text{rPS}}$ , where applicable reparandum word accuracy  $F_{\text{rm}}$ , and F1 accuracy for edit term words  $F_{\text{e}}$ , which includes interregna. For utterance segmentation we also use word-level F1 scores for utterance boundaries (end-of-utterance words)  $F_{\text{uttSeg}}$ . Carrying out the task live, on speech recognition hypotheses which very well may not be identical to the annotated gold-standard transcription, requires the use of time-based metrics of local accuracy in a time window (i.e. *within this time window, has a disfluency/utterance boundary been detected, even if not on the identical words?*)– we therefore calculate the F1 score over 10 second windows of each speaker’s channel. While this windowing can give higher scores on certain phenomena, it tends to follow the word-level F-score so is a good time-based indicator of accuracy.

For utterance segmentation, for comparison to previous work we also use **NIST-SU** error rate (Ang et al., 2005). NIST-SU is the ratio of the number of incorrect utterance boundary hypotheses (missed boundaries and false positives) made by a system to the number of reference boundaries.

For a more coarse-grained metric which includes both tasks, which is useful in our target domain of interactions in a clinical context (Howes et al., 2014), we look at the **rpS : UttSeg ratio per speaker correlation** (Pearson’s R). This gives us the best approximation as to how good the system

is at estimating repair rate per utterance.

**Timeliness and diachronic metrics** Crucial for the live nature of the system, we measure latency (i.e. *how close to the actual time a disfluency or boundary event occurred has one been predicted?*) and also stability of output over time (i.e. *how much does the output change?*). For latency we use Zwarts et al. (2010)’s *time-to-detection* metric: the average distance (in numbers of words) consumed before first detection of gold standard repairs from the repair onset word,  $\text{TD}_{\text{rPS}}$ .<sup>5</sup> We generalize this measure to the other tags of interest to give  $\text{TD}_{\text{e}}$  and  $\text{TD}_{\text{uttSeg}}$  and also, particularly crucially for the ASR results, report the metrics in terms of time in seconds.<sup>6</sup>

For stability, incorporating insights from the evaluation of incremental processors by Baumann et al. (2011), we measure the **edit overhead (EO)** of the output labels– this is the percentage of unnecessary edits (insertions and deletions) required to get to the final labels outputted by the system.

## 6 Experimental Set-up

We experiment with the 2 joint output representations in Fig. 1 and implement an RNN and LSTM using Theano (Bergstra et al., 2010) as an extension to the code in Mesnil et al. (2013). We also run the 3 individual versions of the tasks with the tag sets shown in Fig. 1 for comparison. We also train a word timings driven classifier which adds information to the decoding step as explained above to try to answer Q2.<sup>7</sup>

**Data** We train on transcripts and test on both transcripts and ASR hypotheses. We use the standard Switchboard training data for disfluency detection (all conversation numbers beginning sw2\*,sw3\* in the Penn Treebank III release: 100k utterances, 650K words) and use the standard heldout data (PTB III files sw4[5-9]\*: 6.4K utterances, 49K words) as our validation set. We test on the standard test data (PTB III files 4[0-1]\*) with punctuation removed from all files.<sup>8</sup> For

<sup>5</sup>Our measure is in fact one word earlier by default than Zwarts et al. (2010) as we take detection after the end of the repair onset word as the earliest possible detection point.

<sup>6</sup>These measures only apply to repairs and utterance boundaries detected correctly.

<sup>7</sup>All experiments are reproducible. The code can be downloaded at [https://github.com/dsg-bielefeld/deep\\_disfluency](https://github.com/dsg-bielefeld/deep_disfluency)

<sup>8</sup>We include partial words as these may in theory become available from the ASR in the live setting.

Table 3: Comparison of the joint vs. individual task performances

the ASR results evaluation, we only select a subset of the heldout and test data whereby both channels achieved below 40% WER to ensure good separation– this left us with 18 dialogues in the validation data and 17 dialogues for testing.

We train all RNNs for a maximum of 50 epochs else halt training if there is no improvement on the best  $F_{rm}$  score on the transcript validation set after 10 epochs.

## 7 Results and Discussion

Our dialogue-final accuracy results are in Table 2. On transcripts, our best per-word  $F_{rps}$  reaches 0.720 and best  $F_e$  reaches 0.918. For utterance segmentation, perword accuracy reaches 0.748 and the lowest NIST-SU error rate is 43.64. This is competitive with (Seeker et al., 2016)’s 0.767 F-score and out-performs (Cuendet, 2006) on the Switchboard data. The best  $rps : uttSeg$  correlation per speaker reaches 0.92 ( $p < 0.0001$ ).

In comparison to incremental approaches, we

outperform (Atterer et al., 2008)’s 0.511 accuracy on end-of-utterance. Their work allows no prediction lag in a strictly incremental setting, so is at a disadvantage, however our result of 0.748 on transcripts is reported alongside the average time to detection of 0.399 words, which suggests on average the uttSeg when predicted correctly, is done so with no latency.

With the exception of one metric, the LSTM outperforms the RNN on transcripts. The systems using the timing model in general outperform those with lexical information only on the utterance segmentation metrics, whilst not having an impact on disfluency detection.

According to the window-based accuracies, on ASR results there is significant degradation in accuracy for repair onsets (best  $F_{rps}$ =0.557) however utterance segmentation did not suffer the same loss, with the best system achieving 0.685 accuracy. The  $rps : uttSeg$  Pearson’s R correlation per speaker reaches 0.81 ( $p < 0.0001$ ) in a system with otherwise poor performance– the second

Eval. method	System	$TTD_{rps}$ (word)	$TTD_{rps}$ (time in s)	$TTD_e$ (word)	$TTD_e$ (time in s)	$TTD_{uttSeg}$ (word)	$TTD_{uttSeg}$ (time in s)	EO

Table 4: Incremental results on transcripts and ASR results.

best achieved was 0.79 ( $p < 0.0001$ ).

For disfluency detection, standard approaches use pre-segmented utterances to evaluate performance, so this result is difficult to compare. However in the simple task, the accuracy of 0.720 repair onset prediction is respectable (comparable to (Georgila, 2009)), and is useful enough to allow realistic relative repair rates, in line with our motivation. The complex tagging system performs poorly on repairs compared to the literature, however the lack of segmentation makes this a considerably harder task, in the same way as dialogue act tagging results are lower on unsegmented transcripts (Martínez-Hinarejos et al., 2015). Edit term detection performs very well at 0.918, approaching the state-of-the-art on Switchboard reported at 0.938 (Hough and Purver, 2014).

**The utility of a joint task** As can be seen in Table 3, the overall best performing systems on the individual tasks do not reach the results in any relevant metric of the best performing combined system. The disfluency-only systems were run ignoring all utterance boundary information, which puts this setting at a disadvantage to previous approaches, however it is clear that on unsegmented data our posing of the task jointly is useful.

**Incrementality** Incrementally the differences between the architectures was negligible— results for the LSTM are in Table 4. The latency for repair onset detection is very low, being detected as little as 0.196 seconds after the onset word is finished (or on transcripts largely directly after the word has been consumed as  $TTD_{rps}$  (word) = 0.003). Utterance boundaries were detected just over a second after the end of the last word of the previous utterance. However, the fact that  $TTD_{uttSeg}$  on the word level reaches 0.283 suggests the time-based average is being weighed down by occa-

sional long silences, which could be thresholded in future work. The EO measure of stability is severely affected by jittering ASR hypotheses, but given its worst result is 21.46% this is still a fairly stable incremental system.

**Error Analysis** To explore the errors being made by the systems, and how the RNN and LSTM may differ in ability, we performed an error analysis on the simple versions with the timing models— see Fig. 4. One can observe a boost in recall for various repair types in the LSTM, where it is performing better on repairs with longer reparanda. Characterizing repetitions as verbatim repeats, substitutions as the other repairs marked with a repair phase, and deletes as those without one, we see the LSTM outperforming the RNN on the rarer types. Whilst the problem is attenuated by the memory facility of the LSTM, our best system still suffers the vanishing gradient problem for predicting longer repairs with reparanda over 3 words long. Also we show in *uttSeg* detection all systems falter on long distance projections with coordinating conjunctions, which would potentially be dealt with more easily in a parsing framework, or a hierarchical deep learning framework.

We also investigated the *uttSeg* detection errors and see that the networks are generally not confusing disfluencies with boundaries. However, our best system incorrectly labelled 3.6% of the reference *uttSegs* as *rpS* (hence also affecting the precision of the *rpS* prediction)— upon inspection these were largely abandoned utterances, which according to the constraint C3 we posited above are not marked as disfluencies in the same way intra-utterance repairs are in the reference. Due to the original annotation instructions of (Meteer et al., 1995), these are segmented and not included in the traditional disfluency detection task. However,

(a)		RNN	LSTM

Figure 4: Error analysis: (a) recall rates for *rpS* onsets of repairs with different reparandum lengths and (b) types, and (c) the source of errors in *uttSeg* detection.

intuitively these can be construed as a disfluency type, and in future we will treat them as a special type of *uttSeg*/disfluency hybrid.

As can be seen in Fig. 4 (c) other main sources of error are on coordinating conjunctions (CC) such as ‘and’ and ‘or’, nouns with nominative subject marking case like ‘I’ and ‘we’ (subj), other proper nouns, variants of ‘it’ and grounding utterances like ‘yeah’ and ‘okay’. *uttSeg* detection in both systems achieved high precision but relatively low recall.

## 8 Conclusion

We have presented the joint task of incremental utterance segmentation and disfluency detection and

show a simple deep learning system which performs it on transcripts and ASR results. As regards the research questions posed in §3.4, in answer to Q1, we showed that, all else being equal, a deep learning system can perform both tasks jointly improves over equivalent systems doing the individual tasks. In answer to Q2, we showed that word timing information, both from transcripts and ASR results, helps the utterance segmentation and the joint task across all settings whilst not aiding disfluency detection on its own, and in response to Q3, we achieve a good online accuracy vs. final accuracy trade-off in a live, incremental, system, however still experience some time delays for utterance segmentation in our most accurate system.

We conclude that our joint-task system for disfluency detection and utterance segmentation shows a new benchmark for the joint task on Switchboard data and due its incremental functioning on unsegmented data, including ASR result streams, it is suitable for live systems, such as conversation agents in the psychiatric domain. In future work we intend to optimize the inputs to our networks after this exploration, including using raw acoustic features, and combining the task with language modelling and dialogue act tagging.

## Abstract

A major motivation for unsupervised morphological analysis is to reduce the sparse data problem in under-resourced languages. Most previous work focuses on segmenting surface forms into their constituent morphs (e.g., *taking*: *tak* + *ing*), but surface form segmentation does not solve the sparse data problem as the analyses of *take* and *taking* are not connected to each other. We extend the MorphoChains system (Narasimhan et al., 2015) to provide morphological analyses that can abstract over spelling differences in functionally similar morphs. These analyses are not required to use all the orthographic material of a word (*stopping*: *stop* + *ing*), nor are they limited to only that material (*acidified*: *acid* + *ify* + *ed*). On average across six typologically varied languages our system has a similar or better F-score on EMMA (a measure of underlying morpheme accuracy) than three strong baselines; moreover, the total number of distinct morphemes identified by our system is on average 12.8% lower than for Morfessor (Virpioja et al., 2013), a state-of-the-art surface segmentation system.

## 1 Introduction

Most previous work on unsupervised morphological analysis has focused on the problem of **segmentation**: segmenting surface forms into their constituent morphs (Goldsmith, 2001; Creutz and Lagus, 2007; Poon et al., 2009; Lee et al., 2011; Virpioja et al., 2013; Sirts and Goldwater, 2013). However, the focus on surface segmentation is largely due to ease of model definition and implementation rather than linguistic correctness. Even in languages with primarily concatenative morphology, spelling (or phonological) changes often occur at

morpheme boundaries, so that a single morpheme may have multiple surface forms. For example, the past tense in English may surface as *-ed* (*walked*), *-d* (*baked*), *-ted* (*emitted*), *-ped* (*skipped*), etc.

A major motivation for unsupervised morphological analysis is to reduce the sparse data problem in under-resourced languages. While surface segmentation can help, the example above illustrates its limitations: for more effective parameter sharing, a system should recognize that *-ed*, *-d*, *-ted*, and *-ped* share the same linguistic function. The importance of identifying underlying morphemes rather than surface morphs is widely recognized, for example by the MorphoChallenge organizers, who in later years provided datasets and evaluation measures to encourage this deeper level of analysis (Kurimo et al., 2010). Nevertheless, only a few systems have attempted this task (Goldwater and Johnson, 2004; Naradowsky and Goldwater, 2009), and as far as we know, only one, the rule-based MORSEL (Lignos et al., 2009; Lignos, 2010), has come close to the level of performance achieved by segmentation systems such as Morfessor (Virpioja et al., 2013).

We present a system that adapts the unsupervised MorphoChains segmentation system (Narasimhan et al., 2015) to provide morphological analyses that aim to abstract over spelling differences in functionally similar morphemes. Like MorphoChains, our system uses an unsupervised log-linear model whose parameters are learned using contrastive estimation (Smith and Eisner, 2005). The original MorphoChains system learns to identify child-parent pairs of morphologically related words, where the child (e.g., *stopping*) is formed from the parent (*stop*) by adding an affix and possibly a spelling transformation (both represented as features in the model). However, these spelling transformations are never used to output underlying morphemes, instead the system just returns a segmentation by post-processing the inferred child-parent pairs.

We extend the MorphoChains system in sev-

eral ways: first, we use the spelling transformation features to output underlying morphemes for each word rather than a segmentation; second, we broaden the types of morphological changes that can be identified to include compounds; and third, we modify the set of features used in the log-linear model to improve the overall performance. We evaluate using EMMA (Spiegler and Monson, 2010), a measure that focuses on the identity rather than the spelling of morphemes. On average across six typologically varied languages (English, German, Turkish, Finnish, Estonian, Arabic), our system outperforms both the original MorphoChains system and the MORSEL system, and performs similarly to the surface segmentation system Morfessor. These results are (to our knowledge) the best to date from a system for identifying underlying morphemes; moreover, the total number of distinct morphemes identified by our system is on average 12.8% lower than for Morfessor, suggesting that it does a better job of abstracting over surface spellings and inducing a compact representation of the data.

## 2 Morphological Chains and Analyses

We base our work on the MorphoChains segmentation system (Narasimhan et al., 2015),<sup>1</sup> which defines a **morphological chain** as a sequence of **child-parent pairs**. Each pair consists of two morphologically related words where the child must be longer than the parent. To analyse a word we want to find the best parent for that word; we do so recursively until we conclude that the **stop condition** is met (i.e. a word doesn’t have a morphological parent). The word *standardizes*, for example, produces the following chain:

*standardizes* → *standardize* → *standard*

which consists of the child-parent pairs (*standardizes*, *standardize*), (*standardize*, *standard*) and (*standard*, NONE). Each child-parent pair is annotated with a **type** indicating the kind of **transformation** that relates the child-parent pair. The set of transformations defined by MorphoChains is: **suffixation** as in (*dogs*, *dog*), **prefixation** as in (*undone*, *done*), **deletion** as in (*baked*, *bake*)<sup>2</sup>, **repetition** as in (*stopped*, *stop*), and **modification** as in

<sup>1</sup>We modified the implementation available at <https://github.com/karthikncode/MorphoChain>.

<sup>2</sup>The system could in principle learn that *bake* is the parent of *baked* with type *suffix*, which would imply the analysis *bake* + *d*. However, we hope it learns instead the type *delete*, which implies the (correct) analysis *bake* + *ed*. Similar alternative analyses are possible for the other example types shown.

Word	MorphoChains	Our Model
stopping	stopp +ing	stop +ing
doubled	double +d	double +ed
acidified	acid +ifi +ed	acid +ify +ed

Table 1: Examples outputs of two models.

(*worried*, *worry*). We add a sixth type, **compound-ing** as in (*darkroom*, *room*). The delete, repeat, and modify types all assume the change occurs to the final character of the stem, while compounding can simply concatenate the two stems, or can introduce an extra character (as in *higher-rate* or German *schilddruese* + *n* + *krebs* (‘thyroid cancer’).

Any word (*undone*) has many possible parents, some linguistically plausible (*undo*, *done*) and others not (*und*, *ndone*). Our system, like MorphoChains, learns a log-linear model to discriminate plausible from implausible parents amongst the complete **parent candidate set** for each word. The candidate set is generated by taking all possible splits of the word and applying all possible transformation types. For example, some parent candidates for the word *dogs* include (*dog*, suffix), (*do*, suffix), (*gs*, prefix), (*doga*, delete), (*dogb*, delete), (*doe*, delete), and (*doe*, modify). The last two imply analyses of *doe* + *gs* and *doe* + *s*, respectively.

The examples above indicate how analyses can be induced recursively by tracking the transformation type and orthographic change associated with each parent-child pair. However, the original MorphoChains algorithm did not do so, instead it only used the transformation types to predict morph boundaries. Table 1 contrasts the word segmentation into morphs produced by the original MorphoChains model and the morpheme analysis produced by our model. Table 2 provides additional examples of our recursive analysis process.

### 2.1 Model

We predict child-parent pairs using a log-linear model, following Narasimhan et al. (2015). The model consists of a set of features represented by a feature vector  $\phi : \mathcal{W} \times \mathcal{Z} \rightarrow \mathbb{R}^d$ , where  $\mathcal{W}$  is a set of words and  $\mathcal{Z}$  is the set of (*parent*, *type*) pairs for words in  $\mathcal{W}$ . The model defines the conditional probability of a particular (*parent*, *type*) pair  $z \in \mathcal{Z}$  given word  $w \in \mathcal{W}$  as:

$$P(z|w) = \frac{e^{\theta \cdot \phi(w,z)}}{\sum_{z' \in C(w)} e^{\theta \cdot \phi(w,z')}} , z \in C(w) \quad (1)$$

Step	Word	Child-Parent Pair	Type	Change	Analysis
1	<b>acidified</b>	( <i>acidified</i> , <i>acidify</i> )	modify	add <i>+ed</i>	<i>+ed</i>
2		( <i>acidify</i> , <i>acid</i> )	suffix	add <i>+ify</i>	<i>+ify +ed</i>
3		( <i>acid</i> , NONE)	stop	add <i>acid</i>	<b>acid +ify +ed</b>
1	<b>doubled</b>	( <i>doubled</i> , <i>double</i> )	delete	add <i>+ed</i>	<i>+ed</i>
2		( <i>double</i> , NONE)	stop	add <i>double</i>	<b>double +ed</b>
1	<b>higher-rate</b>	( <i>higher-rate</i> , <i>rate</i> )	compound	keep <i>higher</i>	
2		( <i>rate</i> , NONE)	stop	add <i>rate</i>	<i>rate</i>
3		( <i>higher</i> , <i>high</i> )	suffix	add <i>+er</i>	<i>+er rate</i>
4		( <i>high</i> , NONE)	stop	add <i>high</i>	<b>high +er rate</b>

Table 2: Examples of step-by-step derivations of morphological analysis of English words.

where  $C(w) \subset \mathcal{Z}$  denotes the set of parent candidates for  $w$  and  $\theta$  is a weight vector.

Our goal is to learn the feature weights in an unsupervised fashion. Following Narasimhan et al. (2015), we do so using Contrastive Estimation (CE) (Smith and Eisner, 2005). In CE every training example  $w \in \mathcal{W}$  serves as both a positive example and a set of implied negative examples—strings that are similar to  $w$  but don’t occur in the corpus. The negative examples are the source of the probability mass allocated to the positive examples. The word  $w$  and its negative examples constitute the **neighbourhood**  $\mathcal{N}(w)$  of  $w$ .

Given the list of words  $\mathcal{W}$  and their neighbourhoods, the CE likelihood is defined as:

$$L_{CE}(\theta, \mathcal{W}) = \prod_{w^* \in \mathcal{W}} \frac{\sum_{z \in C(w^*)} e^{\theta \cdot \phi(w^*, z)}}{\sum_{w \in \mathcal{N}(w^*)} \sum_{z \in C(w)} e^{\theta \cdot \phi(w, z)}}. \quad (2)$$

We use the same neighbourhood functions as Narasimhan et al. (2015). Specifically, for each word  $w$  in the corpus  $\mathcal{W}$ , we create neighbours in two ways: by swapping two adjacent characters of  $w$  (*walking*  $\rightarrow$  *walkign*) and by swapping two pairs of adjacent characters, where one pair is at the beginning of the word, and the other at the end of the word (*walking*  $\rightarrow$  *awlkign*).

We use LBFGS-B (Zhu et al., 1997) to optimize the regularized log-likelihood of the model:

$$LL_{CE}(\theta, \mathcal{W}) = \sum_{w^* \in \mathcal{W}} \left[ \log \sum_{z \in C(w^*)} e^{\theta \cdot \phi(w^*, z)} - \log \sum_{w \in \mathcal{N}(w^*)} \sum_{z \in C(w)} e^{\theta \cdot \phi(w, z)} \right] - \lambda \|\theta\|^2 \quad (3)$$

## 2.2 Features

MorphoChains used a rich set of features from which we have kept some, discarded others and added new ones to improve overall performance. This section describes our set of features, with examples shown in Table 3.

**Presence in Training Data** We want features that signal which parents are valid words. Narasimhan et al. (2015) used each word’s log frequency. However the majority of words in the training data (word frequency lists) occur only once, which makes their frequency information unreliable.<sup>3</sup> Instead, we use an out-of-vocabulary feature (OOV) for parents that don’t occur in the training data.

**Semantic Similarity** Morphologically related words exhibit semantic similarity among their word embeddings (Schone and Jurafsky, 2000; Baroni et al., 2002). Semantic similarity was an important feature in MorphoChains: Narasimhan et al. (2015) concluded that up to 25 percent of their model’s precision was due to the semantic similarity feature. We use the same feature here (COS). For a child-parent pair ( $w_A, w_B$ ) with word embeddings  $v_{w_A}$  and  $v_{w_B}$  respectively we compute semantic similarity as:

$$\text{cos}(w_A, w_B) = \frac{v_{w_A} \cdot v_{w_B}}{\|v_{w_A}\| \|v_{w_B}\|} \quad (4)$$

**Affixes** Candidate pairs where the child contains a frequently occurring affix are more likely to be correct. To identify possible affixes to use as features, Narasimhan et al. (2015) counted the number of words that end (or start) with each substring

<sup>3</sup>The prevalence of singleton word types in the MorphoChallenge 2010 training data for English, German, Turkish ranges from 50.73 to 58.76 %.

No	Child	Parent Candid.	Active Features
1	<i>dog</i>	( <i>og</i> , prefix)	OOV, PREF= <i>d</i>
2	<i>decided</i>	( <i>decide</i> , delete)	DELETED= <i>e</i> , SUF= <i>ed</i> , SUFLIST

Table 4: The likely English affixes found by using Letter Successor Entropy.

and selected the most frequent ones. However, all words that end with *ing* also end with *ng* and *g*, which means that they also become affix candidates. Furthermore, there are more words that end with *ng* or *g* than with *ing*, therefore valid affixes might be excluded from the list because of their more frequent substrings.

We therefore modify the affix features in two ways. First, we identify a more precise set of likely affixes using Letter Successor Entropy (LSE) values (Hafer and Weiss, 1974), which are typically high at morph boundaries. LSE is computed at each point in the word as the entropy of the distribution over the next character given the word prefix so far. When selecting likely affixes, we use an LSE threshold value of 3.0 as suggested by Hafer and Weiss (1974), and we require that the affix has appeared in at least 50 types with a cor-

pus frequency of at least 100. We then define two features (PREFLIST, SUFLIST), which are active if the proposed prefix or suffix for a parent-child pair is in the set of likely prefixes or suffixes. Table 4 shows the list of likely English affixes found by using LSE (62 suffixes and 42 prefixes). For German and Turkish, our other two development languages (see §3), the lists contain 498 suffixes/183 prefixes and 181 suffixes/35 prefixes, respectively.<sup>4</sup>

In addition, we use a much larger set of affix features, PREF= $x$  and SUF= $x$ , where  $x$  is instantiated with all possible word prefixes (suffixes) for which both  $w$  and  $xw$  ( $wx$ ) are words in the training data.

**Transformations** To help distinguish between probable and improbable transformations, we introduce transformation-specific features. For deletion we use the deleted letter (DELETED). For repetition we use the repeated letter and its preceding 2- and 1-character contexts (REPEATED, RENV2 RENV1). For modification we use the combination of the involved letters (MODIFIED). Finally, for compounding we use the headword (i.e. the parent of the compound), the modifier and the connector, if such exists (HEAD, MODIFIER, CONNECTOR). Since these compound features can be very sparse, we also add a single COMPOUND feature, which is active when both parts of the compound are present in the training data.

**Stop Condition** To identify words with no parents we use two types of binary features suggested

<sup>4</sup>In MorphoChains, the number of affixes was set manually for each language tested: 300 for English, 500 for Turkish, and 100 for Arabic.

by Narasimhan et al. (2015).  $\text{STOPCOS}=y$  is the maximum cosine similarity between the word and any of its parent candidates (using bins of size 0.1), and  $\text{STOPLEN}=x$  is instantiated for all possible word lengths  $x$  in the training data. For illustration, if we are considering whether *decided* is a word with no parents (Table 3 Example 10), the binary features  $\text{STOPLEN}=7$  and  $\text{STOPCOS}=0.5$  become active.

We discard the starting and ending character unigram and bigram features used by MorphoChains, because of the large number<sup>5</sup> and the sparsity of these features.

### 2.3 Data Selection

Most unsupervised morphology learners are sensitive to the coverage and the quality of training data. In a large corpus, however, many word types occur only once because of the Zipfian distribution of word types. Low-frequency types can be either rare but valid words or they can be foreign words, typos, non-words, etc. This makes learning from low-frequency words unreliable, but discarding them dramatically reduces the size of the training data (including many valid words).

To seek balance between the quality and the coverage of the training data we try to identify which low-frequency words are likely to provide useful statistical support for our model, so we can include those in the training data and discard the other low-frequency words. First, we set a frequency-based **pruning threshold** (PT) at the frequency for which at least 50% of the words above this frequency have a word embedding (see §3); next we set a **learning threshold** (LT) at the median frequency of the words with frequencies above PT; finally we adopt the algorithm by Neuvel and Fulop (2002) to decide which words with frequencies below PT can be useful to analyse the words with frequencies above LT. We filter out any remaining words with frequencies below PT.

The outline of the adapted version of the algorithm by Neuvel and Fulop (2002) is:

1) For every word pair in the top 20k most frequent words in training data:

1.1) We find the pair’s **orthographic similarities** as the longest common subsequence: *receive* ⇔ *reception*.

1.2) We find the pair’s **orthographic differ-**

**ences** with respect to their orthographic similarities: *receive* ⇔ *reception*.

2) For all word-pairs with the same orthographic differences we merge their similarities and differences into **Word Formation Strategies** (WFS): so *receive* ⇔ *reception*, *conceive* ⇔ *conception*, *deceive* ⇔ *deception* give *###ceive* ⇔ *###ception*, where \* and # stand for the optional and mandatory character wild cards respectively.

3) We discard those WFS that that are suggested by less than 10 word pairs;

4) For each WFS and for each word with a frequency below PT:

4.1) if a word  $w$  matches either of the sides of a WFS and the other side of a WFS predicts a word  $w'$  with a frequency above the LT, we keep  $w$  in the training data, otherwise we discard it.

For more detailed description of the algorithm see Neuvel and Fulop (2002).

## 3 Experiments

**Data** We conduct experiments on six languages: Arabic, English, Estonian, Finnish, German and Turkish. For the word embeddings required by our system and the MorphoChains baseline, we used *word2vec* (Mikolov et al., 2013) to train a Continuous Bag of Words model on a sub-sample of the Common Crawl (CC) corpus<sup>6</sup> for each language (Table 5 lists corpus sizes). We trained 100-dimensional embeddings for all words occurring at least 25 times, using 20 iterations and default parameters otherwise.

For all languages except Estonian, we train and evaluate all systems on the data from the Morpho Challenge 2010 competition.<sup>7</sup> The training data consists of word lists with word frequencies. The official test sets are not public, but a small labelled training and development set is provided for each language in addition to the large unannotated word list, since the challenge included semi-supervised systems. Thus, for experiments on Arabic, English, Finnish, German and Turkish we evaluated on the annotated training and development gold standard analyses from the Morpho Challenge 2009/2010 competition data sets. The gold standard labels include part of speech tags and functional labels for inflectional morphemes, with multiple analyses given for words with part of speech ambiguity or

<sup>5</sup>For English there can be 676 different letter bigrams of which 99% occur at least once at the beginning of some word in the word frequency list.

functionally different but orthographically equivalent inflectional morphemes. For example, *rockiness* is analysed as *rock\_N y\_s ness\_s*, while *rocks* has two analyses: *rock\_N +PL* and *rock\_V +3SG*.

For Estonian we train on word lists extracted from Common Crawl and test on data prepared by Sirts and Goldwater (2013). The Estonian test set contains only surface segmentation into morphs (e.g. *kolmandal* is analysed *kolmanda l*). Table 5 provides information about each dataset.

Since we are developing an unsupervised system, we want to make sure that it generalizes to new languages. We therefore divide the languages into three **development languages** (English, German, Turkish) and three **test languages** (Finnish, Estonian, Arabic). We used the development languages to choose features, design the data selection procedure and select best values for hyperparameters. The system that performed best on those languages was then used unmodified on the test languages.

**Hyperparameters** In addition to threshold values described above, we use the same  $\lambda = 1$  (Equation 3) as Narasimhan et al. (2015). To control for under segmentation we downscale weights of the stop features by a factor of 0.8. We set the maximum affix length to 8 characters and the minimum word length to 1 character.

**Evaluation Metric** We test our model on the task of unsupervised morpheme analysis induction. We follow the format of Morpho Challenge 2010 and use Evaluation Metric for Morphological Analysis

(EMMA) (Spiegler and Monson, 2010) to evaluate predicted outputs. EMMA works by finding the optimal one-to-one mapping between the model’s output and the reference analysis (i.e., the spelling of the morphemes in the analysis doesn’t matter). These are used to compute precision, recall, and F-score against the reference morphemes.

**Baselines** We compare our model to three other systems: Morfessor 2.0 (Virpioja et al., 2013), MORSEL (Lignos et al., 2009; Lignos, 2010) and MorphoChains (Narasimhan et al., 2015). We also use a trivial baseline *Words* which outputs the input word.

Morfessor (*Morf.2.0*) is a family of probabilistic algorithms that perform unsupervised word segmentation into morphs. Since the release of the initial version of Morfessor, it has become popular as an automatic tool for processing morphologically complex languages.

MORSEL is a rule-based unsupervised morphology learner designed for affixal morphology. Like our own system, it outputs morphological analyses of words rather than segmentations. MORSEL achieved excellent performance on the Morpho Challenge 2010 data sets.

MorphoChains (*MC*) is the model upon which our own system is based, but as noted above it performs segmentation rather than analysis. In contrast to Morfessor and MORSEL, which analyse words based only on orthographic patterns, MorphoChains (like our extension) uses both orthographic and the semantic information.

All three baselines have multiple hyperparameters. Since performance tends to be most sensitive to the treatment of word frequency (including possibly discarding low-frequency words), for each system we tuned the hyperparameters related to word frequency to optimize average performance on the development languages, and kept these hyperparameters fixed for the test languages.

## 4 Results and Discussion

Table 6 gives the performance of all models on the three development languages. Our model outperforms all baselines on every language, and is a clear improvement over the original MorphoChains.<sup>8</sup>

<sup>8</sup>In the results reported by Narasimhan et al. (2015), MorphoChains appeared to outperform Morfessor, whereas we find the opposite. There are several possible reasons for the discrepancy. First, Narasimhan et al. (2015) used a segmentation-based metric rather than EMMA, so the scores are not comparable. Second, Narasimhan et al. (2015) appear to have tuned

Table 6: Results on development languages. Scores calculated using EMMA. *Words*=Trivial baseline which outputs the input word.

To see where the benefit is coming from, we performed ablation tests (Table 7). Results show the importance of the LSE-based affix features (Model-A). Using these features gives gains of +1.0%, 3.8% and 0.6% F-1 absolute on English, German and Turkish respectively over using the raw affix occurrence frequencies as used by Narasimhan et al. (2015). We can see that our data selection scheme (Model-D) is important for English (+3.5%) and German (+1.1%). Although we expected that the data selection scheme would have the biggest impact on Turkish because of its small training data, it has very little effect on this language. As expected, the compounding transformation (Model-C) has a prominent impact on German (+2.7%) and a modest effect on English and Turkish. The three features PREFLIST, SUFLIST, COMPOUND (Model-B) have the least impact on the model’s performance (on average 0.5% F-1 absolute), however the effect is substantial considering that this gain is achieved

their hyperparameters separately for each language. Finally, it is not clear how they tuned the frequency-related hyperparameters for Morfessor. We found that Morfessor performed better than MorphoChains when either low frequency words are pruned from its input, or its log-frequency option is used rather than raw frequency.

by merely 3 features as opposed to a new feature type with many instantiations.

Table 8 shows some example outputs for English, German and Turkish. These analyses include some correctly identified spelling changes (Example 1) compounds (Example 4), and purely concatenative morphology (Example 6). In Example 2, *+ble* is counted as incorrect because our model predicts *+ble* both for *deplorable* and *reproducible* while the reference analysis uses *able\_s* and *ible\_s*, respectively. Since EMMA uses one-to-one alignment, it deems one of the alignments wrong. The opposite problem occurs in Example 4: our model analyses *aus* in two ways, either as a prefix *aus+* or as a separate word *aus* (part of a compound), whereas the reference analysis always treats it as a separate word *aus*. Example 6 illustrates an over-segmentation error, caused by encountering two similar forms of the verb *giy*, *giymeyin* and *giymeyi*.

Performance of all models on the three test languages is shown in Table 9. On average, our model does better than MorphoChains and MORSEL, but slightly worse than Morfessor. However, this difference is mainly due to Morfessor’s very good performance on Estonian, which is the only test set using gold standard segmentations rather than analyses. All systems perform poorly on Arabic since they do not handle templatic morphology; nevertheless our model and Morfessor perform considerably

better than the others. Overall, our model performs consistently near the top even if not the best for any of the three languages.

**Lexical Inventory Size** One of the motivations for unsupervised morphological analysis is to reduce data sparsity in downstream applications, which implies that for a given level of accuracy, systems that produce a more compact representation (i.e., a smaller morpheme inventory) should be preferred. To see how compactly each model represents the test set, we count the number of unique morphemes (or morphs, or labels) in the predicted output of each model and compare it with the number of labels in the reference analysis and the num-

ber of words in the test set. Table 10 summarizes this information<sup>9</sup>. For all languages except Estonian our model finds the most compact set of items. The number of distinct morphemes identified by our model is only about 5%, 4.5% and 8.0% larger than in the reference analysis for English, German and Finnish respectively. On average our model identified 12.8% and 14.8% fewer morphemes than Morfessor and MorphoChains respectively, while on average performing no worse or better than the two word segmentation systems. MORSEL produces the second most compact output with only a 3.2% larger set of distinct morphemes than our model, leaving the two word segmentation systems, Morfessor and MorphoChains, in the third and the fourth place respectively. These results suggest that systems that attempt to output morphological analysis succeed in reusing the same morphemes more frequently than the systems that perform surface segmentation.

## 5 Conclusion

We presented an unsupervised log-linear model that learns to identify morphologically related words

<sup>9</sup>Arabic is excluded because of the low overall performance of all models (maximum recall 22.4%).

and the affixes and spelling transformations that relate them. It uses these to induce morpheme-level analyses of each word and an overall compact representation of the corpus. In tests on six languages, our system’s EMMA scores are considerably better than its inspiration, the segmentation system MorphoChains, and it also outperformed the rule-based analysis system MORSEL. Our system achieved similar EMMA performance to Morfessor but with a more compact representation—the first probabilistic system we are aware of to do so well. In future work, we hope to investigate further improvements to the system and perform extrinsic evaluation on downstream tasks.

## Abstract

Part of speech (POS) taggers and dependency parsers tend to work well on homogeneous datasets but their performance suffers on datasets containing data from different genres. In our current work, we investigate how to create POS tagging and dependency parsing experts for heterogeneous data by employing topic modeling. We create topic models (using Latent Dirichlet Allocation) to determine genres from a heterogeneous dataset and then train an expert for each of the genres. Our results show that the topic modeling experts reach substantial improvements when compared to the general versions. For dependency parsing, the improvement reaches 2 percent points over the full training baseline when we use two topics.

## 1 Introduction

POS tagging and dependency parsing perform well when trained and tested on datasets that are predominantly in the same text domain. However, there is decrease in accuracy for heterogeneous datasets, i.e., for datasets that consist of a mixture of data from different domains. Our current work focuses on improving POS tagging and dependency parsing for such heterogeneous datasets from a variety of different genres by creating experts for automatically detected topics. In our case, the datasets consist of newspaper reports on the one hand and biomedical extracts on the other.

For determining the topic of a sentence, we use Latent Dirichlet Allocation (LDA), which finds the latent topic structure in a document. In our case, a document to be clustered consists of a single sentence. We then assign each sentence to

the most likely topic, for both training and test sentences. We consequently train an expert for each topic and then use this expert to POS tag and parse the test sentences belonging to this topic. We assume that the topics detected by the topic modeler do not only pertain to lexical differences, which can be beneficial for the POS tagger and the parser, but also to syntactic phenomena. Thus, one topic may focus on “incomplete” sentences, such as headlines in a newspaper.

Our work is related to domain adaptation since the aim is to improve (morpho-)syntactic analysis for different domains. However, our approach can be regarded as a more general approach to the problem of domains as it is based on automatically determining the genres present in the dataset. Thus, no manual work is involved.

Our results show small to considerable improvements over a competitive baseline of using the full training set. For POS tagging, there is an improvement of 0.3 percent points over the full training set. For dependency parsing, the gain is more pronounced: almost 2% over the full training set.

The remainder of the paper is structured as follows: Section 2 discusses our research questions and section 3 the related work in the area. Section 4 describes the setup for our experiments, and section 5 shows the experimental results. We draw our conclusions in Section 6.

## 2 Research Questions

Our aim is to create POS tagging and parsing experts for heterogeneous datasets, with sentences from different genres. For example, the dataset might be a mixture of newspaper articles, blogs, financial reports, research papers and even specialized texts such as biomedical research papers and law texts. We create experts such that each

expert would learn specific information about its own genre. We determine these experts by performing topic modeling on sentences and then train an expert on the sentences of the topic. We group sentences based on their most probable topic. To test our hypothesis that topic modeling can serve to group sentences into topics, we create a mixed dataset from the financial domain (using the Penn Treebank (Marcus et al., 1994)) and from the biomedical domain (using the GENIA Corpus (Tateisi and Tsujii, 2004)) such that the new hand-crafted corpus consists of sentences from both domains in equal measure. Consequently, there is a clear difference in the genres in our corpus, and we have gold standard topic information.

We perform topic modeling on training and test data simultaneously: We assign a test sentence to the topic with the highest probability. This means that we currently simplify the problem of assigning new sentences to topics. In the future, we plan to assign new sentences to topics based their similarity to sentences in the topics created during training, following the work by Plank and van Noord (2011).

Our current research focuses on answering the following questions for POS tagging and parsing tasks:

### **Question 1: Does Topic Modeling Detect Topics?**

In this question, we investigate whether an unsupervised topic modeler can detect topics in a heterogeneous corpus. We use our artificially created heterogeneous corpus containing sentences from the Wall Street Journal (WSJ) section of the Penn Treebank (Marcus et al., 1994) and from the GENIA Corpus (Tateisi and Tsujii, 2004) and take their original corpus as the gold standard topic. We assume that a good split into the known topics, financial news and biomedical abstracts, will also improve POS tagging and parsing accuracy. If we assume two topics, we should be able to see a clear distinction between WSJ and GENIA sentences. I.e., for each topic, we should have a clear correspondence of its sentences to either WSJ or GENIA. We thus calculate the percentage of sentences in a given topic that belong to GENIA and expect that one topic should have a high percentage and the other one a low percentage. We also experiment with a larger number of topics, to see if we can profit from a finer grained topic defini-

tion. However, this advantage will be offset by a smaller training set since we split into more sets.

### **Question 2: Does POS Tagging Benefit from Using Topics?**

In this question, we examine whether the performance of POS tagging improves if we create experts based on the topics detected by the topic modeler. Thus, we use the topics created for the previous sections and train a POS tagging expert on the training part of each topic. We then use the expert to tag the test sentences from this topic. In this setting, we can see if the experts can effectively handle the data sparseness caused by dividing the training set into multiple experts. We experiment with one setting in which we use topic modeling as hard clustering, i.e., we assign each sentence to the topic for which the topic modeler gave the highest probability. We also experiment with soft clustering, in which we add each sentence to all topics, weighted by its probability distribution.

### **Question 3: Does Dependency Parsing Benefit from the Topics?**

Here, we investigate the effects of using topic modeling experts for dependency parsing. We first use gold POS tags in order to abstract away from POS tagging quality. In a second step, we investigate the interaction between POS tagging and parsing experts. I.e., we are interested in whether dependency parsing can profit from using the POS tags that were determined by the POS tagging experts. This allows us to determine whether integrating POS information given by the POS experts can improve dependency parsing or whether there is no interaction between the two levels.

### **Question 4: What do the Experts Learn?**

In this question, we will analyze the results from question 3 in more detail to investigate how the topic modeling experts improve parsing results. We are interested in whether there are specific types of sentences or dependencies that are grouped by the topic models, so that the parsing experts focus on a specific subset of syntactic properties.

## **3 Related Work**

To the best of our knowledge, there is little direct correlation between our work on POS tagging and

parsing experts to that of the previous work done in the area. However, our work is comparable to domain adaptation since we create experts to tag and parse heterogeneous datasets. The work in this area is largely driven by the unavailability of examples from the target domain. Our work focuses on creating experts using topic modeling which will be able to tag and parse target domain sentences belonging to a specific topic. Compared to POS tagging, there has been significant work on domain adaptation in dependency parsing.

Dredze et al. (2007) found that problems in domain adaptation are compounded by differences in the annotation schemes between the treebanks. Blitzer et al. (2006) experimented with structural correspondence learning (SCL), which focuses on finding frequently occurring pivot features that occur commonly across domains in the unlabeled data but equally characterize source and target domains. Similar to our work, Blitzer et al. used the WSJ as the source and MEDLINE abstracts as the target domain. They established that SCL reaches better results in both POS tagging and parsing than supervised and semi-supervised learning even when there is no training data available in the target domain.

For POS tagging, Clark et al. (2003) applied an agreement-based and a baseline co-training method by using a Markov model tagger and a maximum entropy tagger. In case of the baseline, all the sentences from one tagger are added to train the other whereas in the agreement-based method, both taggers have to reach to the same decision for a sentence to be added to the training. Kübler and Baucom (2011) used a similar concept but with three different taggers and showed that selecting sentences as well as sequences of words for which all taggers agree yield the highest gains. Sagae and Tsujii (2007) emulate a single iteration of co-training by using MaxEnt and SVM, selecting the sentences where both models agreed and adding these sentences to the training set. Their approach reached the highest results on the domain adaptation task of CoNLL 2007 (Nivre et al., 2007).

In the CoNLL 2007 shared task on domain adaptation for dependency parsing, Attardi et al. (2007) used a tree revision method that corrects the mistakes caused by the base parser for the target domain. Later, Kawahara and Uchimoto (2008) employed a single parser approach using a second order MST parser and combining labeled

data from the known domain with unlabeled data of the new domain by simple concatenation and judging the efficacy of the resulting most reliable parses. Finkel and Manning (2009) devised a new model for named entity recognition as well as dependency parsing by using hierarchical Bayesian prior. This is influenced by the notion that different domains may have different features specific to each domain. However, instead of applying a constant prior over all the parameters, a hierarchical Bayesian global is used. This enables sharing of information across domains but also allows to override this information if there is ample evidence.

McClosky et al. (2010) designed the problem as “multiple source parse adaptation”, in which a parser was trained on multiple domains and learned the statistics as well as domain differences which affects the parser accuracy. Their parser outperformed the state-of-the-art baselines. This approach is similar to our work as we create experts based on topics, and each expert learns the specifics of the particular topic with which it is associated.

The closest approach to ours is the one by Plank and van Noord (2011), who employ a similar idea of using topic modeling for creating parsing experts. However, their task is to determine in a domain adaption setting which sentences of an out-of-domain training set are the most similar to the test set. Thus, they create a specialized training set for every document they need to parse while we create more general experts. In the work by Plank and van Noord (2011), the topic distribution in a document is used as features for their similarity metrics.

## 4 Experimental Setup

### 4.1 Data Sets

For our experiments, we use the Wall Street Journal (WSJ) section of the Penn Treebank (Marcus et al., 1994) and the GENIA Corpus (Tateisi and Tsujii, 2004). Both corpora use the Penn Treebank POS tagset (Santorini, 1990) with minor differences: The tagset used in GENIA is based on the Penn Treebank tagset, but it uses the tags for proper names and symbols only in very restricted contexts.

For the WSJ corpus, we extract the POS annotation from the syntactically annotated corpus. The GENIA Corpus comprises biomedical abstracts

from Medline, and it is annotated on different linguistic levels, including POS tags, syntax, coreference, and events, among others. We use GENIA 1.0 trees (Ohta et al., 2002) created in the Penn Treebank format<sup>1</sup>. Both treebanks were converted to dependencies using `pennconverter` (Johansson and Nugues, 2007).

For our experiments, we need a balanced data set, both for the training and the test set. Since GENIA is rather small and since there is no standard data split for GENIA, we decided to extract the last 850 sentences for the test set. The remaining 17 181 sentences are used for training. For WSJ, we chose the same number of sentences for both training and the test set, the training sentences are selected randomly from sections 02-21 and the test sentences from section 22.

## 4.2 Topic Modeling

Probabilistic topic modeling is a class of algorithms which detects the thematic structure in a large volume of documents. Topic modeling is unsupervised, i.e., it does not require annotated documents (Blei, 2012) but rather discovers similarity between documents. Latent Dirichlet Allocation (LDA) is one of the topic modeling algorithms. It is a generative probabilistic model that approximates the underlying hidden topical structure of a collection of texts based on the distribution of words in the documents (Blei et al., 2003).

We use the topic modeling toolkit MALLET (McCallum, 2002). The topic modeler in MALLET implements Latent Dirichlet Allocation (LDA), clustering documents into a predefined number of topics. As a result, it provides different types of information such as:

- Topic keys: The highest ranked words per topic with their probabilities;
- Document topics: The topic distribution for each document (i.e., the probability that a document belongs to a given topic); and
- Topic state, which correlates all words and topics.

For our experiments, we use sentences as documents. Based on the document topic information, we then group the sentences into topics. We collect all sentences from the training and test set, cluster them via the MALLET topic modeler, and

determine for which expert(s) the sentence is relevant. There are several ways of determining the best expert, see below. Then, we separate the sentences for each expert into training and test sentences, based on the previously determined data splits (see above).

We can determine experts based on hard or soft clustering decisions: For hard clustering, the sentences are assigned to hard topics, based on the topic that has the highest probability in that sentence. I.e., if for sentence  $s_x$ , MALLET lists the topic  $t_1$  as the topic with the highest probability, then  $s_x$  is added to the data set of topic  $t_1$ . In other words, the data set of topic  $t_1$  consists of all sentences for which MALLET showed topic  $t_1$  as the most likely topic. This means that the data set sizes vary between topics.

For soft clustering experiments, we utilize the entire topic distribution of a sentence by weighting sentences in the training data based on their topic distribution. We simulate weighting training sentences by adding multiple copies to the training files of the experts. Thus, for 2-topic experiments, a sentence with 80% probability for topic 1 will be included 8 times in the expert for topic 1 and 2 times in the expert for topic 2, rounding up small percentages so that every sentence will be added to every expert at least once. Thus, we use a more fine grained topic model while mitigating data sparseness, but we risk adding non-typical / irrelevant sentences to experts.

## 4.3 POS Tagging

For part of speech tagging, we use the TnT (Trigrams'n'Tags) tagger (Brants, 2000). TnT is based on a second order Markov Model and has an elaborate model for guessing the POS tags for unknown words. We use TnT mainly because of its speed and because it allows the manual inspection of the trained models (emission and transition frequencies).

## 4.4 Dependency Parsing

For the parsing experiments, we used the dependency parser of the MATE Tools<sup>2</sup>, a Java implementation of a graph-based parser (Bohnet, 2010).

## 4.5 Evaluation

We used the script `tnt-diff` that is part of TnT to evaluate the POS tagging results and the

9			98.92	99.33
10			94.85	95.35

Table 1: Distribution of sentences from the WSJ+GENIA data set given 2 and 10 topics (showing the percentage of GENIA sentences per topic).

CoNLL shared task evaluation script<sup>3</sup> for evaluating the parsing results.

#### 4.6 Baselines

We use two baselines: For the first baseline, we take the complete training set when no topic modeling is performed. Note that this is a very competitive baseline since the topic modeling experts have access to considerably smaller amounts of training data. In order to avoid differences in accuracy resulting from different training set sizes, we create a second baseline by splitting the sentences randomly into the same number of groups as the number of topics, while maintaining the equal distribution of WSJ and GENIA sentences. I.e., we assume the same number of random “topics”, all of the same size. Thus, in the 2-topic setting with the genres, we create two separate training sets, each containing half of the WSJ training set and half of the GENIA one. In this setting, we test all experts on the whole test set and average over the results.

## 5 Experimental Results

### 5.1 Does Topic Modeling Detect Topics?

Here we investigate whether LDA can separate the sentences into meaningful topics. Table 1 shows the distribution of sentences in the training and test set into different topics when we assume 2 or 10 topics. These results indicate that the topic modeler separates topics very efficiently. For the 2-

<sup>3</sup><http://ilk.uvt.nl/conll/software/eval.pl>

Setting	Accuracy	
	2 topics	10 topics
Full training set	96.69	
Random split	96.41	95.48
Topic model	<b>96.95</b>	96.38
Soft Clustering	96.8	<b>96.88</b>

Table 2: Results of the POS tagging experiments.

topic experiments, a clear split is evident as the majority of the GENIA sentences are clustered in topic 2; the misclassified sentences constitute less than 1%. For the 10-topic experiments, we notice that topics 2, 4, 7, 8, 9, and 10 contain mainly GENIA sentences while the remaining topics cover mainly WSJ sentences. In both settings, the error rate is between 0.2% and 5%, i.e., we obtain a distinct split between GENIA and WSJ, which should give us a good starting point for the following experiments.

### 5.2 POS Tagging Experts

In this section, we investigate whether the POS tagger can benefit from using topic modeling, i.e., whether POS tagging results can be improved by training experts for genres provided by topic modeling. We compare the topic modeling approach to our two baselines for the 2-topic and 10-topic setting. We also perform a soft clustering experiment, in which each sentence is added to every topic, weighted by its probability (see section 4.2).

The results in Table 2 show that if we assume a 2-topic setting, the experts perform better than both baselines, i.e., the model trained on the full training set and the model with randomly chosen “topics”. The 2-topic expert model reaches an accuracy of 96.95%, which is slightly higher than the full training set accuracy of 96.69%. We know that the 2-topic setting provides a clear separation between WSJ and GENIA (Table 1). Thus, this setting outperforms the full training set using a smaller amount of training data. There is also an increase of 0.54 percent points over the accuracy of the 2 random split setting.

For the 10-topic setting, the topic expert model outperforms the random split of the same size by 0.9 percent points, which is a higher difference than for the 2-topic setting. This shows that the finer grained splits model important information. However, the topic expert model does not reach the accuracy of the baseline using the full training

Setting	LAS		UAS	
	2 topics	10 topics	2 topics	10 topics
Full training set	88.67		91.71	
Random split	87.84	84.91	90.86	88.64
Topic model	<b>90.51</b>	88.38	<b>92.14</b>	90.3
Soft clustering	89.86	<b>89.91</b>	91.99	<b>91.84</b>

Table 3: Results of the dependency parsing experiments using gold POS tags.

set. This can be attributed to the reduced size of the training set for the experts.

Since training set size is a detrimental factor for the larger number of topics, we also conducted an experiment where we used soft clustering so that every sentence is represented in every topic, but to a different degree. The last row in table 2 reports the results of this experiment. We notice that the 2-topic experts cannot benefit from the soft clustering. Since the separation between WSJ and GENIA is very clearly defined for the 2-topic experiments, the advantage of having a larger training set is outweighed by too many irrelevant examples from the other topic. However, the 10-topic model profits from the soft clustering, which indicates that soft clustering can alleviate the data sparseness problem of the POS tagging experts for larger numbers of topics. A more detailed analysis of the POS tagging results (on a slightly different data split), see (Mukherjee et al., 2016). This work includes an experiment showing that the POS tagging experts also increase performance for the WSJ corpus only, showing that POS tagging experts also perform better on more homogeneous collections, i.e., they adjust to less obvious differences between sentences.

### 5.3 Dependency Parsing Experts

#### 5.3.1 Using Gold POS Tags

We now look into the parsing experiments using gold standard POS tags. The choice of gold POS tags allows us to focus on the contribution of the topic modeling experts on parsing results.

The results of the experiments are shown in Table 3, for 2-topic and 10-topic settings and in comparison to the two baselines, for the hard and soft clustering experiments. The hard clustering results indicate that the 2-topic expert model reaches an improvement over the baseline using the full training set for both the labeled attachment score (LAS) and the unlabeled attachment score (UAS). We find an increase of around 2% over the baseline

for LAS, and an increase of 0.43% for UAS. However, for the 10-topic setting, both the LAS and the UAS are slightly lower than the baseline. For LAS, the difference is 0.29 percent points while for UAS, the difference is 1.41 percent points. This shows that the gain in LAS and UAS is offset by the reduced training set, parallel to the results for POS tagging. Both the 2-topic and the 10-topic experts outperform the random split baseline (which uses similar training set sizes), with a gain of more than 3 percent points.

The soft clustering results show the same trends as in the POS tagging experiments: For the 2-topic setting, soft clustering outperforms the full baseline by 1.19 percent points. But it does not exceed the hard clustering results. In the 10-topic setting, soft clustering outperforms the full baseline as well as the hard clustering setting. This is because sentences with a 50% probability of belonging to topic 1 and a 40% probability for topic 3 need to be considered to belong to both topics. This result also shows that this method effectively handles the training data sparsity in the 10-topic setting.

#### 5.3.2 Using the POS Tagger

In section 5.3, we use the gold standard POS tags in the POS tags. In this section, we explore the results of using POS tags from the POS tagger TnT as the input for the parser. This gives rise to four major scenarios:

1. The full training set is used for POS tagging and for parsing (full baseline).
2. Random splits are used for parsing and POS tagging. I.e., the POS tagger and parser are trained on random splits (random baseline).
3. Topic models are used for training the parser, but TnT is trained on the whole training set.
4. Topic models are used for training the parser and the POS tagger.

Setting	LAS		UAS	
	2 topics	10 topics	2 topics	10 topics
1. Full set POS + full set parsing	86.70		90.26	
2. Random split POS + random split parsing	85.77	81.33	89.11	85.73
3. Full set POS + topic model parsing	88.30	86.13	90.43	88.47
4. Topic model POS + Topic model parsing	<b>88.35</b>	85.68	<b>90.55</b>	88.15

Table 4: Results of the dependency parsing experiments using TnT POS tags.

Sentence	Fulltext	2-topic
	LAS	LAS
Phyllis Kyle, Stephenson Newport News , Va .	0	25.00
But volume rose only to 162 million shares from 143 million Friday .	46.15	61.54
Fidelity , for example , prepared ads several months ago in case of a market plunge .	47.06	82.35
CALL IT un-advertising .	50.00	75.00
( See related story : ” And Bills to Make Wishes Come True ” – WSJ Oct. 17 , 1989 .	52.38	61.90

Table 5: Comparison of LAS for the sentences with the lowest LAS in the fulltext setting.

We use the random split case as the lower baseline for these experiments and the full training set as the more competitive baseline. Table 4 shows the results.

Table 4 shows that in the 2-topic setting, using topic modeling experts on the POS level as well as on the parsing level reaches the highest results with an improvement of around 2% in LAS in comparison to the full baseline parser, from 86.70% to 88.35%. The gain in UAS is considerably smaller: The topic modeling expert reaches 90.55% as opposed to 90.26% for the full baseline. In contrast, the topic modeling setting for the 10-topic setting outperforms the random baseline but does not reach the full baseline, thus mirroring the trends we have seen before.

When we compare the experiments where we use the full POS tagging baseline along with topic model parsing experts (row 3 in table 4) to the full topic model (row 4), we see that the latter model reaches only very minimal gains by using the topic modeling POS tagger when we use 2 topics, and we have a negative trend when we use 10 topics. I.e. the overall quality of the POS tagger is more important than its specialization. Thus, even if the topic model POS tagger outperforms its full baseline, the learned adaptations only have a minimal effect on parsing accuracy.

## 5.4 Analysis of Results

We now have a closer look at the results presented for the parsing experiments using gold POS tags in section 5.3.1. The results show that the 2-topic parsing experts outperform the general parser trained on the full training set by almost 2 percent points. We looked at the 5 sentences that had the lowest LAS when we used the general parser. These sentences are shown in table 5, along with their LAS for both settings. The table clearly shows that the topic expert parsers reach a much higher LAS across all these sentences, and the highest increase reaches 35 percent points. We also see that there are two headlines among these sentences. They are different in their syntactic patterns from other sentences and thus difficult to parse. For this reason, we decided to have a closer at all “incomplete” sentences, i.e., sentences that do not have verbs, as an approximation of headlines. We found that of the 1 310 sentences in the training set, 437 were grouped into topic 1, the other 873 sentences in topic 2. In the test set, we had 65 such sentences, 15 in topic 1 and 50 in topic 2. For the sentences in topic 1, we calculate an LAS of 76.54, for the ones in topic 2 an LAS of 89.91. These results show that the parser expert for topic 2 has adapted substantially better to the syntax of such untypical sentences than the parser expert for topic 1.

We also looked at the dependency labels that were mislabeled most often by the more general,

Gold Dep.	Pred. Dep.	Fulltext	Topic 1	Topic 2
ADV	NMOD	121	37	86
PMOD	NMOD	101	21	67
NMOD	ADV	100	34	57
AMOD	NMOD	91	26	83
CONJ	NMOD	86	13	56

Table 6: The 5 most frequent dependency label confusions of the full baseline parser.

full baseline parser. The 5 most frequent combinations are shown in table 6, with their frequencies in the test sentences of the two topics. These numbers show that the topic 1 expert is much better adapted to these confusion sets, resulting in lower error rates than the topic 2. This shows very dramatically that the two topics learn different patterns.

## 6 Conclusion and Future Work

In these experiments, we have shown that we can improve parsing results on heterogeneous domains by using unsupervised topic modeling to separate the data into different topics. We can then train POS tagging and parsing experts on the individual topics, which show an increased accuracy in comparison to their counterparts trained on the whole, heterogeneous training set. We can mitigate the data sparsity resulting from having to split the training set into different topics by assigning every sentence to every topic but weighting their importance to a topic by the probabilities of the topic modeler. We also showed that while the POS tagger and the dependency parser individually profit from the split into topic experts, the combination of topic expert POS tagger and parser does not improve over using a POS tagger trained on the whole data set. We will have to investigate the reasons for this behavior in future work.

We will also investigate methods of how to assign test sentences to topics without having to re-run the topic modeler on the whole data set.

## Abstract

In this paper, we present how the principles of universal dependencies and morphology have been adapted to Hungarian. We report the most challenging grammatical phenomena and our solutions to those. On the basis of the adapted guidelines, we have converted and manually corrected 1,800 sentences from the Szeged Treebank to universal dependency format. We also introduce experiments on this manually annotated corpus for evaluating automatic conversion and the added value of language-specific, i.e. non-universal, annotations. Our results reveal that converting to universal dependencies is not necessarily trivial, moreover, using language-specific morphological features may have an impact on overall performance.

## 1 Introduction

Morphological tagging and syntactic parsing are key components in most natural language processing (NLP) applications. Linguistic resources and parsers for morphological and syntactic analysis have been developed for several languages, see e.g. the shared tasks on morphologically rich languages (Seddah et al., 2013; Seddah et al., 2014). However, the comparison of results achieved for different languages is not straightforward as most languages and databases apply a unique tagset, moreover, they were annotated following different guidelines. In order to overcome these issues, the project Universal Dependencies and Morphology (UD) has recently been initiated within the NLP community (Nivre, 2015). The main goal of the UD project is to develop a “universal”, i.e. a language-independent morphological and syntactic representation which can contribute to the im-

plementation of multilingual morphological and syntactic parsers from a computational linguistic point of view. Furthermore, it can enhance studies on linguistic typology and contrastive linguistics.

From the viewpoint of syntactic parsing, the languages of the world are usually categorized according to their level of morphological richness (which is negatively correlated with configurationality). At one end, there is English, a strongly configurational language while there is Hungarian at the other end of the spectrum with rich morphology and free word order (Fraser et al., 2013). In this paper, we present how UD principles were adapted to Hungarian, with special emphasis on Hungarian-specific phenomena.

Hungarian is one of the prototypical morphologically rich languages thus our UD principles can provide important best practices for the universalization of other morphologically rich languages. The UD guidelines for Hungarian were motivated by both linguistic considerations and data-driven observations. We developed a converter from the existing Szeged Dependency Treebank (Vincze et al., 2010) to UD and manually corrected 1,800 sentences from the newspaper domain. The experiences gained during the converter development and during the manual correction could reinforce the linguistic guidelines. Moreover, the manually corrected gold standard corpus provides the opportunity for empirical evaluations like assessing the converter and comparing dependency parsers employing the original and the universal morphological representations. Thus, we evaluated the quality of the automatic conversion, which reveals that converting to universal dependencies is not necessarily trivial, at least for Hungarian. We also show that using different morphological tagsets may have an impact on overall parsing performance and utilizing language-specific, i.e. non-universal, information has a considerable

added value at both the morphological and syntactic layers.

The chief contributions of the paper are the introduction of

- the universal morphology and dependency principles for Hungarian, leading to insights for other morphologically rich languages,
- empirical experiments on the upper bound of the accuracy of automatic conversion and pre-parsing,
- comparative evaluations for assessing the added value of language-specific information at the morphological and syntactic layers along with the interaction of these two.

## 2 Related Work

Standardized tagsets for both morphological and syntactic annotations have been constantly developed in the international NLP community. For instance, the MSD morphological coding system was developed for a set of Eastern European languages (Erjavec, 2012), within the MULTEXT-EAST project. Intersect functions as an interlingua for several morphological coding systems, which can convert different tagsets to the same morphological representation (Zeman, 2008). There have also been some attempts to define a common set of parts-of-speech: Rambow et al. (2006) defined a multilingual tagset for part-of-speech (POS) tagging and parsing, while McDonald and Nivre (2007) identified eight POS tags based on data from the CoNLL-2007 Shared Task (Nivre et al., 2007). Petrov et al. (2012) offered a tagset of 12 POS tags and applied this tagset to 22 languages.

Now, Universal Dependencies (UD) is the latest standardized tagset that we are aware of. UD is an international project that aims at developing a unified annotation scheme for dependency syntax and morphology in a language-independent framework (Nivre, 2015). Hungarian was among the first 10 languages of the project, participating also in the first official release in January 2015. In the latest release (Version 1.3, May 2016), there are annotated datasets available for 40 languages, including English, German, French, Hungarian and Irish, among others<sup>1</sup>. In these datasets, the very same tagsets are applied at the morphological and

syntactic levels and texts are annotated on the basis of the same linguistic principles, to the widest extent possible.

The UD tagset encodes morphological information in the form of POS tags and feature–value pairs. As for syntactic information, each word is assigned to its parent word in the dependency tree and the grammatical function of the specific word is encoded in dependency labels. Dependency labels, POS tags and features are universal (i.e. there is a fixed set of them without the possibility of introducing new members), but values and dependency labels can have language-specific additions if needed. Features are divided into the categories lexical features and inflectional features. Lexical features are features that are characteristics of the lemmas rather than the word forms, whereas inflectional features are those that are characteristics of the word forms. Both lexical and inflectional features can have layered features: some features are marked more than once on the same word, e.g. a Hungarian noun may denote its possessor’s number as well as its own number. In this case, the Number feature has an added layer, Num[psor].

Up to now, several papers have been published on the general principles behind UD (Nivre, 2015; Nivre et al., 2016) or on specific treebanks. For instance, there are UD treebanks available for agglutinative languages such as Finnish (Haverinen et al., 2014; Pyysalo et al., 2015), Estonian (Muischnek et al., 2016) and Japanese (Tanaka et al., 2016), for Slavic languages (Zeman, 2015) and spoken Slovenian (Dobrovoljc and Nivre, 2016) and for Nordic languages such as Norwegian (Øvrelid and Hohle, 2016), Danish (Johannsen et al., 2014) and Swedish (Nivre, 2014), together with several other languages (Persian (Seraji et al., 2016) and Basque (Aranzabe et al., 2014), just to name a few). Recently, a further extension on the UD relations has been proposed: enhanced English dependencies are described in Schuster and Manning (2016).

Our UD principles introduced in this paper follow the central UD guidelines (Nivre, 2015) and we did our best to align with the existing guidelines for other morphologically rich languages as well. On the other hand, there are several Hungarian-specific phenomena that required changes and extensions of the original UD principles.

The only available manually annotated tree-

<sup>1</sup><http://universaldependencies.org/>

bank for Hungarian is the Szeged Corpus (Csendes et al., 2004) and Szeged Dependency Treebank (Vincze et al., 2010). It contains approximately 82,000 sentences and 1.5 million tokens, all manually annotated for POS-tagging and constituency and dependency syntax. We developed an automatic tool that converts the morphological descriptions of the Szeged Corpus to universal morphology tags and the dependency trees of the Szeged Treebank to universal dependencies.

### 3 Universal Morphology for Hungarian

In this section, we present the morphological tagset applied to Hungarian.

When adapting the principles of Universal Morphology to Hungarian, we were able to automatically convert most of the morphological features used in the Szeged Treebank 2.5 (Vincze et al., 2014), which was based on MSD principles (Erjavec, 2012). However, we faced some problematic issues, which we will discuss in detail in this section. The details of universal morphological codeset of Hungarian are available on our website<sup>2</sup>.

#### 3.1 Possessive constructions

The possessor in Hungarian possessive constructions can have two different surface forms, without any difference in meaning: the possessor can be morphologically marked or not, just like the English constructions *the girl's doll* and *the doll of the girl*. Thus, both of the following possessive constructions are widely used:

- (1) a szomszéd kertje  
the neighbor garden-3SGPOSS  
the neighbor's garden
- (2) a szomszédnak a kertje  
the neighbor-DAT the garden-3SGPOSS  
the neighbor's garden

In Example 1, the possessor is not marked, i.e. it shares its form with the nominative form of the noun, however, in Example 2, the possessor is morphologically marked, sharing its form with the dative form of the noun. Nevertheless, the possessed is morphologically marked in both cases, which was a novelty in the UD project as the languages already included in the data do not mark

<sup>2</sup><http://rgai.inf.u-szeged.hu/project/nlp/research/msdkr/univmorph.html>

the possessor on the possessed noun but use determiners for this purpose (cf. *my car* but *az autóm* (the car-1SGPOSS)). Moreover, the number of the possessed can be marked on the noun in elliptical constructions such as:

- (3) Láttam az  
see-PAST-2SGPOSS-ACC the  
autódat , de a  
car-2SG-POSS , but the  
szomszédét nem .  
neighbor-POSSD.SG-ACC not  
I could see your car but not that of the neighbor.
- (4) Láttam a  
see-PAST-2SGPOSS-ACC the  
gyerekeidet , de a  
child-2SG-PL-POSS , but the  
szomszédéit nem .  
neighbor-POSSD.PL-ACC not  
I could see your children but not those of the neighbor.

Hence, we had to introduce novel morphological features to mark the person and number features of the possessor on Hungarian nouns. Number denotes the number of the noun, Number[psor] and Person[psor] denote the number and person of the possessor, and Number[psed] denotes the number of the possessed. Below, there is a sample word annotated according to the Universal Morphology principles.

- (5) házaiménak  
house-1SGPOSS-PL-POSSD.SG-DAT  
to that of my houses  
NOUN  
Case=Dat|Number=Plur|Number[psed]=Sing  
|Number[psor]=Sing|Person[psor]=1

#### 3.2 Object-verb agreement

Another Hungarian-specific feature was the definiteness of the object. As a special type of agreement, the definiteness of their objects determines which paradigm of the verb is to be chosen. In other words, the form of the verb changes when the definiteness of the object also changes (Törkenczy, 2005). For instance, proper nouns and NPs with a definite article are typical examples of definite objects and trigger the objective form of the verb (see Example 6) while bare nouns and NPs with an indefinite article are indefinite objects

(see Example 7) and trigger the subjective form of the verb. Second person objects also trigger a special form of the verb as listed in Example 8:

- (6) Látom Pistit .  
 see-1SGOBJ Steve-ACC .  
 I can see Steve.
- (7) Látok egy gyereket az udvaron .  
 see-1SGSUBJ a kid-ACC the yard-SUP .  
 I can see a kid in the yard.
- (8) Látlak .  
 see-1SGOBJ2 .  
 I can see you.

In this way, the feature Definiteness needs to be applied to verbs in Hungarian, moreover, it has a language-specific feature due to the special form triggered by the second person objects. Thus, Definiteness has three possible values in Hungarian: Definite, Indefinite, 2.

### 3.3 Determiners and pronouns

Determiners, pronouns and ordinal numbers also constituted a peculiarity. According to Hungarian grammatical traditions, ordinal numbers have been treated as numerals but in the universal morphology, they have to be annotated as adjectives. Thus, their POS tags were automatically converted to adjectives.

Demonstrative pronouns were also treated differently in the original annotation used in the Szeged Treebank and in universal morphology. While demonstrative pronouns *ez* and *az* are tagged as pronouns independently of their positions, in universal morphology such words occurring before an article should be tagged as a determiner (see Example 9) but when they are used as an NP, they should be tagged as a pronoun (see Example 10).

- (9) Olvastam azt a könyvet .  
 read-PAST-1SGOBJ that-ACC the book-ACC .  
 I have read that book.
- (10) Olvastam azt .  
 read-PAST-1SGOBJ that-ACC .  
 I have read that.

These cases were also automatically converted, following the universal morphology guidelines.

### 3.4 Verbal prefixes

In our original treebank, verbal particles that were spelt as a separate token had their own part-of-speech, i.e. verbal particle. According to the UD description however, not all function words that are traditionally called particles automatically qualify for the PART tag. They may be adpositions or adverbs by origin, therefore should be tagged ADP or ADV, respectively. Thus, we manually compiled a list that contained the original part-of-speech of words that were tagged as verbal prefixes, for instance, *el* “away” was treated as an adverb and *agyon* brain-SUP as a noun – the latter is usually used in phrases like *agyonüt* “kill someone by hitting on his head”. Based on this list, we were able to automatically assign UD POS tags to verbal prefixes.

## 4 Universal Dependency in Hungarian

When adapting the universal dependency labels to Hungarian, we could find a one-to-one correspondence between the original labels of the Szeged Treebank and the UD labels only in most of the cases, and these labels could be automatically converted to the UD format, making use of the dependency and morphological annotations found in the original treebank. However, we encountered some problematic cases during conversion, which we will discuss below in detail. The details of universal dependency rules of Hungarian are available on our website<sup>3</sup>.

### 4.1 Non-overt copulas

Traditionally, it is the verb that functions as the head of the clause in dependency grammars but in certain languages, there are verbless clauses where the predicate consists of a single nominal element (typically a noun or an adjective) at the surface level. The dependency analysis of such sentences may be problematic due to the lack of an overt verb. Some studies such as Polguère and Mel’čuk (2009) argue for a zero copula in such cases, especially when the copula is empty only in certain slots of the verbal paradigm. For instance, in Hungarian, the copula has its zero form only in the present tense, indicative mood, third person forms as shown in Examples 11-14:

- (11) Present tense, indicative mood, Sg1:

<sup>3</sup><http://rgai.inf.u-szeged.hu/dependency>

Én tanár vagyok .  
I teacher be-1SG .

I am a teacher.

(12) Present tense, indicative mood, Sg3:

Ő tanár .  
he teacher .

He is a teacher.

(13) Past tense, indicative mood, Sg3:

Ő tanár volt .  
he teacher be-PAST-3SG.

He was a teacher.

(14) Present tense, imperative mood, Sg3:

Ő legyen tanár !  
he be-IMP-3SG teacher !

He should be a teacher.

The original dependency analysis in the Szeged Treebank inserts a zero copula (VAN), i.e. a virtual node in the dependency tree, which functions as the head of the clause and the nominal predicate is attached to it. Figure 1 shows such an analysis of the sentence *E gondolat sem új* (this thought not new) “This thought is not novel at all”.

Beside the function head analysis (i.e. where function words, e.g. the copula is the head), there is another approach to dependencies, namely, the content head analysis, where the head is a content word instead of a function word. In the latter case, the main grammatical relations can be found among content words and all the other function words are attached to the main structure. UD applies the content head analysis, which means that in copular constructions, the nominal element is the head and the copula (if present) is attached to it with a `cop` relation. In a similar way, the head of adpositional constructions is the noun and the adposition is attached to it.

Sentences with nominal predicates were automatically converted from the original treebank into the UD format: Figure 2 shows the UD analysis of the sentence found in Figure 1. Likewise, postpositional constructions were converted: the noun was treated as the head and the postposition was attached to it with a `case` label.

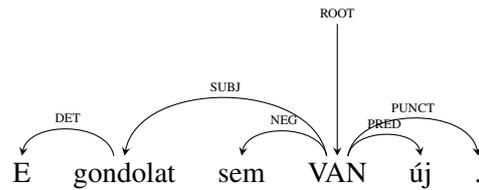

Figure 1: A function head analysis in the Szeged Dependency Treebank (*E gondolat sem VAN új* (this thought IS not new) “This thought is not novel at all”).

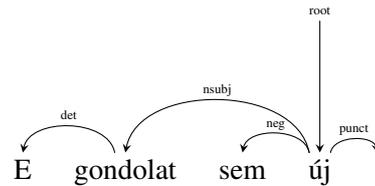

Figure 2: A content head analysis in the Hungarian UD treebank (*E gondolat sem új* (this thought not new) “This thought is not novel at all”).

## 4.2 Subordinate clauses

Subordinate clauses proved also to be a problematic issue as UD principles make a sharp distinction among several types of subordinate clauses – e.g. clausal subject, clausal object, adverbial clause – in contrast with the Szeged Dependency Treebank, which applies one single label for all types of subordinate clauses. Some types of subordinate clauses had a special label in the constituency version of the treebank hence their conversion was straightforward. In other cases, we could rely on manually constructed conversion rules but the resulting trees had to be corrected manually.

## 4.3 Multiword named entities

The UD treatment of multiword named entities required a Hungarian-specific solution. According to the UD principles, the first token of the multiword expressions should be marked as the head. However, in Hungarian, it is always the last element of the multiword expression that is inflected. Examples 15-16 demonstrate that the first element cannot be inflected, only the last one:

- (15) Találkoztam Kovács Jánossal .  
meet-PAST-1SG Kovács János-INSTR .  
I met János Kovács<sup>4</sup>.

<sup>4</sup>The standard order of person names is surname + first

- (16) \*Találkoztam Kováccsal János .  
meet-PAST-1SG Kovács-INSTR János .  
I met János Kovács.

Due to the above morphosyntactic facts, we marked the last token of multiword named entities as the head in the Hungarian UD treebank while all the other UD treebanks mark the first token as the head.

#### 4.4 Dative forms

In Hungarian, nouns that bear the suffix *-nAk* can fulfill several grammatical roles in the sentence such as:

- (17) indirect object:

Laci adott a  
Leslie give-PAST-3SG the  
**barátjának** egy almát .  
friend-3SGPOSS-DAT an apple-ACC .

Leslie gave an apple to his friend.

- (18) possessor:

Laci elvette a  
Leslie take-PAST-3SGOBJ the  
**barátjának** a  
friend-3SGPOSS-DAT the  
könyvét .  
book-3SGPOSS-ACC .

Leslie took his friend's book.

- (19) dativus ethicus:

**Nekem** nehogy eladd  
I-DAT so.as.not.to sell-IMP-2SGOBJ  
az autódat !  
the car-2SGPOSS-ACC !

As for me, you should not sell you car.

- (20) experiencer:

**Nekem** nagyon tetszett az  
I-DAT very like-PAST-3SG the  
előadás .  
performance .

I really liked the performance.

- (21) semantic subject:

name in Hungarian.

**Lacinak** bocsánatot  
Leslie-DAT apology-ACC  
kellett kérnie a  
must-PAST-3SG ask-INF-3SG the  
barátjától .  
friend-3SGPOSS-ABL .

Leslie had to apologize to his friend.

While these forms do not show any difference at the morphological level, they have very different roles at the syntactic and semantic levels. Thus we decided not to make any distinction in the morphological annotation but they should have different syntactic labels. Indirect objects are marked with the label *iobj*, possessors with the label *nmod:poss* and other occurrences with *nmod:obl*. Obviously, these annotations had to be carried out manually as most of these cases could not be easily and unequivocally converted to the UD format only on the basis of morphology and syntax. Consider the following examples (Example 19 is repeated for convenience):

- (22) Nekem nehogy eladd  
I-DAT so.as.not.to sell-IMP-2SGOBJ  
az autódat !  
the car-2SGPOSS-ACC !

As for me, you should not sell your car.

- (23) Nehogy eladd nekem az  
so.as.not.to sell-IMP-2SGOBJ I-DAT the  
autódat !  
car-2SGPOSS-ACC !

You should not sell your car to me.

Example 22 contains a dativus ethicus whereas Example 23 contains an indirect object. The two sentences only have different word orders thus their automatic distinction would not be straightforward.

#### 4.5 Light verb constructions

Light verb constructions are verb + noun combinations where most of the semantic content of the whole expression is carried by the noun while the syntactic head is the verb (e.g. *to have a shower, to make a decision*). They are not uniformly treated in Version 1.3 of the UD treebanks. Light verb constructions are either not marked at all or if they are marked, they may have a special structure or special labels (Nivre and Vincze, 2015). The Hungarian treebank belongs to the latter group, that is, members of light verb constructions bear a special

label. For instance, Figure 3 shows that the label `dobj:lvc` can be found between the nominal and verbal component of the light verb construction *döntést hoz* (decision-ACC bring) “to make a decision”. In this way, the `dobj` part of the label marks that syntactically it is a verb–object relation but semantically, it is a light verb construction, marked by the `lvc` extension of the label.

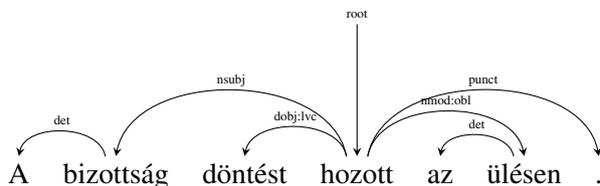

Figure 3: Light verb construction in the Hungarian UD treebank (*A bizottság döntést hozott az ülésen* (the committee decision-ACC bring-PAST-3SG the meeting-SUP) “The committee made a decision at the meeting”).

## 5 Experiments

We developed a converter from the existing Szeged Dependency Treebank (Vincze et al., 2010) to UD and manually corrected 1,800 sentences from the newspaper domain. The manually corrected UD sentences are available in the UD repository v3.0. The experiences gained during the manual correction could reinforce the linguistic conversion rules and the manually corrected gold standard corpus provides the opportunity for empirical evaluations which we introduce in this section.

### 5.1 On the Accuracy of Automatic Converters

Most of the UD treebanks are the result of automatic conversion from a dependency treebank of originally different principles. The accuracy of these automatic converters is unknown, i.e. we do not know how much information was lost or how much noise was introduced by the converters. To empirically investigate this in the case of Hungarian UD, we compared the converted and the manually corrected, i.e. gold standard, trees of the 1800 sentences.

The converter itself is based on linguistic rules (it is available on our website<sup>5</sup>) which were itera-

<sup>5</sup><http://rgai.inf.u-szeged.hu/dependency>

tively improved by manually investigating the results of conversion on sentences of the Szeged Dependency Treebank. The final version of the converted achieves an UAS of 87.81 and a LAS of 75.99 on the 1800 sentences compared against the manually corrected UD trees. We believe that this level of accuracy is not sufficient for releasing the rest of the 80,000 sentences of the automatically converted Szeged Dependency Treebank. On the other hand, some of the shortcomings of the automatic conversion could be corrected by exploiting annotation found in other versions of the Szeged Treebank. For instance, the type of certain subordinate clauses is marked in the constituency version of the treebank, which can be transformed into UD labels. Moreover, coreference annotations from the subcorpora annotated for coreference relations could enhance the proper attachment of relative clauses. We intend to add these pieces of information to our converter in the future, hence higher accuracy scores can be provisioned for the automatic conversion process: just with the above mentioned corrections, an additional 6 percentage points could be achieved in terms of LAS as about 20% of the errors are due to subordinate or relative clauses.

### 5.2 On the Price of Universality

We carried out experiments for investigating whether there is any difference between using the original MSD (Vincze et al., 2014) and the new universal morphological (UM) descriptions. We were particularly interested in the utility of the two representations for dependency parsing. We trained two models of the MarMot morphological tagger (Mueller et al., 2013) using the two morphological representation in 10-fold cross-tagging on our manually corrected 1800 sentences. Then we trained and evaluated the Bohnet dependency parser (Bohnet, 2010) on the train/test split of the UD repository v3.0 utilizing the two different predicted morphological descriptions. We used the default parameters for both the MarMot and the Bohnet parser.

Table 1 presents unlabeled (UAS) and labeled (LAS) attachment scores achieved by the parser on the test set. The first column of the table indicates whether the universal morphology (UM) or the original MSD morphological codes were employed in the experiment. The second column of the table shows which dependency label set

Morph. labels	Dep labels	UAS	LAS (full label)	LAS (main label)
UM	full label	81.94	76.98	78.39
MSD	full label	82.27	77.50	78.75
UM	main label	81.70	–	78.39
MSD	main label	82.17	–	78.58

Table 1: Dependency parsing results on the Hungarian Universal Dependency dataset. In the case of *LAS(main label)* we do not check the language specific part of the dependency labels in the evaluations while we compare the universal and language-specific dependency labels at *LAS(full label)*.

was used for training the Bohnet parser. *main label* refers here to the universal dependency labels while *full label* refers to using the concatenation of universal and language-specific labels. The difference between the last two columns of the table is that we checked the full or only the main dependency labels at evaluations.

Table 1 shows the MSD outperforms UM consistently at each of the experiments. Although these differences are not high, this suggests that some information encoded in the MSD morphology is not represented in UM, i.e. we have to pay a price to be universal. We can observe the greatest difference when training and evaluating on full dependency labels, i.e. language-specific morphological features contribute to the prediction of language-specific dependency labels.

We made a manual error analysis of the results with regard to attachment (UAS) errors, i.e. we compared the outputs of the dependency parsers trained by using predicted universal codes and predicted MSD morphological codes, respectively. Results are presented in Table 2. We found that the benefits of the original language-specific annotation (MSD) mostly manifests in the treatment of subordinate clauses, adverbial modifiers and infinitival complements. These results might be explained by the fact that in certain cases, MSD contains more detailed grammatical information than the UM formalism. For instance, MSD encodes whether a conjunction connects clauses or words/phrases, which information is missing from UM. Also, higher results were achieved for cases when two nouns or adjectives were following each other and one of them modified the other (as in *magas rangú képviselői* “representatives of high standings”). However, sentences containing an overt or covert form of the copula could be parsed more effectively by using universal morphology codes.

Error type	MSD	%	UM	%
Coordination	100	32.05	98	30.34
Article	44	14.10	44	13.62
Adverbial	35	11.22	43	13.31
Other	37	11.86	31	9.60
Part/adj compl.	31	9.94	32	9.91
Adjacent N/A	15	4.81	20	6.19
Subordination	13	4.17	17	5.26
Copula	14	4.49	11	3.41
Infinitive	9	2.88	15	4.64
Nominal arg.	8	2.56	8	2.48
Possessor	6	1.92	4	1.24
Total	312	100	323	100

Table 2: Error analysis: the number and ratio of specific error types.

### 5.3 The Added Value of Language-specific UD Labels

We also investigated the impact of the language-specific parts of the dependency labels. As the numbers in Table 1 show, slightly better results can be achieved both in terms of UAS and LAS when training the model with *full labels* than with *main labels*. This highlights the importance of adding language specific distinctions to the universal ones because they may contain information that can be exploited during the tree decoding. They contribute even to unlabeled attachment decisions. To take an example, UD does not make any distinction among different types of nominal modifiers, treating them as *nmod*. However, for Hungarian, we applied extra labels such as *nmod:poss* for possessors (see Section 3.1) and *nmod:obl* for nominal arguments of the verb. As for the first, it should always be attached to the possessed noun, whereas the second one is attached to a verb (see also Examples 18 and 19 with the dative morphological case). Thus, the parser can learn these fine-grained distinctions, which might be beneficial for the unlabeled attachment scores as well.

Also, we would like to point out that the utilization of language-specific labels does not contradict the UD principles. In UD, each language should select the appropriate labels according to their needs but there is no need to apply all of the labels/features. General labels like `nsubj` or `dobj` will be used in most (maybe all) of the UD languages but there are other labels or feature-value pairs that are applicable for only a handful of languages. These ones are now called as “language-specific” features but in principle, their status is not different from those that are more widely applied. So we believe that introducing “language-specific” additions does not harm the UD principles. Moreover, the chief objective of our experiments was to highlight the added value of language-specific features and we were able to show that they can even improve parsing accuracy when evaluated exclusively on the general labels. The main goal of UD is to provide a way where the parsing results over languages are comparable, hence using language specific features during decoding but evaluating only on general labels is in line with this comparison principle. Moreover, it indicates for UD treebank developers that – besides general labels – language-specific ones have to be taken seriously.

## 6 Conclusions

In this paper, the principles of universal dependencies and morphology for Hungarian were introduced by reporting the most challenging grammatical phenomena and our solutions to those. We converted then manually corrected 1,800 sentences from the Szeged Treebank to universal dependency format and introduced experiments on this manually annotated corpus for evaluating automatic conversion and the added value of language-specific, i.e. non-universal, annotations. We would like to draw the attention to the importance of understanding i) the information loss of the automatic UD converters; ii) what is the price of being constrained by universal morphology principles and; iii) the utility of exploiting language-specific dependency labels in UD.

## Abstract

Neural attention models have achieved great success in different NLP tasks. However, they have not fulfilled their promise on the AMR parsing task due to the data sparsity issue. In this paper, we describe a sequence-to-sequence model for AMR parsing and present different ways to tackle the data sparsity problem. We show that our methods achieve significant improvement over a baseline neural attention model and our results are also competitive against state-of-the-art systems that do not use extra linguistic resources.

## 1 Introduction

Abstract Meaning Representation (AMR) (Banasescu et al., 2013) is a semantic formalism where the meaning of a sentence is encoded as a rooted, directed graph. Figure 1 shows an example of an AMR in which the nodes represent the AMR concepts and the edges represent the relations between the concepts they connect. AMR concepts consist of predicate senses, named entity annotations, and in some cases, simply lemmas of English words. AMR relations consist of core semantic roles drawn from the Propbank (Palmer et al., 2005) as well as very fine-grained semantic relations defined specifically for AMR. These properties render the AMR representation useful in applications like question answering and semantics-based machine translation.

The task of AMR graph parsing is to map natural language strings to AMR semantic graphs. Recently, a sizable new corpus of English/AMR pairs (LDC2015E86) has been released. Different parsers have been developed to tackle this problem (Flanigan et al., 2014; Wang et al., 2015b;

<sup>\*</sup>Both authors contribute equally.

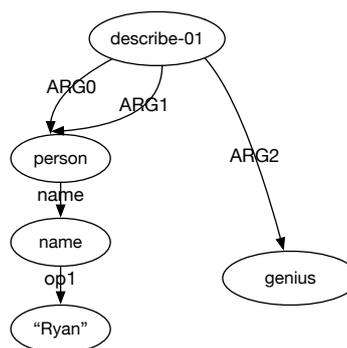

Figure 1: An example of AMR graph representing the meaning of: “Ryan’s description of himself: a genius.”

Artzi et al., 2015; Pust et al., 2015; Peng et al., 2015). Most of these parsers have used external resources such as dependency parses, semantic lexicons, etc., to tackle the sparsity issue.

Recently, Sutskever et al. (2014) introduced a neural network model for solving the general sequence-to-sequence problem, and Bahdanau et al. (2014) proposed a related model with an attention mechanism that is capable of handling long sequences. Both models achieve state-of-the-art results on large scale machine translation tasks.

However, sequence-to-sequence models mostly work well for large scale parallel data, usually involving millions of sentence pairs. Vinyals et al. (2015) present a method which linearizes parse trees into a sequence structure and therefore a sequence-to-sequence model can be applied to the constituent parsing task. Competitive results have been achieved with an attention model on the Penn Treebank dataset, with only 40K annotated sentences.

AMR parsing is a much harder task in that the target vocabulary size is much larger, while the size of the dataset is much smaller. While for constituent parsing we only need to predict non-

terminal labels and the output vocabulary is limited to 128 symbols, AMR parsing has both concepts and relation labels, and the target vocabulary size consists of tens of thousands of symbols. Barzdins and Gosko (2016) applied a similar approach where AMR graphs are linearized using depth-first search and both concepts and relations are treated as tokens (see Figure 3). Due to the data sparsity issue, their AMR parsing results are significantly lower than state-of-the-art models when using the neural attention model.

In this paper, we present a method which linearizes AMR graphs in a way that captures the interaction of concepts and relations. To overcome the data sparsity issue for the target vocabulary, we propose a categorization strategy which first maps low frequency concepts and entity subgraphs to a reduced set of category types. In order to map each type to its corresponding target side concepts, we use heuristic alignments to connect source side spans and target side concepts or subgraphs. During decoding, we use the mapping dictionary learned from the training data or heuristic rules for certain types to map the target types to their corresponding translation as a postprocessing procedure.

Experiments show that our linearization strategy and categorization method are effective for the AMR parsing task. Our model improves significantly in comparison with the previously reported sequence-to-sequence results and provides a competitive benchmark in comparison with state-of-the-art results without using dependency parses or other external semantic resources.

## 2 Sequence-to-sequence Parsing Model

Our model is based on an existing sequence-to-sequence parsing model (Vinyals et al., 2015), which is similar to models used in neural machine translation.

### 2.1 Encoder-Decoder

**Encoder.** The encoder learns a context-aware representation for each position of the input sequence by mapping the inputs  $w_1, \dots, w_m$  into a sequence of hidden layers  $h_1, \dots, h_m$ . To model the left and right contexts of each input position, we use a bidirectional LSTM (Bahdanau et al., 2014). First, each input’s word embedding representation  $x_1, \dots, x_m$  is obtained through a lookup table. Then these embeddings serve as the input to

two RNNs: a forward RNN and a backward RNN. The forward RNN can be seen as a recurrent function defined as follows:

$$h_i^{fw} = f(x_i, h_{i-1}^{fw}) \quad (1)$$

Here the recurrent function  $f$  we use is Long-Short-Term-Memory (LSTM) (Hochreiter and Schmidhuber, 1997). The backward RNN works similarly by repeating the process in reverse order. The outputs of forward RNN and backward RNN are then depth-concatenated to get the final representation of the input sequence.

$$h_i = [h_i^{fw}, h_{m-i+1}^{bw}] \quad (2)$$

**Decoder.** The decoder is also an LSTM model which generates the hidden layers recurrently. Additionally, it utilizes an attention mechanism to put a “focus” on the input sequence. At each output time step  $j$ , the attention vector  $d'_j$  is defined as a weighted sum of the input hidden layers, where the masking weight  $\alpha_i^j$  is calculated using a feed-forward neural network. Formally, the attention vector is defined as follows:

$$u_i^j = v^T \tanh(W_1 h_i + W_2 d_j) \quad (3)$$

$$\alpha_i^j = \text{softmax}(u_i^j) \quad (4)$$

$$d'_j = \sum_{i=1}^m \alpha_i^j h_i \quad (5)$$

where  $d_j$  is the output hidden layer at time step  $j$ , and  $v$ ,  $W_1$ , and  $W_2$  are parameters for the model. Here the weight vector  $\alpha_1^j, \dots, \alpha_m^j$  is also interpreted as a soft alignment in the neural machine translation model, which similarly could also be treated as a soft alignment between token sequences and AMR relation/concept sequences in the AMR parsing task. Finally, we concatenate the hidden layer  $d_j$  and attention vector  $d'_j$  to get the new hidden layer, which is used to predict the output sequence label.

$$P(y_j | w, y_{1:j-1}) = \text{softmax}(W_3 [d_j, d'_j]) \quad (6)$$

### 2.2 Parse Tree as Target Sequence

Vinyals et al. (2015) designed a reversible way of converting the parse tree into a sequence, which they call linearization. The linearization is performed in the depth-first traversal order. Figure 2 shows an example of the linearization result. The target vocabulary consists of 128 symbols.

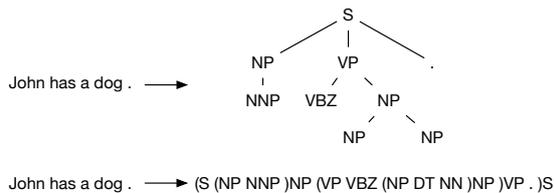

Figure 2: Example parsing task and its linearization.

In practice, they found that using the attention model is more data efficient and works well on the parsing task. They also reversed the input sentence and normalized the part-of-speech tags. After decoding, the output parse tree is recovered from the output sequence of the decoder in a post-processing procedure. Overall, the sequence-to-sequence model is able to match the performance of the Berkeley Parser (Petrov et al., 2006).

### 3 AMR Linearization

Barzdins and Gosko (2016) present a similar linearization procedure where the depth-first traversal result of an AMR graph is used as the AMR sequence (see Figure 3). The bracketing structure of AMR is hard to maintain because the prediction of relation (with left parenthesis) and the prediction of an isolated right parenthesis are not correlated. As a result, the output AMR sequences usually have parentheses that do not match.

We present a linearization strategy which captures the bracketing structure of AMR and the connection between relations and concepts. Figure 3 shows the linearization result of the AMR graph shown in Figure 1. Each relation connects the head concept to a subgraph structure rooted at the tail concept, which shows one branch below the head concept. We use the relation label and left parenthesis to show the beginning of the branch (subgraph) and use right parenthesis paired with the relation label to show the end of the branch. We additionally add “-TOP-” at the beginning to show the start of the traversal of the AMR graph and add “)-TOP-” at the end to show the end of traversal. When a symbol is revisited, we replace the symbol with “-RET-”. We additionally add the revisited symbol before “-RET-” to decide where the reentrancy is introduced to.<sup>1</sup> We also get rid of

<sup>1</sup>This is an approximation because one concept can appear multiple times, and we simply attach the reentrancy to the most recent appearance of the concept. An additional index would be needed to identify the accurate place of reentrancy.

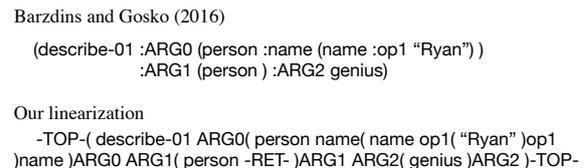

Figure 3: Comparison of AMR linearization

variables and only keep the full concept label. For example, “g / genius” to “genius”.

We can easily recover the original AMR graph from its linearized sequence. The sequence also captures the branching information of each relation explicitly by representing it with a start symbol and an end symbol specific to that relation. During our experiments, most of the output sequences have a matching bracketing structure using this linearization strategy. The idea of linearization is basically a depth-first traversal of the AMR where the original graph structure can be reconstructed with the linearization result. Even though we call it a sequence, its core idea is actually generating a graph structure from top-down.

### 4 Dealing with the Data Sparsity Issue

While sequence-to-sequence models can be successfully applied to constituent parsing, they do not work well on the AMR parsing task as shown by Barzdins and Gosko (2016). The main bottleneck is that the size of target vocabulary for AMR parsing is much larger than constituent parsing, tens of thousands in comparison with 128, and the size of training data is less than half of that available for parsing.

In this section, we present a categorization method which significantly reduces the target vocabulary size, as the alignment from the attention model does not work well on the relatively small dataset. To adjust for the alignment errors made by the attention model, we propose to add supervision from an alignment produced by an external aligner which can use lexical information to overcome the limit of data size.

#### 4.1 AMR Categorization

We define several types of categories and map low frequency words into these categories.

1. DATE: we reduce all the date entity subgraphs to this category, ignoring details of the specific date entity.

Sentence side (lemmatized, lower cased)	AMR side
Before linearization:	
chinese seismology be gallop down the wrong road .	(g / gallop-01 :ARG0 (s / seismology :mod (c / country :wiki "China" :name (n / name :op1 "China"))) :ARG1 (r / road :mod (w / wrong)) :direction (d / down))
After linearization:	
NE_country-0 -SURF--0 be -VERB--0 down the wrong -SURF-1 .	-TOP-( -VERB--0 ARG0( -SURF--0 mod( NE_country-0 )mod )ARG0 ARG1( -SURF-1 mod( wrong )mod )ARG1 direction( down )direction )-TOP-

Figure 4: An example of categorized sentence-AMR pair.

2.  $NE_{\{ent\}}$ : we reduce all named entity subgraphs to this category, where *ent* is the root label of each subgraph, such as *country* or *person*.
3. -VERB-: we map predicate variables with low frequency ( $n < 50$ ) to this category
4. -SURF-: we map non-predicate variables with low frequency ( $n < 50$ ) to this category
5. -CONST-: we map constants other than numbers, “-”, “interrogative”, “expressive”, “imperative” to this category.
6. -RET-: we map all revisited concepts to this category.
7. -VERBAL-: we additionally use the verbalization list <sup>2</sup> from the AMR website and map matched subgraphs to this category.

After the re-categorization, the vocabulary size is substantially reduced to around 2000, though this vocabulary size is still very large for the relatively small dataset. These categories and the frequent concepts amount to more than 90% of all the target words, and each of these are learned with a larger number of occurrences.

## 4.2 Categorize Source Sequence

The source side tokens also have sparsity issues. For example, even if we have mapped the number *1997* to “DATE”, we can not easily generalize it

<sup>2</sup><http://amr.isi.edu/download/lists/verbalization-list-v1.06.txt>

to the token *1993* if it does not appear in the training data. Also, some special 6-digit date formats such as “YYMMDD” are hard to learn using co-occurrence statistics.

Our basic approach to dealing with this issue is to generalize these sparse tokens or spans to some special categories (currently we use the same set of categories defined in the previous section). On the training data, we can use the heuristic alignment. For example, if we learned from the heuristic alignment that “010911” is aligned to a date-entity of September 11, 2001 on the AMR side, we use the same category “DATE” to replace this token. We distinguish this alignment from other date alignments by assigning a unique indexed category “DATE-X” to both sides of the alignment, where “X” counts from 0 and adds one for each new date entity from left to right on the sentence side. The same index strategy goes for all the other categories. Figure 4 shows an example of the linearized parallel sequence. The first infrequent non-predicate variable “seismology” is mapped to “-SURF-0”, then “wrong” to “-SURF-1” based on its position on the sentence side. The indexed category labels are then projected onto the target side based on the heuristic alignment. During this re-categorization procedure, we build a map  $Q$  from each token or span to its most likely concept or category on the target side based on relative frequency. We also dump a DATE template for recognizing new date entities by abstracting away specific date fields such as “1997” to “YEAR”, “September” to “MONTH”. For example, we build a template “MONTH DAY, YEAR”

from the specific date mention “June 6, 2007”.

During decoding, we are only given the sentence. We first use the date templates learned from the training data to recognize dates in each sentence. We also use a named entity tagger to recognize named entity mentions in the sentence. We use the entity name and wiki information from  $Q$  if there is a match of the entity mention, otherwise for convenience we simply use “person” as the entity name and use wiki “-”. For each of the other tokens, we first look it up in  $Q$  and replace it with the most likely mapping. If there is no match, we further look it up in the verbalization list. In case there is still no match, we use the part of speech information to assign its category. We replace verbs with category “-VERB-” and nouns with category “-SURF-”. In accordance with the categorized token sequence, we also index each category in the resulting sequence from left to right.

### 4.3 Recovering AMR graph

During decoding, our output sequences usually have categories and we need to map each category to AMR concepts or subgraphs. When we categorize the tokens in each sentence before decoding, we save the mapping from each category to its original token as table  $D$ . As we use the same set of categories on both source and target sides, we heuristically align target side category label to its source side counterpart from left to right. Given table  $D$ , we know which source side token it comes from and use the most frequent concept or subgraph of the token to replace the category.

### 4.4 Supervised Attention Model

In this section, we propose to learn the attention vector in a supervised manner. There are two main motivations behind this. First, the neural attention model usually utilizes millions of data points to train the model, which learns a quite reasonable attention vector that at each output time step constrains the decoder to put a focus on the input sequences (Bahdanau et al., 2014; Vinyals et al., 2015). However, we only have 16k sentences in the AMR training data and our output vocabulary size is quite large, which makes it hard for the model to learn a useful alignment between the input sequence and AMR concepts/relations. Second, as argued by Liu et al. (2016), the sequence-to-sequence model tries to calculate the attention vector and predict the current output label simultaneously. This makes it impossible for the learned

soft alignment to combine information from the whole output sentence context. However, traditional word alignment can easily use the whole output sequence, which will produce a more informed alignment.

Similar to the method used by Liu et al. (2016), we add an additional loss to the original objective function to model the disagreement between the reference alignment and the soft alignment produced by the attention mechanism. Formally, for each input/output sequence pair  $(\mathbf{w}, \mathbf{y})$  in the training set, the objective function is defined as:

$$-\frac{1}{n} \sum_{j=1}^n \log p(y_j | \mathbf{w}, y_{1:j-1}) + \lambda \Theta(\bar{\alpha}^j, \alpha^j) \quad (7)$$

where  $\bar{\alpha}^j$  is the reference alignment for output position  $j$ , which is provided by the existing aligner,  $\alpha^j$  is the soft alignment,  $\Theta()$  is cross-entropy function,  $n$  is the length of output sequence and  $\lambda$  is the hyperparameter which serves as a trade-off between sequence prediction and alignment supervision. Note that the supervised attention part doesn’t affect the decoder which will predict the output label given learned weights.

One issue with this method is how we represent  $\bar{\alpha}$ . As the output of conventional aligner is a hard decision, alignment is either one or zero for each input position. In addition, multiple input words could be aligned to one single concept. Finally, in the AMR sequences, there are many output labels (mostly relations) which don’t align to any word in the input sentence. We utilize a heuristic method to process the reference alignment. We assign an equal probability among the words that are aligned to one AMR concept. Then if the output label doesn’t align to any input word, we assign an even probability for every input word.

## 5 Experiments

We evaluate our system on the released dataset (LDC2015E86) for SemEval 2016 task 8 on meaning representation parsing (May, 2016). The dataset contains 16,833 training, 1,368 development and 1,371 test sentences which mainly cover domains like newswire, discussion forum, etc. All parsing results are measured by Smatch (version 2.0.2) (Cai and Knight, 2013).

### 5.1 Experiment Settings

We first preprocess the input sentences with tokenization and lemmatization. Then we extract

the named entities using the Illinois Named Entity Tagger (Ratinov and Roth, 2009).

For training all the neural AMR parsing systems, we use 256 for both hidden layer size and word embedding size. Stochastic gradient descent is used to optimize the cross-entropy loss function and we set the drop out rate to be 0.5. We train our model for 150 epochs with initial learning rate of 0.5 and learning rate decay factor 0.95 if the model doesn't improve for the 3 last epochs.

## 5.2 Baseline Model

Our baseline model is a plain sequence-to-sequence model which has been used in the constituent parsing task (Vinyals et al., 2015). While they use a 3-layer deep LSTM, we only use a single-layer LSTM for both encoder and decoder since our data is relatively small and empirical comparison shows that stacking more layers doesn't help in our case. AMR linearization follows Section 3 without categorization. Since we don't restrict the input/output vocabulary in this case, our vocabulary size is quite large: 10,886 for output vocabulary and 2,2892 for input vocabulary. We set them to 10,000 and 20,000 respectively and replace the out of vocabulary words with `_UNK_`.

## 5.3 Impact of Re-Categorization

We first inspect the influence of utilizing categorization on the input and output sequence. Table 1 shows the Smatch evaluation score on development set.

System	P	R	F
Baseline	0.42	0.34	0.37
Re-Categorization ( $n = 50$ )	0.55	0.46	0.50

Table 1: Re-Categorization impact on development set

We see from the table that re-categorization improves the F-score by 13 points on the development set. As mentioned in section 4.1, by setting the low frequency threshold  $n$  to 50 and re-categorizing them into a reduced set of types, we now reduce the input/output vocabulary size to (2,000, 6,000). This greatly reduces the label sparsity and enables the neural attention model to learn a better representation on this small scale data. Another advantage of this method

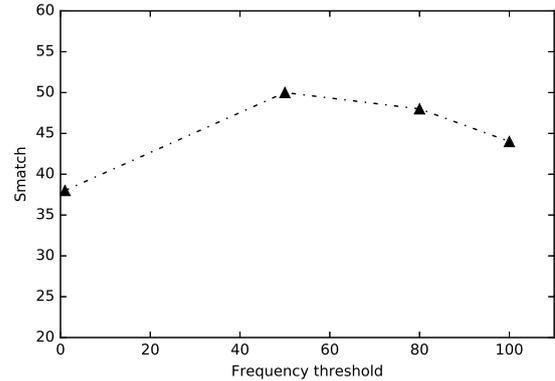

Figure 5: AMR parsing performance on development set given different categorization frequency.

is that although AMR tries to abstract away surface forms and retain the semantic meaning structure of the sentence, a large portion of the concepts are coming from the surface form and have exactly same string form both in input sentence and AMR graph. For example, `nation` in sentence is mapped to concept (`n / nation`) in the AMR. For the frequent concepts in the output sequence, since the model can observe many training instances, we assume that it can be predicted by the attention model. For the infrequent concepts, because of the categorization step, we only require the model to predict the concept type and its relative position in the graph. By applying the post-processing step mentioned in Section 4.3, we can easily recover the categorized concepts to their original form.

We also inspect how the value of re-categorization frequency threshold  $n$  affects the AMR parsing result. As shown in Figure 5, setting  $n$  to 0, which means no output labels will be categorized into types `-VERB-` and `-SURF-`, doesn't improve the baseline system. The reason is that we still have a large output vocabulary size and training data is still sparse with respect to the low frequency output labels. Also, if we set  $n$  too high, although the output vocabulary size becomes smaller, some of the frequent output labels that the model handles well originally will be put into the coarse-grained types, losing information in the recovery process. Thus we can see from the plot that after the optimal point the Smatch score will drop. Therefore, we choose to set  $n = 50$  in the subsequent experiments.

## 5.4 Impact of Supervised Alignment

**Choice of External Aligner.** There are two existing AMR aligners: one is a rule-based aligner coming with JAMR (Flanigan et al., 2014), which defines regular expression patterns to greedily match between AMR graph fragment and input token spans; another one is an unsupervised aligner (Pourdamghani et al., 2014) which adopts the traditional word alignment method in machine translation. Although evaluated on different set of manual alignment test sentences, both aligners achieved  $\sim 90\%$  F1 score. Here we choose to use the second aligner, as it covers broader domains.

**Different alignment configurations** To balance between the sequence learning and alignment agreement, We empirically tune the hyperparameter  $\lambda$  and set it to 0.3. For the external alignment we use for reference, we convert it to a vector with equal probability as discussed in Section 4.4. We then train a sequence-to-sequence model with re-categorized input/output and report the result on development set.

System	P	R	F
Baseline	0.42	0.34	0.37
Categorization ( $n = 50$ )	0.55	0.46	0.50
SuperAttn+Cate ( $n = 50$ )	0.56	0.49	0.52

Table 2: Supervised attention impact on development set

As shown in Table 2, the supervised attention model is able to further improve the Smatch score by another 2 points, which are mainly contributed by 3 points increase in recall. Since the reference/external alignment is mostly between the input tokens and AMR graph concepts, we believe that the supervised attention model is able to constrain the decoder so that it will output concepts which can be aligned to some tokens in the input sentence.

System	P	R	F
SuperAttn+Cate ( $n = 50$ )	0.56	0.49	0.52
NO-RELATION-ALIGN	0.46	0.40	0.43

Table 3: Supervised attention impact on development set

Because we have relations in the AMR graph, the alignment problem here is different from the

word alignment in machine translation. To verify the effectiveness of our setup, we also compare our configuration to the condition **NO-RELATION-ALIGN** where we only ignore the alignment between sentence and AMR relations by putting an all zero vector as the reference attention for each output relation label. From Table 3 we see that simply ignoring the reference attention for relations would greatly affect the model performance, and how we effectively represent the reference alignment for relations is crucial for the supervised attention model.

## 5.5 Results

In this section we report our final result on the test set of SemEval 2016 Task 8 and compare our model with other parsers. We train our model utilizing re-categorization and supervised attention with hyperparameters tuned on the development set. Then we apply our trained model on the test set.

Firstly, we compare our model to the existing sequence-to-sequence AMR parsing model of Barzdins and Gosko (2016). As shown in table 4, the word-level model in Barzdins and Gosko (2016) is basically our baseline model. The second model they use is a character-based sequence-to-sequence model. Our model can also be regarded as a word-level model; however, by utilizing carefully designed categorization and supervised attention, our system outperforms both their results by a large margin.

System	P	R	F
<b>Our system</b>	<b>0.55</b>	<b>0.50</b>	<b>0.52</b>
Barzdins and Gosko (2016) <sup>†</sup>	-	-	0.37
Barzdins and Gosko (2016) <sup>*</sup>	-	-	0.43

Table 4: Compare to other sequence-to-sequence AMR parser. Barzdins and Gosko (2016)<sup>†</sup> is the word-level neural AMR parser, Barzdins and Gosko (2016)<sup>\*</sup> is the character-level neural AMR parser.

Table 5 gives the comparison of our system to some of the teams participating in SemEval16 Task 8. Since a large portion of the teams extend on the state-of-the-art system CAMR (Wang et al., 2015b; Wang et al., 2015a; Wang et al., 2016), here we just pick typical teams that represent different approaches. We can see from the table that our system fails to outperform the state-

of-the-art system. However, the best performing system CAMR uses a dependency structure as a starting point, where dependency parsing has achieved high accuracy recently and can be trained on larger corpora. Also, it utilizes semantic role labeling and complex features, which makes the training process a long pipeline. Our system only needs minimal preprocessing, and doesn't need the dependency parsing step. Our approach is competitive with the SHRG (Synchronous Hyperedge Replacement Grammar) method of Peng et al. (2015), which does not require a dependency parser and uses SHRG to formalize the string-to-graph problem as a chart parsing task. However, they still need a concept identification stage, while our model can learn the concepts and relations jointly.

System	P	R	F
Our system	0.55	0.50	0.52
Peng and Gildea (2016)	0.56	0.55	0.55
CAMR	0.70	0.63	0.66

Table 5: Comparison to other AMR parsers.

## 6 Discussion

In this paper, we have proposed several methods to make the sequence-to-sequence model work competitively against conventional AMR parsing systems. Although we haven't outperformed state-of-the-art system using the conventional methods, our results show the effectiveness of our approaches to reduce the sparsity problem when training sequence-to-sequence model on a relatively small dataset. Our work could be aligned with the effort to handle low-resource data problems when building the end-to-end neural network model.

In neural machine translation, the attention model is traditionally trained on millions of sentence pairs, while facing low-resource language pairs, the neural MT system performance tends to downgrade (Zoph et al., 2016). There has been growing interest in tackling sparsity/low-resource problem in neural MT. Zoph et al. (2016) use a transfer learning method to first pre-train the neural model on rich-resource language pairs and then import the learned parameters to continue training on low-resource language pairs so that the model can alleviate the sparsity problem through shared

parameters. Firat et al. (2016) builds a multilingual neural system where the attention mechanism can be shared between different language pairs. Our work could be seen as parallel efforts to handle the sparsity problem since we focus on the input/output categorization and external alignment, which are both handy for low-resource languages.

In this paper, we haven't used any syntactic parser. However, as shown in previous works (Flanigan et al., 2014; Wang et al., 2015b; Artzi et al., 2015; Pust et al., 2015), using dependency features helps improve the parsing performance significantly because of the linguistic similarity between the dependency tree and AMR structure. An interesting extension would be to use a linearized dependency tree as the source sequence and apply sequence-to-sequence to generate the AMR graph. Our parser could also benefit from the modeling techniques in Wu et al. (2016).

## 7 Conclusion

Neural attention models have achieved great success in different NLP tasks. However, they have not been as successful on AMR parsing due to the data sparsity issue. In this paper, we described a sequence-to-sequence model for AMR parsing and present different ways to tackle the data sparsity problems. We show that our methods have led to significant improvement over a baseline neural attention model, and our model is also competitive against models that do not use extra linguistic resources.

## Abstract

In recent years, knowledge graphs such as Freebase that capture facts about entities and relationships between them have been used actively for answering factoid questions. In this paper, we explore the problem of automatically generating question answer pairs from a given knowledge graph. The generated question answer (QA) pairs can be used in several downstream applications. For example, they could be used for training better QA systems. To generate such QA pairs, we first extract a set of keywords from entities and relationships expressed in a triple stored in the knowledge graph. From each such set, we use a subset of keywords to generate a natural language question that has a unique answer. We treat this subset of keywords as a sequence and propose a sequence to sequence model using RNN to generate a natural language question from it. Our RNN based model generates QA pairs with an accuracy of 33.61 percent and performs 110.47 percent (relative) better than a state-of-the-art template based method for generating natural language question from keywords. We also do an extrinsic evaluation by using the generated QA pairs to train a QA system and observe that the F1-score of the QA system improves by 5.5 percent (relative) when using automatically generated QA pairs in addition to manually generated QA pairs available for training.

## 1 Introduction

Knowledge graphs store information about millions of *things* (or entities) and relationships between them. Freebase<sup>1</sup> is one such knowledge graph that describes and organizes more than 3 billion *facts* in a consistent ontology. Knowledge graphs usually capture relationships between different *things* that can be viewed as triples (for example, CEO(Sundar Pichai, Google)). Such triples are often referred to as facts and can be used for answering factoid questions. For example, the above triple can be used to answer the question “*Who is the CEO of Google ?*”. It is not surprising that knowledge graphs are increasingly used for building Question Answering systems (Ferrucci, 2012; Yahya et al., 2013; He et al., 2014; Zou et al., 2014).

In this paper, we focus on exploiting knowledge graphs for a related but different purpose. We propose that such triples or facts can be used for automatically generating Question Answer (QA) pairs. The generated QA pairs can then be used in certain downstream applications. For example, if some domain-specific knowledge graphs are available (such as History, Geography) then such QA pairs generated from them can be used for developing quiz systems for educational purposes.

We now formally define the problem and then illustrate it with the help of an example. Consider a triple consisting of a subject, predicate and object. Typically, the predicate has a domain (subject type) and a range (object type) associated with it. The predicate may have zero or more parents in the knowledge graph. For the sake of simplicity let us assume that the predicate has a single parent. We define a set consisting of the subject, predicate, object, domain, range and predicate parent. We propose an approach

<sup>1</sup><https://www.freebase.com/>

<i>Predicate</i>	CEO
<i>Subject</i>	Sundar Pichai
<i>Object</i>	Google
<i>Parent Predicate</i>	designation
<i>Domain</i>	person
<i>Range</i>	organization
<i>Keywords</i>	CEO, designation, Sundar Pichai, person, Google, organization

Table 1: An example set of keywords constructed from the triple *CEO(Sundar Pichai, Google)*

to generate natural language factoid questions using a subset of this set such that the answer to the question also lies in the set. Given the set of keywords, as shown in Table 1, we could generate the following QA pairs (keywords are italicized):

**Q:** What is the *designation* of *Sundar Pichai* at *Google*?

**A:** *CEO*

**Q:** Which *organization* is *Sundar Pichai* the *CEO* of?

**A:** *Google*

The above problem is similar to the problem of generating questions from Web queries (instead of entities and relations) which was first suggested by Lin (Lin, 2008). However, unlike existing works on query-to-questions which mainly rely on template based approaches, we formulate this as a sequence to sequence generation problem wherein the ordered set of keywords is an input sequence and the natural language question is the output sequence. We use a Recurrent Neural Network (RNN) (Werbos, 1990; Rumelhart et al., 1988) based model with Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) units to generate questions from the given set of keywords.

The input to our question generation model is a set of keywords extracted from triples in a knowledge graph. For this, it is important to first select a subset of triples from which interesting and meaningful questions can be constructed. For example, no interesting questions can be constructed from the triple *wikipedia\_page\_ID(Google, 57570)* and hence we should eliminate such triples. Further, even for an interesting triple, it may be possible to use only certain subsets of keywords to construct

a meaningful question. For example, for the set of keywords shown in Table 1, it is not possible to use the subset  $\{person, designation\}$  to form an interesting question. Hence, we need to automatically identify the right set of keywords that should be used to form the question such that the answer also lies in the set. In addition to the question generation model, we also propose a method for extracting a meaningful subset of keywords from the triples represented in the knowledge graph.

While our goal in this paper is to generate a set of question answer pairs for a given entity in a knowledge graph, we train the RNN model for generating natural language questions from a sequence of keywords using an open domain Community Question Answering (CQA) data. This ensures that the same trained RNN can be used with different knowledge graphs.

The main contributions of our work can be summarized as follows:

- We propose a method for extracting triples and keywords from a knowledge graph for constructing question keywords and answer pairs.
- We formulate the problem of generating natural language questions from keywords as a sequence to sequence learning problem that performs 110.47 % (relative) better than existing template based approaches.
- We train our model using 1M questions from WikiAnswers thereby ensuring that it is not tied to any specific knowledge graph.
- Finally, we show that appending the automatically generated QA pairs to existing training data for training a state of the art QA system (Jonathan Berant, 2014) improves the performance of the QA system by 5.5 percent (relative).

The remainder of this paper is organized as follows. In next section, we describe related work, followed by a description of our overall approach for extracting keywords from triples and generating natural language question answer pairs from them. We then describe the experiments performed to evaluate our system and then end with concluding remarks.

## 2 Related Work

There is only very recent work around generation of question answer pairs from knowledge graph (Seyler et al., 2015). On the other hand, there are several works around question generation that have been proposed in past with different motivations. We first present a brief overview of the question generation techniques proposed in the literature along with their limitations and then discuss the work around generation of questions answer pairs from knowledge graph.

A number of papers have looked at the problem of generating vocabulary questions using WordNet (Miller et al., 1990) and distributional similarity techniques (Brown et al., 2005; Heilman and Eskenazi, 2007). There are numerous works in automatic question generation from text. Many proposed methods are *syntax based* methods that use the parse structure of sentences, identify key phrases and apply some known transformation rules to create questions (Ali et al., 2010; Kalady et al., 2010; Varga, 2010). Mannem et al. (2010) further use semantic role labeling for transformation rules. There are also *template based* methods proposed where a question template is a pre-defined text with placeholder variables to be replaced with content from source text. Cai et al. (2006) propose an XML markup language that is used to manually create question templates. This is sensitive to the performance of syntactic and semantic parsing. Heilman and Smith (2010) use a rule based approach to transform a declarative sentence into several candidate questions and then rank them using a logistic regression model. These approaches involve creating templates manually and thus require huge manual work and have low recall.

A problem that has been studied recently and is similar to our problem of generating questions using knowledge graph is that of generating questions from Web queries. The motivation here is to automatically generate questions from queries for community-based question answering services such as Yahoo! Answers and WikiAnswers. The idea was first suggested by (Lin, 2008) and further developed by (Zhao et al., 2011) and (Zheng et al., 2011). Both of these approaches are template based approaches where the templates are learnt using a huge question corpus along with query logs. Dror et al. (2013) further proposed a learning to rank based method to obtain grammatically

correct and diverse questions from a given query where the candidate questions are generated using the approach proposed by (Zhao et al., 2011). These approaches use millions of query question pairs to learn question templates and thus have better generalization performance compared to earlier methods where templates were learnt manually.

Recently, Seyler et al. (2015) proposed a method to generate natural language questions from knowledge graphs given a topic of interest. They also provide a method to estimate difficulty of generated questions. The generation of question is done by manually created template patterns and therefore is limited in application. In contrast we propose an RNN based method to learn generation of natural language questions from a set of keywords. The model can be trained using a dataset containing open domain keywords and question pairs.

## 3 Approach

In this section we propose an approach to generate Question Answer (QA) pairs for a given entity  $E$ . Let  $KG$  be the knowledge graph which contains information about various entities in the form of triples. A triple consists of a subject, a predicate and an object. Subjects and objects are nodes in the  $KG$ , which could represent a person, a place, an abstract concept or any physical entity. Predicates are edges in the  $KG$ . They define type of relationship between the subject and the object.

The framework to generate QA pairs consists two major modules. The first module, **Question Keywords and Answer Extractor**, is language independent and extracts required knowledge about the entity  $E$  from the  $KG$ . The second module is a language dependent **RNN based Natural Language Question Generator**. When fed with the information extracted from the first part it generates natural language QA pairs.

### 3.1 Question Keywords and Answer Extractor

Question keywords are keywords necessary to generate a question in natural language, or it could also be viewed as a concise representation of a natural language question. For example, to generate a QA pair for the entity *London*. We can generate a natural language question like *What is the capital city of United Kingdom?* with the keywords  $\{Capital, City, United Kingdom\}$ . Also

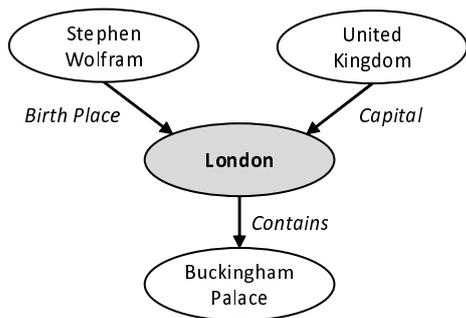

Figure 1: Triples with the entity *London* in a knowledge graph

since *London* is the answer to the above question,  $(\{Capital, City, United Kingdom\}, London)$  together will form a Question Keyword and Answer (QKA) pair. One important note is that *Capital, City, United Kingdom* and *London* are the English labels of the node that represent these entities in the *KG*.

	Column A	Column B	Column C
Subject	United Kingdom	Stephen Wolfram	<b>London</b>
Domain	Country	Person	Location
Predicate	Capital	Birth Place	Contains
Object	<b>London</b>	<b>London</b>	Buckingham Palace
Range	City	Location	Location

Table 2: Examples of 5-tuples (subject, domain, predicate, object, range) for the entity *London*

In order to retrieve information about the given entity *E*, we need to first identify the node *n* that represents the entity *E* in the *KG*. One way to identify node *n* is to leverage the label (e.g. *rdfs:label*) property.

The next step is to retrieve all the neighbours of *n*. Let  $m_i$  be a neighbour of *n* in *KG*, connected by a predicate  $p_i$ . Here *i* is the index over all predicates whose subject or object is *n*. Figure 1 shows the entity *London* with three neighbours *United Kingdom*, *Stephen Wolfram* and *Buckingham Palace*. Each of these neighbours are related to *London* by a predicate. For example, *Stephen Wolfram* is related to *London* as it is his *Birth Place*.

Given a predicate  $p_i$ , let  $sub(p_i)$  be the subject of  $p_i$  and  $obj(p_i)$  be the object of  $p_i$ . A predicate is usually defined with a domain (subject type) and a range (object type) to provide better semantics. The domain and range defines the entity types that can be used as the subject and object of the predicate respectively. Let  $domain(p_i)$  and  $range(p_i)$  be the domain and range of  $p_i$  respectively. Let

$\{sub(p_i), domain(p_i), p_i, obj(p_i), range(p_i)\}$  be the 5-tuple associated with every  $p_i$ . Some examples of 5-tuples are shown column wise in Table 2.

We now describe how QKA pairs are extracted from 5-tuple. Let  $Q_k$  be the question keywords set and  $A_k$  be the answer to the question to be generated using  $Q_k$ .  $(Q_k, A_k)$  together will form a QKA pair. In this work, we consider only a single 5-tuple to generate a QKA pair. For example, we can generate QKA pair like  $(\{Capital, City, United Kingdom\}, London)$  using *Column A* of Table 2. But we will not generate QKA pair like  $(\{Capital, City, United Kingdom, Birth Place, Stephen Wolfram\}, London)$  using both *Column A & B* of Table 2.

We use the following rules to generate QKA pairs from 5-tuples.

- Unique Forward Relation :** If  $p_i$  is unique for  $sub(p_i)$  in *KG*, then  $Q_k$  will include  $sub(p_i)$ ,  $p_i$  and  $range(p_i)$ .  $A_k$  will be  $obj(p_i)$ . If  $p_i$  is not unique for  $sub(p_i)$ , then there could be multiple possible answers to the generated question including  $obj(p_i)$ , and therefore we do not generate such a QKA pair. When this is applied to *Column A* of Table 2, we generate  $(\{Capital, City, United Kingdom\}, London)$  as a QKA pair. There is no QKA pair generated for *Column C* using this rule as *London* contains many locations like *Buckingham Palace, City of Westminster*, etc.
- Unique Reverse Relation :** If  $p_i$  is unique for  $obj(p_i)$  in *KG*, then  $Q_k$  will include  $obj(p_i)$ ,  $p_i$  and  $domain(p_i)$ .  $A_k$  is  $sub(p_i)$ . Similar to unique forward relation, this rule can be applied to *Column A* of Table 2 and cannot be applied to *Column B & C*.

### 3.2 RNN based Natural Language Question Generator

In the previous sub-section, we proposed an approach for creating *question keywords* and *answer* pairs. Now we propose a model for generating natural language questions from a given set of question keywords. We treat the keywords,  $QK = \{qk_1, \dots, qk_m\}$ , as an input sequence and the question,  $Q = \{q_1, \dots, q_l\}$ , as the output sequence. This design choice of treating a set of keywords as a sequence and not as a bag of words

allows us to generate different semantically valid questions from the same set  $K$  based on the order of the words in the set. For example, given the question keywords,  $QK = \{King, Sweden\}$  we can generate two semantically valid questions by changing the order of King and Sweden: (i) Who is the King of Sweden? and (ii) Does Sweden have a King?

We propose a Natural Language Question Generation (NLQG) model that first encodes the input sequence using some distributed representation and then decodes the output sequence from this encoded representation. Specifically, we use a RNN based encoder and decoder recently proposed for language processing tasks by number of groups (Cho et al., 2014; Sutskever et al., 2014). We now formally define the encoder and decoder models.

Let  $m$  be the number of keywords in the input sequence. We represent each keyword using a fixed size vector  $x_i \in \mathbb{R}^n$ . The function of the encoder is to map this sequence of  $x_i$ 's to a fixed size encoding. We use a RNN to compute  $h_m$  using the following recursive equation:

$$h_i = \Phi(h_{i-1}, x_i), \quad (1)$$

where,  $h_i \in \mathbb{R}^n$  is the hidden representation at position  $i$ .  $h_m$  is the final encoded hidden state vector for this sequence. We use LSTM units (Hochreiter and Schmidhuber, 1997) as  $\Phi$  for our implementation based on its recent success in language processing tasks (Bahdanau et al., 2015).

The function of the decoder is to compute the probability of the output sequence  $Q = \{q_1, \dots, q_l\}$  given the encoded vector  $h_m$ . Note that  $l$  is the length of the output sequence and may be different from  $m$ . This joint conditional probability of  $Q$  is decomposed into  $l$  conditional probabilities:

$$p(q_1, \dots, q_l | h_m) = \prod_{j=1}^l p(q_j | \{q_1, \dots, q_{j-1}\}, h_m). \quad (2)$$

Now we model  $p(q_j | q_{<j}, h_m)$  at each position  $j$  by using a RNN decoder as follows:

$$p(q_j | q_{<j}, h_m) = \Theta(q_{j-1}, g_j, h_m), \quad (3)$$

where  $\Theta$  is a non-linear function, that outputs the probability of  $q_j$ , and  $g_j$  is the hidden state of the decoder RNN.

To train this RNN model, we use a keyword sequence and question pairs generated from an open

domain Community Question Answering website. We provide more details on how the data is created and used for training in the experiments section.

At runtime, every permutation of the question keywords  $QK$  extracted is fed as input to the trained RNN. We pick the question  $Q$  with the highest probability of generation across all permutations, as the question generated from the question keywords  $QK$ .

## 4 Experiments

In this section we perform experiments to demonstrate how the proposed approach outperforms the existing template based approach for generating questions from the keywords. We also evaluate the quality of the QA pairs generated from knowledge graph.

### 4.1 Datasets

For training the K2Q-RNN model we require a set of keywords and question pairs. We use a large collection of open-domain questions available from WikiAnswers dataset<sup>2</sup>. This dataset has around 20M questions. We randomly selected 1M questions from this corpus for training and 5k questions for testing (the maximum length of a question was restricted to 50 words). We extract keywords from the selected questions by retaining only Nouns, Verbs and Adjectives in the question. The parts of speech tags were identified using Stanford Tagger (Toutanova et al., 2003). We form an ordered sequence of keywords by retaining these extracted words in the same order in which they appear in the original question. This sequence of keywords along with the original question forms one input-output sequence pair for training.

### 4.2 Methods

We evaluate and compare the following methods:

**K2Q-RNN:** This is our approach proposed in the paper. For the encoder we use a bi-directional RNN containing one hidden layer of 1000 units. Each word in the input vocabulary is represented using a word vector which is randomly initialized and learnt during the training process. The decoder also contains one hidden layer comprising of 1000 units. At the output layer of the decoder a softmax function gives the distribution over the entire target vocabulary. We use the top 30,000

<sup>2</sup> Available at <http://knowitall.cs.washington.edu/oqa/data/wikianswers/>

most frequent words in the 1M training questions as the target vocabulary. If any sequence contains a word not belonging to this list then that word is mapped to a special token ([UNK]) that is also considered a part of the output vocabulary. We use a mini batch stochastic gradient descent algorithm together with Adadelta (Zeiler, 2012) to train our model. We used a mini-batch size of 50 and trained the model for 10 epochs. We used the beam search with the beam size to 12 to generate the question that approximately maximizes conditional probability defined in Equation 2.

**K2Q-PBSMT:** As mentioned earlier, we treat the problem of generating questions from keywords as a sequence to sequence translation problem. A Phrase Based Machine Translation System (PBSMT) can also be employed for this task by considering that the keyword sequences belong to a source language and the question sequences belong to a target language. We compare our approach with a standard phrase-based MT system, MOSES (Koehn et al., 2007) trained using the same 1M sequence pairs constructed from the WikiAnswers dataset. We used a 5-gram language model trained on the 1M target question sequences and tuned the parameters of the decoder using 1000 held-out sequence (these were held out from the 1M training pairs).

**K2Q-Template:** For template based approach we use the method proposed by (Zhao et al., 2011) along with the Word2Vec (Mikolov et al., 2015) ranking as proposed by (Raghu et al., 2015). The Word2Vec ranking provides better generalization than the ranking proposed by (Zhao et al., 2011). We learn the templates using the same 1M training pairs extracted from WikiAnswers.

### 4.3 Evaluation metrics

We evaluate the performance of K2Q RNN with other baselines to compare the K2Q approaches, we use BLEU score (Papineni et al., 2002) between the generated question and the reference question. BLEU score is typically used in evaluating the performance of MT systems and captures the average n-gram overlap between the generated sequence and the reference sequence. We consider n-grams upto length 4. BLEU score does not capture the true performance of the system. For example, if the trained model simply reproduces all keywords in the generated question then also the unigram overlap will be high resulting in a higher

Method	BLEU Score	Human Judgment accuracy (%)
K2Q-Template	25.58	28.57
K2Q-PBSMT	50.90	44.29
K2Q-RNN	50.14	60.13

Table 3: Automatic Evaluation (column 2): The BLEU scores of generated questions for the test set. Human Evaluation (Column 3): Percentage of perfect questions generated by *K2Q-Template*, *K2Q-PBSMT*, and *K2Q-RNN*

BLEU score. Further, we had only one reference question (ground truth) per test instance which is not sufficient to capture the different ways of expressing the question. In this case, BLEU score will be unnecessarily harsh on the model even if it generates a valid paraphrase of the reference question. To account for this we also perform a manual evaluation. We show the generated output to four human annotator and ask him/her to assign following ratings to the generated question, Rating 4 : Perfect without error, Rating 3 : Good with one error, missing/addition of article or preposition, but still meaningful, Rating 2 : Many errors, Rating 1 : Failure.

## 4.4 Results

### 4.4.1 RNN based Natural Language Question Generator

We first evaluate the performance of K2Q approaches using 5000 test instances from the WikiAnswers dataset. We extract the keyword sequence from these test questions using the same method described above. We compute the BLEU score by comparing the generated question with the original question. The results are presented in Table 3. Both K2Q-RNN and K2Q-PBSMT clearly outperform the template based method which shows that there is merit in formulating this problem as a sequence to sequence learning problem. To be sure that the results are not misleading due to some of the drawbacks of BLEU score as described earlier, we also do a manual evaluation. For this, we randomly selected 700 questions from the test set. We showed the questions generated by the three methods to different human annotators and asked them to assign a score of 1 to 4 to each question (based on the guidelines described earlier). The evaluators had no knowledge about the method used to generate each question shown to them. We only consider questions with rating 4 (perfect without any errors) for each

Table 5: Example question-answer pairs extracted for different entities by using *Freebase* and *K2Q-RNN*. Question-Answer pairs are considered correct if and only if both are marked with ✓ by human judges.

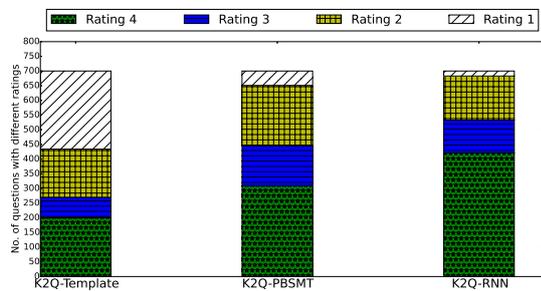

Figure 2: Ratings given by human judges for generated questions for *K2Q-Template*, *K2Q-PBSMT* and *K2Q-RNN* ( Best viewed in color).

method and calculate the accuracy, shown in Table 3. Figure 2 shows the distribution of ratings assigned by the annotators. Once gain *K2Q-RNN* and *K2Q-PBSMT* outperform the template based approach. Further, the human evaluation shows *K2Q-RNN* performs better than *K2Q-PBSMT*. Table 4 shows example questions that may have a high BLEU score for *K2Q-PBSMT*, however the *K2Q-RNN* has a better human judgement.

Next, we also compare the performance of these methods for input keyword sequences of different lengths. For this, we consider all test instances having  $k$  keywords and mark the generated question as correct if it was given a rating of 4 by the human annotator. The results of this experiment are plotted in Figure 3 where the x-axis represents number of keywords and y-axis represents the percentage of test instances for which correct (rating 4) questions were generated. Once again we see that *K2Q-RNN* clearly outperforms the other methods at all input sequence sizes.

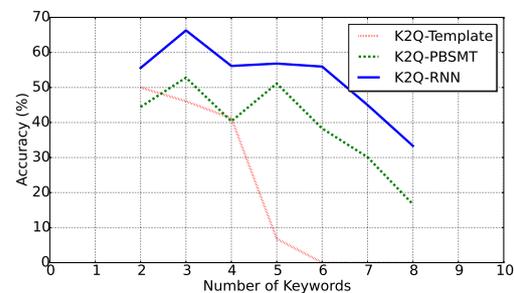

Figure 3: The plot shows the performance of 3 methods *K2Q-Template*, *K2Q-PBSMT*, and *K2Q-RNN* as a functions of number of keywords.

#### 4.4.2 Generating Question-Answers pairs from Freebase

In this section we describe the performance of *K2Q-RNN* for generating QA pairs from a Knowledge Graph. For our evaluation purpose, we use *Freebase* as the Knowledge Graph. We randomly picked 27 *Freebase* entities of various types (person, location, organization, etc) and extracted all 5-tuples containing them. To create a diverse QA pairs we retained only two instances (5-tuples) for each predicate or relation type. Some predicates (like summary, quotations) have long text as their objects, some predicates (like Daylife Topic ID, Hero image ID) are difficult for annotator to validate. So, we filtered the list further by removing above mentioned predicates and generated a total of 485 QKA pairs. We manually evaluated these generated QA pairs and marked them as correct only if generated question along with the answer together convey the information represented

Train Sources	Train	Test	F1-score(%)
WQ	3778	2032	39.9
WQ+GQA	11334	2032	42.1
WQ+GT	11334	2032	43.6

Table 6: PARASEMPRE Evaluation: WQ=WebQuestions, GQA=Generated QA pairs from *SimpleQuestions* test dataset, GT=Ground truth data from *SimpleQuestions* test dataset.

in the 5-tuple. A few QA pairs were marked correct by the annotators, even though the question was not grammatically correct but convey the right intent. Some examples of such questions are *melting point of propyl alcohol?*, *stanford university student radio station?*. Overall, **33.61%** of the QA pairs generated by our method were annotated correct. Table 5 shows some correct and incorrect QA pairs generated by our method.

#### 4.4.3 Extrinsic Evaluation

As an extrinsic evaluation of the quality of our QA generation model, we use QA pairs generated by our model to improve the performance of a state of the art QA system called PARASEMPRE (Jonathan Berant, 2014). PARASEMPRE is a semantic parser, which maps natural language questions to intermediate logical forms which in turn are used to answer the question. The standard training set used for training PARASEMPRE is a part of the *WebQuestions* and contains 3778 QA pairs. We appended this train with 7556 automatically generated QA pairs (resulting in tripling of the training set). Table 6 then compares the same system trained on the following different training sets: (i) Only Web Questions (WQ) dataset (ii) WQ + Generated Question Answers (GQA) and (iii) WQ + Ground Truth (GT) QA pairs. The GT QA pairs were obtained from the *SimpleQuestions* (Bordes et al., 2015) test data and have a one-to-one correspondence to the GQA data (hence the results are comparable). We see a relative improvement of 5.5% in the *F1-score* of the system by adding GQA. Further, the performance gains are comparable to those obtained by using GT QA pairs.

#### 4.4.4 Error analysis

We inspected all the QA pairs generated by our method to identify some common mistakes. We found that most errors corresponded to (i) con-

fusion between is/are and do/does (ii) incorrect use of determiners (missing articles, confusion between a/the and addition of extra articles). Another problem occurs when the extracted keyword sequence contains a stop word. This happens when dealing with triples such as (*{also known as, Andre Agassi}*, *Agassi*). Since, during training we retain only content words (nouns, adjectives, verbs) in the input sequence, the model fails to deal with such stop words at test time and simply produces unknown token (UNK) in the output. Another set of errors corresponds to mismatch between the subject type and question type. For example, we observed that in a few cases, the model incorrectly generates a *what question* instead of a *who question* when the answer type is a person.

## 5 Conclusions

In this paper we propose a method for generating QA pairs for an given entity using a knowledge graph. We also propose an RNN based approach for generating natural language questions from an input keyword sequence. The proposed method performs significantly better than previously proposed template based method. We also do an extrinsic evaluation to show that the generated QA pairs help in improving the performance of a downstream QA system. In future, we plan to extend this work to support predicates with stop words and support predicates in various tenses.

## Abstract

To analyze the limitations and the future directions of the extractive summarization paradigm, this paper proposes an Integer Linear Programming (ILP) formulation to obtain *extractive oracle summaries* in terms of ROUGE<sub>n</sub>. We also propose an algorithm that enumerates all of the oracle summaries for a set of reference summaries to exploit F-measures that evaluate which system summaries contain how many sentences that are extracted as an oracle summary. Our experimental results obtained from Document Understanding Conference (DUC) corpora demonstrated the following: (1) room still exists to improve the performance of extractive summarization; (2) the F-measures derived from the enumerated oracle summaries have significantly stronger correlations with human judgment than those derived from single oracle summaries.

## 1 Introduction

Recently, compressive and abstractive summarization are attracting attention (e.g., Almeida and Martins (2013), Qian and Liu (2013), Yao et al. (2015), Banerjee et al. (2015), Bing et al. (2015)). However, extractive summarization remains a primary research topic because the linguistic quality of the resultant summaries is guaranteed, at least at the sentence level, which is a key requirement for practical use (e.g., Hong and Nenkova (2014), Hong et al. (2015), Yogatama et al. (2015), Parveen et al. (2015)).

The summarization research community is experiencing a paradigm shift from extractive to compressive or abstractive summarization. Currently our question is: “Is extractive summariza-

tion still useful research?” To answer it, the ultimate limitations of the extractive summarization paradigm must be comprehended; that is, we have to determine its upper bound and compare it with the performance of the state-of-the-art summarization methods. Since ROUGE<sub>n</sub> is the de-facto automatic evaluation method and is employed in many text summarization studies, an oracle summary is defined as a set of sentences that have a maximum ROUGE<sub>n</sub> score. If the ROUGE<sub>n</sub> score of an oracle summary outperforms that of a system that employs another summarization approach, the extractive summarization paradigm is worthwhile to leverage research resources.

As another benefit, identifying an oracle summary for a set of reference summaries allows us to utilize yet another evaluation measure. Since both oracle and extractive summaries are sets of sentences, it is easy to check whether a system summary contains sentences in the oracle summary. As a result, F-measures, which are available to evaluate a system summary, are useful for evaluating classification-based extractive summarization (Mani and Bloedorn, 1998; Osborne, 2002; Hirao et al., 2002). Since ROUGE<sub>n</sub> evaluation does not identify which sentence is important, an F-measure conveys useful information in terms of “important sentence extraction.” Thus, combining ROUGE<sub>n</sub> and an F-measure allows us to scrutinize the failure analysis of systems.

Note that more than one oracle summary might exist for a set of reference summaries because ROUGE<sub>n</sub> scores are based on the unweighted counting of n-grams. As a result, an F-measure might not be identical among multiple oracle summaries. Thus, we need to enumerate the oracle summaries for a set of reference summaries and compute the F-measures based on them.

In this paper, we first derive an Integer Linear Programming (ILP) problem to extract an oracle

summary from a set of reference summaries and a source document(s). To the best of our knowledge, this is the first ILP formulation that extracts oracle summaries. Second, since it is difficult to enumerate oracle summaries for a set of reference summaries using ILP solvers, we propose an algorithm that efficiently enumerates all oracle summaries by exploiting the branch and bound technique. Our experimental results on the Document Understanding Conference (DUC) corpora showed the following:

1. Room still exists for the further improvement of extractive summarization, *i.e.*, where the ROUGE<sub>n</sub> scores of the oracle summaries are significantly higher than those of the state-of-the-art summarization systems.
2. The F-measures derived from multiple oracle summaries obtain significantly stronger correlations with human judgment than those derived from single oracle summaries.

## 2 Definition of Extractive Oracle Summaries

We first briefly describe ROUGE<sub>n</sub>. Given set of reference summaries  $\mathbf{R}$  and system summary  $S$ , ROUGE<sub>n</sub> is defined as follows:

$$\text{ROUGE}_n(\mathbf{R}, S) = \frac{|\mathbf{R}| \sum_{j=1}^{|U(\mathcal{R}_k)|} \min\{N(g_j^n, \mathcal{R}_k), N(g_j^n, S)\}}{\sum_{k=1}^{|\mathbf{R}|} \sum_{j=1}^{|U(\mathcal{R}_k)|} N(g_j^n, \mathcal{R}_k)}. \quad (1)$$

$\mathcal{R}_k$  denotes the multiple set of n-grams that occur in  $k$ -th reference summary  $R_k$ , and  $\mathcal{S}$  denotes the multiple set of n-grams that appear in system-generated summary  $S$  (a set of sentences).  $N(g_j^n, \mathcal{R}_k)$  and  $N(g_j^n, \mathcal{S})$  return the number of occurrences of n-gram  $g_j^n$  in the  $k$ -th reference and system summaries, respectively. Function  $U(\cdot)$  transforms a multiple set into a normal set. ROUGE<sub>n</sub> takes values in the range of  $[0, 1]$ , and when the n-gram occurrences of the system summary agree with those of the reference summary, the value is 1.

In this paper, we focus on extractive summarization, employ ROUGE<sub>n</sub> as an evaluation measure,

and define the oracle summaries as follows:

$$O = \arg \max_{S \subseteq D} \text{ROUGE}_n(\mathbf{R}, S) \quad (2)$$

*s.t.*  $\ell(S) \leq L_{\max}$ .

$D$  is the set of all the sentences contained in the input document(s), and  $L_{\max}$  is the length limitation of the oracle summary.  $\ell(S)$  indicates the number of words in the system summary. Eq. (2) is an NP-hard combinatorial optimization problem, and no polynomial time algorithms exist that can attain an optimal solution.

## 3 Related Work

Lin and Hovy (2003) utilized a naive exhaustive search method to obtain oracle summaries in terms of ROUGE<sub>n</sub> and exploited them to understand the limitations of extractive summarization systems. Ceylan et al. (2010) proposed another naive exhaustive search method to derive a probability density function from the ROUGE<sub>n</sub> scores of oracle summaries for the domains to which source documents belong. The computational complexity of naive exhaustive methods is exponential to the size of the sentence set. Thus, it may be possible to apply them to single document summarization tasks involving a dozen sentences, but it is infeasible to apply them to multiple document summarization tasks that involve several hundred sentences.

To describe the difference between the ROUGE<sub>n</sub> scores of oracle and system summaries in multiple document summarization tasks, Riedhammer et al. (2008) proposed an approximate algorithm with a genetic algorithm (GA) to find oracle summaries. Moen et al. (2014) utilized a greedy algorithm for the same purpose. Although GA or greedy algorithms are widely used to solve NP-hard combinatorial optimization problems, the solutions are not always optimal. Thus, the summary does not always have a maximum ROUGE<sub>n</sub> score for the set of reference summaries. Both works called the summary found by their methods the oracle, but it differs from the definition in our paper.

Since summarization systems cannot reproduce human-made reference summaries in most cases, oracle summaries, which can be reproduced by summarization systems, have been used as training data to tune the parameters of summarization systems. For example, Kulesza and Tasker (2011) and Sipos et al. (2012) trained their summarizers

bound of the  $\text{ROUGE}_n$  score with the maximum  $\text{ROUGE}_n$  score in the search history. For instance, in Fig. 1, we reach node  $s_2$  by following this path: “Root  $\rightarrow s_1, \rightarrow s_2$ ”. If we estimate the maximum  $\text{ROUGE}_n$  score (upper bound) obtained by searching for the descendant of  $s_2$  (the subtree in the blue rectangle), we can decide whether the depth-first search should be continued. When the upper bound of the  $\text{ROUGE}_n$  score exceeds the current maximum  $\text{ROUGE}_n$  in the search history, we have to continue. When the upper bound is smaller than the current maximum  $\text{ROUGE}_n$  score, no summary is optimal that contains  $s_1, s_2$ , so we can skip subsequent search activity on the subtree and proceed to check the next branch: “Root  $\rightarrow s_1 \rightarrow s_3$ ”.

To estimate the upper bound of the  $\text{ROUGE}_n$  score, we re-define it for two distinct sets of sentences,  $V$  and  $W$ , *i.e.*,  $V \cap W = \phi$ , as follows:

$$\begin{aligned} \text{ROUGE}_n(\mathbf{R}, V \cup W) &= \text{ROUGE}_n(\mathbf{R}, V) \\ &+ \text{ROUGE}'_n(\mathbf{R}, V, W). \end{aligned} \quad (9)$$

Here  $\text{ROUGE}'_n$  is defined as follows:

$$\begin{aligned} \text{ROUGE}'_n(\mathbf{R}, V, W) &= \\ \frac{\sum_{k=1}^{|\mathbf{R}|} \sum_{t_n \in U(\mathcal{R}_k)} \min\{N(t_n, \mathcal{R}_k \setminus \mathcal{V}), N(t_n, \mathcal{W})\}}{\sum_{k=1}^{|\mathbf{R}|} \sum_{t_n \in U(\mathcal{R}_k)} N(t_n, \mathcal{R}_k)}. \end{aligned} \quad (10)$$

$\mathcal{V}, \mathcal{W}$  are the multiple sets of  $n$ -grams found in the sets of sentences  $V$  and  $W$ , respectively.

**Theorem 1.** *Eq. (9) is correct.*

We omit the proof of Theorem 1 due to space limitations.

## 5.2 Upper Bound of $\text{ROUGE}_n$

Let  $V$  be the set of sentences on the path from the current node to the root node in the search tree, and let  $W$  be the set of sentences that are the descendants of the current node. In Fig. 1,  $V = \{s_1, s_2\}$  and  $W = \{s_3, s_4, s_5, s_6\}$ . According to Theorem 1, the upper bound of the  $\text{ROUGE}_n$  score is defined as:

$$\begin{aligned} \widehat{\text{ROUGE}}_n(\mathbf{R}, V) &= \text{ROUGE}_n(\mathbf{R}, V) + \\ \max_{\Omega \subseteq W} \{ \text{ROUGE}'_n(\mathbf{R}, V, \Omega) : \ell(\Omega) \leq L_{\max} - \ell(V) \} \end{aligned} \quad (11)$$

## Algorithm 1 Algorithm to Find Upper Bound of $\text{ROUGE}_n$

---

```

1: Function:  $\widehat{\text{ROUGE}}_n(\mathbf{R}, V)$ 
2:    $W \leftarrow \text{descendant}(\text{last}(V)), W' \leftarrow \phi$ 
3:    $U \leftarrow \text{ROUGE}(\mathbf{R}, V)$ 
4:   for each  $w \in W$  do
5:      $\text{append}(W', \frac{\text{ROUGE}'_n(\mathbf{R}, V, \{w\})}{\ell(w)})$ 
6:   end for
7:    $\text{sort}(W', \text{'descend'})$ 
8:   for each  $w \in W'$  do
9:     if  $L_{\max} - \ell(\{w\}) \geq 0$  then
10:       $U \leftarrow U + \text{ROUGE}'_n(\mathbf{R}, V, \{w\})$ 
11:       $L_{\max} \leftarrow L_{\max} - \ell(\{w\})$ 
12:     else
13:       $U \leftarrow U + \frac{\text{ROUGE}'_n(\mathbf{R}, V, \{w\})}{\ell(\{w\})} \times L_{\max}$ 
14:      break the loop
15:     end if
16:   end for
17:   return  $U$ 
18: end

```

---

Since the second term on the right side in Eq. (11) is an NP-hard problem, we turn to the following relation by introducing inequality,  $\text{ROUGE}'_n(\mathbf{R}, V, \Omega) \leq \sum_{\omega \in \Omega} \text{ROUGE}'_n(\mathbf{R}, V, \{\omega\})$ ,

$$\begin{aligned} \max_{\Omega \subseteq W} \{ \text{ROUGE}'_n(\mathbf{R}, V, \Omega) : \ell(\Omega) \leq L_{\max} - \ell(V) \} \\ \leq \max_{\mathbf{x}} \left\{ \sum_{i=1}^{|\mathcal{W}|} \text{ROUGE}'_n(\mathbf{R}, V, \{w_i\}) x_i : \right. \\ \left. \sum_{i=1}^{|\mathcal{W}|} \ell(\{w_i\}) x_i \leq L_{\max} - \ell(V) \right\}. \end{aligned} \quad (12)$$

Here,  $\mathbf{x} = (x_1, \dots, x_{|\mathcal{W}|})$  and  $x_i \in \{0, 1\}$ . The right side of Eq. (12) is a knapsack problem, *i.e.*, a 0-1 ILP problem. Although we can obtain the optimal solution for it using dynamic programming or ILP solvers, we solve its linear programming relaxation version by applying a greedy algorithm for greater computation efficiency. The solution output by the greedy algorithm is optimal for the relaxed problem. Since the optimal solution of the relaxed problem is always larger than that of the original problem, the relaxed problem solution can be utilized as the upper bound. Algorithm 1 shows the pseudocode that attains the upper bound of  $\text{ROUGE}_n$ . In the algorithm,  $U$  indicates the upper bound score of  $\text{ROUGE}_n$ . We first set the initial score of upper bound  $U$  to  $\text{ROUGE}_n(\mathbf{R}, V)$  (line 3). Then we compute the density of the  $\text{ROUGE}'_n$  scores ( $\text{ROUGE}'_n(\mathbf{R}, V, \{w\})/\ell(w)$ ) for each sentence  $w$  in  $W$  and sort them in descending order (lines 4 to 6). When we have room to add  $w$  to the summary, we update  $U$  by adding the  $\text{ROUGE}'_n(\mathbf{R}, V, \{w\})$  (line 10) and update length

---

**Algorithm 2** Greedy algorithm to obtain initial score

---

```

1: Function: GREEDY( $\mathbf{R}, D, L_{\max}$ )
2:  $L \leftarrow 0, S \leftarrow \phi, E \leftarrow D$ 
3: while  $E \neq \phi$  do
4:    $s^* \leftarrow \arg \max_{s \in E} \left\{ \frac{\text{ROUGE}_n(\mathbf{R}, S \cup \{s\}) - \text{ROUGE}_n(\mathbf{R}, S)}{\ell(\{s\})} \right\}$ 
5:    $L \leftarrow L + \ell(\{s^*\})$ 
6:   if  $L \leq L_{\max}$  then
7:      $S \leftarrow S \cup \{s^*\}$ 
8:   end if
9:    $E \leftarrow E \setminus \{s^*\}$ 
10: end while
11:  $i^* \leftarrow \arg \max_{i \in D, \ell(\{i\}) \leq L_{\max}} \text{ROUGE}_n(\mathbf{R}, \{i\})$ 
12:  $S^* \leftarrow \arg \max_{K \subseteq \{i^*\}, S} \text{ROUGE}_n(\mathbf{R}, K)$ 
13: return  $\text{ROUGE}_n(\mathbf{R}, S^*)$ 
14: end

```

---

constraint  $L_{\max}$  (line 11). When we do not have room to add  $w$ , we update  $U$  by adding the score obtained by multiplying the density of  $w$  by the remaining length,  $L_{\max}$  (line 13), and exit the while loop.

### 5.3 Initial Score for Search

Since the branch and bound technique prunes the search by comparing the best solution found so far with the upper bounds, obtaining a good solution in the early stage is critical for raising search efficiency.

Since  $\text{ROUGE}_n$  is a monotone submodular function (Lin and Bilmes, 2011), we can obtain a good approximate solution by a greedy algorithm (Khuller et al., 1999). It is guaranteed that the score of the obtained approximate solution is larger than  $\frac{1}{2}(1 - \frac{1}{e})\text{OPT}$ , where  $\text{OPT}$  is the score of the optimal solution. We employ the solution as the initial  $\text{ROUGE}_n$  score of the candidate oracle summary.

Algorithm 2 shows the greedy algorithm. In it,  $S$  denotes a summary and  $D$  denotes a set of sentences. The algorithm iteratively adds sentence  $s^*$  that yields the largest gain in the  $\text{ROUGE}_n$  score to current summary  $S$ , provided the length of the summary does not violate length constraint  $L_{\max}$  (line 4). After the while loop, the algorithm compares the  $\text{ROUGE}_n$  score of  $S$  with the maximum  $\text{ROUGE}_n$  score of the single sentence and outputs the larger of the two scores (lines 11 to 13).

### 5.4 Enumeration of Oracle summaries

By introducing threshold  $\tau$  as the best  $\text{ROUGE}_n$  score in the search history, pruning decisions involve the following three conditions:

---

**Algorithm 3** Branch and bound technique to enumerate oracle summaries

---

```

1: Read  $\mathbf{R}, D, L_{\max}$ 
2:  $\tau \leftarrow \text{GREEDY}(\mathbf{R}, D, L_{\max}), O_{\tau} \leftarrow \phi$ 
3: for each  $s \in D$  do
4:   append( $S, (\text{ROUGE}_n(\mathbf{R}, \{s\}), s)$ )
5: end for
6: sort( $S, \text{'descend'}$ )
7: call FINDORACLE( $S, C$ )
8: output  $O_{\tau}$ 
9: Procedure: FINDORACLE( $Q, V$ )
10: while  $Q \neq \phi$  do
11:    $s \leftarrow \text{shift}(Q)$ 
12:   append( $V, s$ )
13:   if  $L_{\max} - \ell(V) \geq 0$  then
14:     if  $\text{ROUGE}_n(\mathbf{R}, V) \geq \tau$  then
15:        $\tau \leftarrow \text{ROUGE}_n(\mathbf{R}, V)$ 
16:       append( $O_{\tau}, V$ )
17:       call FINDORACLE( $Q, V$ )
18:     else if  $\widehat{\text{ROUGE}}_n(\mathbf{R}, V) \geq \tau$  then
19:       call FINDORACLE( $Q, V$ )
20:     end if
21:   end if
22:   pop( $V$ )
23: end while
24: end

```

---

1.  $\text{ROUGE}_n(\mathbf{R}, V) \geq \tau$ ;
2.  $\text{ROUGE}_n(\mathbf{R}, V) < \tau, \widehat{\text{ROUGE}}_n(\mathbf{R}, V) < \tau$ ;
3.  $\text{ROUGE}_n(\mathbf{R}, V) < \tau, \widehat{\text{ROUGE}}_n(\mathbf{R}, V) \geq \tau$ .

With case 1, we update the oracle summary as  $V$  and continue the search. With case 2, because both  $\text{ROUGE}_n(\mathbf{R}, V)$  and  $\widehat{\text{ROUGE}}_n(\mathbf{R}, V)$  are smaller than  $\tau$ , the subtree whose root node is the current node (last visited node) is pruned from the search space, and we continue the depth-first search from the neighbor node. With case 3, we do not update oracle summary as  $V$  because  $\text{ROUGE}_n(\mathbf{R}, V)$  is less than  $\tau$ . However, we might obtain a better oracle summary by continuing the depth-first search because the upper bound of the  $\text{ROUGE}_n$  score exceeds  $\tau$ . Thus, we continue to search for the descendants of the current node.

Algorithm 3 shows the pseudocode that enumerates the oracle summaries. The algorithm reads a set of reference summaries  $\mathbf{R}$ , length limitation  $L_{\max}$ , and set of sentences  $D$  (line 1) and initializes threshold  $\tau$  as the  $\text{ROUGE}_n$  score obtained by the greedy algorithm (Algorithm 2). It also initializes  $O_{\tau}$ , which stores oracle summaries whose  $\text{ROUGE}_n$  scores are  $\tau$ , and priority queue  $C$ , which stores the history of the depth-first search (line 2). Next, the algorithm computes the  $\text{ROUGE}_n$  score for each sentence and stores  $S$  after sorting them in descending order. After that, we start a depth-first search by recursively call-

Year	Topics	Docs.	Sents.	Words	Refs.	Length
01	30	10	365	7706	89	100
02	59	10	238	4822	116	100
03	30	10	245	5711	120	100
04	50	10	218	4870	200	100
05	50	29.5	885	18273.5	300	250
06	50	25	732.5	15997.5	200	250
07	45	25	516	11427	180	250

Table 1: Statistics of data set

ing procedure FINDORACLE. In the procedure, we extract the top sentence from priority queue  $Q$  and append it to priority queue  $V$  (lines 11 to 12). When the length of  $V$  is less than  $L_{\max}$ , if  $\text{ROUGE}_n(\mathbf{R}, V)$  is larger than threshold  $\tau$  (case 1), we update  $\tau$  as the score and append current  $V$  to  $O_\tau$ . Then we continue the depth-first search by calling the procedure the FINDORACLE (lines 15 to 17). If  $\widehat{\text{ROUGE}}_n(\mathbf{R}, V)$  is larger than  $\tau$  (case 3), we do not update  $\tau$  and  $O_\tau$  but reenter the depth-first search by calling the procedure again (lines 18 to 19). If neither case 1 nor case 3 is true, we delete the last visited sentence from  $V$  and return to the top of the recurrence.

## 6 Experiments

### 6.1 Experimental Setting

We conducted experiments on the corpora developed for a multiple document summarization task in DUC 2001 to 2007. Table 1 show the statistics of the data. In particular, the DUC-2005 to -2007 data sets not only have very large numbers of sentences and words but also a long target length (the reference summary length) of 250 words.

All the words in the documents were stemmed by Porter’s stemmer (Porter, 1980). We computed  $\text{ROUGE}_1$  scores, excluding stopwords, and computed  $\text{ROUGE}_2$  scores, keeping them. Owczarzak et al. (2012) suggested using  $\text{ROUGE}_1$  and keeping stopwords. However, as Takamura et al. argued (Takamura and Okumura, 2009), the summaries optimized with non-content words failed to consider the actual quality. Thus, we excluded stopwords for computing the  $\text{ROUGE}_1$  scores.

We enumerated the following two types of oracle summaries: those for a set of references for a given topic and those for each reference in the set of references.

## 6.2 Results and Discussion

### 6.2.1 Impact of Oracle $\text{ROUGE}_n$ scores

Table 2 shows the average  $\text{ROUGE}_{1,2}$  scores of the oracle summaries obtained from both a set of references and each reference in the set (“multi” and “single”), those of the best conventional system (Peer), and those obtained from summaries produced by a greedy algorithm (Algorithm 2).

Oracle (single) obtained better  $\text{ROUGE}_{1,2}$  scores than Oracle (multi). The results imply that it is easier to optimize a reference summary than a set of reference summaries. On the other hand, the  $\text{ROUGE}_{1,2}$  scores of these oracle summaries are significantly higher than those of the best systems. The best systems obtained  $\text{ROUGE}_1$  scores from 60% to 70% in “multi” and from 50% to 60% in “single” as well as  $\text{ROUGE}_2$  scores from 40% to 55% in “multi” and from 30% to 40% in “single” for their oracle summaries.

Since the systems in Table 2 were developed over many years, we compared the  $\text{ROUGE}_n$  scores of the oracle summaries with those of the current state-of-the-art systems using the DUC-2004 corpus and obtained summaries generated by different systems from a public repository<sup>1</sup> (Hong et al., 2014). The repository includes summaries produced by the following seven state-of-the-art summarization systems: CLASSY04 (Conroy et al., 2004), CLASSY11 (Conroy et al., 2011), Submodular (Lin and Bilmes, 2012), DPP (Kulesza and Tasker, 2011), RegSum (Hong and Nenkova, 2014), OCCAMS\_V (Davie et al., 2012; Conroy et al., 2013), and ICSISumm (Gillick and Favre, 2009; Gillick et al., 2009). Table 3 shows the results.

Based on the results, RegSum (Hong and Nenkova, 2014) achieved the best  $\text{ROUGE}_1=0.331$  result, while ICSISumm (Gillick and Favre, 2009; Gillick et al., 2009) (a compressive summarizer) achieved the best result with  $\text{ROUGE}_2=0.098$ . These systems outperformed the best systems (Peers 65 and 67 in Table 2), but the differences in the  $\text{ROUGE}_n$  scores between the systems and the oracle summaries are still large. More recently, Hong et al. (2015) demonstrated that their system’s combination approach achieved the current best  $\text{ROUGE}_2$  score, 0.105, for the DUC-2004 corpus. However, a large difference remains between the  $\text{ROUGE}_2$  score of oracle and

their summaries.

In short, the ROUGE<sub>n</sub> scores of the oracle summaries are significantly higher than those of the current state-of-the-art summarization systems, both extractive and compressive summarization. These results imply that further improvement of the performance of extractive summarization is possible.

On the other hand, the ROUGE<sub>n</sub> scores of the oracle summaries are far from ROUGE<sub>n</sub> = 1. We believe that the results are related to the summary’s compression rate. The data set’s compression rate was only 1 to 2%. Thus, under tight length constraints, extractive summarization basically fails to cover large numbers of n-grams in the reference summary. This reveals the limitation of the extractive summarization paradigm and suggests that we need another direction, compressive or abstractive summarization, to overcome the limitation.

### 6.2.2 ROUGE Scores of Summaries Obtained from Greedy Algorithm

Table 2 also shows the ROUGE<sub>1,2</sub> scores of the summaries obtained from the greedy algorithm (greedy summaries). Although there are statistically significant differences between the ROUGE

	single	multi
ROUGE <sub>1</sub>	.451	.419
ROUGE <sub>2</sub>	.536	.530

Table 4: Jaccard Index between both oracle and greedy summaries

scores of the oracle summaries and greedy summaries, those obtained from the greedy summaries achieved near optimal scores, *i.e.*, approximation ratio of them are close to 0.9. These results are surprising since the algorithm’s theoretical lower bound is  $\frac{1}{2}(1 - \frac{1}{e})(\simeq 0.32)$ OPT.

On the other hand, the results do not support that the differences between them are small at the sentence-level. Table 4 shows the average Jaccard Index between the oracle summaries and the corresponding greedy summaries for the DUC-2004 corpus. The results demonstrate that the oracle summaries are much less similar to the greedy summaries at the sentence-level. Thus, it might not be appropriate to use greedy summaries as training data for learning-based extractive summarization systems.

### 6.2.3 Impact of Enumeration

Table 5 shows the median number of oracle summaries and the rates of the reference summaries that have multiple oracle summaries for each data set. Over 80% of the reference summaries and about 60% to 90% of the topics have multiple oracle summaries. Since the ROUGE<sub>n</sub> scores are based on the unweighted counting of n-grams, when many sentences have similar meanings, *i.e.*, many redundant sentences, the number of oracle summaries that have the same ROUGE<sub>n</sub> scores increases. The source documents of multiple document summarization tasks are prone to have many such redundant sentences, and the amount of oracle summaries is large.

	Median				Rate			
	single		multi		single		multi	
	ROUGE <sub>1</sub>	ROUGE <sub>2</sub>						
01	8	9	4	5	.854	.787	.833	.733

07	23	16	4	2	.910	.878	.733	.711

Table 5: Median number of oracle summaries and rates of reference summaries and topics with multiple oracle summaries for each data set

The oracle summaries offer significant benefit with respect to evaluating the extracted sentences. Since both the oracle and system summaries are sets of sentences, it is easy to check whether each sentence in the system summary is contained in one of the oracle summaries. Thus, we can exploit the F-measures, which are useful for evaluating classification-based extractive summarization (Mani and Bloedorn, 1998; Osborne, 2002; Hirao et al., 2002). Here, we have to consider that the oracle summaries, obtained from a reference summary or a set of reference summaries, are not identical at the sentence-level (e.g., the average Jaccard Index between the oracle summaries for the DUC-2004 corpus is around 0.5). The F-measures are varied with the oracle summaries that are used for such computation. For example, assume that we have system summary  $S = \{s_1, s_2, s_3, s_4\}$  and oracle summaries  $O_1 = \{s_1, s_2, s_5, s_6\}$  and  $O_2 = \{s_1, s_2, s_3\}$ . The precision for  $O_1$  is 0.5, while that for  $O_2$  is 0.75; the recall for  $O_1$  is 0.5, while that for  $O_2$  is 1; the F-measure for  $O_1$  is 0.5, while that for  $O_2$  is 0.86.

Thus, we employ the scores gained by averaging all of the oracle summaries as evaluation measures. Precision, recall, and F-measure are defined as follows:  $P = \{\sum_{O \in O_{all}} |O \cap S| / |S|\} / |O_{all}|$ ,  $R = \{\sum_{O \in O_{all}} |O \cap S| / |O|\} / |O_{all}|$ ,  $F\text{-measure} = 2PR / (P + R)$ .

To demonstrate F-measure’s effectiveness, we investigated the correlation between an F-measure and human judgment based on the evaluation results obtained from the DUC-2004 corpus. The results include summaries generated by 17 systems, each of which has a mean coverage score assigned by a human subject. We computed the correla-

tion coefficients between the average F-measure and the average mean coverage score for 50 topics. Table 6 shows Pearson’s  $r$  and Spearman’s  $\rho$ . In the table, “F-measure ( $R_1$ )” and “F-measure ( $R_2$ )” indicate the F-measures calculated using oracle summaries optimized to ROUGE<sub>1</sub> and ROUGE<sub>2</sub>, respectively. “M” indicates the F-measure calculated using multiple oracle summaries, and “S” indicates F-measures calculated using randomly selected oracle summaries. “multi” indicates oracle summaries obtained from a set of references, and “single” indicates oracle summaries obtained from a reference summary in the set. For “S,” we randomly selected a single oracle summary and calculated the F-measure 100 times and took the average value with the 95% confidence interval of the F-measures by bootstrap resampling.

The results demonstrate that the F-measures are strongly correlated with human judgment. Their values are comparable with those of ROUGE<sub>1,2</sub>. In particular, F-measure ( $R_1$ ) (single-M) achieved the best Spearman’s  $\rho$  result. When comparing “single” with “multi,” Pearson’s  $r$  of “multi” was slightly lower than that of “single,” and the Spearman’s  $r$  of “multi” was almost the same as those of “single.” “M” has significantly better performance than “S.” These results imply that F-measures based on oracle summaries are a good evaluation measure and that oracle summaries have the potential to be an alternative to human-made reference summaries in terms of automatic evaluation. Moreover, the enumeration of the oracle summaries for a given reference summary or a set of reference summaries is essential for automatic evaluation.

Metric	$r$	$\rho$
ROUGE <sub>1</sub>	.861	.760
ROUGE <sub>2</sub>	<b>.907</b>	.831
F-measure (R <sub>1</sub> ) (single-M)	.857	<b>.855</b>
F-measure (R <sub>1</sub> ) (single-S)	.815-.830	.811-.830
F-measure (R <sub>2</sub> ) (single-M)	.904	.826
F-measure (R <sub>2</sub> ) (single-S)	.855-.865	.740-.760
F-measure (R <sub>1</sub> ) (multi-M)	.814	.841
F-measure (R <sub>1</sub> ) (multi-S)	.794-.802	.803-.813
F-measure (R <sub>2</sub> ) (multi-M)	.824	.846
F-measure (R <sub>2</sub> ) (multi-S)	.806-.816	.797-.817

### 6.2.4 Search Efficiency

To demonstrate the efficiency of our search algorithm against the naive exhaustive search method, we compared the number of feasible solutions (sets of sentences that satisfy the length constraint) with the number of summaries that were checked in our search algorithm.

Table 7 shows the median number of feasible solutions and checked summaries yielded by our method for each data set (in the case of “single”). The differences in the number of feasible solutions between ROUGE<sub>1</sub> and ROUGE<sub>2</sub> are very large. Input set ( $|D|$ ) of ROUGE<sub>1</sub> is much larger than ROUGE<sub>2</sub>. On the other hand, the differences between ROUGE<sub>1</sub> and ROUGE<sub>2</sub> in our method are of the order of 10 to 10<sup>2</sup>. When comparing our method with naive exhaustive searches, its search space is significantly smaller. The differences are of the order of 10<sup>7</sup> to 10<sup>30</sup> with ROUGE<sub>1</sub> and 10<sup>4</sup> to 10<sup>17</sup> with ROUGE<sub>2</sub>. These results demonstrate the efficiency of our branch and bound technique.

In addition, we show an example of the processing time for extracting one oracle summary and enumerating all of the oracle summaries for the reference summaries in the DUC-2004 corpus with a Linux machine (CPU: Intel<sup>®</sup> Xeon<sup>®</sup> X5675 (3.07GHz)) with 192 GB of RAM. We utilized CPLEX 12.1 to solve the ILP problem. Our algorithm was implemented in C++ and compiled with GCC version 4.4.7. The results show that we needed 0.026 and 0.021 sec. to extract one oracle summary per reference summary and 0.047 and 0.031 sec. to extract one oracle summary per set of reference summaries for ROUGE<sub>1</sub> and ROUGE<sub>2</sub>, respectively. We needed 11.90 and 1.40 sec. to enumerate the oracle summaries per reference summary and 102.94 and 3.65 sec. per set of reference summaries for ROUGE<sub>1</sub> and

	ROUGE <sub>1</sub>		ROUGE <sub>2</sub>	
	Naive	Proposed	Naive	Proposed
01	3.66×10 <sup>13</sup>	5.75×10 <sup>3</sup>	3.32×10 <sup>7</sup>	1.00×10 <sup>3</sup>
02	1.12×10 <sup>12</sup>	4.64×10 <sup>3</sup>	1.34×10 <sup>7</sup>	8.87×10 <sup>2</sup>
03	1.62×10 <sup>11</sup>	3.65×10 <sup>3</sup>	6.37×10 <sup>6</sup>	8.19×10 <sup>2</sup>
04	9.65×10 <sup>10</sup>	4.47×10 <sup>3</sup>	6.90×10 <sup>6</sup>	9.83×10 <sup>2</sup>
05	5.48×10 <sup>36</sup>	2.32×10 <sup>6</sup>	3.48×10 <sup>21</sup>	7.03×10 <sup>4</sup>
06	1.94×10 <sup>32</sup>	1.97×10 <sup>6</sup>	2.11×10 <sup>20</sup>	5.08×10 <sup>4</sup>
07	4.14×10 <sup>28</sup>	1.40×10 <sup>6</sup>	1.81×10 <sup>19</sup>	2.60×10 <sup>4</sup>

Table 7: Median number of summaries checked by each search method

ROUGE<sub>2</sub>, respectively. The extraction of one oracle summary for a reference summary can be achieved with the ILP solver in practical time and the enumeration of oracle summaries is also efficient. However, to enumerate oracle summaries, we needed several weeks for some topics in DUCs 2005 to 2007 since they hold a huge number of source sentences.

## 7 Conclusions

To analyze the limitations and the future direction of extractive summarization, this paper proposed (1) Integer Linear Programming (ILP) formulation to obtain extractive oracle summaries in terms of ROUGE<sub>n</sub> scores and (2) an algorithm that enumerates all oracle summaries to exploit F-measures that evaluate the sentences extracted by systems.

The evaluation results obtained from the corpora of DUCs 2001 to 2007 identified the following: (1) room still exists to improve the ROUGE<sub>n</sub> scores of extractive summarization systems even though the ROUGE<sub>n</sub> scores of the oracle summaries fell below the theoretical upper bound ROUGE<sub>n</sub>=1. (2) Over 80% of the reference summaries and from 60% to 90% of the sets of reference summaries have multiple oracle summaries, and the F-measures computed by utilizing the enumerated oracle summaries showed stronger correlation with human judgment than those computed from single oracle summaries.

## Abstract

We present a memory augmented neural network for natural language understanding: Neural Semantic Encoders. NSE is equipped with a novel memory update rule and has a variable sized encoding memory that evolves over time and maintains the understanding of input sequences through *read*, *compose* and *write* operations. NSE can also access<sup>1</sup> multiple and shared memories. In this paper, we demonstrated the effectiveness and the flexibility of NSE on five different natural language tasks: natural language inference, question answering, sentence classification, document sentiment analysis and machine translation where NSE achieved state-of-the-art performance when evaluated on publically available benchmarks. For example, our shared-memory model showed an encouraging result on neural machine translation, improving an attention-based baseline by approximately 1.0 BLEU.

## 1 Introduction

Recurrent neural networks (RNNs) have been successful for modeling sequences (Elman, 1990). Particularly, RNNs equipped with internal short memories, such as long short-term memories (LSTM) (Hochreiter and Schmidhuber, 1997) have achieved a notable success in sequential tasks (Cho et al., 2014; Vinyals et al., 2015). LSTM is powerful because it learns to control its short term memories. However, the short term memories in LSTM are a part of the training parameters. This imposes some practical difficulties in training and modeling long sequences with LSTM.

<sup>1</sup>By access we mean changing the memory states by the *read*, *compose* and *write* operations.

Recently several studies have explored ways of extending the neural networks with an external memory (Graves et al., 2014; Weston et al., 2015; Grefenstette et al., 2015). Unlike LSTM, the short term memories and the training parameters of such a neural network are no longer coupled and can be adapted. In this paper we propose a novel class of memory augmented neural networks called Neural Semantic Encoders (NSE) for natural language understanding. NSE offers several desirable properties. NSE has a variable sized encoding memory which allows the model to access entire input sequence during the reading process; therefore efficiently delivering long-term dependencies over time. The encoding memory evolves over time and maintains the memory of the input sequence through *read*, *compose* and *write* operations. NSE sequentially processes the input and supports word compositionality inheriting both temporal and hierarchical nature of human language. NSE can read from and write to a set of relevant encoding memories simultaneously or multiple NSEs can access a shared encoding memory effectively supporting knowledge and representation sharing. NSE is flexible, robust and suitable for practical NLU tasks and can be trained easily by any gradient descent optimizer.

We evaluate NSE on five different real tasks. For four of them, our models set new state-of-the-art results. Our results suggest that a NN model with the shared memory between encoder and decoder is a promising approach for sequence transduction problems such as machine translation and abstractive summarization. In particular, we observe that the attention-based neural machine translation can be further improved by shared-memory models. We also analyze memory access pattern and compositionality in NSE and show that our model captures semantic and syntactic structures of input sentence.

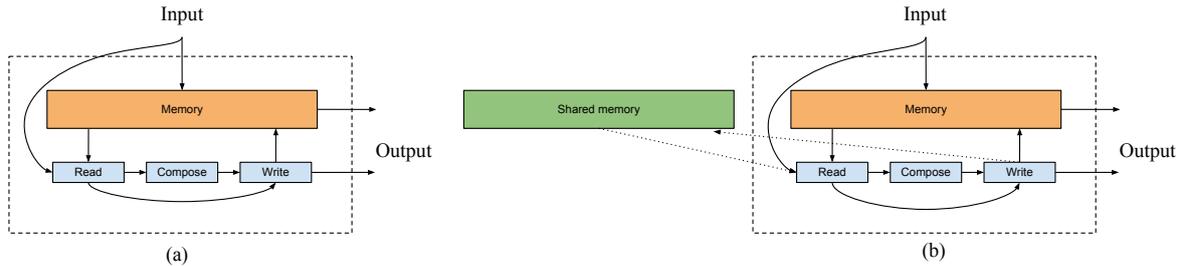

Figure 1: High-level architectures of the Neural Semantic Encoders. NSE reads and writes its own encoding memory in each time step (a). MMA-NSE accesses multiple relevant memories simultaneously (b).

## 2 Related Work

One of the pioneering work that attempts to extend deep neural networks with an external memory is Neural Turing Machines (NTM) (Graves et al., 2014). NTM implements a centralized controller and a fixed-sized random access memory. The NTM memory is addressable by both content (i.e. soft attention) and location based access mechanisms. The authors evaluated NTM on algorithmic tasks such as copying and sorting sequences.

**Comparison with Neural Turing Machines:** NSE addresses certain drawbacks of NTM. NTM has a single centralized controller, which is usually an MLP or RNN while NSE takes a modular approach. The main controller in NSE is decomposed into three separate modules, each of which performs for *read*, *compose* or *write* operation. In NSE, the *compose* module is introduced in addition to the standard memory update operations (i.e. read-write) in order to process the memory entries and input information.

The main advantage of NSE over NTM is in its memory update. Despite its sophisticated addressing mechanism, the NTM controller does not have mechanism to avoid *information collision* in the memory. Particularly the NTM controller emits two separate set of access weights (i.e. read weight and erase and write weights) that do not explicitly encode the knowledge about where information is read from and written to. Moreover the fixed-size memory in NTM has no memory allocation or de-allocation protocol. Therefore unless the controller is intelligent enough to track the previous read/write information, which is hard for an RNN when processing long sequences, the memory content is overlapped and information is over-

written throughout different time scales. We think that this is a potential reason that makes NTM hard to train and makes the training not stable. We also note that the effectiveness of the location based addressing introduced in NTM is unclear. In NSE, we introduce a novel and systematic memory update approach based on the soft attention mechanism. NSE writes new information to the most recently read memory locations. This is accomplished by sharing the same memory key vector between the read and write modules. The NSE memory update is scalable and potentially more robust to train. NSE is provided with a variable sized memory and thus unlike NTM, the size of the NSE memory is more relaxed. The novel memory update mechanism and the variable sized memory together prevent NSE from the *information collision* issue and avoid the need of the memory allocation and de-allocation protocols. Each memory location of the NSE memory stores a token representation in input sequence during encoding. This provides NSE with an anytime-access to the entire input sequence including the tokens from the future time scales, which is not permitted in NTM, RNN and attention-based encoders.

Lastly, NTM addresses small algorithmic problems while NSE focuses on a set of large-scale language understanding tasks.

The RNNSearch model proposed in (Bahdanau et al., 2015) can be seen as a variation of memory augmented networks due to its ability to read the historic output states of RNNs with soft attention. The work of Sukhbaatar et al. (2015) combines the soft attention with Memory Networks (MemNNs) (Weston et al., 2015). Similar to RNNSearch, MemNNs are designed with non-writable memories. It constructs layered memory representa-

tions and showed promising results on both artificial and real question answering tasks. We note that RNNSearch and MemNNs avoid the memory update and management overhead by simply using a non-writable memory storage. Another variation of MemNNs is Dynamic Memory Network (Kumar et al., 2016) that is equipped with an episodic memory and seems to be flexible in different settings.

Although NSE differs from other memory-augmented NN models in many aspects, they all use soft attention mechanism with a type of similarity measures to retrieve relevant information from the external memory. For example, NTM implements cosine similarity and MemNNs use vector dot product. NSE uses the vector dot product for the similarity measure in NSE because it is faster to compute.

Other related work includes Neural Program-Interpreters (Reed and de Freitas, 2016), which learns to run sub-programs and to compose them for high-level programs. It uses execution traces to provide the full supervision. Researchers have also explored ways to add unbounded memory to LSTM (Grefenstette et al., 2015) using a particular data structure. Although this type of architecture provides a flexible capacity to store information, the memory access is constrained by the data structure used for the memory bank, such as stack and queue.

Overall it is expensive to train and to scale the previously proposed memory-based models. Most models required a set of clever engineering tricks to work successfully. Most of the aforementioned memory augmented neural networks have been tested on synthetic tasks whereas in this paper we evaluated NSE on a wide range of real and large-scale natural language applications.

### 3 Proposed Approach

Our training set consists of  $N$  examples  $\{X^i, Y^i\}_{i=1}^N$ , where the input  $X^i$  is a sequence  $w_1^i, w_2^i, \dots, w_{T_i}^i$  of tokens while the output  $Y^i$  can be either a single target or a sequence. We transform each input token  $w_t$  to its word embedding  $x_t$ .

Our Neural Semantic Encoders (NSE) model has four main components: read, compose and write modules and an encoding memory  $M \in R^{k \times l}$  with a variable number of slots, where  $k$  is the embedding dimension and  $l$  is the length

of the input sequence. Each memory slot vector  $m_t \in R^k$  corresponds to the vector representation of information about word  $w_t$  in memory. In particular, the memory is initialized by the embedding vectors  $\{x_t\}_{t=1}^l$  and is evolved over time, through *read*, *compose* and *write* operations. Figure 1 (a) illustrates the architecture of NSE.

#### 3.1 Read, Compose and Write

NSE performs three main operations in every time step. After initializing the memory slots with the corresponding input representations, NSE processes an embedding vector  $x_t$  and retrieves a memory slot  $m_{r,t}$  that is expected to be associatively coherent (i.e. semantically associated) with the current input word  $w_t$ .<sup>2</sup> The slot location  $r$  (ranging from 1 to  $l$ ) is defined by a key vector  $z_t$  which the read module emits by attending over the memory slots. The compose module implements a composition operation that combines the memory slot with the current input. The write module then transforms the composition output to the encoding memory space and writes the resulting new representation into the slot location of the memory. Instead of composing the raw embedding vector  $x_t$ , we use the hidden state  $o_t$  produced by the read module at time  $t$

Concretely, let  $e_l \in R^l$  and  $e_k \in R^k$  be vectors of ones and given a read function  $f_r^{LSTM}$ , a composition  $f_c^{MLP}$  and a write  $f_w^{LSTM}$  NSE in Figure 1 (a) computes the key vector  $z_t$ , the output state  $h_t$ , and the encoding memory  $M_t$  in time step  $t$  as

$$o_t = f_r^{LSTM}(x_t) \quad (1)$$

$$z_t = \text{softmax}(o_t^\top M_{t-1}) \quad (2)$$

$$m_{r,t} = z_t^\top M_{t-1} \quad (3)$$

$$c_t = f_c^{MLP}(o_t, m_{r,t}) \quad (4)$$

$$h_t = f_w^{LSTM}(c_t) \quad (5)$$

$$M_t = M_{t-1}(\mathbf{1} - (z_t \otimes e_k)^\top) + (h_t \otimes e_l)(z_t \otimes e_k)^\top \quad (6)$$

where  $\mathbf{1}$  is a matrix of ones,  $\otimes$  denotes the outer product which duplicates its left vector  $l$  or  $k$  times to form a matrix. The read function  $f_r^{LSTM}$  sequentially maps the word embeddings to the internal space of the memory  $M_{t-1}$ . Then Equation 2 looks for the slots related to the input by computing association degree between each memory slot

<sup>2</sup>Such a coherence is calculated by a soft attention with dot product similarity.

and the hidden state  $o_t$ . We calculate the association degree by the dot product and transform this scores to the fuzzy key vector  $z_t$  by normalizing with *softmax* function. Since our key vector is fuzzy, the slot to be composed is retrieved by taking weighted sum of the all slots as in Equation 3. This process can also be seen as the soft attention mechanism (Bahdanau et al., 2015). In Equation 4 and 5, we compose and process the retrieved slot with the current hidden state and map the resulting vector to the encoder output space. Finally, we write the new representation to the memory location pointed by the key vector in Equation 6 where the key vector  $z_t$  emitted by the read module is reused to inform the write module of the most recently read slots. First the slot information that was retrieved is erased and then the new representation is located. NSE performs this iterative process until all words in the input sequence are read. The encoding memories  $\{M\}_{t=1}^T$  and output states  $\{h\}_{t=1}^T$  are further used for the tasks.

Although NSE reads a single word at a time, it has an anytime-access to the entire sequence stored in the encoding memory. With the encoding memory, NSE maintains a mental image of the input sequence. The memory is initialized with the raw embedding vector at time  $t = 0$ . We term such a freshly initialized memory a *baby* memory. As NSE reads more input content in time, the *baby* memory evolves and refines the encoded mental image.

The read  $f_r^{LSTM}$ , the composition  $f_c^{MLP}$  and the write  $f_w^{LSTM}$  functions are neural networks and are the training parameters in our NSE. As the name suggests, we use LSTM and multi-layer perceptron (MLP) in this paper. Since NSE is fully differentiable, it can be trained with any gradient descent optimizer.

### 3.2 Shared and Multiple Memory Accesses

For sequence to sequence transduction tasks like question answering, natural language inference and machine translation, it is beneficial to access other relevant memories in addition to its own one. The shared or the multiple memory access allows a set of NSEs to exchange knowledge representations and to communicate with each other to accomplish a particular task throughout the encoding memory.

NSE can be extended easily, so that it is able to read from and write to multiple memories si-

multaneously or multiple NSEs are able to access a shared memory. Figure 1 (b) depicts a high-level architectural diagram of a multiple memory access-NSE (MMA-NSE). The first memory (in green) is the shared memory accessed by more than one NSEs. Given a shared memory  $M^n \in R^{k \times n}$  that has been encoded by processing a relevant sequence with length  $n$ , MMA-NSE with the access to one relevant memory is defined as

$$o_t = f_r^{LSTM}(x_t) \quad (7)$$

$$z_t = softmax(o_t^\top M_{t-1}) \quad (8)$$

$$m_{r,t} = z_t^\top M_{t-1} \quad (9)$$

$$z_t^n = softmax(o_t^\top M_{t-1}^n) \quad (10)$$

$$m_{r,t}^n = z_t^{n\top} M_{t-1}^n \quad (11)$$

$$c_t = f_c^{MLP}(o_t, m_{r,t}, m_{r,t}^n) \quad (12)$$

$$h_t = f_w^{LSTM}(c_t) \quad (13)$$

$$M_t = M_{t-1}(\mathbf{1} - (z_t \otimes e_k)^\top) + (h_t \otimes e_l)(z_t \otimes e_k)^\top \quad (14)$$

$$M_t^n = M_{t-1}^n(\mathbf{1} - (z_t^n \otimes e_k)^\top) + (h_t \otimes e_n)(z_t^n \otimes e_k)^\top \quad (15)$$

and this is almost the same as standard NSE. The read module now emits the additional key vector  $z_t^n$  for the shared memory and the composition function  $f_c^{MLP}$  combines more than one slots.

In MMA-NSE, the different memory slots are retrieved from the shared memories depending on their encoded semantic representations. They are then composed together with the current input and written back to their corresponding slots. Note that MMA-NSE is capable of accessing a variable number of relevant shared memories once a composition function that takes in dynamic inputs is chosen.

## 4 Experiments

We describe in this section experiments on five different tasks, in order to show that NSE can be effective and flexible in different settings.<sup>3</sup> We report results on natural language inference, question answering (QA), sentence classification, document sentiment analysis and machine translation. All five tasks challenge a model in terms of language understanding and semantic reasoning.

The models are trained using Adam (Kingma and Ba, 2014) with hyperparameters selected on

<sup>3</sup>Code for the experiments and NSEs is available at <https://bitbucket.org/tsendeemts/nse>.

Model	$d$	$ \theta _M$	Train	Test
Classifier with handcrafted features (Bowman et al., 2015)	-	-	99.7	78.2
LSTM encoders (Bowman et al., 2015)	300	3.0M	83.9	80.6
Dependency Tree CNN encoders (Mou et al., 2016)	300	3.5M	83.3	82.1
SPINN-PI encoders (Bowman et al., 2016)	300	3.7M	89.2	83.2
NSE	300	3.4M	86.2	84.6
MMA-NSE	300	6.3M	87.1	<b>84.8</b>
LSTM attention (Rocktäschel et al., 2016)	100	242K	85.4	82.3
LSTM word-by-word attention (Rocktäschel et al., 2016)	100	252K	85.3	83.5
MMA-NSE attention	300	6.5M	86.9	85.4
mLSTM word-by-word attention (Wang and Jiang, 2015)	300	1.9M	92.0	86.1
LSTMN with deep attention fusion (Cheng et al., 2016)	450	3.4M	89.5	86.3
Decomposable attention model (Parikh et al., 2016)	200	582K	90.5	86.8
Full tree matching NTI-SLSTM-LSTM global attention (Munkhdalai and Yu, 2017)	300	3.2M	88.5	<b>87.3</b>

Table 1: Training and test accuracy on natural language inference task.  $d$  is the word embedding size and  $|\theta|_M$  the number of model parameters.

development set. We chose two one-layer LSTM for read/write modules on the tasks other than QA on which we used two-layer LSTM. The pre-trained 300-D Glove 840B vectors and 100-D Glove 6B vectors (Pennington et al., 2014) were obtained for the word embeddings.<sup>4</sup> The word embeddings are fixed during training. The embeddings for out-of-vocabulary words were set to zero vector. We crop or pad the input sequence to a fixed length. A padding vector was inserted when padding. The models were regularized by using dropouts and an  $l_2$  weight decay.<sup>5</sup>

#### 4.1 Natural Language Inference

The natural language inference is one of the main tasks in language understanding. This task tests the ability of a model to reason about the semantic relationship between two sentences. In order to perform well on the task, NSE should be able to capture sentence semantics and be able to reason the relation between a sentence pair, i.e., whether a premise-hypothesis pair is entailing, contradictory or neutral. We conducted experiments on the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015), which consists of 549,367/9,842/9,824 premise-hypothesis pairs for train/dev/test sets and target label indicating their relation.

Following the setting in (Mou et al., 2016; Bowman et al., 2016) the NSE output for each sentence was the input to a MLP, where the input layer computes the concatenation  $[h_i^p; h_i^h]$ , absolute difference  $h_i^p - h_i^h$  and elementwise product  $h_i^p \cdot h_i^h$  of the two sentence representations. In addition, the MLP has a hidden layer with 1024 units with

*ReLU* activation and a *softmax* layer. We set the batch size to 128, the initial learning rate to  $3e-4$  and  $l_2$  regularizer strength to  $3e-5$ , and train each model for 40 epochs. The write/read neural nets and the last linear layer were regularized by using 30% dropouts.

We evaluated three different variations of NSE show in Table 1. The NSE model encodes each sentence simultaneously by using a separate memory for each sentence. The second model - MMA-NSE first encodes the premise and then the hypothesis sentence by sharing the premise encoded memory in addition to the hypothesis memory. For the third model, we use inter-sentence attention which selectively reconstructs the premise representation.

Table 1 shows the results of our models along with the results of published methods for the task. The classifier with handcrafted features extracts a set of lexical features. The next group of models are based on sentence encoding. While most of the sentence encoder models rely solely on word embeddings, the dependency tree CNN and the SPINN-PI models make use of sentence parser output. The SPINN-PI model is similar to NSE in spirit that it also explicitly computes word composition. However, the composition in the SPINN-PI is guided by supervisions from a dependency parser. NSE outperformed the previous sentence encoders on this task. The MMA-SNE further slightly improved the result, indicating that reading the premise memory is helpful while encoding the hypothesis.

The last set of methods designs inter-sentence relation with parameterized soft attention (Bahdanau et al., 2015). Our MMA-NSE attention model is similar to the LSTM attention model.

<sup>4</sup><http://nlp.stanford.edu/projects/glove/>

<sup>5</sup>More detail on hyper-parameters can be found in code.

Particularly, it attends over the premise encoder outputs  $\{h^p\}_{t=1}^T$  in respect to the final hypothesis representation  $h_t^h$  and constructs an attentively blended vector of the premise. This model obtained 85.4% accuracy score. The best performing model for this task performs tree matching with attention mechanism and LSTM.

## 4.2 Answer Sentence Selection

Answer sentence selection is an integral part of the open-domain question answering. For this task, a model is trained to identify the correct sentences that answer a factual question, from a set of candidate sentences. We experiment on WikiQA dataset constructed from Wikipedia (Yang et al., 2015). The dataset contains 20,360/2,733/6,165 QA pairs for train/dev/test sets.

The MLP setup used in the language inference task is kept same, except that we now replace the *softmax* layer with a *sigmoid* layer and model the following conditional probability distribution.

$$p_{\theta}(y = 1|h_t^q, h_t^a) = \text{sigmoid}(o^{QA}) \quad (16)$$

where  $h_t^q$  and  $h_t^a$  are the question and the answer encoded vectors and  $o^{QA}$  denotes the output of the hidden layer of the MLP. We trained the MMA-NSE attention model to minimize the *sigmoid* cross entropy loss. MMA-NSE first encodes the answers and then the questions by accessing its own and the answer encoding memories. In our preliminary experiment, we found that the multiple memory access and the attention over answer encoder outputs  $\{h^a\}_{t=1}^T$  are crucial to this problem. Following previous work, we adopt MAP and MRR as the evaluation metrics for this task.<sup>6</sup>

We set the batch size to 4 and the initial learning rate to 1e-5, and train the model for 10 epochs. We used 40% dropouts after word embeddings and no

<sup>6</sup>We used *trac\_eval* script to calculate the evaluation metrics

Model	MAP	MRR
Classifier with features (2013)	0.5993	0.6068
Paragraph Vector (2014)	0.5110	0.5160
Bigram-CNN (2014)	0.6190	0.6281
3-layer LSTM (2016)	0.6552	0.6747
3-layer LSTM attention (2016)	0.6639	0.6828
NASM (2016)	0.6705	0.6914
MMA-NSE attention	<b>0.6811</b>	<b>0.6993</b>

Table 2: Experiment results on answer sentence selection.

$l_2$  weight decay. The word embeddings are pre-trained 300-D Glove 840B vectors. For this task, a linear mapping layer transforms the 300-D word embeddings to the 512-D LSTM inputs.

Table 2 presents the results of our model and the previous models for the task.<sup>7</sup> The classifier with handcrafted features is a SVM model trained with a set of features. The Bigram-CNN model is a simple convolutional neural net. While the LSTM and LSTM attention models outperform the previous best result by nearly 5-6% by implementing deep LSTM with three hidden layers, NASM improves it further and sets a strong baseline by combining variational auto-encoder (Kingma and Welling, 2014) with the soft attention. Our MMA-NSE attention model exceeds the NASM by approximately 1% on MAP and 0.8% on MRR for this task.

## 4.3 Sentence Classification

We evaluated NSE on the Stanford Sentiment Treebank (SST) (Socher et al., 2013). This dataset comes with standard train/dev/test sets and two subtasks: binary sentence classification or fine-grained classification of five classes. We trained our model on the text spans corresponding to labeled phrases in the training set and evaluated the model on the full sentences.

The sentence representations were passed to a two-layer MLP for classification. The first layer of the MLP has *ReLU* activation and 1024 or 300 units for binary or fine-grained setting. The second layer is a *softmax* layer. The read/write modules are two one-layer LSTM with 300 hidden units and the word embeddings are the pre-trained 300-D Glove 840B vectors. We set the batch size to 64, the initial learning rate to 3e-4 and  $l_2$  regularizer strength to 3e-5, and train each model for 25 epochs. The write/read neural nets and the last linear layer were regularized by 50% dropouts.

Table 3 compares the result of our model with the state-of-the-art methods on the two subtasks. Most best performing methods exploited the parse tree provided in the treebank on this task with the exception of the DMN. The Dynamic Memory Network (DMN) model is a memory-augmented network. Our model outperformed the DMN and set the state-of-the-art results on both subtasks.

<sup>7</sup>Inclusion of simple word count feature improves the performance by around 0.15-0.3 across the board

Model	Bin	FG
RNTN (Socher et al., 2013)	85.4	45.7
Paragraph Vector (Le and Mikolov, 2014)	87.8	48.7
CNN-MC (Kim, 2014)	88.1	47.4
DRNN (Irsoy and Cardie, 2015)	86.6	49.8
2-layer LSTM(Tai et al., 2015)	86.3	46.0
Bi-LSTM(Tai et al., 2015)	87.5	49.1
CT-LSTM(Tai et al., 2015)	88.0	51.0
DMN (Kumar et al., 2016)	88.6	52.1
NSE	<b>89.7</b>	<b>52.8</b>

Table 3: Test accuracy for sentence classification. Bin: Binary, FG: fine-grained 5 classes.

#### 4.4 Document Sentiment Analysis

We evaluated our models for document-level sentiment analysis on two publically available large-scale datasets: the IMDB consisting of 335,018 movie reviews and 10 different classes and Yelp 13 consisting of 348,415 restaurant reviews and 5 different classes. Each document in the datasets is associated with human ratings and we used these ratings as gold labels for sentiment classification. Particularly, we used the pre-split datasets of (Tang et al., 2015).

We stack a NSE or LSTM on the top of another NSE for document modeling. The first NSE encodes the sentences and the second NSE or LSTM takes sentence encoded outputs and constructs document representations. The document representation is given to a output *softmax* layer. The whole network is trained jointly by backpropagating the cross entropy loss. We used one-layer LSTM with 100 hidden units for the read/write modules and the pre-trained 100-D Glove 6B vectors for this task. We set the batch size to 32, the initial learning rate to  $3e-4$  and  $l_2$  regularizer strength to  $1e-5$ , and trained each model for 50 epochs. The write/read neural nets and the document-level NSE/LSTM were regularized by 15% dropouts and the softmax layer by 20% dropouts. In order to speedup the training, we created document buckets by considering the number of sentences per document, i.e., documents with the same number of sentences were put together in the same bucket. The buckets were shuffled and updated per epoch. We did not use curriculum scheduling (Bengio et al., 2009), although it is observed to help sequence training.

Table 4 shows our results. We report two performance metrics: accuracy and MSE. The best results on the task were previously obtained by Conv-GRNN and LSTM-GRNN, which are also

Model	Yelp 13		IMDB	
	Acc	MSE	Acc	MSE
Classifier (2015)	59.8	0.68	40.5	3.56
PV (2015)	57.7	0.86	34.1	4.69
CNN (2015)	59.7	0.76	37.6	3.30
Conv-GRNN (2015)	63.7	0.56	42.5	2.71
LSTM-GRNN (2015)	65.1	0.50	45.3	3.00
NSE-NSE	66.6	0.48	<b>48.3</b>	<b>1.94</b>
NSE-LSTM	<b>67.0</b>	<b>0.47</b>	48.1	1.98

Table 4: Results of document-level sentiment classification. PV: paragraph vector, Acc: accuracy, and MSE: mean squared error.

Model	Train	Dev	Test
Baseline LSTM-LSTM	28.06	17.96	17.02
NSE-LSTM	28.73	17.67	17.13
NSE-NSE	29.89	<b>18.53</b>	<b>17.93</b>

Table 5: BLEU scores for English-German translation task.

stacked models. These models first learn the sentence representations with a CNN or LSTM and then combine them for document representation using a gated recurrent neural network (GRNN). Our NSE models outperformed the previous state-of-the-art models in terms of both accuracy and MSE, by approximately 2-3%. On the other hand, all systems tend to show poor results on the IMDB dataset. That is, the IMDB dataset contains longer documents than the Yelp 13 and it has 10 classes while the Yelp 13 dataset has five classes to distinguish.<sup>8</sup> The stacked NSEs (NSE-NSE) performed slightly better than the NSE-LSTM on the IMDB dataset. This is possibly due to the encoding memory of the document level NSE that preserves the long dependency in documents with a large number of sentences.

#### 4.5 Machine Translation

Lastly, we conducted an experiment on neural machine translation (NMT). The NMT problem is mostly defined within the encoder-decoder framework (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014). The encoder provides the semantic and syntactic information about the source sentences to the decoder and the decoder generates the target sentences by conditioning on this information and its partially produced translation. For an efficient encoding, the attention-based NMT was introduced (Bahdanau et al., 2015).

<sup>8</sup>The average number of sentences and words in a document for IMDB: 14, 152 and Yelp 13: 9, 326

For NTM, we implemented three different models. The first model is a baseline model and is similar to the one proposed in (Bahdanau et al., 2015) (RNNSearch). This model (LSTM-LSTM) has two LSTM for the encoder/decoder and has the soft attention neural net, which attends over the source sentence and constructs a focused encoding vector for each target word. The second model is an NSE-LSTM encoder-decoder which encodes the source sentence with NSE and generates the targets with the LSTM network by using the NSE output states and the attention network. The last model is an NSE-NSE setup, where the encoding part is the same as the NSE-LSTM while the decoder NSE now uses the output state and has an access to the encoder memory, i.e., the encoder and the decoder NSEs access a shared memory. The memory is encoded by the first NSEs and then read/written by the decoder NSEs. We used the English-German translation corpus from the IWSLT 2014 evaluation campaign (Cettolo et al., 2012). The corpus consists of sentence-aligned translation of TED talks. The data was pre-processed and lowercased with the Moses toolkit.<sup>9</sup> We merged the dev2010 and dev2012 sets for development and the tst2010, tst2011 and tst2012 sets for test data<sup>10</sup>. Sentence pairs with length longer than 25 words were filtered out. This resulted in 110,439/4,998/4,793 pairs for train/dev/test sets. We kept the most frequent 25,000 words for the German dictionary. The English dictionary has 51,821 words. The 300-D Glove 840B vectors were used for embedding the words in the source sentence whereas a lookup embedding layer was used for the target German words. Note that the word embeddings are usually optimized along with the NMT models. However, for the evaluation purpose we in this experiment do not optimize the English word embeddings. Besides, we do not use a beam search to generate the target sentences.

The LSTM encoder/decoders have two layers with 300 units. The NSE read/write modules are two one-layer LSTM with the same number of units as the LSTM encoder/decoders. This ensures that the number of parameters of the models is roughly the equal. The models were trained to minimize word-level cross entropy loss and were regularized by 20% input dropouts and the

<sup>9</sup><https://github.com/moses-smt/mosesdecoder>

<sup>10</sup>We modified `prepareData.sh` script: <https://github.com/facebookresearch/MIXER>

30% output dropouts. We set the batch size to 128, the initial learning rate to 1e-3 for LSTM-LSTM and 3e-4 for the other models and  $l_2$  regularizer strength to 3e-5, and train each model for 40 epochs. We report BLEU score for each models.<sup>11</sup>

Table 5 reports our results. The baseline LSTM-LSTM encoder-decoder (with attention) obtained 17.02 BLEU on the test set. The NSE-LSTM improved the baseline slightly. Given this very small improvement of the NSE-LSTM, it is unclear whether the NSE encoder is helpful in NMT. However, if we replace the LSTM decoder with another NSE and introduce the shared memory access to the encoder-decoder model (NSE-NSE), we improve the baseline result by almost 1.0 BLEU. The NSE-NSE model also yields an increasing BLEU score on dev set. The result demonstrates that the attention-based NMT systems can be improved by a shared-memory encoder-decoder model. In addition, memory-based NMT systems should perform well on translation of long sequences by preserving long term dependencies.

## 5 Qualitative Analysis

### 5.1 Memory Access and Compositionality

NSE is capable of performing multiscale composition by retrieving associative slots for a particular input at a time step. We analyzed the memory access order and the compositionality of memory slot and the input word in the NSE model trained on the SNLI data.

Figure 2 shows the word association graphs for the two sentence picked from SNLI test set. The association graph was constructed by inspecting the key vector  $z$ . For an input word, we connect it to the most active slot pointed by  $z$ <sup>12</sup>.

Note the graph components clustered around the semantically rich words: "sits", "wall" and "autumn" (a) and "Three", "puppies", "tub" and "vet" (b). The memory slots corresponding to words that are semantically rich in the current context are the most frequently accessed. The graph is able to capture certain syntactic structures including phrases (e.g., "hand built rock wall") and modifier relations (between "sits" and "quietly" and

<sup>11</sup>We computed the BLEU score with `multi-bleu.perl` script of the Moses toolkit

<sup>12</sup>Since  $z$  is fuzzy, we visualize the highest scoring slot. For a few inputs,  $z$  pointed to a slot corresponding to the same word. In this case, we masked out those slots and showed the second best scoring slot.

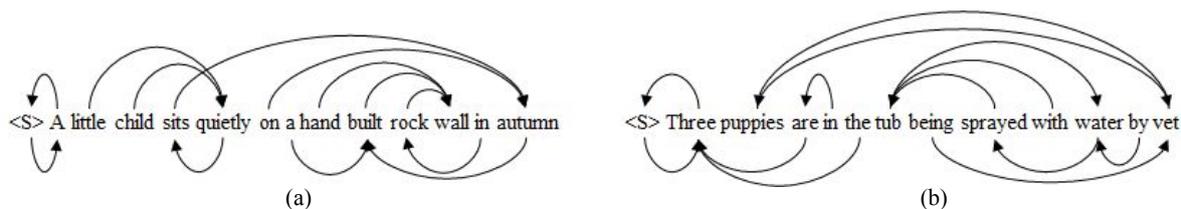

Figure 2: Word association or composition graphs produced by NSE memory access. The directed arcs connect the words that are composed via *compose* module. The source nodes are input words and the destination nodes (pointed by the arrows) correspond to the accessed memory slots.  $\langle S \rangle$  denotes the beginning of sequence.

between "tub" and "sprayed with water"). Another interesting property is that the model tends to perform sensible compositions while processing the input sentence. For example, NSE retrieved the memory slot corresponding to "wall" or "Three" when reading the input "rock" or "are".

In Appendix A, we show a step-by-step visualization of NSE memory states for the first sentence. Note how the encoding memory is evolved over time. In time step four ( $t = 4$ ), the memory slot for "quietly" encodes information about "quiet(ly) little child". When  $t = 6$ , the model forms another composition involving "quietly", "quietly sits". In the last time step, we are able to find the most or the least frequently accessed slots in the memory. The least accessed slots correspond to function words while the frequently accessed slots are content words and tend to carry out rich semantics and intrinsic compositions found in the input sentence. Overall the model is less constrained and is able to compose multiword expressions.

## 6 Conclusion

Our proposed memory augmented neural networks have achieved the state-of-the-art results when evaluated on five representative NLP tasks. NSE is capable of building an efficient architecture of the single, shared and multiple memory accesses for a specific NLP task. For example, for the NLI task NSE accesses premise encoded memory when processing hypothesis. For the QA task, NSE accesses answer encoded memory when reading question for QA. In machine translation, NSE shares a single encoded memory between encoder and decoder. Such flexibility in the architectural choice of the NSE memory access allows for

the robust models for a better performance.

The initial state of the NSE memory stores information about each word in the input sequence. We in this paper used word embeddings to represent the words in the memory. Different variations of word representations such as character-based models are left to be evaluated for memory initialization in the future. We plan to extend NSE so that it learns to select and access a relevant subset from a memory set. One could also explore unsupervised variations of NSE, for example, to train them to produce encoding memory and representation vector of entire sentences or documents using either new or existing models such as the skip-gram model (Mikolov et al., 2013).

## Acknowledgments

We would like to thank Abhyuday Jagannatha and the anonymous reviewers for their insightful comments and suggestions. ## Abstract

Comparing NLP systems to select the best one for a task of interest, such as named entity recognition, is critical for practitioners and researchers. A rigorous approach involves setting up a hypothesis testing scenario using the performance of the systems on query documents. However, often the hypothesis testing approach needs to send a large number of document queries to the systems, which can be problematic. In this paper, we present an effective alternative based on the multi-armed bandit (MAB). We propose a hierarchical generative model to represent the uncertainty in the performance measures of the competing systems, to be used by Thompson Sampling to solve the resulting MAB. Experimental results on both synthetic and real data show that our approach requires significantly fewer queries compared to the standard benchmarking technique to identify the best system according to F-measure.

## 1 Introduction

As new NLP systems are (continually) introduced for a task of interest, such as named entity recognition (NER), it is crucial for practitioners and researchers to select the best system. These systems may be designed based on different models and/or learning algorithms. For instance, due to recent advancement in NER research, several NER systems have been proposed and then supported in APIs such as OpenNLP (Ingersoll et al., 2013), Stanford NER (Finkel et al., 2005), ANNIE (Cunningham et al., 2002) and Meaning Cloud (MeaningCloud-LLC, 1998) to name a few.

Often, the competing NLP systems are benchmarked according to their average performance measure, e.g. F-measure capturing both Precision and Recall, across a set of example documents. Each document produces a single F-measure and the true performance of the system is considered to be the expected value across all possible documents from the domain. Performance on individual documents correspond to samples from the performance distribution of the system, and can then be used to determine the best system (or set of systems should the highest performing system not be unique) using rigorous hypothesis testing. However, this approach usually requires querying each competing system with a large number of documents, which can be problematic if either the number of test documents is limited, or the systems are implemented as APIs by a third party and performing each query incurs a cost.

In this paper, we present a statistically effective method to identify the best system from a pool of systems. Our approach requires significantly fewer example documents to reach similar guarantees as the traditional hypothesis testing set up, hence reducing the cost and increasing the speed of inference. Inspired by the previous work (Scott, 2015; Gabillon et al., 2012; Maron and Moore, 1993), We formulate the benchmarking problem as a sequential decision process of choosing the best arm as the results of new queried documents are received. More specifically, our formulation is based on the best arm identification in a multi-armed bandit (MAB) decision process. This allows us to adapt Thompson Sampling (Thompson, 1933) and its variants (Russo, 2016) to efficiently solve the resulting MAB problem.

A crucial difference between the MAB approach and the traditional hypothesis testing is that it is a *sequential* testing process, instead of a static testing process which forces the benchmarker to

wait for a *final answer* at the end of an experiment. As such, we need to model the uncertainty regarding the estimated F-measure of each competing system, and continually update it as each new document is queried. We propose a novel hierarchical model for this purpose, which is generally applicable to document-level evaluation tasks based on F-measure. The inference in our model is done using standard sampling techniques, such as Gibbs sampling.

We analyse empirically the performance of our approach versus the standard hypothesis testing baselines on synthetic datasets as well as real data for the tasks of sentiment classification and named entity recognition. The empirical results confirm that the number of query documents needed to achieve a particular statistical significance level with our approach is much lower than that required by the hypothesis testing baselines.

## 2 Best Arm Selection in Multi-Armed Bandit

Our aim is to identify the best system among a finite set of systems based on the noisy sequential measurements of their quality. We formulate this problem as the best arm selection in multi-armed bandit. MAB is a sequential decision process where at each time step  $n$  an arm  $a_n$  from the collection of  $K$  slot machines is chosen and played by the gambler. Each arm  $a \in \{1, \dots, K\}$  is associated with an *unknown* reward distribution  $f(y|\theta_a)$  from which the reward is generated when the arm is pulled. In the best arm selection problem, the gambler’s goal is to select the arm which has the highest expected reward.

In the common formulation of the MAB, the gambler wants to maximise his cumulative rewards. Intuitively, maximising cumulative rewards eventually leads to the selection of the best arm since it is the optimal decision. However, (Bubeck et al., 2009) gives a theoretical analysis that any strategies for optimising cumulative reward is sub-optimal in identifying the best performing arm. To this end, several algorithms have been proposed for the best arm selection e.g. (Maron and Moore, 1993; Gabillon et al., 2012; Russo, 2016). Although originally developed for maximising cumulative rewards, (Chapelle and Li, 2011; Scott, 2015) provide extensive empirical evidence for the practical success of the Thompson Sampling algorithm for the best arm selection. In what follows,

we present Thompson Sampling (TS) and one of its variants, called Pure Exploration TS (PETS), designed specifically for the best arm selection.

### 2.1 Thompson Sampling

Let us denote by  $(a_1, y_1), \dots, (a_T, y_T)$  the sequence of pulled arms and the revealed rewards,  $a_t$  is the arm pulled at time step  $t$  and  $y_t$  is its associated reward. Note that this sequence is continually growing as the experiment progresses and new arms are pulled. Let  $f(y|\theta_a)$  be the probability distribution to model the unknown reward function of the arm  $a$ . Had we known the parameters of the reward functions, the best arm could then be selected as

$$\operatorname{argmax}_a E_{f(y|\theta_a)}[y] = \operatorname{argmax}_a \int f(y|\theta_a)y dy.$$

Let us denote the collection of all parameters by  $\Theta := (\theta_1, \dots, \theta_K)$ . Assuming a prior over the parameters  $\pi_0(\Theta)$ , we take a Bayesian approach and reason about the posterior of the parameters:

$$\pi_T(\Theta) = \frac{\pi_0(\Theta)L_T(\Theta)}{\int_{\Theta'} \pi_0(\Theta')L_T(\Theta')d\Theta'}$$

where  $\Theta$  is the parameter domain, and  $L_T(\Theta)$  is the likelihood of the observed data  $\{(a_t, y_t)\}_1^T$

$$L_T(\Theta) := \prod_{t=1}^T f(y_t|\theta_{a_t}).$$

The posterior probability that a particular arm  $a$  is optimal (i.e. has the highest expected reward) is:

$$\alpha_{T,a} := \int_{\Theta_a} \pi_T(\Theta)d\Theta$$

where  $\Theta_a$  is the set of those parameter values under which the arm  $a$  would be selected as the optimal arm:

$$\Theta_a := \{\Theta \in \Theta | E_{f(y|\theta_a)} = \operatorname{argmax}_{a'} E_{f(y|\theta_{a'})}\}$$

In Thompson Sampling the next arm to pull is sampled according to the posterior probability of the arm being optimal. That is, an arm  $a$  is selected with probability  $\alpha_{T,a}$ . Efficient implementation of Thompson Sampling generates a sample from  $\alpha_{T,a}$  indirectly by first generating a sample from  $\pi_T(\Theta)$  and then selecting the next arm to pull by  $\operatorname{argmax}_a E_{f(y|\hat{\theta}_a)}[y]$ .

---

**Algorithm 1** Pure Exploration TS (PETS)

     $b \leftarrow a$   
    **while**  $b = a$  **do**  
       $\hat{\Theta} \sim \pi_t(\Theta)$   
       $b \leftarrow \operatorname{argmax}_k E_{f(y|\hat{\theta}_k)}[y]$   
    **end while**  
    Pull  $b$  and update the posterior  $\pi_{t+1}(\Theta)$   
  **end if**  
   $t \leftarrow t + 1$   
**end while**

---

## 2.2 Pure Exploration Thompson Sampling

Thompson sampling can perform poorly for the best arm identification problem. The reason is that once it discovers a particular arm is performing well, it becomes overconfident and almost always selects that arm in the future iterations. In case that arm is not the best arm, it takes a long time for the algorithm to divert from it. For example, if  $\alpha_{T,a} = 90\%$ , then the algorithm selects an arm other than  $a$  on average on every 10 iterations, which would make it significantly longer to get to a point where  $\alpha_{T',a'} = 95\%$ , i.e. the point where the algorithm terminates with confidence 95% in a different arm  $a'$ .

Let  $\alpha_T := (\alpha_{T,1}, \dots, \alpha_{T,K})$  be the vector of arm probabilities to be optimal. Pure Exploration Thompson Sampling (Russo, 2016) addresses the above deficiency of Thompson Sampling by throwing away, with probability  $\beta$ , the arm  $a$  sampled from  $\alpha_T$ . Instead, it samples another arm  $b \neq a$  with the probability proportional to  $\alpha_{T,b}$ . The exploration parameter  $\beta$  prevents the algorithm from exclusively focusing on one arm. Usually  $\beta$  is set to .5 but we empirically investigate other values for this parameter in §4. We can revert to basic Thompson Sampling by setting  $\beta = 1$  in PETS. Similar to Thompson Sampling, this arm selection method can be efficiently implemented as shown in Algorithm 1. We terminate the algorithm when it reaches a maximum number of queries or when  $\alpha_{T,a} \geq 1 - \delta$ , where  $\delta$  is the confidence parameter provided in the input.

## 3 A Probabilistic Generative Model of F-measure

In this section we present a novel hierarchical Bayesian model for capturing the uncertainty over systems' F-measures, as the prediction outcome on new query documents are received. We present this model for F-measure, however, we note that it can be extended for other performance measures as well.

F-measure is defined as the harmonic mean of the precision and recall:

$$\begin{aligned} \text{F-measure} &:= \frac{2}{\frac{1}{\text{precision}} + \frac{1}{\text{recall}}} \\ \text{precision} &:= \frac{TP}{TP + FP}, \quad \text{recall} := \frac{TP}{TP + FN} \end{aligned}$$

where  $(TP, FP, TN, FN)$  denote true positive, false positive, true negative, and false negative counts. These counts result from comparing the predictions of a system with the ground truth annotations, and they sum to the total number of annotated data items  $N$ . We denote the normalised version of the counts by *rates*  $(\hat{TP}, \hat{FP}, \hat{TN}, \hat{FN})$ , which are derived by dividing the raw counts by  $N$ . Importantly, the rate statistics are enough to calculate precision, recall, and F-measure.

Instead of modelling the uncertainty over the F-measure of a system directly, we model the uncertainty over its rate statistics. Any distribution over  $(\hat{TP}, \hat{FP}, \hat{TN}, \hat{FN})$  then induces a distribution over F-measure. The benefit of working with the rate statistics is that they relate more naturally to the observed  $(TP, FP, TN, FN)$  counts, as established in our generative model in the following.

More specifically, we assume a hierarchical model to generate the rate statistics of the systems and the observed  $(TP_d, FP_d, TN_d, FN_d)$  counts over a collection of documents  $d \in \mathcal{D}$ . For each system, we draw its rate statistics  $\theta_k := (\hat{TP}_k, \hat{FP}_k, \hat{TN}_k, \hat{FN}_k)$  from a Dirichlet prior. To generate the counts statistics resulting from applying the system  $a_t$  on the document  $d_t$ , we first generate a document-specific rate vector  $\mu_{d_t}$  from a Dirichlet distribution centred around  $\theta_{a_t}$ . Note that including explicit document-specific rates  $\mu_{d_t}$  in the model (from which the binomial counts are drawn) is necessary in order to allow for sufficient variation in the observed error rates across documents, due to the inherent differences in difficulty of labelling different documents.<sup>1</sup>

<sup>1</sup>In other words, in order to model the observed vari-

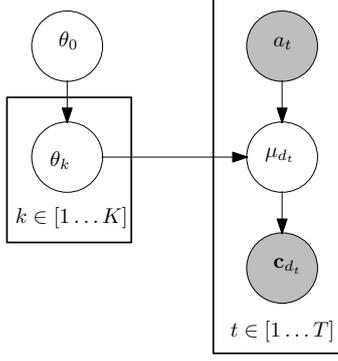

Figure 1: The graphical model for the probabilistic generation of a system’s parameters  $\theta_k$  and a document’s counts  $c_{d_t}$ , as the selected system  $a_t$  is applied onto the document  $d_t$  at the time step  $t$ . The observed quantities are shaded.

We then generate the observed counts  $c_{d_t} := (TP_{d_t}, FP_{d_t}, TN_{d_t}, FN_{d_t})$  from the Binomial distribution with parameters  $\mu_{d_t}$  and  $N_{d_t}$ , where  $N_{d_t}$  is the number data items in  $d_t$ . In summary, the generative model is as follows:

$$\begin{aligned} \forall k \in [1..K] & : \theta_k \sim \text{Dirichlet}(\theta_0, \alpha_0) \\ \forall t \in [1..T] & : \mu_{d_t} \sim \text{Dirichlet}(\theta_{a_t}, \alpha) \\ & c_{d_t} \sim \text{Binomial}(\mu_{d_t}, N_{d_t}) \end{aligned}$$

where  $\alpha_0$  and  $\alpha$  are the concentration parameters, which we set to 1 in our experiments in §4. Figure 1 depicts the graphical model.

For inference, the quantities of interest are the unknown rates for the systems  $\{\theta_k\}_{k=1}^K$ . The observed quantities are document-specific counts  $\{c_{d_t}\}_{t=1}^T$ , and we would like to marginalise out the latent document-specific rate variables  $\{\mu_{d_t}\}_{t=1}^T$ . We resort to Gibbs sampling for inference in our model. That is, we iteratively select a hidden variable and sample a value from its posterior given all the other variables are fixed to their current values. In our experiments, we collect 1000 samples from the posterior.<sup>2</sup> Algorithm 2 depicts the sampling-based inference for the posterior embedded in the PETS algorithm for the best system identification.

F-measure is a frequently used evaluation measure, which can straightforwardly be parametrized to allow for varying the importance of precision

ability in (TP,FP,TN,FN) counts, we had to use a Dirichlet-Compound-Multinomial with shared Dirichlet prior rather than a simple Multinomial with a shared Dirichlet Prior.

<sup>2</sup>We make use of the JAGS (Just Another Gibbs Sampler) toolkit (Plummer, 2003) for inference in our model.

## Algorithm 2 Identifying the best system

---

**Require:**  $K$ : Number of arms,  $J$ : Number of samples from posterior  $\pi(\cdot)$ ,  $\mathcal{D}$ : Document collection,  
 $\text{Fmeasure}(\hat{T}P, \hat{T}N, \hat{F}P, \hat{F}N) := \frac{2\hat{T}P}{2\hat{T}P + \hat{F}P + \hat{F}N}$ ,  
 $\text{NextDoc}(a, \mathcal{D})$ : Next document for an arm  $a$  from  $\mathcal{D}$

- 1: **for**  $k \in [1..K]$  **do**
- 2:    $\mathcal{D}_k \leftarrow \text{NextDoc}(k, \mathcal{D})$
- 3:    $\mathcal{S}_k \leftarrow \{\tilde{\theta}_j | \forall j \in [1..J] : \tilde{\theta}_j \stackrel{\text{Gibbs}}{\sim} \pi(\theta_j | \mathcal{D}_k)\}$
- 4: **end for**
- 5: **while** termination condition is not met **do**
- 6:   **for**  $k \in [1..K]$  **do**
- 7:      $f_k \sim \{\text{Fmeasure}(\tilde{\theta}) | \tilde{\theta} \in \mathcal{S}_k\}$
- 8:   **end for**
- 9:    $a \leftarrow \text{argmax}_k f_k$
- 10:    $r \sim \text{uniform}(0, 1)$
- 11:    $b \leftarrow a$
- 12:   **if**  $r > \beta$  **then**
- 13:     **while**  $b = a$  **do**
- 14:       **for**  $k \in [1..K]$  **do**
- 15:          $f_k \sim \{\text{Fmeasure}(\tilde{\theta}) | \tilde{\theta} \in \mathcal{S}_k\}$
- 16:       **end for**
- 17:        $b \leftarrow \text{argmax}_k f_k$
- 18:     **end while**
- 19:   **end if**
- 20:    $\mathcal{D}_b \leftarrow \mathcal{D}_b \cup \text{NextDoc}(b, \mathcal{D})$
- 21:    $\mathcal{S}_b \leftarrow \{\tilde{\theta}_j | \forall j \in [1..J] : \tilde{\theta}_j \stackrel{\text{Gibbs}}{\sim} \pi(\theta_j | \mathcal{D}_b)\}$
- 22: **end while**

---

versus recall:

$$\text{F}_{\beta}\text{-measure} := \frac{2}{\frac{\beta}{\text{precision}} + \frac{1-\beta}{\text{recall}}}$$

where  $\beta$  is a parameter trading off precision and recall. We note that our approach can be applied straightforwardly to  $\text{F}_{\beta}$ -measure to put more weight on precision or recall where appropriate.

## 4 Empirical Results and Analysis

We designed two sets of experiments to examine the efficiency and performance of each algorithm using synthetic data as well as real data for sentence level sentiment classification and named entity recognition tasks. With the synthetic data, we analyse our probabilistic generative model for F-measure in combination with the arm selection algorithms. With the real data, we showcase the statistical efficiency of our best system identification approach compared to the standard hypothesis testing approach (Demšar, 2006).

In the real data experiments, we define the “best system” as the system with the highest F-measure based on all documents in the collection. The “success rate” in the NER/Sentiment tasks is then simply the percentage of times the best system is correctly identified (i.e. ranked highest when the system selection algorithm is terminated) over multiple runs of the selection algorithm on random

reorderings of the document collection. We emphasise that, in these experiments, we simulate a scenario where the aim is to select the best system with the minimum number of queries to showcase the effectiveness of our approach.

#### 4.1 Baselines

As baselines, we consider the minimum number of documents needed by the standard statistical power approach. The power of a binary hypothesis testing is the probability that the test correctly rejects the null hypothesis ( $H_0$ ) when the alternative hypothesis ( $H_1$ ) is true. In order to find a lower-bound for the number of documents, we make use of the power calculation for a paired T-Test.

The T-Test indicates whether or not the difference between two groups' averages most likely reflects a "real" difference in the population from which the groups were sampled. Assuming we have two competing systems, we can set up a T-Test to assess whether there is a meaningful difference between the F-measures of the two systems.

We assume an efficient experimental design where the same number of (identical) documents are sent to each system. Assuming a typical power setting of 80% and a significance level of 5%, we can calculate an "Oracle baseline" by making use of the true effect size (the standardised difference in mean performance) across the top two systems.<sup>3</sup> Obviously this quantity would not be known a-priori of running the experiment, hence the sample size calculated based on this effect size provides a lower-bound on the number of samples that ought to be needed<sup>4</sup>.

Across the systems, average performance on individual documents will vary due to variations in the inherent difficulty of each document. In other words, some documents are harder to label than others. Thus we make use of a paired sample test for the power calculation. Effect sizes are calculated as follows:

- For the synthetic experiments, the variation in difficulty of the documents is not modelled, so we calculate the effect size by simply using the parameters of the simulation as:

<sup>3</sup>For the power calculation, we use the following R command `power.t.test(delta=effect, sd=1, sig.level=0.05, power=.8, type="paired", alternative="one.sided")`.

<sup>4</sup>Note that the T-Test assumes Gaussian distributed data, but the violation of this assumption is unlikely to greatly affect the sample size estimates.

$\frac{\mu_1 - \mu_2}{\sqrt{(\sigma_1^2 + \sigma_2^2)}}$ , where  $\mu_1$  is the mean performance on the best system and  $\mu_2$  is the mean performance on the second best system (likewise for the standard deviations  $\sigma_1$  and  $\sigma_2$ ).

- For the experiments on real data, variation will be document dependent and hence we calculate the effect size as  $\frac{AVG(f_1 - f_2)}{STDEV(f_1 - f_2)}$ , where we directly measure the average and standard deviation of the performance differences between the top performing APIs across the documents.

Since we are comparing many APIs at once, and a priori of running the experiment we don't know which two systems are the best, we make use of two settings for the confidence level (aka P-value threshold) for the power calculation:

- **Baseline<sub>2</sub>**: Assume the top two systems are known a priori and use the significance level of 5% directly to produce a lower bound on the number of iterations.
- **Baseline<sub>K-1</sub>**: Assume one system is new and is being compared with all other  $k - 1$  APIs. We reduce the required significance level  $\alpha$  using a Bonferroni correction to be  $\alpha / (k - 1)$  to take into account the  $k - 1$  comparisons being performed.

We stress that this is an unrealistic scenario in which the effect size is known before running the experiment. If this value is not known or needs to be estimated before the experiment a much larger value would be used, for example a value based on the error threshold  $\epsilon$  might be appropriate.

#### 4.2 Synthetic Data Experiments

**Datasets.** For the synthetic data, we generate the  $(TP, FP, TN, FN)$  counts of applying the competing systems on hypothetical documents, assuming that we know the systems' *true* rates. An important factor in the difficulty of the problem is the difference in the Fscore of the top two performing systems, which we denote by *margin*. We consider three levels of problem difficulty by considering the margin  $m \in \{.01, .025, .05\}$ , and for each margin we consider 5 configurations whose competing systems have the specified margin. Having the true  $(\hat{TP}, \hat{FP}, \hat{TN}, \hat{FN})$  rates for a competing system, the count statistics for its results on hypothetical documents are

	margin .05		margin .025		margin .01	
	# queries	success%	# queries	success%	# queries	success%
Baseline <sub>2</sub>	120	-	440	-	2725	-
Baseline <sub>K-1</sub>	185	-	680	-	4195	-
Hierarchical						
+ Thomp. Samp.	22 ± 5	100	41 ± 6	96	66 ± 8	100
+ Pure Eexpl. TS	19 ± 3	100	27 ± 5	100	64 ± 9	96
Gaussian						
+ Thomp. Samp.	513 ± 46	100	1169 ± 84	100	2000 ± 0	100
+ Pure Eexpl. TS	360 ± 33	100	848 ± 63	100	1965 ± 19	100

Table 1: Average number of queries across different margins. The number of systems is 5, and the maximum number of queries is set to 2000, and  $\delta = 0.05$ .

then generated based on our generative model. For each competing configuration, we repeat the experiment multiple times in order to account for the randomness inherent in the algorithms and the generated documents. In different experiments, we let the number of competing systems  $K$  be  $\{5, 10, 20\}$ .

**Margin and the number of systems.** In this experiment, we investigate the relation between the margin and the number of documents queried by each algorithm. Intuitively, as the margin between the top performing systems decreases, more queries are required to segregate the best system among the top performing ones. We run each algorithm for 500 times on the competing configurations for each margin with  $K = 5$ . The maximum number of queries allowed is 2000, and the algorithm can terminate earlier as soon as  $\alpha_{T,a} \geq .95$ , i.e.  $\delta = 0.05$ .

Table 1 summarises the average number of queries and the success rates of TS and PETS in combination with our hierarchical Bayesian model for F-measure across different margins. We see that the number of query documents increases as the margin decreases. It is also worth noting that PETS requires slightly smaller number of queries than Thompson Sampling. Interestingly, the number of samples required by the hypothesis testing baselines is much more than that required by the TS/PETS combined with our hierarchical model.

We then ask the question whether the number of competing systems is important. Table 2 summarises the average number of queries and the success rate of each algorithm on the competing configurations for the margin 0.05 for varying number of systems  $K \in \{5, 10, 20\}$ . As seen, the

number of queries increases (sub)linearly with the number of competing systems.

**Hierarchical vs Gaussian.** We compare our hierarchical model for capturing the uncertainty over F-measure with the Gaussian distribution. That is, we associate a Gaussian distribution to each system to model its posterior over the F-measure. The use of the Gaussian distribution to model the mean of sampled F-measures is motivated by the law of large numbers. This approach directly models the uncertainty of a system’s F-measure, as opposed to our indirect modelling approach where posterior distribution is constructed using the distribution of  $(\hat{F}P, \hat{F}N, \hat{T}P, \hat{T}N)$  rates.

Tables 1 and 2 show the average number of queries and success rates for algorithms using our hierarchical model vs the Gaussian distribution based model. The general trend is that using the Gaussian model in TS/PETS requires significantly more queries compared to the hierarchical model as well as the baselines. Needing more queries compared to the baselines highlights the importance of choosing the right distribution for capturing the uncertainty over the F-measure in TS/PETS. Needing more queries compared to the hierarchical variant is somewhat expected as the synthetic data is generated according to the hierarchical model. However, we will see similar trends in the experiments on the real data.

### 4.3 Sentiment Analysis

We consider the task of sentence level sentiment prediction for medical documents. The aim is to benchmark systems according to how well they can predict the polarity of sentences contained in a medical report, where each report corresponds

	$K : 5$		$K : 10$		$K : 20$	
	# queries	success%	# queries	success%	# queries	success%
Baseline <sub>2</sub>	120	-	245	-	400	-
Baseline <sub><math>K-1</math></sub>	185	-	380	-	620	-
Hierarchical						
+ Thomp. Samp.	22 ± 5	100	43 ± 6	96	70 ± 14	100
+ Pure Eexpl. TS	19 ± 3	100	35 ± 5	100	64 ± 13	100
Gaussian						
+ Thomp. Samp.	513 ± 46	100	1019 ± 59	100	1404 ± 75	100
+ Pure Eexpl. TS	360 ± 33	100	661 ± 38	100	937 ± 62	100

Table 2: Average number of queries across different number of competing systems. The margin is 0.05, and the maximum number of queries is set to 2000, and  $\delta = 0.05$ .

to a patient.

**Dataset.** We make use of a biomedical corpus (Martinez et al., 2015) consisting of CT reports for fungal disease detection collected from three hospitals. For each report, only the free text section were used, which contains the radiologist’s understanding of the scan and the reason for the requested scan as written by clinicians. Every report was de-identified: any potentially identifying information such as name, address, age/birthday, gender were removed. There are a total of 358 test documents, where the average number of sentences per document is 23.

**Competing Systems.** We make use of a variant of the coarse-to-fine model proposed in (McDonald et al., 2007) for sentiment analysis. Briefly speaking, the model couples the sentiment of the sentences contained in a report with the overall sentiment of the report. We train four versions of the model, each of which corresponds to a different training condition:

- $M_{\text{full}}$ : where the model is trained on the fully annotated data  $D_F$ , i.e. the data annotated at both the sentence and report level.
- $M_{\text{partial}}$ : where the model is trained on both  $D_F$  and the partially annotated data  $D_P$  in which the sentence level annotation is missing but the reports are labeled.
- $M_{\text{unlab}}$ : where the model is trained on  $D_F$  and  $D_U$  in which the annotation is missing at both sentence and report level.
- $M_{\text{all}}$ : where the model is trained on all of the available data described above.

	# queries	% success
Baseline <sub>2</sub>	856	-
Baseline <sub><math>K-1</math></sub>	1320	-
Hierarchical		
+ Thomp. Samp.	152 ± 36	100
+ Pure Eexpl. TS	123 ± 37	100
Gaussian		
+ Thomp. Samp.	500 ± 0	100
+ Pure Eexpl. TS	500 ± 0	100

Table 3: Sentiment classification for biomedical reports with 4 competing models. The maximum number of queries is set to 500, and  $\delta = 0.05$ .

We expect  $M_{\text{all}}$  to outperform the other models. The aim is to analyse the behaviour of our best system selection methods on real data compared to the baselines.

**Results.** Table 3 presents the results. As seen the number of queries needed for the TS/PETS combined with the hierarchical model is much less than that of the baselines and the Gaussian variant.

#### 4.4 Named Entity Recognition

In our second set of experiment, we attempt to see how our frameworks and  $F_1$  models perform using realistic data.

**MASC Corpus.** For benchmarking the NER systems, we use the Manually Annotated Sub-Corpus (MASC) (Ide et al., 2008) that includes 19 different domains. The corpus consists of approximately 500K words of contemporary American English written and spoken data drawn from the

Open American National Corpus (OANC). This corpus includes a wide variety of linguistic annotations with a balanced selection of texts from a broad range of genres/domains. The diversity of the corpus will enable us to assess the robustness of tools across different domains. The number of documents in the MASC corpus is about 392.

**Competing Systems.** We evaluate the performance of 5 popular NER systems implemented as API in third party implementations:

- OpenNLP (Ingersoll et al., 2013): The Apache OpenNLP library is a machine learning based toolkit for the text processing. It is based on the maximum entropy and perceptron.
- Stanford NER (Finkel et al., 2005): It is based on linear chain Conditional Random Field (CRF) sequence models. It is part of the Stanford CoreNLP, which is an integrated suite of NLP tools in Java.
- ANNIE (Cunningham et al., 2002): ANNIE uses gazetteer-based lookups and finite state machines for entity identification and classification. It can recognise persons, locations, organisations, dates, addresses and other named entity types. ANNIE is part of the GATE framework. It can be used as a Web Service but it also provides its own interface for independent use.
- Meaning Cloud (MeaningCloud-LLC, 1998): It is based on a hybrid approach combining machine learning with a rule based system. The software is available as a cloud based solution and on-premise as a plugin module for the GATE framework.
- LingPipe (Alias-i, 2008): It is a set of Java libraries developed by Alias-I for NLP. The NER component is based on a 1st-order Hidden Markov Model with variable-length  $n$ -grams as the feature set and uses the IOB annotation scheme for the output.

**Results.** Table 4 presents the results. As seen the number of queries needed for the TS/PETS combined with the hierarchical model is much less than that of the baselines and the Gaussian variant.

	# queries	% success
Baseline <sub>2</sub>	125	-
Baseline <sub>K-1</sub>	240	-

+ Pure Eexpl. TS	412 ± 2	100

Table 4: Named entity recognition on MASC documents with 5 competing systems. The maximum number of queries is set to 2000, and  $\delta = .05$ .

## 5 Conclusion

We have presented a novel approach for benchmarking NLP systems based on the multi-armed bandit (MAB) problem. We have proposed a hierarchical generative model to represent the uncertainty in the performance measures of the competing systems, to be used by the Thompson Sampling algorithm to solve the resulting MAB problem. Experimental results on both synthetic and real data show that our approach requires significantly fewer queries compared to the standard benchmarking technique to identify the best system according to F-measure. Future work includes applying our approach to other NLP problems, particularly emerging document-level problem settings such document-wise machine translation.

## Abstract

We present a Character-Word Long Short-Term Memory Language Model which both reduces the perplexity with respect to a baseline word-level language model and reduces the number of parameters of the model. Character information can reveal structural (dis)similarities between words and can even be used when a word is out-of-vocabulary, thus improving the modeling of infrequent and unknown words. By concatenating word and character embeddings, we achieve up to 2.77% relative improvement on English compared to a baseline model with a similar amount of parameters and 4.57% on Dutch. Moreover, we also outperform baseline word-level models with a larger number of parameters.

## 1 Introduction

Language models (LMs) play a crucial role in many speech and language processing tasks, among others speech recognition, machine translation and optical character recognition. The current state of the art are recurrent neural network (RNN) based LMs (Mikolov et al., 2010), and more specifically long short-term memory models (LSTM) (Hochreiter and Schmidhuber, 1997) LMs (Sundermeyer et al., 2012) and their variants (e.g. gated recurrent units (GRU) (Cho et al., 2014)). LSTMs and GRUs are usually very similar in performance, with GRU models often even outperforming LSTM models despite the fact that they have less parameters to train. However, Jozefowicz et al. (2015) recently showed that for the task of language modeling LSTMs work better than GRUs, therefore we focus on LSTM-based LMs.

In this work, we address some of the drawbacks of NN based LMs (and many other types of LMs).

A first drawback is the fact that the parameters for infrequent words are typically less accurate because the network requires a lot of training examples to optimize the parameters. The second and most important drawback addressed is the fact that the model does not make use of the internal structure of the words, given that they are encoded as one-hot vectors. For example, ‘felicity’ (great happiness) is a relatively infrequent word (its frequency is much lower compared to the frequency of ‘happiness’ according to Google Ngram Viewer (Michel et al., 2011)) and will probably be an out-of-vocabulary (OOV) word in many applications, but since there are many nouns also ending on ‘ity’ (ability, complexity, creativity . . .), knowledge of the surface form of the word will help in determining that ‘felicity’ is a noun. Hence, subword information can play an important role in improving the representations for infrequent words and even OOV words.

In our character-word (CW) LSTM LM, we concatenate character and word embeddings and feed the resulting character-word embedding to the LSTM. Hence, we provide the LSTM with information about the structure of the word. By concatenating the embeddings, the individual characters (as opposed to e.g. a bag-of-characters approach) are preserved and the order of the characters is implicitly modeled. Moreover, since we keep the total embedding size constant, the ‘word’ embedding shrinks in size and is partly replaced by character embeddings (with a much smaller vocabulary and hence a much smaller embedding matrix), which decreases the number of parameters of the model.

We investigate the influence of the number of characters added, the size of the character embeddings, weight sharing for the characters and the size of the (hidden layer of the) model. Given that common or similar character sequences do not always occur at the beginning of words (e.g. ‘overfitting’ – ‘underfitting’), we also examine adding the charac-

ters in forward order, backward order or both orders.

We test our CW LMs on both English and Dutch. Since Dutch has a richer morphology than English due to among others its productive compounding (see e.g. (Réveil, 2012)), we expect that it should benefit more from a LM augmented with formal/morphological information.

The contributions of this paper are the following:

1. We present a method to combine word and subword information in an LSTM LM: concatenating word and character embeddings. As far as we know, this method has not been investigated before.
2. By decreasing the size of the word-level embedding (and hence the huge word embedding matrix), we effectively reduce the number of parameters in the model (see section 3.3).
3. We find that the CW model both outperforms word-level LMs with the same number of hidden units (and hence a larger number of parameters) and word-level LMs with the same number of parameters. These findings are confirmed for English and Dutch, for a small model size and a large model size. The size of the character embeddings should be proportional to the total size of the embedding (the concatenation of characters should not exceed the size of the word-level embedding), and using characters in the backward order improves the perplexity even more (see sections 3.1, 4.3 and 4.4).
4. The LM improves the modeling of OOV words by exploiting their surface form (see section 4.7).

The remainder of this paper is structured as follows: first, we discuss related work (section 2); then the CW LSTM LM is described (section 3) and tested (section 4). Finally, we give an overview of the results and an outlook to future work (section 5).

## 2 Related work

Other work that investigates the use of character information in RNN LMs either completely replaces the word-level representation by a character-level one or combines word and character information. Much research has also been done on modeling other types of subword information (e.g. morphemes, syllables), but in this discussion, we limit ourselves to characters as subword information.

Research on replacing the word embeddings entirely has been done for neural machine translation (NMT) by Ling et al. (2015) and Costa-jussà and Fonollosa (2016), who replace word-level embeddings with character-level embeddings. Chung et al. (2016) use a subword-level encoder and a character-level decoder for NMT. In dependency parsing, Ballesteros et al. (2015) achieve improvements by generating character-level embeddings with a bidirectional LSTM. Xie et al. (2016) work on natural language correction and also use an encoder-decoder, but operate for both the encoder and the decoder on the character level.

Character-level word representations can also be generated with convolutional neural networks (CNNs), as Zhang et al. (2015) and Kim et al. (2016) have proven for text classification and language modeling respectively. Kim et al. (2016) achieve state-of-the-art results in language modeling for several languages by combining a character-level CNN with highway (Srivastava et al., 2015) and LSTM layers. However, the major improvement is achieved by adding the highway layers: for a small model size, the purely character-level model without highway layers does not perform better than the word-level model (perplexity of 100.3 compared to 97.6), even though the character model has two hidden layers of 300 LSTM units each and is compared to a word model of two hidden layers of only 200 units (in order to keep the number of parameters similar). For a model of larger size, the character-level LM improves the word baseline (84.6 compared to 85.4), but the largest improvement is achieved by adding two highway layers (78.9). Finally, Jozefowicz et al. (2016) also describe character embeddings generated by a CNN, but they test on the 1B Word Benchmark, a data set of an entirely different scale than the one we use.

Other authors combine the word and character information (as we do in this paper) rather than doing away completely with word inputs. Chen et al. (2015) and Kang et al. (2011) work on models combining words and Chinese characters to learn embeddings. Note however that Chinese characters more closely match subwords or words than phonemes. Bojanowski et al. (2015) operate on the character level but use knowledge about the context words in two variants of character-level RNN LMs. Dos Santos and Zadrozny (2014) join word and character representations in a deep neural network for part-of-speech tagging. Finally, Miyamoto and

Cho (2016) describe a LM that is related to our model, although their character-level embedding is generated by a bidirectional LSTM and we do not use a gate to determine how much of the word and how much of the character embedding is used. However, they only compare to a simple baseline model of 2 LSTM layers of each 200 hidden units without dropout, resulting in a higher baseline perplexity (as mentioned in section 4.3, our CW model also achieves larger improvements than reported in this paper with respect to that baseline).

We can conclude that in various NLP tasks, characters have recently been introduced in several different manners. However, the models investigated in related work are either not tested on a competitive baseline (Miyamoto and Cho, 2016) or do not perform better than our models (Kim et al., 2016). In this paper, we introduce a new and straightforward manner to incorporate characters in a LM that (as far as we know) has not been investigated before.

### 3 Character-Word LSTM LMs

A word-level LSTM LM works as follows: a word encoded as a one-hot column vector  $\mathbf{w}_t$  (at time step  $t$ ) is fed to the input layer and multiplied with the embedding matrix  $\mathbf{W}_w$ , resulting in a word embedding  $\mathbf{e}_t$ :

$$\mathbf{e}_t = \mathbf{W}_w \times \mathbf{w}_t \quad (1)$$

The word embedding of the current word  $\mathbf{e}_t$  will be the input for a series of non-linear operations in the LSTM layer (we refer to (Zaremba et al., 2015) for more details about the equations of the LSTM cell). In the output layer, probabilities for the next word are calculated based on a softmax function.

In our character-word LSTM LM, the only difference with the baseline LM is the computation of the ‘word’ embedding, which is now the result of word and character input rather than word input only. We concatenate the word embedding with embeddings of the characters occurring in that word:

$$\mathbf{e}_t^\top = [(\mathbf{W}_w \times \mathbf{w}_t)^\top (\mathbf{W}_c^1 \times \mathbf{c}_t^1)^\top \dots (\mathbf{W}_c^n \times \mathbf{c}_t^n)^\top] \quad (2)$$

where  $\mathbf{c}_t^1$  is the one-hot encoding of the first character added,  $\mathbf{W}_c^1$  its embedding matrix and  $n$  the total number of characters added to the model. The word  $\mathbf{w}_t$  and its characters  $\mathbf{c}_t^1, \mathbf{c}_t^2 \dots \mathbf{c}_t^n$  are each projected onto their own embeddings, and the concatenation

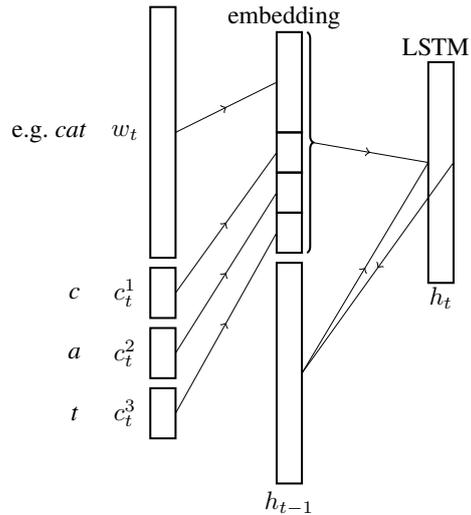

Figure 1: Concatenating word and character embeddings in an LSTM LM.

of the embeddings is the input for the LSTM layer. By concatenating the embeddings, we implicitly preserve the order of the characters: the embedding for e.g. the first character of a word will always correspond to the same portion of the input vector for the LSTM (see figure 1). We also experimented with adding word and character embeddings (a method which does not preserve the order of the characters), but that did not improve the perplexity of the LM.

The number of characters added ( $n$ ) is fixed. If a word is longer than  $n$  characters, only the first (or last, depending on the order in which they are added)  $n$  characters are added. If the word is shorter than  $n$ , it is padded with a special symbol. Because we can still model the surface form of OOV words with the help of their characters, this model reduces the number of errors made immediately after OOV words (see section 4.7).

#### 3.1 Order of the characters

The characters can be added in the order in which they appear in the word (in the experiments this is called ‘forward order’), in the reversed order (‘backward order’) or both (‘both orders’). In English and Dutch (and many other languages), suffixes can bear meaningful relations (such as plurality and verb conjugation) and compounds typically have word-final heads. Hence, putting more emphasis on the end of a word might help to better model those properties.

### 3.2 Weight sharing

Note that in equation 2 each position in the word is associated with different weights: the weights for the first character  $\mathbf{c}_t^1$ ,  $\mathbf{W}_c^1$ , are different from the weights for the character in the second position,  $\mathbf{W}_c^2$ . Given that the input ‘vocabulary’ for characters is always the same, one could argue that the same set of weights  $\mathbf{W}_c$  could be used for all positions in the word:

$$\mathbf{e}_t^\top = [(\mathbf{W}_w \times \mathbf{w}_t)^\top (\mathbf{W}_c \times \mathbf{c}_t^1)^\top \dots (\mathbf{W}_c \times \mathbf{c}_t^n)^\top] \quad (3)$$

However, one could also argue in favor of the opposite case (no shared weights between the characters): for example, an ‘s’ at the end of a word often has a specific meaning, such as indicating a third person singular verb form of the present tense (in English), which it does not have at other positions in the word. Both models with and without weight sharing are tested (see section 4.6).

### 3.3 Number of parameters

Given that a portion of the total embedding is used for modeling the characters, the actual ‘word’ embedding is smaller which reduces the number of parameters significantly. In a normal word-level LSTM LM, the number of parameters in the embedding matrix is

$$V \times E \quad (4)$$

with  $V$  the vocabulary size and  $E = E_w$  the total embedding size/word embedding size. In our CW model however, the number of parameters is

$$V \times (E - n \times E_c) + n \times (C \times E_c) \quad (5)$$

with  $n$  the number of characters,  $E_c$  the size of the character embedding and  $C$  the size of the character vocabulary. Since  $V$  is by far the dominant factor, reducing the size of the purely word-level embedding vastly reduces the total number of parameters to train. If we share the character weights, that number becomes even smaller:

$$V \times (E - n \times E_c) + C \times E_c \quad (6)$$

## 4 Experiments

### 4.1 Setup

All LMs were trained and tested with TensorFlow (Abadi et al., 2015). We test the performance of

the CW architectures for a small model and a large model, with hyperparameters based on Zaremba et al. (2015) and Kim et al. (2016)). The small LSTM consists of 2 layers of 200 hidden units and the large LSTM has 2 layers of 650 hidden units. The total size of the embedding layer always equals the size of the hidden layer. During the first 4/6 (small/large model) epochs, the learning rate is 1, after which we apply an exponential decay:

$$\eta_i = \alpha \eta_{i-1} \quad (7)$$

where  $\eta_i$  is the learning rate at epoch  $i$  and  $\alpha$  the learning rate decay, which is set to 0.5 for the small LSTM and to 0.8 for the large LSTM. The smaller  $\alpha$ , the faster the learning rate decreases. The total number of epochs is fixed to 13/39 (small/large model). During training, 25% of the neurons are dropped (Srivastava et al., 2014) for the small model and 50% for the large model. The weights are randomly initialized to small values (between -0.1 and 0.1 for the small model and between -0.05 and 0.05 for the large model) based on a uniform distribution. We train on mini-batches of 20 with backpropagation through time, where the network is unrolled for 20 steps for the small LSTM and 35 for the large LSTM. The norm of the gradients is clipped at 5 for both models.

For English, we test on the publicly available Penn Treebank (PTB) data set, which contains 900k word tokens for training, 70k word tokens as validation set and 80k words as test set. This data set is small but widely used in related work (among others Zaremba et al. (2015) and Kim et al. (2016)), enabling the comparison between different models. We adopt the same pre-processing as used by previous work (Mikolov et al., 2010) to facilitate comparison, which implies that the dataset contains only lowercase characters (the size of the character vocabulary is 48). Unknown words are mapped to  $\langle unk \rangle$ , but since we do not have the original text, we cannot use the characters of the unknown words for PTB.

The Dutch data set consists of components g, h, n and o of the Corpus of Spoken Dutch (CGN) (Oostdijk, 2000), containing recordings of meetings, debates, courses, lectures and read text. Approximately 80% was chosen as training set (1.4M word tokens), 10% as validation set (180k word tokens) and 10% as test set (190k word tokens). The size of the Dutch data set is chosen to be similar to the size of the English data set. We also use the same vocabulary size as used for Penn Treebank (10k), since

we want to compare the performance on different languages and exclude any effect of the vocabulary size. However, we do not convert all uppercase characters to lowercase (although the data is normalized such that sentence-initial words with a capital are converted to lowercase if necessary) because the fact that a character is uppercase is meaningful in itself. The character vocabulary size is 88 (Dutch also includes more accented characters due to French loan words, e.g. ‘café’). Hence, we do not only compare two different languages but also models with only lowercase characters and models with both upper- and lowercase characters. Moreover, since we have the original text at our disposal (as opposed to PTB), we can use the characters of the unknown words and still have a character-level representation.

## 4.2 Baseline models

In our experiments, we compare the CW model with two word-level baselines: one with the same number of hidden units in the LSTM layers (thus containing more parameters) and one with approximately the same number of parameters as the CW model (like Kim et al. (2016) do), because we are interested in both reducing the number of parameters and improving the performance. For the latter baseline, this implies that we change the number of hidden units from 200 to 175 for the small model and from 650 to 475 for the large, keeping the other hyperparameters the same.

The number of parameters for those models is larger than for all CW models except when only 1 or 2 characters are added. The size difference between the CW models and the smaller word-level models becomes larger if more characters are added, if the size of the characters embeddings is larger and if the character weights are shared. The size of the embedding matrix for a word-level LSTM of size 475 is  $10,000 \times 475 = 4,750,000$  ( $V$  is 10k in all our experiments), whereas for a CW model with 10 character embeddings of size 25 it is of size  $10,000 \times (650 - 10 \times 25) + 10 \times (48 \times 25) = 412,000$  (the size of the character vocabulary for PTB is 48), following equation 5. If the character weights are shared, the size of the embedding matrix is only 401,200 (equation 6).

The baseline perplexities for the smaller word-level models are shown in table 1. In the remainder of this paper, ‘ $w_x$ ’ = means word embeddings of size  $x$  for a word-level model and ‘ $c_x$ ’ means character embeddings of size  $x$  for CW models.

Corpus	Size	Perplexity		
		Validation	Test	
PTB	small	w200	100.7	96.86
		w175	102.62	98.82
	large	w650	87.38	83.6
		w465	88.39	84.38
CGN	small	w200	69.13	76
		w175	69.6	76.78
	large	w650	63.36	70.69
		w475	63.88	70.88

Table 1: Perplexities for the baseline models. Baselines w200 and w650 have the same number of hidden units as the CW models and baselines w175 and w475 approximately have the same number of parameters as the CW models.

## 4.3 English

In figure 2, the results for a small model trained on Penn Treebank are shown. Almost all CW models outperform the word-based baseline with the same number of parameters (2 LSTM layers of 175 units). Only the CW models in which the concatenated character embeddings take up the majority of the total embedding (more than 7 characters of embedding size 15) perform worse. With respect to the word-level LM with more parameters, only small improvements are obtained. The smaller the character embeddings, the better the performance of the CW model. For example, for a total embedding size of only 200, adding 8 character embeddings of size 15 results in an embedding consisting of 120 units ‘character embedding’ and only 80 units ‘word embedding’, which is not sufficient. The two best performing models add 3 and 7 character embeddings of size 5, giving a perplexity of 100.12 and 100.25 respectively, achieving a relative improvement of 2.44%/2.31% w.r.t. the w175 baseline and 0.58%/0.45% w.r.t. the w200 baseline. For those models, the ‘word embedding’ consists of 185 and 165 units respectively.

We test the performance of the CW architecture on a large model too. In figure 3, the results for different embedding sizes are shown. Just like we saw for the small model, the size of the character embeddings should not be too large: for embeddings of size 50 (‘c50’), the performance drops when a larger number of characters is added. The best result is obtained by adding 8 characters with embeddings of size 25 (‘c25’): a perplexity of 85.97 (2.74%/1.61% relative improvement with respect to

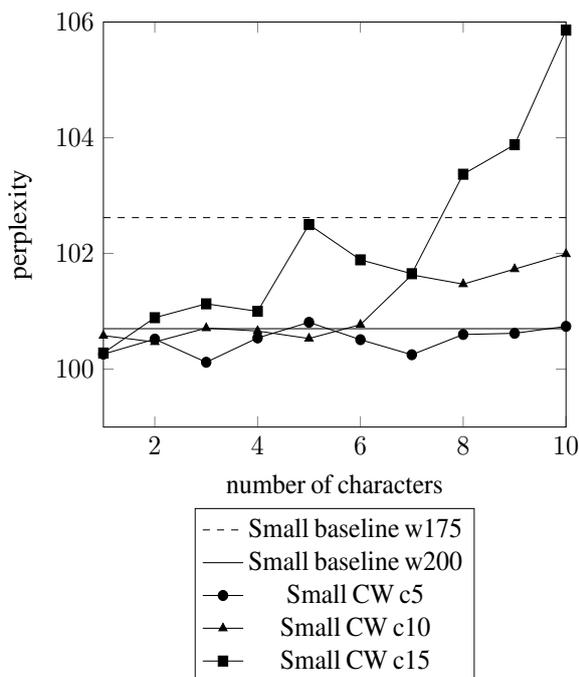

Figure 2: Validation perplexity results on PTB, small model. Different sizes for the character embeddings are tested (‘c5’, ‘c10’, ‘c15’).

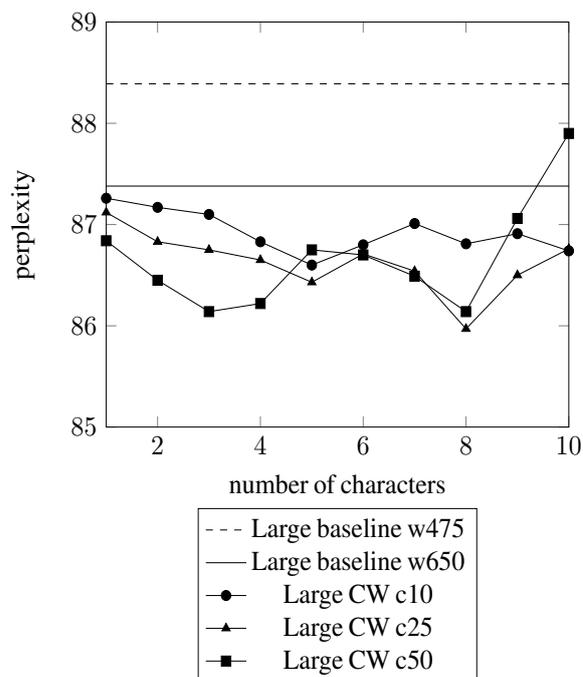

Figure 3: Validation perplexity results on PTB, large model. Different sizes for the character embeddings are tested (‘c10’, ‘c25’, ‘c50’).

the w475/w650 baseline). For embeddings of size 10, adding more than 10 characters gives additional improvements (see figure 4).

We also verify whether the order in which the characters are added is important (figure 4). The best result is achieved by adding the first 3 and the last 3 characters to the model (‘both orders’), giving a perplexity of 85.69, 3.05%/1.87% relative improvement with respect to the w475/w650 baseline. However, adding more characters in both orders causes a decrease in performance. When only adding the characters in the forward order or the backward order, adding the characters in backward order seems to perform slightly better overall (best result: adding 9 characters in the backward order gives a perplexity of 85.7 or 3.04%/1.92% improvement with respect to the w475/w650 baseline).

We can conclude that the size of the character embeddings should be proportional to the total embedding size: the word-level embedding should be larger than the concatenation of the character-level embeddings. Adding characters in the backward order is slightly better than adding them in the forward order, and the largest improvement is made for the large LSTM LM. The test perplexities for some of the best performing models (table 2) confirm these findings.

If we compare the test perplexities with two related models that incorporate characters, we see that our models perform better. Kim et al. (2016) generate character-level embeddings with a convolutional neural network and also report results for both a small and a large model. Their small character-level model has more hidden units than ours (300 compared to 200), but it does not improve with respect to the word-level baseline (since we do not use highway layers, we only compare with the results for models without highway layers). Their large model slightly improves their own baseline perplexity (85.4) by 0.94%. Compare with our results: 2.64% perplexity reduction for the best small LSTM (c5 with  $n = 3$ ) and 2.77% for the best large LSTM (c10 with  $n = 3 + 3(b)$ ). Miyamoto and Cho (2016) only report results for a small model that is trained without dropout, resulting in a baseline perplexity of 115.65. If we train our small model without dropout we get a comparable baseline perplexity (116.33) and a character-word perplexity of 110.54 (compare to 109.05 reported by Miyamoto and Cho (2016)). It remains to be seen whether their model performs equally well compared to better baselines. Moreover, their hybrid character-word model is more complex than ours because it uses a bidirectional LSTM to generate

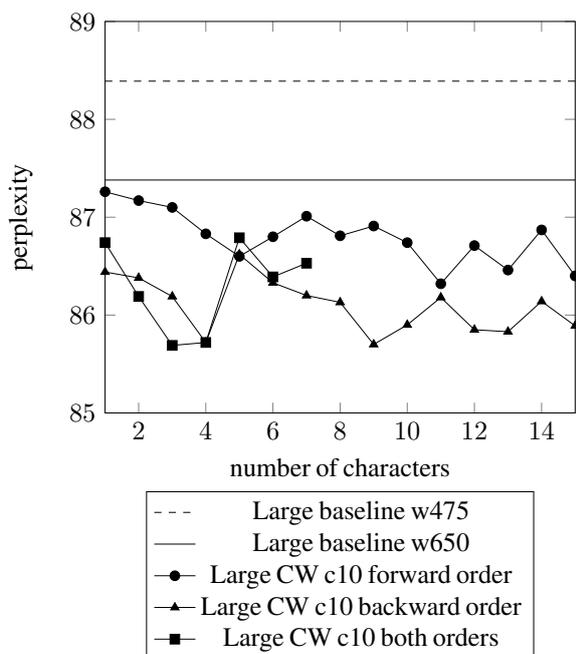

Figure 4: Validation perplexity results on PTB, large model. Several options for the order in which the characters are added are investigated.

the character-level embedding (instead of a lookup table) and a gate to determine the mixing weights between the character- and word-level embeddings.

#### 4.4 Dutch

As we explained in the introduction, we expect that using information about the internal structure of the word will help more for languages with a richer morphology. Although Dutch is still an analytic language (most grammatical relations are marked with separate words or word order rather than morphemes), it has a richer morphology than English because compounding is a productive and widely used process and because it has more lexical variation due to inflection (e.g. verb conjugation, adjective inflection). The results for the LSTM LMs trained on Dutch seem to confirm this hypothesis (see figure 5).

The CW model outperforms the baseline word-level LM both for the small model and the large model. The best result for the small model is obtained by adding 2 or 3 characters, giving a perplexity of 67.59 or 67.65 which equals a relative improvement of 2.89%/2.23% (w175/w200) and 2.80%/2.14% (w175/w200) respectively.

For the large model, we test several embedding sizes and orders for the characters. The best model is the one to which 6 characters in backward order are added, with a perplexity of 60.88 or

Small model	Perplexity
Baseline w175/w200	98.82/96.86
(Kim et al., 2016)	100.3
(Miyamoto and Cho, 2016)	109.05
c5 with $n=3$	<b>96.21</b>
c5 with $n=7$	96.35
Large model	Perplexity
Baseline w475/w650	84.38/83.6
(Kim et al., 2016)	84.6
c25 with $n=8$	82.69
c10 with $n=9(b)$	82.68
c10 with $n=3+3(b)$	<b>82.04</b>

Table 2: Test perplexity results for the best models on PTB. Baseline perplexities are for sizes w175/w200 for a small model and w475/w650 for a large model.  $n$  = number of characters added, (b) means backward order. Comparison with other character-level LMs (Kim et al., 2016) (we only compare to models without highway layers) and character-word models (Miyamoto and Cho, 2016) (they do not use dropout and only report results for a small model).

4.70%/3.91% (w475/w650) relative improvement. Just like for PTB, an embedding size of 25 proves to be the best compromise: if the characters are added in the normal order, 4 characters with embeddings of size 25 is the best model (perplexity 61.47 or 3.77%/2.98% (w475/w650) relative improvement).

These results are confirmed for the test set (table 3). The best small model has a perplexity of 75.04 which is 2.27% compared to the baseline and the best large model has a perplexity of 67.64, a relative improvement of 4.57%. The larger improvement for Dutch might be due to the fact that it has a richer morphology and/or the fact that we can use the surface form of the OOV words for the Dutch data set (see sections 4.1 and 4.7).

#### 4.5 Random CW models

In order to investigate whether the improvements of the CW models are not caused by the fact that the characters add some sort of noise to the input, we experiment with adding real noise – random ‘character’ information – rather than the real characters. Both the number of characters (the length of the random ‘word’) and the ‘characters’ themselves are generated based on a uniform distribution. In table 4, the relative change in perplexity, averaged over models to which 1 to 10 characters are added,

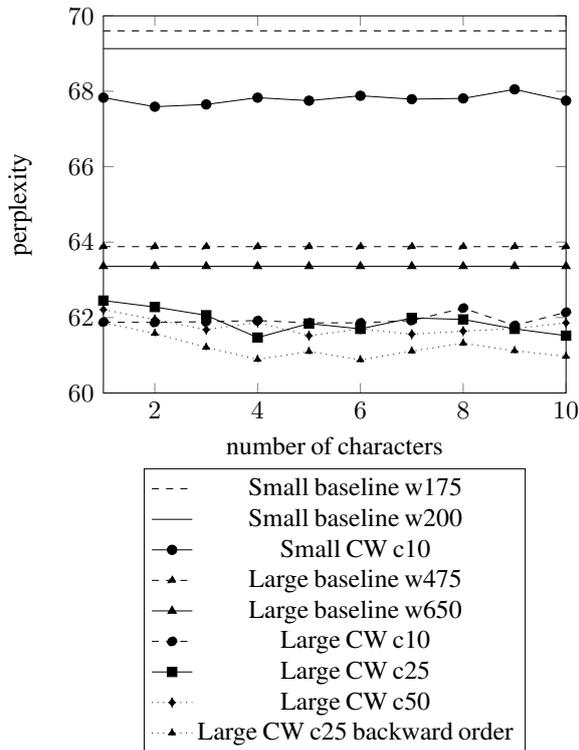

Figure 5: Validation perplexity results on CGN. Several options for the size and order of the character embeddings are investigated.

Small model	Perplexity
Baseline w175/w200	76.78/76
c10 with $n=2$	75.23
c10 with $n=3$	<b>75.04</b>
Large model	Perplexity
Baseline w475/w650	70.88/70.69
c25 with $n=4$	68.79
c25 with $n=6$ ( <i>b</i> )	<b>67.64</b>

Table 3: Test perplexity results for the best models on CGN. Baseline perplexities are for sizes w175/w200 for a small model and w475/w650 for a large model.  $n$  = number of characters added, (*b*) means backward order.

with respect to the baseline word-level LM and the CW model with real characters is shown.

For English, adding random information had a negative impact on the performance with respect to both the baseline and the CW model. For Dutch on the other hand, adding some random noise to the word-level model gave small improvements. However, the random models perform much worse than the CW models. We can conclude that the characters provide meaningful information to the LM.

		Relative change in valid perplexity w.r.t.	
		Baseline	Char-Word
PTB	small c5	0.34 (0.30)	0.54 (0.46)
	large c15	0.00 (0.29)	0.53 (0.49)
CGN	small c10	-0.18 (0.53)	1.79 (0.47)
	large c10	-0.15 (0.26)	1.52 (1.24)

Table 4: Relative change in validation perplexity for models to which **random** information is added, w.r.t. word-level and CW models. The improvements are averaged over the results for adding 1 to 10 characters/random information, the numbers between brackets are standard deviations. Negative numbers indicate a decrease in perplexity.

#### 4.6 Sharing weights

We repeat certain experiments with the CW models, but with embedding matrices that are shared across all character positions (see section 3.2). Note that sharing the weights does not imply that the position information is lost, because for example the first portion of the character-level embedding always corresponds to the character on the first position. Sharing the weights ensures that a character is always mapped onto the same embedding, regardless of the position of that character in the word, e.g. both occurrences of ‘i’ in ‘felicity’ are represented by the same embedding. This effectively reduces the number of parameters.

We compare the performance of the CW models with weight sharing with the baseline word-level LM and the CW model without weight sharing. In table 5, the relative change with respect to those LMs is listed.

CW models with weight sharing generally improve with respect to a word-level baseline, except for the small English LM. For Dutch, the improvements are more pronounced. The difference with the CW model without weight sharing is small (right column), although *not* sharing the weights works slightly better, which suggests that characters can convey different meanings depending on the position in which they occur. Again, the results are more clear-cut for Dutch than for English.

#### 4.7 Dealing with out-of-vocabulary words

As we mentioned in the introduction, we expect that by providing information about the surface form of OOV words (namely, their characters), the number of errors induced by those words should decrease.

		Relative change in valid perplexity w.r.t.	
		Baseline	Char-Word
PTB	small c10	0.53 (0.88)	0.19 (0.67)
	large c10	- 0.54 (0.37)	- 0.02 (0.22)
CGN	small c10	- 1.70 (0.34)	0.24 (0.30)
	large c10	- 2.10 (0.32)	0.15 (0.50)

Table 5: Relative change in validation perplexity for CW models with **weight sharing** for the characters, w.r.t. baseline and CW models without weight sharing. The improvements are averaged over the results for adding 1 until 10 characters, the numbers between brackets are standard deviations. Negative numbers indicate a decrease in perplexity.

We conduct the following experiment to check whether this is indeed the case: for the CGN test set, we keep track of the probabilities of each word during testing. If an OOV word is encountered, we check the probability of the target word given by a word-level LM and a CW LM. The word-level model is a large model of size 475 and the CW model is a large model in which 6 characters embeddings of size 25 in the backward order are used (the best performing CW model in our experiments).

We observe that in 17,483 of the cases, the CW model assigns a higher probability to the target word following an OOV word, whereas the opposite happens only in 10,724 cases. This is an indication that using the character information indeed helps in better modeling the OOV words.

## 5 Conclusion and future work

We investigated a character-word LSTM language model, which combines character and word information by concatenating the respective embeddings. This both reduces the size of the LSTM and improves the perplexity with respect to a baseline word-level LM. The model was tested on English and Dutch, for different model sizes, several embedding sizes for the characters, different orders in which the characters are added and for weight sharing of the characters. We can conclude that for almost all setups, the CW LM outperforms the word-level model, whereas it has fewer parameters than the word-level model with the same number of LSTM units. If we compare with a word-level LM with approximately the same number of parameters, the improvement is larger.

One might argue that using a CNN or an RNN

to generate character-level embeddings is a more general approach to incorporate characters in a LM, but this model is simple, easier to train and smaller. Moreover, related models using a CNN-based character embedding (Kim et al., 2016) do not perform better.

For both English and Dutch, we see that the size of the character embedding is important and should be proportional to the total embedding size: the total size of the concatenated character embeddings should not be larger than the word-level embedding. Not using the characters in the order in which they appear in the word, but in the reversed order (and hence putting more emphasis on the end of the word), performs slightly better, although adding only a few characters both from the beginning and the end of the word achieves good performance too.

Using random inputs instead of the characters performed worse than using the characters themselves, thus refuting the hypothesis that the characters simply introduce noise. Sharing the weights/embedding matrices for the characters reduces the size of the model even more, but causes a small increase in perplexity with respect to a model without weight sharing. Finally, we observe that the CW models are better able to deal with OOV words than word-level LMs.

In future work, we will test other architectures to incorporate character information in a word-level LSTM LM, such as combining a character-level LSTM with a word-level LSTM. Another representation that might be useful uses character co-occurrence vectors (by analogy with the acoustic co-occurrences used by Van hamme (2008; 2012)) rather than one-hot character vectors, because co-occurrences intrinsically give information about the order of the characters. Other models could be more inspired by human language processing: according to the theory of *blocking*, we humans have both a mental lexicon of frequent words and a morphological module that is used to process infrequent/ unknown words or to create new words (see e.g. (Aronoff and Anshen, 2001)). This could correspond to a word-level LM for frequent words and a subword-level LM for infrequent words.

## Abstract

We propose a novel hierarchical Recurrent Neural Network (RNN) for learning sequences of Dialogue Acts (DAs). The input in this task is a sequence of utterances (i.e., conversational contributions) comprising a sequence of tokens, and the output is a sequence of DA labels (one label per utterance). Our model leverages the hierarchical nature of dialogue data by using two nested RNNs that capture long-range dependencies at the dialogue level and the utterance level. This model is combined with an attention mechanism that focuses on salient tokens in utterances. Our experimental results show that our model outperforms strong baselines on two popular datasets, Switchboard and MapTask; and our detailed empirical analysis highlights the impact of each aspect of our model.

## 1 Introduction

The sequence-labeling task involves learning a model that maps an input sequence to an output sequence. Many NLP problems can be treated as sequence-labeling tasks, e.g., part-of-speech (PoS) tagging (Toutanova et al., 2003; Toutanova and Manning, 2000), machine translation (Brown et al., 1993) and automatic speech recognition (Gales and Young, 2008). Recurrent Neural Nets (RNNs) have been the workhorse model for many NLP sequence-labeling tasks, e.g., machine translation (Sutskever et al., 2014) and speech recognition (Amodei et al., 2015), due to their ability to capture long-range dependencies inherent in natural language.

In this paper, we propose a hierarchical RNN for labeling a sequence of utterances (i.e., contributions) in a dialogue with their Dialogue Acts

(DAs). This task is particularly useful for dialogue systems, as knowing the DA of an utterance supports its interpretation, and the generation of an appropriate response. The DA classification problem differs from the aforementioned tasks in the structure of the input and the immediacy of the output. The input in these tasks is a sequence of tokens, e.g., a sequence of words in PoS tagging; while in DA classification, the input is hierarchical, i.e., a conversation comprises a sequence of utterances, each of which has a sequence of tokens (Figure 1). In addition, to be useful for dialogue systems, the DA of an utterance must be determined immediately, hence a bi-directional approach is not feasible.

As mentioned above, RNNs are able to capture long-range dependencies. This ability was harnessed by Shen and Lee (2016) for DA classification. However, they ignored the conversational dimension of the data, treating the utterances in a dialogue as separate instances — an assumption that results in loss of information. To overcome this limitation, we designed a two-layer RNN model that leverages the hierarchical nature of dialogue data: an outer-layer RNN encodes the conversational dimension, and an inner-layer RNN encodes the utterance dimension.

One of the difficulties of sequence labeling is that different elements of an input sequence have different degrees of importance for the task at hand (Shen and Lee, 2016), and the noise introduced by less important elements might degrade the performance of a labeling model. To address this problem, we incorporate into our model the attention mechanism described in (Shen and Lee, 2016), which has yielded performance improvements in DA classification compared to traditional RNNs.

Our empirical results show that our *hierarchical RNN model with an attentional mechanism* out-

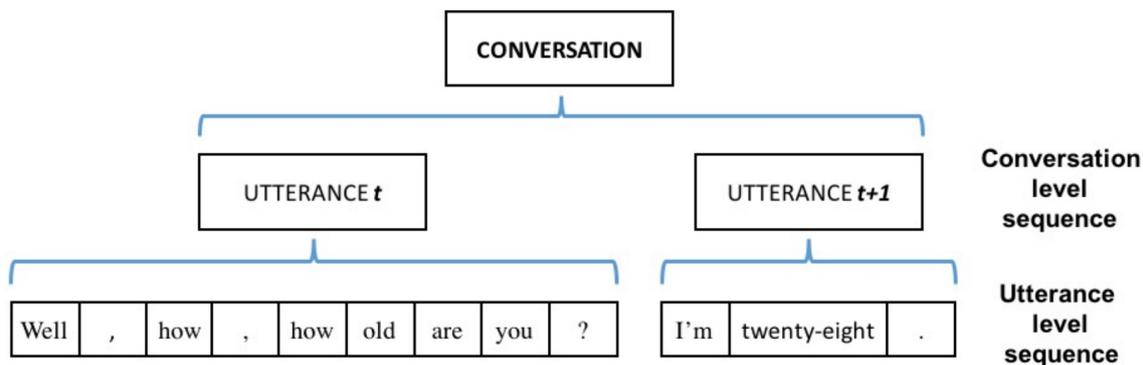

Figure 1: Switchboard data example.

performs strong baselines on two popular datasets: Switchboard (Jurafsky et al., 1997; Stolcke et al., 2000) and MapTask (Anderson et al., 1991). In addition, we provide an empirical analysis of the impact of the main aspects of our model on performance: utterance RNN, conversation RNN, and information source for the attention mechanism.

This paper is organised as follows. In the next section, we discuss related research in DA classification. In Section 3, we describe our RNN. Our experiments and results are presented in Section 4, followed by our analysis and concluding remarks.

## 2 Related Research

**Independent DA classification.** In this approach, each utterance is treated as a separate instance, which allows the application of general classification algorithms. Julia *et al.* (2010) employed a Support Vector Machine (SVM) with n-gram features obtained from an utterance-level Hidden Markov Model (HMM) to ascribe DAs to audio signals and textual transcriptions of the MapTask corpus. Webb *et al.* (2005) used a similar approach, employing cue phrases as features.

**Sequence-based DA classification.** This approach takes advantage of the sequential nature of conversations. In one of the earliest works in DA classification, Stolcke *et al.* (2000) used an HMM with a trigram language model to classify DAs in the Switchboard corpus, achieving an accuracy of 71.0%. In this work, the trigram language model was employed to calculate the symbol emission probability of the HMM. Surendran *et al.* (2006) also used an HMM, but employed output symbol probabilities produced by an SVM classifier, instead of emission probabilities obtained from

a trigram language model. More recently, the Recurrent Convolutional Neural Network model proposed by Kalchbrenner and Blunsom (2013) achieved an accuracy of 73.9% on the Switchboard corpus. In this work, a Convolutional Neural Network encodes each utterance into a vector, which is then treated as input to a conversation-level RNN. The DA is then classified using a softmax layer applied on top of the hidden states of the RNN.

**Attention in Neural Models.** Attentional Neural Models have been successfully applied to sequence-to-sequence mapping tasks, notably machine translation and DA classification. Bahdanau *et al.* (2014) proposed an attentional encoder-decoder architecture for machine translation. The encoder encodes the input sequence into a sequence of hidden vectors; the decoder decodes the information stored in the hidden sequence to generate the output; and the attentional mechanism is used to summarize a sentence into a context vector dynamically, helping the decoder decide which part of the sequence to attend to when generating a target word. As mentioned above, Shen and Lee (2016) employed an attentional RNN for independent DA classification; they achieved an accuracy of 72.6% on textual transcriptions of the Switchboard corpus.

## 3 Model Description

Suppose we have a sequence of observations  $\mathbf{o} := \{\mathbf{o}_1, \mathbf{o}_2, \dots, \mathbf{o}_m\}$  and the corresponding sequence of labels  $\mathbf{y} := \{y_1, y_2, \dots, y_m\}$ , where each observation  $\mathbf{o}_t$  is a sequence. Our hierarchical-attentional model, denoted *HA-RNN*, learns the conditional probability  $P(\mathbf{y}|\mathbf{o})$  relating the ob-

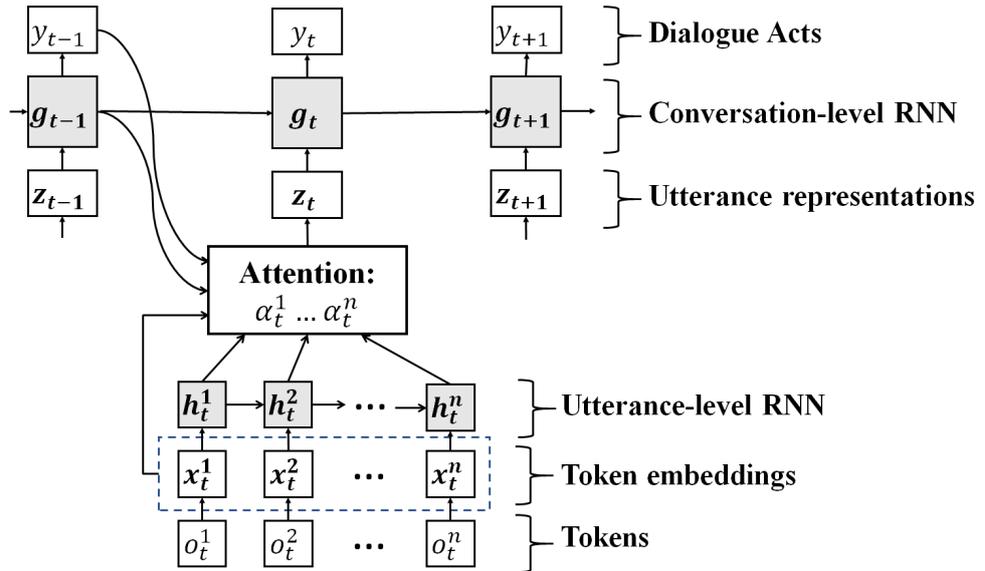

Figure 2: HA-RNN – Hierarchical-attentional RNN model.

served sequence to its label sequence, based on the following decomposition:

$$\begin{aligned}
 &P(\{y_1, y_2, \dots, y_m\} | \{\mathbf{o}_1, \mathbf{o}_2, \dots, \mathbf{o}_m\}) \\
 &= \prod_{t=1}^m P(y_t | \mathbf{y}_{<t}, \mathbf{o}_{\leq t}) \quad (1)
 \end{aligned}$$

Note that our model conditions on the full history, rather than a finite history as done in Markov models, such as maximum entropy Markov models (McCallum et al., 2000).

We employ neural networks to model the constituent conditional distributions. Our model comprises three main elements (Figure 2): (1) an *utterance-level RNN* that encodes the information within the utterances; (2) an *attentional mechanism* that highlights the important parts of an input utterance, and summarizes the information within the utterance into a real-valued vector; and (3) a *conversation-level RNN* that encodes the information of the whole dialogue sequence. As discussed in Section 1, our hierarchical-RNN design was motivated by the structure of the input data, while the attentional mechanism has proven to be effective in DA classification (Shen and Lee, 2016).

**Utterance-level RNN.** This RNN was implemented using LSTM (Hochreiter and Schmidhuber, 1997; Graves, 2013). First, an embedding matrix maps each token (e.g., word or punctuation marker) into a dense vector representation. Let us denote the sequence of tokens in the  $t$ -th utterance as  $\mathbf{o}_t := \{o_t^1, o_t^2, \dots, o_t^n\}$ , which is

mapped into the sequence of embedding vectors  $\mathbf{x}_t := \{x_t^1, x_t^2, \dots, x_t^n\}$  using the token embedding table  $\mathbf{w}$ :

$$\mathbf{x}_t^i = \mathbf{e}_w(o_t^i) \quad (2)$$

The utterance RNN then takes as input this sequence of vectors, and produces a sequence of corresponding hidden vectors  $\mathbf{h}_t = \{h_t^1, h_t^2, \dots, h_t^n\}$ , which capture the information within the tokens, and put the tokens in their sentential context:

$$\mathbf{h}_t^i = \text{RNN}_{utter}(\mathbf{h}_t^{i-1}, \mathbf{x}_t^i) \quad (3)$$

The parameters of the utterance RNN and the token embeddings are learned during training.

**Attentional mechanism.** This mechanism summarizes the hidden vectors of the utterance-level RNN into a single vector representing the whole utterance. The attention vector is a sequence of positive numbers that sum to 1, where each number corresponds to a token in an utterance, and represents the importance of the token for understanding the DA associated with the utterance. The final representation  $\mathbf{z}_t$  of the  $t$ -th utterance is the sum of the corresponding elements of its hidden vectors weighted by attention weights:

$$\mathbf{z}_t = \sum_i \alpha_t^i \mathbf{h}_t^i \quad (4)$$

We posit that the main factors for determining the importance of a token for DA classification are: (1) the meaning of the token, as represented

by its embedding vector; and (2) the full context of the conversation, particularly the previous DA. For example, if the DA of an utterance is *Yes-No-Question*, and there is a “yes” or “no” token in the next utterance, this token is likely to be important. Equation 5 integrates these factors to compute attention scores:

$$s_t^i = \mathbf{U} \cdot \tanh(W^{(\text{in})} \cdot \mathbf{x}_t^i + W^{(\text{co})} \cdot \mathbf{g}_{t-1} + \mathbf{e}_a(y_{t-1}) + \mathbf{b}^{(\text{in})}) \quad (5)$$

where vector  $\mathbf{e}_a(y_{t-1})$  denotes the embedding of the previous DA, which is similar to the embedding of tokens; and vector  $\mathbf{g}_{t-1}$  is the previous hidden vector of the conversation-level RNN, detailed below, which summarizes the conversation so far.  $W^{(\text{in})}$  and  $W^{(\text{co})}$  are parameter matrices for the input tokens and the conversational context respectively, and  $\mathbf{U}$  and  $\mathbf{b}^{(\text{in})}$  are parameter vectors — all of which are learned during training. The scores  $s_t^i$  are mapped into a probability vector by means of a softmax function:

$$\boldsymbol{\alpha}_t = \text{softmax}(\mathbf{s}_t) \quad (6)$$

**Conversation-level RNN.** This RNN is structurally similar to the utterance-level RNN. The input to the conversation-level RNN is the sequence of vectors  $\mathbf{z}$  generated for the utterances in a conversation, which is then encoded by the RNN into a sequence of hidden vectors  $\mathbf{g}$ :

$$\mathbf{g}_t = \text{RNN}_{\text{convers}}(\mathbf{g}_{t-1}, \mathbf{z}_t) \quad (7)$$

This information is then used in the generation of the output DA:

$$y_t | \mathbf{y}_{<t}, \mathbf{o}_{\leq t} \sim \text{softmax}(\mathbf{W}^{(\text{out})} \cdot \mathbf{g}_t + \mathbf{b}^{(\text{out})}) \quad (8)$$

where the matrix  $\mathbf{W}^{(\text{out})}$ , vector  $\mathbf{b}^{(\text{out})}$  and the parameters of the conversation-level network  $\text{RNN}_{\text{convers}}$  are learned during the training.

During testing, ideally a given sequence of observed utterances  $\mathbf{o}$  should be decoded to a label sequence  $\mathbf{y}$  that maximizes the conditional probability  $P(\mathbf{y}|\mathbf{o})$  according to the model. However, finding the highest-scoring label sequence is a computationally hard problem, since the conversation-level RNN does not lend itself to dynamic programming. Therefore, we employ a greedy decoding approach, where, going left-to-right, at each step we choose the  $y_t$  with the highest probability in the local DA distribution. This

method is common practice in sequence-labeling RNNs, e.g., in neural machine translation (Bahdanau et al., 2014; Sutskever et al., 2014; Luong et al., 2015).

## 4 Experiments

### 4.1 Data sets

We tested our models on the Switchboard corpus (Jurafsky et al., 1997; Stolcke et al., 2000) and the MapTask corpus (Anderson et al., 1991) — two popular datasets used for DA classification. At this stage of our research, we consider only transcriptions of the conversations in both corpora (the incorporation of phonetic input (Taylor et al., 1998; Wright Hastie et al., 2002; Julia et al., 2010) is the subject of future work). Thus, we compare our results only with those obtained by systems that employ transcriptions exclusively.

**Switchboard corpus.** This corpus contains DA-annotated transcriptions of 1155 telephone conversations with no specific topic, which have an average of 176 utterances. Originally, there were approximately 226 DA tags in the corpus, but in the DA classification literature, the tags are usually clustered into 42 tags.<sup>1</sup> Table 1(a) shows percentages of the seven most frequent tags in the data. Following (Stolcke et al., 2000), in our experiments we use 1115 conversations for training, 21 for development and 19 for testing.

**MapTask corpus.** This is a richly annotated corpus that comprises 128 dialogues about instruction following, containing 212 utterances on average. Each conversation has an instruction giver and an instruction follower. The instruction giver gives directions with reference to a map, which the instruction follower must follow. The MapTask corpus has 13 DA tags, including the “unclassifiable” tag. Table 1(b) shows percentages of the seven most frequent tags in the data. We randomly split this data into 80% training, 10% development and 10% test sets, which contain 103, 12 and 13 conversations respectively.

### 4.2 Results

We experimented with different embedding sizes and hidden layer dimensions for our model *HA-RNN*, and selected the following, which yielded

<sup>1</sup>The official manual stated that there were originally 220 tags. We follow the tag-clustering procedure by Christopher Potts described in [comprag.christopherpotts.net/swda.html](http://comprag.christopherpotts.net/swda.html).

DA tag	Example	Percentage	DA tag	Example	Percentage
<i>Statement-non-opinion</i>	I'm twenty-eight	36%	<i>Acknowledge</i>	Mmhmm	21%
<i>Acknowledge (Backchannel)</i>	Uh-huh	19%	<i>Instruct</i>	And we're finished	16%
<i>Statement-opinion</i>	I think it's great	13%	<i>Reply_y</i>	Yeah	12%
<i>Agree/Accept</i>	That's exactly it	5%	<i>Explain</i>	I've got a bridge	8%
<i>Abandoned or Turn-Exit</i>	So,	5%	<i>Check</i>	Is that it	8%
<i>Appreciation</i>	I can imagine.	2%	<i>Ready</i>	And then	8%
<i>Yes-No-Question</i>	Do you?	2%	<i>Align</i>	See what i mean	7%

(a) Switchboard

(b) MapTask

Model	Accuracy
<i>RCNN</i>	73.9%
<i>RNN-Attentional-C</i>	72.6%
<i>HMM-trigram-C</i>	71.0%
<i>HA-RNN</i>	<b>74.5%</b>

Table 2: Performance on Switchboard.

Model	Accuracy
<i>HMM-trigram-C</i>	52.3%
<i>Random Forest</i>	52.5%
<i>Random Forest + prev DA</i>	55.3%
<i>HA-RNN</i>	<b>63.3%</b>

Table 3: Performance on MapTask.

the best performance with reasonable run times. The word-embedding size was set to 250, and the DA-embedding size to 180. The hidden dimension of the utterance-level RNN was set to 160, and the hidden dimension of the conversation-level RNN was set to 250. Our model was implemented with the CNN package.<sup>2</sup> During training, the negative log-likelihood was optimized using Adagrad (Duchi et al., 2011), with dropout rate 0.5 to prevent over-fitting (Srivastava et al., 2014). Training terminated when the log-likelihood of the development set did not improve. As mentioned in Section 3, during testing, the sequence of output labels was generated with greedy decoding. Statistical significance was computed on the MapTask test data using McNemar’s test with  $\alpha = 0.05$  (we could not compute statistical significance for the Switchboard results, because they were obtained from the literature, and we did not have access to per-conversation labels).

**Switchboard.** We compare our model’s performance with that of the following strong baselines: (*RCNN*) the recurrent convolutional neural network model from (Kalchbrenner and Blunsom, 2013); (*RNN-Attentional-C*) the attention-based RNN classifier from (Shen and Lee, 2016); and (*HMM-trigram-C*) the HMM-based classifier from (Stolcke et al., 2000).

The results in Table 2 show that our model outperforms these baselines.<sup>3</sup> The higher ac-

<sup>2</sup>[github.com/clab/cnn](https://github.com/clab/cnn).

<sup>3</sup>Two other works on Switchboard DA classification (Gambäck et al., 2011; Webb and Ferguson, 2010) used experimental setups that differ from ours, respectively obtaining

curacy of our model compared to classifier-based approaches (i.e., *RNN-Attentional-C* and *HMM-trigram-C*) confirms that taking into account dependencies among the DAs through the conversation-level RNN improves accuracy. Furthermore, the better performance of our model compared to *RCNN* shows that summarizing utterances with an RNN augmented with an attention architecture is more effective than using a convolution architecture for DA sequence labeling.

**MapTask.** Due to the unavailability of standard training/development/test sets for this dataset, we compare the results obtained by our model with those obtained by our implementation of the following independent DA classifiers: *HMM-trigram-C* (Stolcke et al., 2000); *Random Forest* – an instance-based random forest classifier; and *Random Forest + prev DA* – a random forest classifier that uses the previous DA tag.

The results in Table 3 show that our model outperforms these baselines (statistically significant). These results reinforce the insights from the Switchboard corpus, whereby taking into account conversational dependencies between DAs substantially improves DA-labeling performance.<sup>4</sup>

accuracies of 77.85% and 80.72%. However, these results are not directly comparable to Stolcke *et al.*’s (2000) or ours, and are therefore excluded from our comparison.

<sup>4</sup>Two studies on MapTask DA classification were performed under experimental setups that differ from ours: Julia *et al.* (2010) employed *HMM+SVM* on text transcriptions and audio signals, obtaining an accuracy of 55.4% for transcriptions only. Surendran and Levow (2006) used *Viterbi+SVM*, posting a classification accuracy of 59.1% for transcriptions — the best result among systems that employ transcription data exclusively. Unfortunately, Julia *et al.*’s de-

## 5 Analysis

### 5.1 Architectural analysis

We investigate the influence of the main components of our model on performance by creating variants of our model through the addition or removal of connections or layers. We then compare the performance of these variants with that of the original model in terms of DA-classification accuracy and negative log-likelihood on the test, development and training partitions of our datasets. As done in Section 4, statistical significance is calculated for the test partitions of both datasets using McNemar’s test with  $\alpha = 0.05$ .

**Does an RNN at the utterance level help?** To answer this question, we create a variant, denoted *woUttRNN*, where attentional coefficients are applied directly to the token embeddings. Thus, Equation 4 is changed to Equation 9:

$$\mathbf{z}_t = \sum_i \alpha_t^i \mathbf{x}_t^i \quad (9)$$

As seen in Tables 4 and 5, removing the utterance-level RNN (*woUttRNN*) reduces the accuracy and increases the negative log likelihood for the training, development and test partitions of both datasets. These changes are statistically significant for the test set.

**Which sources of information are critical for computing the attentional component?** In our main model, *HA-RNN*, we calculate the attentional signal using information from the previous DA, the previous hidden vector representation of the conversation-level RNN, and the embeddings of the tokens. To determine the contribution of the first two resources to the performance of the model, we create two variants of *HA-RNN*: *woDA2Attn*, which employs only the previous conversation-level RNN hidden vector; and *woHid2Attn*, which employs only the previous DA. Thus, in *woDA2Attn*, Equation 5 becomes Equation 10, and in *woHid2Attn*, Equation 5 becomes Equation 11:

$$s_t^i = \mathbf{U} \cdot \tanh(W^{(\text{in})} \cdot \mathbf{x}_t^i + W^{(\text{co})} \cdot \mathbf{g}_{t-1} + \mathbf{b}^{(\text{in})}) \quad (10)$$

$$s_t^i = \mathbf{U} \cdot \tanh(W^{(\text{in})} \cdot \mathbf{x}_t^i + \mathbf{e}_a(y_{t-1}) + \mathbf{b}^{(\text{in})}) \quad (11)$$

scription of their MapTask subset is not sufficient to replicate their experiment, and Surendran and Levow’s data split is not accessible. Notwithstanding the difference in conditions, our model’s accuracy is superior to theirs.

As seen in Tables 4 and 5, both of these resources provide valuable information, but the changes in performance due to the omission of these resources are smaller than those obtained with *woUttRNN*. Removing the DA connection (*woDA2Attn*) or the previous conversation-level RNN hidden vector (*woHid2Attn*) leads to statistically significant drops in accuracy and increases in negative log-likelihood on the test partitions of both datasets. The changes in performance with respect to the development and training sets vary across the datasets. As seen in Table 4, both models exhibit accuracy drops (and small increases in negative log-likelihood) on the Switchboard development set, but small accuracy increases (and negative log-likelihood drops) on the Switchboard training set — an indication of over-fitting. In contrast, as seen in Table 5, both models yield a negligible or no drop in accuracy on the MapTask development set, while both yield a drop in accuracy on the training set.

**How important is the RNN at the conversation level?** To answer this question, we create a variant of our *HA-RNN* model, denoted *woConvRNN*, where the recurrent connections between the units in the conversation-level RNN are removed. The LSTM basis function is calculated with a fixed vector  $\mathbf{g}_0$  instead of the previous time step’s vector. Thus Equation 7 becomes Equation 12:

$$\mathbf{g}_t = \mathbf{f}(\mathbf{g}_0, \mathbf{z}_t) \quad (12)$$

As seen in Tables 4 and 5, *HA-RNN* outperforms *woConvRNN* on the training/development/test partitions of both datasets. The difference between the performance of *HA-RNN* and *woConvRNN* is statistically significant for the test set.

**How effective are the DA connections?** We have seen that the DA connections improve our model’s performance when they are used to calculate the attentional signal. However, intuitively, the previous DA can also directly provide information about the current DA. For example, it is often the case that a *Yes-No-Question* is followed by *Reply.y* or *Reply.n*. To reflect this observation, we create another model, denoted *wDA2DA*, that has an additional direct connection between the previous DA and the current DA. That is, Equation 8 becomes Equation 13:

$$y_t | \mathbf{y}_{<t}, \mathbf{o}_{\leq t} \sim \text{softmax}(\mathbf{W}^{(\text{out})} \cdot \mathbf{g}_t + \mathbf{e}_o(y_{t-1}) + \mathbf{b}^{(\text{out})}) \quad (13)$$

	Accuracy			Neg log likelihood		
	Test	Dev	Train	Test	Dev	Train
<i>HA-RNN</i>	<b>63.3%</b>	<b>61.9%</b>	<b>73.4%</b>	<b>3486</b>	3228	<b>18191</b>
<i>woUttRNN</i>	56.9%	58.0%	62.2%	3823	3445	25074
<i>woDA2Attn</i>	61.4%	61.7%	70.1%	3539	<b>3212</b>	19780
<i>woHid2Attn</i>	62.2%	<b>61.9%</b>	71.8%	3487	3248	19132
<i>woConvRNN</i>	58.9%	60.0%	66.9%	3579	3248	20961
<i>wDA2DA</i>	58.2%	58.4%	69.3%	4014	3663	21135

Table 5: Performance of variants of the *HA-RNN* model on MapTask.

As seen in Tables 4 and 5, *wDA2DA* performs much worse than *HA-RNN*. We posit that this happens due to the *exposure bias* problem (Ranzato et al., 2015). That is, during training, the model has access to the correct DA of the previous utterance. However, during testing, the decoding process has access only to predicted DAs, which may lead to the propagation of errors. To quantify the effect of this problem on our model, we designed another experiment where the variants of our model can access the correct DA even during testing; the results for the test partitions of both datasets appear in Table 6.

The results in Table 6 show that exposure bias has different effects on the different variants of our model. As expected, *woDA2Attn*, which does not consider the previous DA, exhibits no change in performance between the oracle and greedy conditions. The models that employ a DA connection to compute the attention signal (*HA-RNN*, *woUttRNN*, *woHid2Attn*, *woConvRNN*) show a slight improvement in accuracy when using the correct DA as input, instead of the predicted DA. In contrast, *wDA2DA* shows large improvements when using the correct DA (3.5% on Switchboard and 6.8% on MapTask), becoming the best-performing model for both datasets. This improvement may

be attributed to the direct connection between the DAs in this model, which increases the influence of previous DAs on the prediction of the current DA — previous DA predictions that are largely correct will substantially improve the performance of *wDA2DA*, while noisy DA predictions will have the opposite effect.

## 5.2 Attentional Analysis

We analyze how our model *HA-RNN* distributes attention over the tokens in an utterance in order to identify tokens in focus.

Figure 3 shows how the attentional vector highlights the most important tokens in sample utterances in the context of the DA-classification task. For example, in “yes I do”, the most important token that identifies the *Reply\_y* class is the token “yes”, which receives most of the probability mass from the attention mechanism.

Table 7 shows the most attended tokens for four classes of DA in MapTask. We compiled these lists by computing the average attention that a token received for all the utterances in a DA class (we excluded tokens that appear less than 5 times). As shown in Table 7, both important tokens “move” and “yes” in Figure 3 appear in their respective DA columns. Two of the most common

labels, *Acknowledge* and *Reply\_y*, have very similar attended tokens. In fact, many utterances in *Acknowledge* and *Reply\_y* have the same text form. Thus, the distinction between the two classes is

highly dependent upon the conversational context. Also, note that although *Reply\_n* is not one of the most common DAs in MapTask, our model can still learn the most important tokens for this DA.

## 6 Conclusions

In this paper, we proposed a novel hierarchical RNN for learning sequences of DAs. Our model leverages the hierarchical nature of dialogue data by using two nested RNNs that capture long-range dependencies at the conversation level and the utterance level. We further combine the model with an attention mechanism to focus on salient tokens in utterances. Our experimental results show that our model outperforms strong baselines on two popular datasets: Switchboard and MapTask. In the future, we plan to address the exposure bias problem, and incorporate acoustic features and speaker information into our model.

## Abstract

Teaching machines to accomplish tasks by conversing naturally with humans is challenging. Currently, developing task-oriented dialogue systems requires creating multiple components and typically this involves either a large amount of handcrafting, or acquiring costly labelled datasets to solve a statistical learning problem for each component. In this work we introduce a neural network-based text-in, text-out end-to-end trainable goal-oriented dialogue system along with a new way of collecting dialogue data based on a novel pipe-lined Wizard-of-Oz framework. This approach allows us to develop dialogue systems easily and without making too many assumptions about the task at hand. The results show that the model can converse with human subjects naturally whilst helping them to accomplish tasks in a restaurant search domain.

## 1 Introduction

Building a task-oriented dialogue system such as a hotel booking or a technical support service is difficult because it is application-specific and there is usually limited availability of training data. To mitigate this problem, recent machine learning approaches to task-oriented dialogue system design have cast the problem as a partially observable Markov Decision Process (POMDP) (Young et al., 2013) with the aim of using reinforcement learning (RL) to train dialogue policies online through interactions with real users (Gašić et al., 2013). However, the language understanding (Henderson et al., 2014; Yao et al., 2014) and language generation (Wen et al., 2015b; Wen et al., 2016) modules still rely on supervised learning and therefore

need corpora to train on. Furthermore, to make RL tractable, the state and action space must be carefully designed (Young et al., 2013; Young et al., 2010), which may restrict the expressive power and learnability of the model. Also, the reward functions needed to train such models are difficult to design and hard to measure at run-time (Su et al., 2015; Su et al., 2016).

At the other end of the spectrum, sequence to sequence learning (Sutskever et al., 2014) has inspired several efforts to build end-to-end trainable, non-task-oriented conversational systems (Vinyals and Le, 2015; Shang et al., 2015; Serban et al., 2015b). This family of approaches treats dialogue as a source to target sequence transduction problem, applying an encoder network (Cho et al., 2014) to encode a user query into a distributed vector representing its semantics, which then conditions a decoder network to generate each system response. These models typically require a large amount of data to train. They allow the creation of effective chatbot type systems but they lack any capability for supporting domain specific tasks, for example, being able to interact with databases (Sukhbaatar et al., 2015; Yin et al., 2015) and aggregate useful information into their responses.

In this work, we propose a neural network-based model for task-oriented dialogue systems by balancing the strengths and the weaknesses of the two research communities: the model is end-to-end trainable<sup>1</sup> but still modularly connected; it does not directly model the user goal, but nevertheless, it still learns to accomplish the required task by providing *relevant* and *appropriate* responses at each turn; it has an explicit representation of database (DB) attributes (slot-value pairs) which it uses to achieve a high task success rate, but has a distributed representation of user intent (dialogue act)

<sup>1</sup>We define *end-to-end trainable* as that each system module is trainable from data except for a database operator.

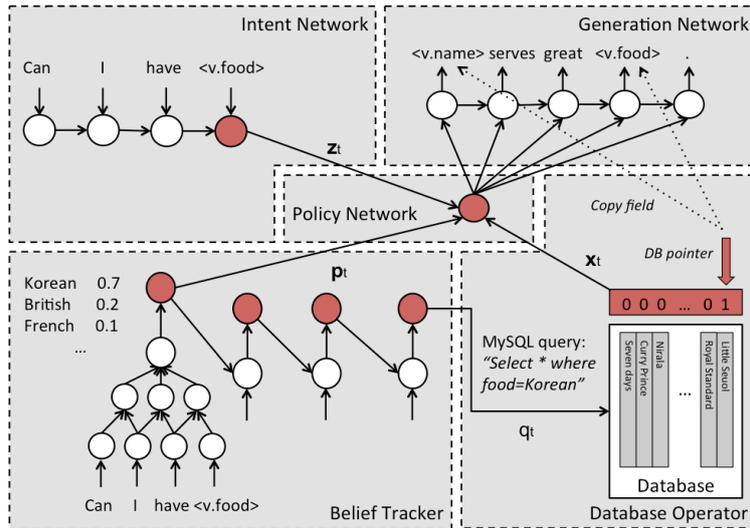

Figure 1: The proposed end-to-end trainable dialogue system framework

to allow ambiguous inputs; and it uses dellexicalisation<sup>2</sup> and a weight tying strategy (Henderson et al., 2014) to reduce the data required to train the model, but still maintains a high degree of freedom should larger amounts of data become available. We show that the proposed model performs a given task very competitively across several metrics when trained on only a few hundred dialogues.

In order to train the model for the target application, we introduce a novel pipe-lined data collection mechanism inspired by the Wizard-of-Oz paradigm (Kelley, 1984) to collect human-human dialogue corpora via crowd-sourcing. We found that this process is simple and enables fast data collection online with very low development costs.

## 2 Model

We treat dialogue as a sequence to sequence mapping problem (modelled by a sequence-to-sequence architecture (Sutskever et al., 2014)) augmented with the dialogue history (modelled by a set of belief trackers (Henderson et al., 2014)) and the current database search outcome (modelled by a database operator), as shown in Figure 1. At each turn, the system takes a sequence of tokens<sup>2</sup> from the user as input and converts it into two internal representations: a distributed representation generated by an intent network and a probability distribution over slot-value pairs called the belief state (Young et al., 2013) generated by a set of belief trackers. The database operator then selects the

<sup>2</sup>Dellexicalisation: we replaced slots and values by generic tokens (e.g. keywords like Chinese or Indian are replaced by <v.food> in Figure 1) to allow weight sharing.

most probable values in the belief state to form a query to the DB, and the search result, along with the intent representation and belief state are transformed and combined by a policy network to form a single vector representing the next system action. This system action vector is then used to condition a response generation network (Wen et al., 2015a; Wen et al., 2015b) which generates the required system output token by token in skeletal form. The final system response is then formed by substituting the actual values of the database entries into the skeletal sentence structure. A more detailed description of each component is given below.

### 2.1 Intent Network

The intent network can be viewed as the encoder in the sequence-to-sequence learning framework (Sutskever et al., 2014) whose job is to encode a sequence of input tokens  $w_0^t, w_1^t, \dots, w_N^t$  into a distributed vector representation  $\mathbf{z}_t$  at every turn  $t$ . Typically, a Long Short-term Memory (LSTM) network (Hochreiter and Schmidhuber, 1997) is used and the last time step hidden layer  $\mathbf{z}_t^N$  is taken as the representation,

$$\mathbf{z}_t = \mathbf{z}_t^N = \text{LSTM}(w_0^t, w_1^t, \dots, w_N^t) \quad (1)$$

Alternatively, a convolutional neural network (CNN) can be used in place of the LSTM as the encoder (Kalchbrenner et al., 2014; Kim, 2014),

$$\mathbf{z}_t = \text{CNN}(w_0^t, w_1^t, \dots, w_N^t) \quad (2)$$

and here we investigate both. Since all the slot-value specific information is dellexicalised, the encoded vector can be viewed as a distributed intent

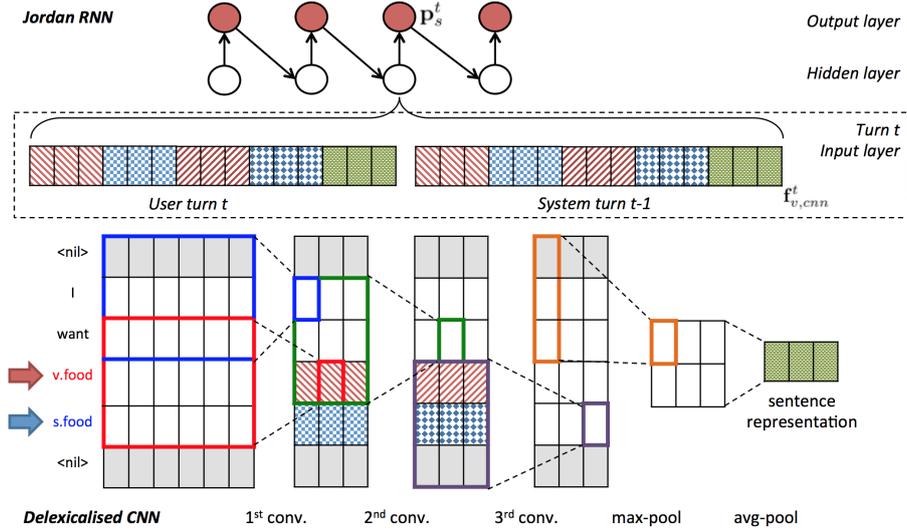

Figure 2: Tied Jordan-type RNN belief tracker with delexicalised CNN feature extractor. The output of the CNN feature extractor is a concatenation of top-level sentence (green) embedding and several levels of intermediate ngram-like embeddings (red and blue). However, if a value cannot be delexicalised in the input, its ngram-like embeddings will all be padded with zeros. We pad zero vectors (in gray) before each convolution operation to make sure the representation at each layer has the same length. The output of each tracker  $\mathbf{p}_s^t$  is a distribution over values of a particular slot  $s$ .

representation which replaces the hand-coded dialogue act representation (Traum, 1999) in traditional task-oriented dialogue systems.

## 2.2 Belief Trackers

Belief tracking (also called Dialogue State tracking) provides the core of a task-oriented spoken dialogue system (SDS) (Henderson, 2015). Current state-of-the-art belief trackers use discriminative models such as recurrent neural networks (RNN) (Mikolov et al., 2010; Wen et al., 2013) to directly map ASR hypotheses to belief states (Henderson et al., 2014; Mrkšić et al., 2016). Although in this work we focus on text-based dialogue systems, we retain belief tracking at the core of our system because: (1) it enables a sequence of free-form natural language sentences to be mapped into a fixed set of slot-value pairs, which can then be used to query a DB. This can be viewed as a simple version of a semantic parser (Berant et al., 2013); (2) by keeping track of the dialogue state, it avoids learning unnecessarily complicated long-term dependencies from raw inputs; (3) it uses a smart weight tying strategy that can greatly reduce the data required to train the model, and (4) it provides an inherent robustness which simplifies future extension to spoken systems.

Using each user input as new evidence, the task of a belief tracker is to maintain a multinomial dis-

tribution  $p$  over values  $v \in V_s$  for each informable slot  $s$ , and a binary distribution for each requestable slot<sup>3</sup>. Each slot in the ontology  $\mathbb{G}^4$  has its own specialised tracker, and each tracker is a Jordan-type (recurrence from output to hidden layer) (Jordan, 1989) RNN<sup>5</sup> with a CNN feature extractor, as shown in Figure 2. Like Mrkšić et al. (2015), we tie the RNN weights together for each value  $v$  but vary features  $\mathbf{f}_v^t$  when updating each pre-softmax activation  $g_v^t$ . The update equations for a given slot  $s$  are,

$$\mathbf{f}_v^t = \mathbf{f}_{v,cnn}^t \oplus p_v^{t-1} \oplus p_{\emptyset}^{t-1} \quad (3)$$

$$g_v^t = \mathbf{w}_s \cdot \text{sigmoid}(\mathbf{W}_s \mathbf{f}_v^t + \mathbf{b}_s) + b'_s \quad (4)$$

$$p_v^t = \frac{\exp(g_v^t)}{\exp(g_{\emptyset,s}) + \sum_{v' \in V_s} \exp(g_{v'}^t)} \quad (5)$$

where vector  $\mathbf{w}_s$ , matrix  $\mathbf{W}_s$ , bias terms  $\mathbf{b}_s$  and  $b'_s$ , and scalar  $g_{\emptyset,s}$  are parameters.  $p_{\emptyset}^t$  is the probability that the user has not mentioned that slot up to turn  $t$  and can be calculated by substituting  $g_{\emptyset,s}$  for  $g_v^t$  in the numerator of Equation 5. In order to model the discourse context at each turn, the feature vector

<sup>3</sup>Informable slots are slots that users can use to constrain the search, such as food type or price range; Requestable slots are slots that users can ask a value for, such as address.

<sup>4</sup>A small knowledge graph defining the slot-value pairs the system can talk about for a particular task.

<sup>5</sup>We don't use the recurrent connection for requestable slots since they don't need to be tracked.

$\mathbf{f}_{v,cnn}^t$  is the concatenation of two CNN derived features, one from processing the user input  $u_t$  at turn  $t$  and the other from processing the machine response  $m_{t-1}$  at turn  $t - 1$ ,

$$\mathbf{f}_{v,cnn}^t = \text{CNN}_{s,v}^{(u)}(u_t) \oplus \text{CNN}_{s,v}^{(m)}(m_{t-1}) \quad (6)$$

where every token in  $u_t$  and  $m_{t-1}$  is represented by an embedding of size  $N$  derived from a 1-hot input vector. In order to make the tracker aware when delexicalisation is applied to a slot or value, the slot-value specialised CNN operator  $\text{CNN}_{s,v}^{(\cdot)}(\cdot)$  extracts not only the top level sentence representation but also intermediate n-gram-like embeddings determined by the position of the delexicalised token in each utterance. If multiple matches are observed, the corresponding embeddings are summed. On the other hand, if there is no match for a particular slot or value, the empty n-gram embeddings are padded with zeros. In order to keep track of the position of delexicalised tokens, both sides of the sentence are padded with zeros before each convolution operation. The number of vectors is determined by the filter size at each layer. The overall process of extracting several layers of position-specific features is visualised in Figure 2.

The belief tracker described above is based on Henderson et al. (2014) with some modifications: (1) only probabilities over informable and requestable slots and values are output, (2) the recurrent memory block is removed, since it appears to offer no benefit in this task, and (3) the n-gram feature extractor is replaced by the CNN extractor described above. By introducing slot-based belief trackers, we essentially add a set of intermediate labels into the system as compared to training a pure end-to-end system. Later in the paper we will show that these tracker components are critical for achieving task success. We will also show that the additional annotation requirement that they introduce can be successfully mitigated using a novel pipe-lined Wizard-of-Oz data collection framework.

### 2.3 Policy Network and Database Operator

**Database Operator** Based on the output  $\mathbf{p}_s^t$  of the belief trackers, the DB query  $q_t$  is formed by,

$$q_t = \bigcup_{s' \in S_I} \{\text{argmax}_v \mathbf{p}_{s'}^t\} \quad (7)$$

where  $S_I$  is the set of informable slots. This query is then applied to the DB to create a binary truth

value vector  $\mathbf{x}_t$  over DB entities where a 1 indicates that the corresponding entity is consistent with the query (and hence it is consistent with the most likely belief state). In addition, if  $\mathbf{x}$  is not entirely null, an associated entity pointer is maintained which identifies one of the matching entities selected at random. The entity pointer is updated if the current entity no longer matches the search criteria; otherwise it stays the same. The entity referenced by the entity pointer is used to form the final system response as described in Section 2.4.

**Policy network** The policy network can be viewed as the glue which binds the system modules together. Its output is a single vector  $\mathbf{o}_t$  representing the system action, and its inputs are comprised of  $\mathbf{z}_t$  from the intent network, the belief state  $\mathbf{p}_s^t$ , and the DB truth value vector  $\mathbf{x}_t$ . Since the generation network only generates appropriate sentence forms, the individual probabilities of the categorical values in the informable belief state are immaterial and are summed together to form a summary belief vector for each slot  $\hat{\mathbf{p}}_s^t$  represented by three components: the summed value probabilities, the probability that the user said they "don't care" about this slot and the probability that the slot has not been mentioned. Similarly for the truth value vector  $\mathbf{x}_t$ , the number of matching entities matters but not their identity. This vector is therefore compressed to a 6-bin 1-hot encoding  $\hat{\mathbf{x}}_t$ , which represents different degrees of matching in the DB (no match, 1 match, ... or more than 5 matches). Finally, the policy network output is generated by a three-way matrix transformation,

$$\mathbf{o}_t = \tanh(\mathbf{W}_{zo}\mathbf{z}_t + \mathbf{W}_{po}\hat{\mathbf{p}}_t + \mathbf{W}_{xo}\hat{\mathbf{x}}_t) \quad (8)$$

where matrices  $\mathbf{W}_{zo}$ ,  $\mathbf{W}_{po}$ , and  $\mathbf{W}_{xo}$  are parameters and  $\hat{\mathbf{p}}_t = \bigoplus_{s \in \mathbb{G}} \hat{\mathbf{p}}_s^t$  is a concatenation of all summary belief vectors.

### 2.4 Generation Network

The generation network uses the action vector  $\mathbf{o}_t$  to condition a language generator (Wen et al., 2015b). This generates template-like sentences token by token based on the language model probabilities,

$$P(w_{j+1}^t | w_j^t, \mathbf{h}_{j-1}^t, \mathbf{o}_t) = \text{LSTM}_j(w_j^t, \mathbf{h}_{j-1}^t, \mathbf{o}_t) \quad (9)$$

where  $\text{LSTM}_j(\cdot)$  is a conditional LSTM operator for one output step  $j$ ,  $w_j^t$  is the last output token (i.e. a word, a delexicalised slot name or a delexicalised

slot value), and  $\mathbf{h}_{j-1}^t$  is the hidden layer. Once the output token sequence has been generated, the generic tokens are replaced by their actual values: (1) replacing delexicalised slots by random sampling from a list of surface forms, e.g.  $\langle s.food \rangle$  to *food* or *type of food*, and (2) replacing delexicalised values by the actual attribute values of the entity currently selected by the DB pointer. This is similar in spirit to the Latent Predictor Network (Ling et al., 2016) where the token generation process is augmented by a set of pointer networks (Vinyals et al., 2015) to transfer entity specific information into the response.

**Attentive Generation Network** Instead of decoding responses directly from a static action vector  $\mathbf{o}_t$ , an attention-based mechanism (Bahdanau et al., 2014; Hermann et al., 2015) can be used to dynamically aggregate source embeddings at each output step  $j$ . In this work we explore the use of an attention mechanism to combine the tracker belief states, i.e.  $\mathbf{o}_t$  is computed at each output step  $j$  by,

$$\mathbf{o}_t^{(j)} = \tanh(\mathbf{W}_{zo}\mathbf{z}_t + \hat{\mathbf{p}}_t^{(j)} + \mathbf{W}_{xo}\hat{\mathbf{x}}_t) \quad (10)$$

where for a given ontology  $\mathbb{G}$ ,

$$\hat{\mathbf{p}}_t^{(j)} = \sum_{s \in \mathbb{G}} \alpha_s^{(j)} \tanh(\mathbf{W}_{po}^s \cdot \hat{\mathbf{p}}_s^t) \quad (11)$$

and where the attention weights  $\alpha_s^{(j)}$  are calculated by a scoring function,

$$\alpha_s^{(j)} = \text{softmax}(\mathbf{r}^\top \tanh(\mathbf{W}_r \cdot \mathbf{u}_t)) \quad (12)$$

where  $\mathbf{u}_t = \mathbf{z}_t \oplus \hat{\mathbf{x}}_t \oplus \hat{\mathbf{p}}_s^t \oplus \mathbf{w}_j^t \oplus \mathbf{h}_{j-1}^t$ , matrix  $\mathbf{W}_r$ , and vector  $\mathbf{r}$  are parameters to learn and  $\mathbf{w}_j^t$  is the embedding of token  $w_j^t$ .

### 3 Wizard-of-Oz Data Collection

Arguably the greatest bottleneck for statistical approaches to dialogue system development is the collection of appropriate training data, and this is especially true for task-oriented dialogue systems. Serban et al (Serban et al., 2015a) have catalogued existing corpora for developing conversational agents. Such corpora may be useful for bootstrapping, but, for task-oriented dialogue systems, in-domain data is essential<sup>6</sup>. To mitigate this problem, we propose a novel crowdsourcing version of the Wizard-of-Oz (WOZ) paradigm (Kelley, 1984) for collecting domain-specific corpora.

<sup>6</sup>E.g. technical support for Apple computers may differ completely from that for Windows, due to the many differences in software and hardware.

Based on the given ontology, we designed two webpages on Amazon Mechanical Turk, one for wizards and the other for users (see Figure 4 and 5 for the designs). The users are given a task specifying the characteristics of a particular entity that they must find (e.g. *a Chinese restaurant in the north*) and asked to type in natural language sentences to fulfil the task. The wizards are given a form to record the information conveyed in the last user turn (e.g. *pricerange=Chinese, area=north*) and a search table showing all the available matching entities in the database. Note these forms contain all the labels needed to train the slot-based belief trackers. The table is automatically updated every time the wizard submits new information. Based on the updated table, the wizard types an appropriate system response and the dialogue continues.

In order to enable large-scale parallel data collection and avoid the distracting latencies inherent in conventional WOZ scenarios (Bohus and Rudnicky, 2008), users and wizards are asked to contribute just a single turn to each dialogue. To ensure coherence and consistency, users and wizards must review all previous turns in that dialogue before they contribute their turns. Thus dialogues progress in a pipe-line. Many dialogues can be active in parallel and no worker ever has to wait for a response from the other party in the dialogue. Despite the fact that multiple workers contribute to each dialogue, we observe that dialogues are generally coherent yet diverse. Furthermore, this turn-level data collection strategy seems to encourage workers to learn and correct each other based on previous turns.

In this paper, the system was designed to assist users to find a restaurant in the Cambridge, UK area. There are three informable slots (*food, pricerange, area*) that users can use to constrain the search and six requestable slots (*address, phone, postcode* plus the three informable slots) that the user can ask a value for once a restaurant has been offered. There are 99 restaurants in the DB. Based on this domain, we ran 3000 HITs (Human Intelligence Tasks) in total for roughly 3 days and collected 1500 dialogue turns. After cleaning the data, we have approximately 680 dialogues in total (some of them are unfinished). The total cost for collecting the dataset was  $\sim 400$  USD.

### 4 Empirical Experiments

**Training** Training is divided into two phases. Firstly the belief tracker parameters  $\theta_b$  are

Table 1: Tracker performance in terms of Precision, Recall, and F-1 score.

Tracker type	Informable			Requestable		
	Prec.	Recall	F-1	Prec.	Recall	F-1
cnn	99.77%	96.09%	97.89%	98.66%	93.79%	96.16%
ngram	99.34%	94.42%	96.82%	98.56%	90.14%	94.16%

trained using the cross entropy errors between tracker labels  $\mathbf{y}_s^t$  and predictions  $\mathbf{p}_s^t$ ,  $L_1(\theta_b) = -\sum_t \sum_s (\mathbf{y}_s^t)^\top \log \mathbf{p}_s^t$ . For the full model, we have three informable trackers (*food*, *pricerange*, *area*) and seven requestable trackers (*address*, *phone*, *postcode*, *name*, plus the three informable slots).

Having fixed the tracker parameters, the remaining parts of the model  $\theta_{\setminus b}$  are trained using the cross entropy errors from the generation network language model,  $L_2(\theta_{\setminus b}) = -\sum_t \sum_j (\mathbf{y}_j^t)^\top \log \mathbf{p}_j^t$ , where  $\mathbf{y}_j^t$  and  $\mathbf{p}_j^t$  are output token targets and predictions respectively, at turn  $t$  of output step  $j$ . We treated each dialogue as a batch and used stochastic gradient descent with a small  $l_2$  regularisation term to train the model. The collected corpus was partitioned into a training, validation, and testing sets in the ratio 3:1:1. Early stopping was implemented based on the validation set for regularisation and gradient clipping was set to 1. All the hidden layer sizes were set to 50, and all the weights were randomly initialised between -0.3 and 0.3 including word embeddings. The vocabulary size is around 500 for both input and output, in which rare words and words that can be delexicalised are removed. We used three convolutional layers for all the CNNs in the work and all the filter sizes were set to 3. Pooling operations were only applied after the final convolution layer.

**Decoding** In order to decode without length bias, we decoded each system response  $m_t$  based on the average log probability of tokens,

$$m_t^* = \operatorname{argmax}_{m_t} \{\log p(m_t | \theta, u_t) / J_t\} \quad (13)$$

where  $\theta$  are the model parameters,  $u_t$  is the user input, and  $J_t$  is the length of the machine response.

As a contrast, we also investigated the MMI criterion (Li et al., 2016) to increase diversity and put additional scores on delexicalised tokens to encourage task completion. This *weighted* decoding strategy has the following objective function,

$$m_t^* = \operatorname{argmax}_{m_t} \{\log p(m_t | \theta, u_t) / J_t - \lambda \log p(m_t) / J_t + \gamma R_t\} \quad (14)$$

where  $\lambda$  and  $\gamma$  are weights selected on validation set and  $\log p(m_t)$  can be modelled by a standalone LSTM language model. We used a simple heuristic for the scoring function  $R_t$  designed to reward giving appropriate information and penalise spuriously providing unsolicited information<sup>7</sup>. We applied beam search with a beamwidth equal to 10, the search stops when an end of sentence token is generated. In order to obtain language variability from the deployed model we ran decoding until we obtained 5 candidates and randomly sampled one as the system response.

**Tracker performance** Table 1 shows the evaluation of the trackers’ performance. Due to delexicalisation, both CNN type trackers and N-gram type trackers (Henderson et al., 2014) achieve high precision, but the N-gram tracker has worse recall. This result suggests that compared to simple N-grams, CNN type trackers can better generalise to sentences with long distance dependencies and more complex syntactic structures.

**Corpus-based evaluation** We evaluated the end-to-end system by first performing a corpus-based evaluation in which the model is used to predict each system response in the held-out test set. Three evaluation metrics were used: BLEU score (on top-1 and top-5 candidates) (Papineni et al., 2002), entity matching rate and objective task success rate (Su et al., 2015). We calculated the entity matching rate by determining whether the actual selected entity at the end of each dialogue matches the task that was specified to the user. The dialogue is then marked as successful if both (1) the offered entity matches, and (2) the system answered all the associated information requests (e.g. *what is the address?*) from the user. We computed the BLEU scores on the template-like output sentences before lexicalising with the entity value substitution.

<sup>7</sup>We give an additional reward if a requestable slot (e.g. address) is requested and its corresponding delexicalised slot or value token (e.g. <v.address> and <s.address>) is generated. We give an additional penalty if an informable slot is never mentioned (e.g. food=None) but its corresponding delexicalised value token is generated (e.g. <v.food>). For more details on scoring, please see Table 5.

Table 2: Performance comparison of different model architectures based on a corpus-based evaluation.

Encoder	Tracker	Decoder	Match(%)	Success(%)	T5-BLEU	T1-BLEU
<b>Baseline</b>						
lstm	-	lstm	-	-	0.1650	0.1718
lstm	turn recurrence	lstm	-	-	0.1813	0.1861
<b>Variant</b>						
lstm	rnn-cnn, w/o req.	lstm	89.70	30.60	0.1769	0.1799
cnn	rnn-cnn	lstm	88.82	58.52	0.2354	0.2429
<b>Full model w/ different decoding strategy</b>						
lstm	rnn-cnn	lstm	86.34	75.16	0.2184	0.2313
lstm	rnn-cnn	+ weighted	86.04	78.40	0.2222	0.2280
lstm	rnn-cnn	+ att.	90.88	80.02	0.2286	0.2388
lstm	rnn-cnn	+ att. + weighted	90.88	83.82	0.2304	0.2369

Table 2 shows the result of the corpus-based evaluation averaging over 5 randomly initialised networks. The *Baseline* block shows two baseline models: the first is a simple turn-level sequence to sequence model (Sutskever et al., 2014) while the second one introduces an additional recurrence to model the dependency on the dialogue history following Serban et al (Serban et al., 2015b). As can be seen, incorporation of the recurrence improves the BLEU score. However, baseline task success and matching rates cannot be computed since the models do not make any provision for a database.

The *Variant* block of Table 2 shows two variants of the proposed end-to-end model. For the first one, no requestable trackers were used, only informable trackers. Hence, the burden of modelling user requests falls on the intent network alone. We found that without explicitly modelling user requests, the model performs very poorly on task completion ( $\sim 30\%$ ), even though it can offer the correct entity most of the time ( $\sim 90\%$ ). More data may help here; however, we found that the incorporation of an explicit internal semantic representation in the full model (shown below) is more efficient and extremely effective. For the second variant, the LSTM intent network is replaced by a CNN. This achieves a very competitive BLEU score but task success is still quite poor ( $\sim 58\%$  success). We think this is because the CNN encodes the intent by capturing several local features but lacks the global view of the sentence, which may easily result in an unexpected overfit.

The *Full model* block shows the performance of the proposed model with different decoding strategies. The first row shows the result of decoding using the average likelihood term (Equation 13) while the second row uses the *weighted* decoding strategy (Equation 14). As can be seen, the *weighted*

decoding strategy does not provide a significant improvement in BLEU score but it does greatly improve task success rate ( $\sim 3\%$ ). The  $R_t$  term contributes the most to this improvement because it injects additional task-specific information during decoding. Despite this, the most effective and elegant way to improve the performance is to use the attention-based mechanism (*+att.*) to dynamically aggregate the tracker beliefs (Section 2.4). It gives a slight improvement in BLEU score ( $\sim 0.01$ ) and a big gain on task success ( $\sim 5\%$ ). Finally, we can improve further by incorporating *weighted* decoding with the attention models (*+ att. + weighted*).

As an aside, we used t-SNE (der Maaten and Hinton, 2008) to produce a reduced dimension view of the action embeddings  $\mathbf{o}_t$ , plotted and labelled by the first three generated output words (full model w/o attention). The figure is shown as Figure 3. We can see clear clusters based on the system intent types, even though we did not explicitly model them using dialogue acts.

**Human evaluation** In order to assess operational performance, we tested our model using paid subjects recruited via Amazon Mechanical Turk. Each judge was asked to follow a given task and to rate the model’s performance. We assessed the subjective success rate, and the perceived comprehension ability and naturalness of response on a scale of 1 to 5. The full model with attention and weighted decoding was used and the system was tested on a total of 245 dialogues. As can be seen in Table 3, the average subjective success rate was 98%, which means the system was able to complete the majority of tasks. Moreover, the comprehension ability and naturalness scores both averaged more than 4 out of 5. (See Appendix for some sample dialogues in this trial.)

We also ran comparisons between the NN model

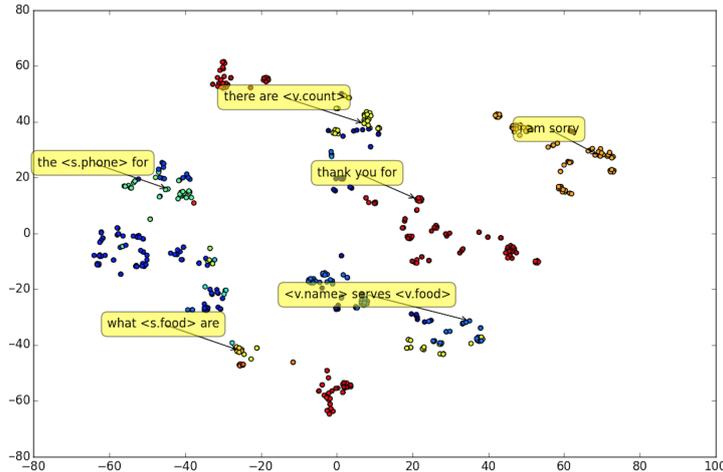

Figure 3: The action vector embedding  $\mathbf{o}_t$  generated by the NN model w/o attention. Each cluster is labelled with the first three words the embedding generated.

Table 3: Human assessment of the NN system. The rating for comprehension/naturalness are both out of 5.

Metric	NN
Success	98%
Comprehension	4.11
Naturalness	4.05
# of dialogues:	245

and a handcrafted, modular baseline system (*HDC*) consisting of a handcrafted semantic parser, rule-based policy and belief tracker, and a template-based generator. The result can be seen in Table 4. The *HDC* system achieved  $\sim 95\%$  task success rate, which suggests that it is a strong baseline even though most of the components were hand-engineered. Over the 164 dialogues tested, the NN system (*NN*) was considered better than the handcrafted system (*HDC*) on all the metrics compared. Although both systems achieved similar success rates, the NN system (*NN*) was more efficient and provided a more engaging conversation (lower turn number and higher preference). Moreover, the comprehension ability and naturalness of the NN system were also rated higher, which suggests that the learned system was perceived as being more natural than the hand-designed system.

## 5 Conclusions and Future Work

This paper has presented a novel neural network-based framework for task-oriented dialogue systems. The model is end-to-end trainable using two

Table 4: A comparison of the NN system with a rule-based modular system (*HDC*).

Metric	NN	HDC	Tie
Subj. Success	96.95%	95.12%	-
Avg. # of Turn	3.95	4.54	-
<b>Comparisons(%)</b>			
Naturalness	46.95*	25.61	27.44
Comprehension	45.12*	21.95	32.93
Preference	50.00*	24.39	25.61
Performance	43.90*	25.61	30.49

\*  $p < 0.005$ , # of comparisons: 164

supervision signals and a modest corpus of training data. The paper has also presented a novel crowd-sourced data collection framework inspired by the Wizard-of-Oz paradigm. We demonstrated that the pipe-lined parallel organisation of this collection framework enables good quality task-oriented dialogue data to be collected quickly at modest cost.

The experimental assessment of the NN dialogue system showed that the learned model can interact efficiently and naturally with human subjects to complete an application-specific task. To the best of our knowledge, this is the first end-to-end NN-based model that can conduct meaningful dialogues in a task-oriented application.

However, there is still much work left to do. Our current model is a text-based dialogue system, which can not directly handle noisy speech recognition inputs nor can it ask the user for confirmation when it is uncertain. Indeed, the extent to which this type of model can be scaled to much larger and wider domains remains an open question which we hope to pursue in our further work.

## Wizard-of-Oz data collection websites

**Task 02004:** You are looking for and it should serve **gastropub food**. You don't care about the **price range**. You want to know the **address**.

Info Desk : Hello , welcome to the Cambridge restaurant system . You can ask for restaurants by area, price range or food type . How may I help you ?  
 Customer : i want a gastropub food  
 Info Desk : There are 4 restaurants serving gastropub food, what price range do you want ?

Next turn

Customer : (Your response)

i dont care about the price range, just give me the address please

Submit the HIT

Figure 4: The user webpage. The worker who plays a user is given a task to follow. For each mturk HIT, he/she needs to type in an appropriate sentence to carry on the dialogue by looking at both the task description and the dialogue history.

Info Desk : Hello , welcome to the Cambridge restaurant system . You can ask for restaurants by area, price range or food type . How may I help you ?  
 Customer : i want a gastropub food  
 Info Desk : There are 4 restaurants serving gastropub food, what price range do you want ?  
 Customer : i dont care

Next turn

Please modify the following answers based on the latest customer response:

- What does user want?
  - What is the **food type** the user wants? gastropub
  - What is the **area** the user wants? not mentioned
  - What is the **price range** the user wants? dont care
- What does user ask?
  - Is the user asking for **food type** of an offered venue? No
  - Is the user asking for **price range** of an offered venue? No
  - Is the user asking for **area** of an offered venue? No
  - Is the user asking for **postcode** of an offered venue? No
  - Is the user asking for **phone number** of an offered venue? No
  - Is the user asking for **address** of an offered venue? No
  - Is the user mentioning any **restaurant names**? No

finish

Info Desk : (Your response)

i would recommend backstreet bistro, a great gastropub restaurant in the centre, do you want their phone number ? end-of-dialogue

Submit the HIT

Name	Food	Area	Price Range	Phone	Address	Postcode
backstreet bistro	gastropub	centre	expensive	01223 306306	2 Slurton Street City Centre	C.B 1, 2 Q.A
royal standard	gastropub	east	expensive	01223 247877	290 Mill Road City Centre	C.B 1, 3 N.L
the cow pizza kitchen and bar	gastropub	centre	moderate	01223 308871	Corn Exchange Street	C.B 2, 3 Q.F
the slug and lettuce	gastropub	centre	expensive	--	34 - 35 Green Street	C.B 2, 3 J.U
nil	gastropub	nil	nil	nil	nil	nil

Showing 1 to 4 of 4 entries (filtered from 110 total entries) Previous 1 Next

Figure 5: The wizard page. The wizard's job is slightly more complex: the worker needs to go through the dialogue history, fill in the form (top green) by interpreting the user input at this turn, and type in an appropriate response based on the history and the DB result (bottom green). The DB search result is updated when the form is submitted. The form can be divided into informable slots (top) and requestable slots (bottom), which contains all the labels we need to train the trackers.

## Scoring Table

Table 5: Additional  $R_t$  term for delexicalised tokens when using weighted decoding (Equation 14). *Not observed* means the corresponding tracker has a highest probability on either *not mentioned* or *dontcare* value, while *observed* mean the highest probability is on one of the categorical values. A positive score encourages the generation of that token while a negative score discourages it.

Delexicalised token	Examples	$R_t$ (observed)	$R_t$ (not observed)
informable slot token	<s.food>, <s.area>,...	0.0	0.0
informable value token	<v.food>, <v.area>,...	+0.05	-0.5
requestable slot token	<s.phone>,<s.address>,...	+0.2	0.0
requestable value token	<v.phone>,<v.address>,...	+0.2	0.0

Human	: what area is that
Machine	: little seoul is located in the centre area of town . would you like their number ?
Human	: yes
Machine	: the telephone number is 01223 308681 . is there anything else i can help you with today ?
Human	: no goodbye
Machine	: thank you for using the cambridge restaurant system , goodbye .
Human	: I want to find a restaurant in the east part of town that serves creative food
Machine	: i am sorry , there are no creative restaurants in the east side of town . would you like a different restaurant ?
Human	: how about indian food?
Machine	: curry prince is a indian restaurant in the east of town . would you like their phone number ?
Human	: yes, may i have the address and phone number?
Machine	: curry prince is located at 451 newmarket road fen ditton and their phone is 01223 566388 . is there anything else i can help you with today ?
Human	: no, thank you goodbye
Machine	: thank you for using the cambridge restaurant system . good bye
Machine	: what food are you interested ?
Human	: english
Machine	: i am sorry , there are no english restaurants . would you like to try a different food type ?
Human	: chinese
Machine	: there are 8 restaurants serving chinese type of cuisine . do you have a preference of area ?
Human	: south part
Machine	: the good luck chinese food takeaway is a chinese restaurant in the south of town . would you like the phone number ?
Human	: no. just address and price range
Machine	: the good luck chinese food takeaway is located at 82 cherry hinton road cherry hinton . is there anything else i can help you with ?
Human	: what is their price range?
Machine	: the good luck chinese food takeaway is expensively priced chinese restaurant in the south area . would you like more information ?
Human	: no goodbye
Machine	: thank you for using the cambridge restaurant system . good bye .
Human	: Is there a gastropub anywhere around here?
Machine	: there are 3 gastropub restaurants . would you like more information ?
Human	: Is there one on the west side?
Machine	: i am sorry , there are no gastropub restaurants in the west side of town . would you like something else ?
Human	: How about east?
Machine	: royal standard is a gastropub restaurant in the east of town .
Human	: What's the address?
Machine	: the address is 290 mill road city centre .
Human	: Thanks, bye
Machine	: thank you for using the cambridge restaurant system . good bye

# May I take your order? A Neural Model for Extracting Structured Information from Conversations

## Abstract

In this paper we tackle a unique and important problem of extracting a structured order from the conversation a customer has with an order taker at a restaurant. This is motivated by an actual system under development to assist in the order taking process. We develop a sequence-to-sequence model that is able to map from unstructured conversational input to the structured form that is conveyed to the kitchen and appears on the customer receipt. This problem is critically different from other tasks like machine translation where sequence-to-sequence models have been used: the input includes two sides of a conversation; the output is highly structured; and logical manipulations must be performed, for example when the customer changes his mind while ordering. We present a novel sequence-to-sequence model that incorporates a special attention-memory gating mechanism and conversational role markers. The proposed model improves performance over both a phrase-based machine translation approach and a standard sequence-to-sequence model.

## 1 Introduction

Extracting structured information from unstructured text is a critically important problem in natural language processing. In this paper, we attack a deceptively simple form of the problem: understanding what a customer wants when ordering at a restaurant. In this problem, we seek to convert the conversation between the customer and the order taker, i.e. the waiter or waitress, into the structured form that is conveyed to the kitchen to prepare the food, and which appears on the customer receipt.

*Waiter:* Hi, how can I help you ?  
*Customer:* We'd like a large cheese pizza.  
*Waiter:* Any toppings?  
*Customer:* Yeah, how about pepperoni and two diet cokes.  
*Waiter:* What size?  
*Customer:* Uh, medium and make that three cokes.  
*Waiter:* Anything else?  
*Customer:* A small Caesar salad with the dressing on the side  
*Waiter:* Sure, is that it?  
*Customer:* Yes, that's all, thanks.

Figure 1: A conversation example of an order-taking interaction at a restaurant.

Item	Size	Qty	Modifiers
Pizza	large	1	add pepperoni
Caesar Salad	small	1	side dressing
Diet Coke	medium	3	

Table 1: An example of the structured data record corresponding to the conversation in Figure 1

We develop this system to analyze real-time interactions with the aim of discovering errors in the order-entry process. Note that the objective is to analyze the interaction and suggest corrections to the human order-taker. Thus, we take both sides of the order-taking interaction as input, and are not attempting to predict the order-taker's side of the conversation.

While we focus on the restaurant domain in this work, this problem is relevant in any scenario in which a conversation results in the creation of structured information. Other examples include a sales interaction which results in a purchase order, a call to a help desk which results in a service record, or a conversation with a travel agent that results in an itinerary.

An example of the problem of interest is shown in Figure 1. The structured data record that corresponds to this conversation is shown in Table 1. There are several things to note about this example:

- The output is a stylized and structured representation of the input
- The items in the structured order may appear in a different sequence than they are mentioned
- Inference occurs across turns, for example that “medium” applies to the coke and not the pizza whose size was earlier specified
- Logical manipulations must be done, for example changing the number of cokes from two to three
- In contrast to machine translation, we do not wish to create a verbatim “translation” of the input, but instead a logical distillation of it

To attack this problem, we implemented two baselines and several sequence-to-sequence models. The first baseline is an information-retrieval approach based on a TF-IDF match (Salton et al., 1975) which finds the most similar conversation in the training data, and returns the associated order. The second uses phrase-based machine translation (Koehn et al., 2003) to “translate” from the conversational input to the tokens in the structured order. We compare these to a sequence-to-sequence (s2s) model with attention (Chan et al., 2016; Bahdanau et al., 2014; Devlin et al., 2015; Yao and Zweig, 2015; Sutskever et al., 2014; Mei et al., 2016), and then extend the s2s model with the addition of a gating mechanism on the attention memory and with an auxiliary input that indicates the conversational role of the speaker (customer or order-taker). We show that it is in fact possible to extract the orders from conversations recorded at a real restaurant <sup>1</sup>, and achieve an F measure of over 70 from raw text and 65 from ASR transcriptions.

## 2 Problem Formulation

The precise problem setting in this paper is as follows. The training data consists of input/output pairs of examples  $(X_1, Y_1), \dots, (X_N, Y_N)$ , where  $X_k$  is a conversation consisting of several utterances, similar to the example shown in Figure 1, and  $Y_k$  is the corresponding structured data record such as the one in Table 1.

<sup>1</sup>The restaurant will remain anonymous for business reasons, and we have changed the names of menu items in our examples accordingly.

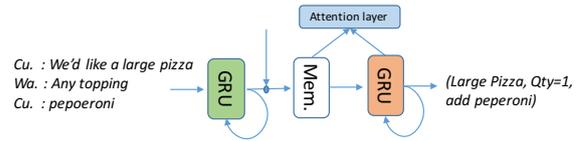

Figure 2: An input unstructured conversation and the corresponding structured record.

Given a conversation  $X_k$ , the goal of our model is to extract the structured data record  $Y_k$  so that:

$$Y_k = \operatorname{argmax}_Y \log P(Y|X_k) \quad (1)$$

We cast this task as a sequence modeling problem which aims to map the sequence of words in a conversation  $X_k$  to the sequence of tokens in the corresponding structured data record  $Y_k$ . The input sequence is formed by concatenating the utterances in the conversation, while the output sequence is formed by concatenating the rows in the structured data record. For example, the utterances in the conversation shown in Figure 1 are concatenated to predict the sequence  $y = \text{Pizza, size=large, qty=1, modifiers=(add peperoni)} \mid \text{Diet Coke, size=medium, qty=3} \mid \text{Caesar Salad, size=small, qty=1, modifiers=(side dressing)}$  which is derived from Table 1. Under this sequential model, the conditional probability of the structured data record  $Y$  given the observed conversation  $X$  can be written as

$$P(Y|X, \theta) = \prod_{t=1}^T P(y_t|y_{1:t-1}, X, \theta) \quad (2)$$

where  $y_{1:t-1}$  denotes the first  $t - 1$  terms in the structured data record and  $\theta$  represents the model parameters.

## 3 Model

The proposed model is based on an encoder-decoder architecture with attention (Bahdanau et al., 2014), as shown in Figure 2. The encoder network reads the input conversation  $\mathbf{X}$  one word at a time and updates its hidden state  $h_t$  according to current input  $w_t$  and previous hidden state  $h_{t-1}$ ,

$$h_t = f_e(w_t, h_{t-1}), t \in \{1, \dots, M\} \quad (3)$$

where  $f_e$  is a nonlinear function which is elaborated in the following section. After reading all the tokens, the encoder network yields a context

vector  $c$  as the representation of the entire conversation.

The decoder then processes this representation and generates a hypothesized structured data record  $Y$  as an output sequence, word by word given the context vector  $c$  and all previous predicted tokens. The conditional probability can be expressed as follows:

$$P(y_t|y_1, \dots, y_{t-1}, \mathbf{X}) = f_d(y_{t-1}, s_t, c) \quad (4)$$

$$s_t = g(y_{t-1}, s_{t-1}, c) \quad t \in \{1, \dots, N\} \quad (5)$$

where  $f_d$  and  $g$  are nonlinear functions and  $s_t$  is the hidden state of decoder at time  $t$ . Critically, our decoder also utilizes an attention mechanism, which stores the intermediate encoder representations of each input word for use by the decoder.

Two improvements to the conventional encoder-decoder model architecture are proposed in this work. First, we incorporate gates controlled by the encoder into the neural attention memory to adaptively modulate the representations in the memory based on their semantic importance. Second, we propose a way to incorporate conversational role information into the model to reflect the fact that different participants in a multi-party interaction have different roles and the meaning of certain utterances may be dependent on the speaker's role.

A detailed illustration of the proposed model is shown in Figure 3. We elaborate on each component of this model in the following sections.

### 3.1 Encoder Network

The encoder network is designed to generate a semantically meaningful representation of unstructured conversations. Several neural network architectures have been proposed for this purpose, including CNNs (Kalchbrenner et al., 2014; Hu et al., 2014), RNNs (Sutskever et al., 2014) and LSTMs (Hochreiter and Schmidhuber, 1997). In this work, we use an encoder constructed from a recurrent neural network with gated RNN units (GRU) (Cho et al., 2014). The GRU has been shown to alleviate the gradient vanishing problem of RNNs, enabling the model to learn long term dependencies in the input sequence. GRUs have been shown to perform comparably to LSTMs (Chung et al., 2014).

At time  $t$ , the new state of a GRU is computed as follows:

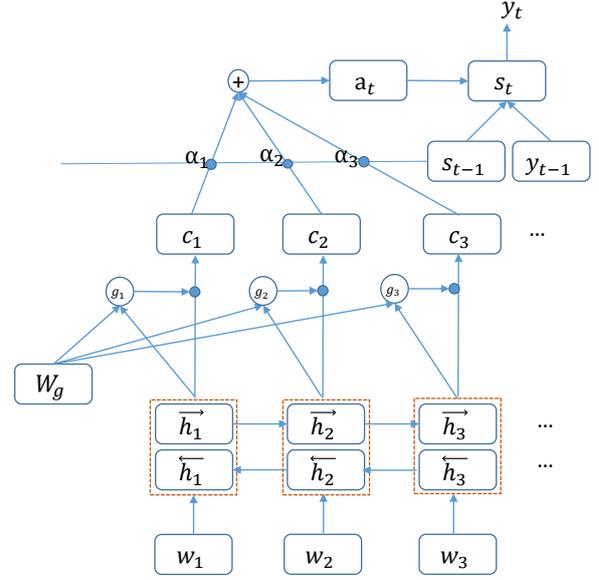

Figure 3: Graphical structure of memory-gated encoder-decoder model with attention mechanism.  $w_1$  represents input;  $\vec{h}_1$  and  $\overleftarrow{h}_1$  are the hidden states of forward and backward GRUs, respectively.  $g_1, \alpha_1$  represent the context gates and attention weights, respectively. Small dot node means element-wise product.

$$z_t = \sigma(W_z x_t + U_z h_{t-1} + b_z) \quad (6)$$

$$r_t = \sigma(W_r x_t + U_r h_{t-1} + b_r) \quad (7)$$

$$\hat{h}_t = \tanh(W_h x_t + U_h (r_t \odot h_{t-1})) \quad (8)$$

$$h_t = (1 - z_t) \odot h_{t-1} + z_t \odot \hat{h}_t \quad (9)$$

where  $\odot$  stands for element-wise multiplication.  $W, U$  are weight matrixes applied to input and previous hidden state, respectively.  $h_t$  is a linear combination of the previous state  $h_{t-1}$  and the hypothesis state  $\hat{h}_t$ .  $\hat{h}_t$  is computed with new sequence information. The update gate,  $z_t$ , controls to what extent the past information is kept and how much new information is added. The reset gate,  $r_t$ , controls to what extent the history state contributes to the hypothesis state. If  $r_t$  is zero, then GRU ignores all the history information.

The conversation encoding is obtained by concatenating the GRU hidden state vectors from the forward and backward directions. Thus the encoder operation can be summarized as follows

$$x_t = W_e w_t, t \in [1, T] \quad (10)$$

$$\vec{h}_t = \overrightarrow{GRU}(x_t), t \in [1, T] \quad (11)$$

$$\overleftarrow{h}_t = \overleftarrow{GRU}(x_t), t \in [T, 1] \quad (12)$$

$$h_t^+ = \vec{h}_t \oplus \overleftarrow{h}_t \quad (13)$$

where  $w_t$  is the one-hot input vector,  $W_e$  is the embedding matrix, and  $x_t$  is the word embedding for  $w_t$ . The functions  $\overrightarrow{GRU}(x_t)$  and  $\overleftarrow{GRU}(x_t)$  represent the GRU operating in the forward and backward directions, respectively, with processing defined by equations 6–9.

This produces a sequence of context vectors,  $h_t^+$  which are subsequently consumed by an attention mechanism in the decoder. We use the final attention vector  $h_T^+$  to initialize the hidden state of the decoder.

### 3.2 Memory Gate

In most sequence-to-sequence tasks such as machine translation, every word in the input is important. However, in our scenario, where the input to the system is conversational speech, not all the words in the conversation contribute to the prediction of structured data record. For example, it is reasonable to ignore the chit-chat that is present in many conversations. Further, in other tasks, gating mechanisms have been shown to be useful to dynamically select important information (Yao et al., 2015; Hochreiter and Schmidhuber, 1997; Tu et al., 2016).

In light of this, we propose the use of an additional memory gate to select important information from the memory vector. The memory gate we use consists of a single-layer feed-forward neural network

$$g_t = \sigma(W_g h_t^+ + b_g) \quad (14)$$

where  $\sigma$  is a sigmoid activation function and  $W_g$  and  $b_g$  are weight matrix and bias, respectively, and  $h_t^+$  is the context vector at time  $t$  defined in equation 10. The gate is then applied to the context vector  $h_t^+$  using an element-wise multiplication operation.

$$c_t = g_t \odot h_t^+ \quad (15)$$

After applying memory gate, the gated context vector  $c_t$  is then fed into attention memory of the decoder network in place of the original context vector  $h_t^+$ . Figure 4 illustrates an example of the gating weights for a sample utterance. The darker colors indicates values close to 1 while the lighter colors indicate values close to 0. As the figure shows, the network learns to suppress semantically unimportant words.

#### 3.2.1 Role Information

In many sequence-to-sequence models, there is no notion of different speakers with different roles. Inspired by the work in dialog generation (Li et al., 2016) and spoken language understanding (Hori et al., 2016), we propose the addition of speaker information into the encoder network to explicitly model the interaction patterns of the customer and order-taker.

Specifically we learn separate word and role embeddings, and concatenate them to form the input. The input to the encoder network becomes:

$$x_t^w = W_e w_t, t \in [1, T] \quad (16)$$

$$x_t^r = W_r r_t, t \in [1, T] \quad (17)$$

$$x_t = x_t^w \oplus x_t^r, t \in [1, T] \quad (18)$$

### 3.3 Decoder Network

The decoder network is used to predict the next word given all the previously predicted words and the context vectors from the encoder network (Luong et al., 2015; Bahdanau et al., 2014).

We use an RNN with GRU units to predict each word  $y_t$  sequentially based on the previously predicted word  $y_{t-1}$  and the output of the attention process  $a_t$  that computes a weighted combination of the context vectors in memory.

If we define  $s_t$  as the hidden layer of the decoder at time  $t$ , the decoder’s operation can be expressed as

$$s_t = \overrightarrow{GRU}(y_{t-1} \oplus a_t) \quad (19)$$

$$y_t = \text{softmax}(W_o s_t + b_o) \quad (20)$$

where  $y_{t-1} \oplus a_t$  is the concatenation of the previously predicted output  $y_{t-1}$  and the output of the attention process  $a_t$ , and  $\overrightarrow{GRU}(\cdot)$  is defined by equations 6–9, as before.

The attention vector  $a_t$  is computed as a linear combination of the gated context vectors generated by the encoder network. This can be written as

$$a_t = \sum_{j=1}^M \alpha_{ij} c_j \quad (21)$$

where the weights  $\alpha_{ij}$  are computed as

$$\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{k=1}^N \exp(e_{ik})} \quad (22)$$

A single-layer feed-forward neural network is used to compute  $e_{ij}$  as

$$e_{ij} = V_a^T \tanh(W_a s_{t-1} + U_a c_j) \quad (23)$$

where  $V_a$ ,  $W_a$ , and  $U_a$  are weight matrices.

### 3.4 Model Training

The model is trained to maximize the log probability of the structured data records given the corresponding conversation,

$$\sum_{(Y_k, X_k) \in D} \log P(Y_k | X_k) \quad (24)$$

where  $D$  is the set containing all the training pairs and  $P(Y_k | X_k)$  is computed with equation 2. The standard adadelta algorithm (Zeiler, 2012) is used for parameter updates. Gradients are clipped to 1 to avoid exponentially increasing values (Pascanu et al., 2013).

## 4 Experiments

In this section, we evaluate our proposed model on two data sets and compare performance with several baseline systems.

### 4.1 Data sets

We conducted experiments on a corpus of conversations between a customer and an order taker (waiter or waitress) captured in a real restaurant environment. The conversations were manually transcribed by professional annotators. There are 4823 examples in the training set, 543 in the development (dev) set, and 843 in the test set. There are approximately 260 unique items in the record and 150 unique modifiers on these items, but not all modifiers apply to all items. We experimented with two version of the dev and test sets. The first is manually transcribed in the same manner as the training set, while the second is generated by a speech recognition decoder that was trained on the conversations in the training set. We denote the second set as *ASR-dev* and *ASR-test*. Table 2 lists the statistics of the data sets. Note that the audio of a conversation was collected as a single file and then automatically segmented into turns for ASR decoding. This process was not perfect and likely introduced some errors. Thus, the average length and number of turns of differ between the ASR transcriptions and the manual transcriptions.

Data Set	Avg Turns	Avg Length	Avg # Items
Training	8.8	53.5	3.7
Dev	9.7	57.07	3.8
Test	8.7	50.96	3.5
ASR-Dev	8.5	49.8	3.8
ASR-Test	7.8	44.7	3.5

Table 2: Statistics of the experimental corpus. The table denotes the average number of utterances in a conversation, average length of a conversation in words, and average number of items in an order.

### 4.2 Experimental setup

All words are lower-cased and an unknown word token is used for words which appear less than four times in the training set. The word embedding matrix is initialized by randomly sampling from a normal distribution, and scaled by 0.01. The recurrent connections of the GRU are initialized with orthogonal matrices (Saxe et al., 2013) and biases are initialized to zero. A single layer GRU is used for both the encoder and decoder. The network has 600 hidden units and uses 300-dimensional word embeddings. The dropout rate is set to 0.5. We did not tune hyper-parameters except for the dimension of the role embedding which is selected from  $\{3, 5, 10\}$  on the dev set. During inference, we use beam search decoding with a beam of 5 to generate the structured records. In order to decode without a length bias, the log probability of decoded results is normalized by the number of tokens.

### 4.3 Evaluation

A typical metric to evaluate a generation system is BLEU score (Papineni et al., 2002) which uses ngram overlap to quantify the degree to which a hypothesis matches the reference. However, our scenario is more demanding: order items are either correct or incorrect. Therefore, we adopt precision and recall at the item level as our evaluation metric. Note that an item is defined as a row in the structured data record and typically includes multiple fields. Using Table 1 as an example, there are three items to be scored. Only when the model produces an item that is exactly the same as the reference item do we count it as correct. As an additional measure, we report accuracy of the entire order, in which every item in an order must be correct for the order to be counted as correct.

	Model		Dev			Test				
	Gate	Role	Recall	Prec	F1	Accy	Recall	Prec	F1	Accy
IR	-	-	26.5	22.7	24.5	11.4	29.7	25.6	27.5	14.1
PBMT	-	-	64.4	19.3	35.2	29.3	62.6	20.8	36.0	28.4

Table 4: Results of different methods on ASR-dev and ASR-test set.

#### 4.4 Baseline systems

We compare the performance of our neural model with baseline models that employ information retrieval (IR) and phrase-based machine translation (PBMT) approaches.

**IR:** The IR method treated the training set of transcriptions as a collection of documents, each mapped to a corresponding order. The test conversation was used as a query to find the most similar training set conversation. The corresponding order was returned as the estimated order. In our experiment, we use TFIDF to compute the similarity score.

**PBMT:** The goal of a phrase-based translation model is to map a conversation into its structured record with alignment and language models. In our experiments, we use the Moses decoder, a state-of-the-art phrase-based MT system available for research purposes. We use GIZA++ (Och and Ney, 2003) to learn word alignment and *irstlm* to learn the language model. The models are trained on the conversation/order pairs in the training set and used to predict the structured data record given a conversation.

#### 4.5 Results

First we discuss the performance of our models on manually transcribed data and then examine the results on ASR recognized data. Table 3 lists the experiment results on manually transcribed dev and test sets. We refer to our model as the neural attention model (NAM). We see that the NAM is superior to both the IR and PBMT methods by a large margin. Both the proposed memory gate and role modifications yield improvements over the basic NAM. When combined, these produce the best performance in terms of accuracy on the dev set, and both F1 and accuracy on the test set. While there are only small differences in the scores among some of the NAM methods, we are unaware of a measure of statistical significance suitable for this task.

Though not reported, we also found that a basic encoder-decoder s2s model without attention performs poorly; it cannot summarize information across multiple turns into a single vector. The attention mechanism, acting on the entire encoding sequence, is critical in our task.

Table 4 shows results on the ASR-dev and ASR-test sets. These data sets are quite noisy since the speech recognizer in this domain has a word error

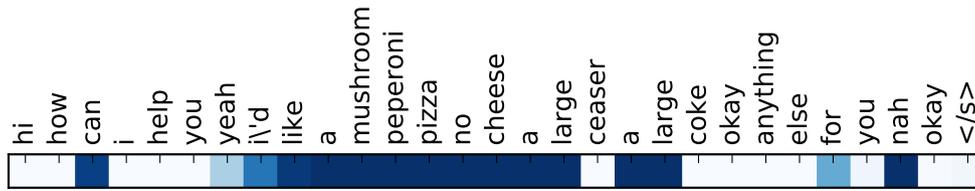

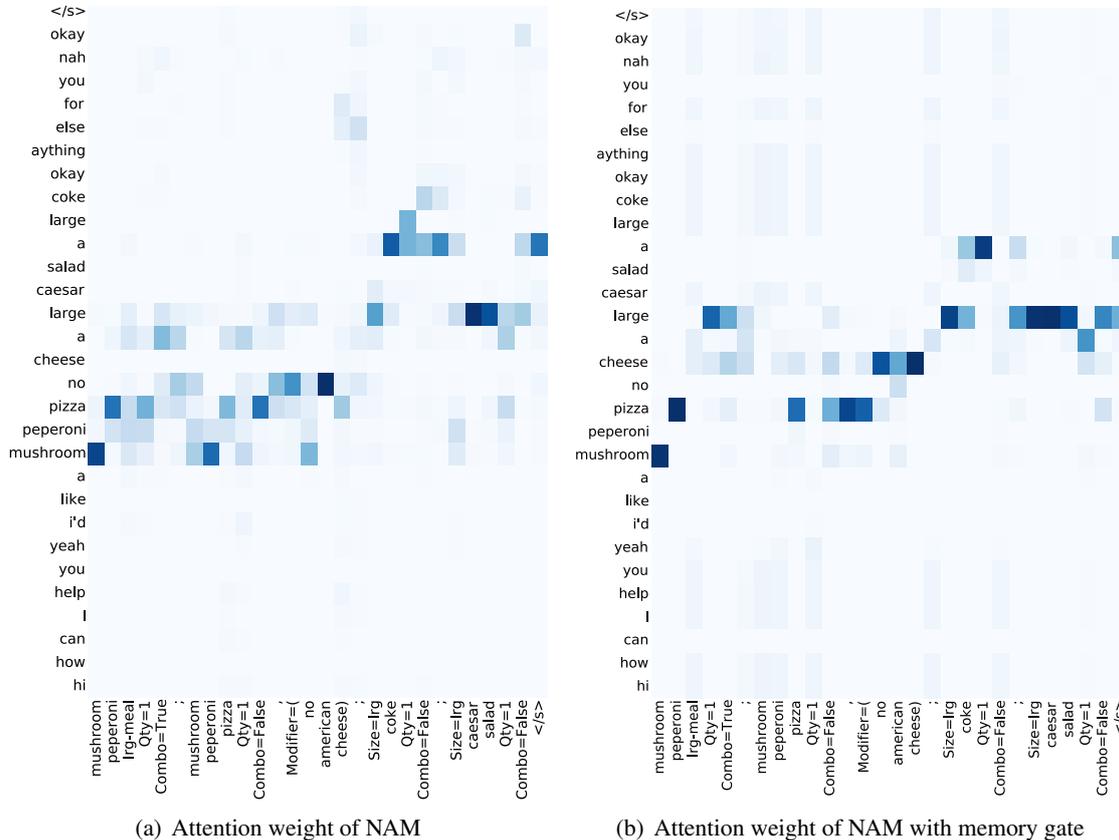

Figure 4: Example of memory gate weights at each time stamp.

(a) Attention weight of NAM

(b) Attention weight of NAM with memory gate

Figure 5: Examples of attention weights of models (a) without memory gate and (b) with memory gate. (b) shows sparse and more focused attention weights. (Better viewed in color.)

rate around 25%. With this noisy data, we find that the memory gate and role additions consistently improve performance. When combined, both F1 and accuracy improved.

#### 4.6 Qualitative analysis

Figure 6 shows a sample input and the output from each model. We see that the NAM augmented with memory gates and role information successfully captures the interaction and generates the correct record.

To better understand the proposed model, we visualize the attention weight at each time step in Figure 5. The figure compares the attention weights produced by a conventional context mem-

ory and the proposed gated context memory. We see that both models are able to learn good soft alignment between the input conversation and the output structured data record. However, the attention weights in 5(b), with our proposed gated attention mechanism, are sparser than those in 5(a) and better able to ignore uninformative terms in the input.

## 5 Related Work

There has been much work on information extraction from single utterances. Kate and Mooney (2006) proposed the use of SVM classifiers based on string kernels to parse natural language to a formal meaning representation. Wong and

*Waiter: My name's Alexis how can I help you.*  
*Customer: Yeah can I get a cheese pizza combo?*  
*Waiter: Something to drink?*  
*Customer: Change that to a mushroom pizza*  
*combo with a large sprite no ice.*  
*Waiter: Okay.*  
*Customer: Thank you.*  
*Waiter: Thank you.*

**NAM:**

*Cheese Pizza, Qty=1, Combo=True*  
*Sprite, Size=Lrg, Qty=1, Modifier=( no ice );*  
*Caesar Salad, Size=Med, Qty=1*

**NAM + Memory Gate:**

*Cheese Pizza, Qty=1, Combo=True*  
*Sprite, Size=Lrg, Qty=1, Modifier=( no ice );*  
*Caesar Salad, Size=Med, Qty=1*  
*Mushroom Pizza, Qty=1, Combo=True*  
*Sprite, Size=Lrg, Qty=1, Modifier=( no ice );*  
*Caesar Salad, Size=Med, Qty=1*

**NAM + Memory Gate + Role:**

*Mushroom Pizza, Qty=1, Combo=True*  
*Sprite, Size=Lrg, Qty=1, Modifier=( no ice );*  
*Caesar Salad, Size=Med, Qty=1*

Figure 6: Examples of outputs generated by each model for the conversation in first row.

Mooney (2006) used syntax-based statistical machine translation method to do semantic parsing. Translation of natural language to a formal meaning representation is captured by a synchronous context-free grammar in (Wu, 1997; Chiang et al., 2006). Quirk et al. (2015) created models to map natural language descriptions to executable code using productions from the formal language. Beltagy and Quirk (2016) improved the performance of semantic parsing on If-Then statements by using neural networks to model derivation trees and leveraged several techniques like synthetic training data from paraphrases and grammar combinations to improve generalization and reduce overfitting. In addition, there are some other research works focusing on text generation from structured data records. Angeli et al. (2010) proposed of a domain independent probabilistic approach to performing content selection and surface realization, making text generation as a local decision process. Konstas and Lapata (2013) created a global model to generate text from structured records, which jointly modeled content selection and surface realization with a probabilistic context-free grammar. In contrast, in this paper we focus on generating structured data records from text descriptions.

Using spoken language understanding techniques, (Mesnil et al., 2015) tag each word in a sentence with a predefined slot. A dialog modeling approach (Young et al., 2013) is also relevant to our task. However, this approach requires the definition of semantic slot names and human labeling of dialog acts in each utterance.

There are a number of relevant applications of neural attention models. Nallapati et al. (2016) proposed using sequence to sequence model to summarize source code into natural language; they used a LSTM as encoder and another attentional LSTM and decoder to jointly learn content selection and realization. Dong and Lapata (2016) presented a sequence to sequence model with a tree structure decoder to map natural language to its logical form. The tree structure decoder shows superior performance on data that has nested output structure. It has also been used in other domains including machine translation (Sutskever et al., 2014; Bahdanau et al., 2014), and image caption generation (Fang et al., 2015). From this perspective, the most related work is (Mei et al., 2016) in which they proposed using a sequence-to-sequence model to map navigational instructions in natural language to actions, which is conceptually similar to our work. However, we start from conversations and our structured data records are more complex.

## 6 Conclusion

In this paper we have presented an end to end method for extracting structured information from unstructured conversations using an encoder-decoder neural network. The restaurant-ordering domain we study is distinguished from past work by its conversational nature, and the need to handle user corrections and modifications. We incorporate a memory gate and role information into the encoder network to selectively keep important information and capture interaction patterns between conversation participants. Experimental results on both a human transcribed data set and ASR-recognized data set demonstrate the feasibility and effectiveness of our approach.

## Abstract

We present a deterministic sieve-based system for attributing quotations in literary text and a new dataset: QuoteLi3<sup>1</sup>. Quote attribution, determining who said what in a given text, is important for tasks like creating dialogue systems, and in newer areas like computational literary studies, where it creates opportunities to analyze novels at scale rather than only a few at a time. We release QuoteLi3, which contains more than 6,000 annotations linking quotes to speaker mentions and quotes to speaker entities, and introduce a new algorithm for quote attribution. Our two-stage algorithm first links quotes to mentions, then mentions to entities. Using two stages encapsulates difficult sub-problems and improves system performance. The modular design allows us to tune either for overall performance or for the high precision appropriate for many use cases. Our system achieves an average F-score of 87.5% across three novels, outperforming previous systems, and can be tuned for precision of 90.4% at a recall of 65.1%.

## 1 Introduction

Dialogue, representing linguistic and social relationships between characters, is an important component of literature. In this paper, we consider the task of quote attribution for literary text: identifying the speaker for each quote. This task is important for developing realistic character-specific conversational models (Vinyals and Le, 2015; Li et al., 2016), analyzing discourse structure, and literary studies (Muzny et al., 2016). But identifying speakers can be difficult; authors often refer to the

speaker only indirectly via anaphora, or even omit mention of the speaker entirely (Table 1).

Prior work has produced important datasets labeling quotes in novels, providing training data for supervised methods. But some of these model the quote-attribution task at the mention-level (Elson and McKeown, 2010; O’Keefe et al., 2012), and others at the entity-level (He et al., 2013), leading to labels that are inconsistent across datasets.

We propose entity-level quote attribution as the end goal but with mention-level quote attribution as an important intermediary step. Our first contribution is the QuoteLi3 dataset, a unified combination of data from Elson and McKeown (2010) and He et al. (2013) with the addition of more than 3,000 new labels from expert annotators. This dataset provides both mention and entity labels for *Pride and Prejudice*, *Emma*, and *The Steppe*.

Next, we describe a new deterministic system that models quote attribution as a two-step process that i) uses textual cues to identify the mention that corresponds to the speaker of a quote, and ii) resolves the mention to an entity. This system improves over previous work by 0.8-2.1 F1 points and its modular design makes it easy to add sieves and incorporate new knowledge.

In summary, our contributions are:

- A unified dataset with both quote-mention and quote-speaker links labeled by expert annotators.
- A new quote attribution strategy that improves on all previous algorithms and allows the incorporation of both rich linguistic features and machine learning components.
- A new annotation tool designed with the specifics of this task in mind.

We freely release the data, system, and annotation tool to the community.<sup>2</sup>

<sup>2</sup>[nlp.stanford.edu/~muzny/quoteli.html](http://nlp.stanford.edu/~muzny/quoteli.html)

Type	Example	Speaker
Explicit	“Do you really think so?” cried <b>Elizabeth</b> , brightening up ...	Elizabeth Bennet
Anaphoric (pronoun)	“You are uniformly charming!” cried <b>he</b> , with an air of awkward gallantry;	Mr. Collins
Anaphoric (other)	“I see your design, Bingley,” said <b>his friend</b> .	Mr. Darcy
Implicit	“Then, my dear, you may have the advantage of your friend, and introduce Mr. Bingley to her.”	Mr. Bennet
	“Impossible, Mr. Bennet, impossible, when I am not acquainted with him myself; how can you be so teasing?”	Mrs. Bennet
	“I honour your circumspection. [...] I will take it on myself.”	Mr. Bennet
	The girls stared at their father. Mrs. Bennet said only, “Nonsense, nonsense!”	Mrs. Bennet

Table 1: Quotes where speakers are mentioned explicitly, by anaphor, or implicitly (conversationally).

## 2 Related Work

Early work in quote attribution focused on identifying spans associated with content (quotes), sources (mentions), and cues (speech verbs) in newswire data. This is the approach taken by Pareti et al. (2012; 2013). More recent work by Almeida et al. (2014) performed entity-level quote attribution and showed that a joint model of coreference and quote attribution can help both tasks.

In the literary domain, Glass and Bangay (2007) did early work modeling both the mention-level and entity-level tasks using a rule-based system. However, their system relied on identifying a main speech verb to then identify the actor (i.e. the mention) and link to the speaker (i.e. the entity) from a character list. This system worked very well but was limited to explicitly cued speakers and did not address implicit speakers at all.

Elson and McKeown (2010) took important first steps towards automatic quote attribution. They formulated the task as one of *mention* identification in which the goal was to link a quote to the mention of its speaker. Their method achieved 83.0% accuracy overall, but used gold-label information at test time. Their corpus, the Columbia Quoted Speech Corpus (CQSC), is the most well-known corpus and was used by follow-up work. However, a result of their Mechanical Turk-based labeling strategy was that this corpus contains many unannotated quotes (see Table 4).

O’Keefe et al. (2012) also treated quote attribution as mention identification, using a sequence labeling approach. Their approach was successful in the news domain but it failed to beat their baseline in the literary domain (53.5% vs 49.8%

Quote Types	<i>Emma</i>	<i>The Steppe</i>
with mention	546 (74.4%)	371 (59.6%)
with speaker	491 (66.9%)	258 (41.5%)

Table 4: Coverage of the CQSC labels

accuracy). This work quantitatively showed that quote attribution in literature was fundamentally different from the task in newswire.

We compare against He et al. (2013), the previous state-of-the-art system for quote attribution. They re-formulated quote attribution as quote-speaker labeling rather than quote-mention labeling. They used a supervised learner and a generative actor topic model (Celikyilmaz et al., 2010) to achieve accuracies ranging from 82.5% on *Pride & Prejudice* to 74.8% on *Emma*.

## 3 Data: The QuoteLi3 Corpus

We build upon the datasets of He et al. (2013) and Elson and McKeown (2010) to create a comprehensive new dataset of quoted speech in literature: QuoteLi3. This dataset covers 3 novels and 3103 individual quotes, each linked to speaker and mention for a total of 6206 labels, more than 3000 of which are newly annotated. It is composed of expert-annotated dialogue from Jane Austen’s *Pride and Prejudice*, *Emma*, and Anton Chekhov’s *The Steppe*.

### 3.1 Previous Datasets

The datasets described in section 2 are valuable but incomplete and hard to integrate with one another given their different designs.

The Columbia Quoted Speech Corpus is a large dataset that includes both quote-mention and

Novel	He et al.		CQSC (Elson and McKeown, 2010)		QuoteLi3	
	q-mention	q-speaker	q-mention	q-speaker	q-mention	q-speaker

<i>All</i>		3103			2296			1901	

Table 3: Breakdown of our dataset by novel and type of quote (uncollapsed). For comparison with the dataset from He et al. (2013), we provide the collapsed statistics assuming one speaker per paragraph.

quote-speaker labels (Elson and McKeown, 2010). It suffers from problems often associated with crowdsourced labels and the use of low-accuracy tools. In this corpus, quote-mention labels were gathered from Mechanical Turk, where each quote was linked to a mention by 3 different annotators. Elson and McKeown (2010) report that 65% of the quotes in CQSC had unanimous agreement and that 17.6% of the quotes in this corpus were unlabeled. To generate quote-speaker labels, an off-the-shelf coreference tool<sup>3</sup> was used to link mentions and form coreference chains. We find that 57.8% of the quotes in this corpus either i) have no speaker label (48.1%) or ii) the speaker cannot be linked to a known character entity (9.7%). O’Keefe et al. (2012) find that 8% of quotes with speaker labels are incorrectly labeled. Our analysis of the relevant part of CQSC for this work is shown in Table 4.

The data from He et al. (2013) includes high-quality speaker labels but lacks quote-mention labels. There is no overlap in the data provided by He et al. (2013) and CQSC, but this work did evaluate their system on a subset of CQSC. This dataset assumes that all quoted text within a paragraph should be attributed to the same speaker.<sup>4</sup> While this assumption is correct for *Pride and Prejudice*, it is incorrect for novels like *The Steppe*, which use more complex conversa-

tional structures<sup>5</sup>. This assumption leads to a problematic method of system evaluation in which all quotes within a paragraph are considered in the gold labels to be one quote, even if they were in fact uttered by different characters. We refer to this strategy as having “collapsed” quotes in our evaluations and present it for the purpose of providing a faithful comparison to previous work.

In QuoteLi3 we add the annotations that are missing from both datasets and correct the existing ones where necessary. A summary of the annotations included in this dataset and comparison to the previous data that we draw from is described in Table 2. Our final dataset is described in Table 3. It features a complete set of annotations for both quote-mention and quote-speaker labels.

### 3.2 Annotation

Two of the authors of the paper were the annotators of our dataset. They used annotation guidelines consisting of an example excerpt and a description, which is included in the supplementary materials §A.5. The annotators were instructed to identify the speaker (from a character list) for each quote and to identify the mention that most directly helped them determine the speaker. Unlike Elson and McKeown (2010), mentions can be pronouns and vocatives, not just explicit name referents. Mentions that were closer to the quote and speech verbs were favored over indirect mentions (such as those in conversational chains). Figure 1 shows an example from *Pride and Prejudice*.

Annotation was done using a browser-based an-

<sup>3</sup>Even current state-of-the-art coreference tools achieve just over 65% average F1 scores (Clark and Manning, 2016).

<sup>4</sup>For first-level quotes, there is typically just one speaker per paragraph. This assumption breaks down in some cases and it is very rarely true for nested quotes.

<sup>5</sup>See supplemental section A.1.

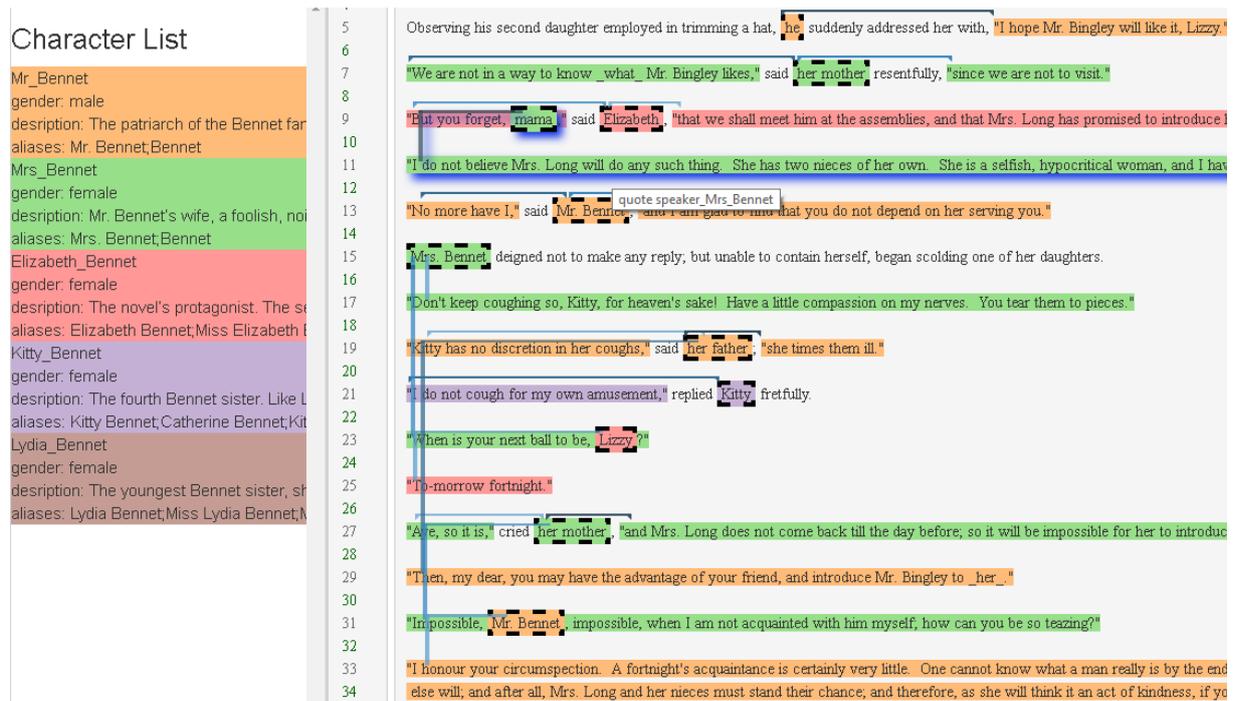

Figure 1: Conversation from *Pride and Prejudice* annotated with our annotation tool. Speakers are indicated by color, mentions are marked by dashed outlines, and quote-to-mention links by blue lines.

notation tool developed by the authors. Previously developed tools were either not designed for the task (BRAT (Stenetorp et al., 2012), WebAnno (Yimam et al., 2013), CHARLES (Vala et al., 2016)) or unavailable (He et al., 2013). One problem with the CQSC annotations was that the annotators were shown short snippets that lacked the context to determine the speaker and no character list. We designed our tool to provide context and a character list including name, aliases, gender, and description of the character. Similar to CHARLES, the character list is not static and the annotator can add to the list of characters. Our tool also features automatic data consistency checks such as ensuring that all quotes are linked to a mention.

Our expert annotators achieved high inter-annotator agreement with a Cohen’s  $\kappa$  of .97 for quote-speaker labels and a  $\kappa$  of .95 for quote-mention labels.<sup>6</sup> To preserve the QuoteLi3 data for train, dev, and testing sets, we calculated this inter-annotator agreement on excerpts from *Alice in Wonderland* and *The Adventures of Huckleberry Finn* containing 176 quotes spoken by 10 characters, chosen to be similar to the data found in QuoteLi3.

<sup>6</sup>The reported agreement is the average of the Cohens kappas from these passages.

### 3.3 Statistics

Table 3 shows the statistics of our annotated corpus. Unlike He et al. (2013), we do not assume that all quotes in the same paragraph are spoken by the same speaker. To compare with the dataset used by He et al. (2013), we provide the collapsed statistics as well. As Table 3 shows, we have roughly the same number of annotated quotes for *Pride and Prejudice* as He et al. (2013). For *Emma* and *The Steppe*, which were taken from the CQSC corpus, we have considerably more quotes because of our added annotations (see Table 4).

## 4 The Quote Attribution Task

The task of quote attribution can be summarized as “who said that?” Given a text as input, the final output is a speaker for each uttered quote in the text. We assume that all quotes have been previously identified. O’Keefe et al. (2012) find that regular-expression approaches to quote detection yield over 99% accuracy for clean English-language data. A number of other approaches to quote detection have been studied in recent years for more complex data (Pouliquen et al., 2007; Pareti et al., 2013; Muzny et al., 2016; Scheible et al., 2016). Following He et al. (2013), we assume that there is a predefined list of characters available, with the name, aliases, and gender of each

character.<sup>7</sup>

Some key challenges in quote attribution are resolving anaphora (i.e., coreference) and following conversational threads. Literature often follows specific patterns that make some quotes easier to attribute than others. Therefore, an approach that anchors conversations on easily identifiable quotes can outperform approaches that do not.

Figure 1 shows an example of a complex conversation at the beginning of *Pride and Prejudice*. This example illustrates the spectrum of easy to difficult cases found in the task: simple explicit named mention (lines 9, 13, 21), nominal mentions (lines 7, 19, 27), and pronoun mentions (line 5). Sometimes explicitly named mentions embedded in more complex sentences can still be challenging as they require good dependency parses. This example also illustrates a conversational chain with alternating speakers between Mrs. Bennet and Elizabeth Bennet (lines 7 to 11), and between Mr. Bennet and Mrs. Bennet (lines 27 to 34). In this case, vocatives (expressions that indicate the party being addressed) are cues for who the other speaker is (lines 9, 23, 31). When the simple alternation pattern is broken, explicit speech verbs with the speaking character are specified. To summarize, there are several explicit cues and some easy cases in a conversation that can be leveraged to make the hard cases easier to address.

First, consider the quote→mention linking subtask. This is an inherently ambiguous task (i.e. any mention from the same coreference chain is valid,) but we know that if the target quote is linked to the annotated mention that this is one correct option. This means that the evaluation of the quote→mention stage is a lower-bound. In other words, since a given quote may have multiple mentions that could be considered correct, our system may choose a “wrong” mention for a quote but link it to the correct speaker in the end. Thus, if our mention→speaker system could perfectly resolve every mention to its correct speaker, our overall quote attribution system would be guaranteed to get at minimum the same results as the quote→mention stage.

The quote→speaker task can be tackled directly without addressing quote→mention, but identifying a mention associated with the speaker allows us to incorporate key outside information. An

<sup>7</sup>Character lists are available on sites like sparknotes.com. The automatic extraction of characters from a novel has been identified as a separate problem (Vala et al., 2015).

other advantage of this approach is that we can then separately analyze and improve the performance of the two stages.

Therefore we evaluate both subtasks to give a more complete picture of when the system fails and succeeds. We use precision, recall, and F1 so that we can tune the system for different needs.

## 5 Approach

Our model is a two-stage deterministic pipeline. The first stage links quotes to specific mentions in the text and the second stage matches mentions to the entity that they refer to.

By doing both quote→mention and mention→entity linking, our system is able to leverage additional contextual information, resulting in a richer, labeled output. Its modular design means that it can be easily updated to account for improvements in various sub-areas such as coreference resolution. We use a sieve-based architecture because having accurate labels for the easy cases allows us to first find anchors that help resolve harder, often conversational, cases. Sieve-based systems have been shown to work well for tasks like coreference resolution (Raghunathan et al., 2010; Lee et al., 2013), entity linking (Hajishirzi et al., 2013), and event temporal ordering (Chambers et al., 2014).

### 5.1 Quote→Mention

The quote→mention stage is a series of deterministic sieves. We describe each in detail in the following sections and show examples in Table 5.

**Trigram Matching** This sieve is similar to patterns used in Elson and McKeown (2010). It uses patterns like Quote-Mention-Verb (e.g. ``...'' she said) where the mention is either a character name or pronoun to isolate the mention. Other patterns include Quote-Verb-Mention, Mention-Verb-Quote, and Verb-Mention-Quote.

**Dependency Parses** The next sieve in our pipeline inspects the dependency parses of the sentences surrounding the target quote. We use the enhanced dependency parses (Schuster and Manning, 2016) produced by Stanford CoreNLP (Chen and Manning, 2014) to extract all verbs and their dependent `nsubj` nodes. If the verb is a common speech verb<sup>8</sup> and its `nsubj` relation points to a

<sup>8</sup>This list of verbs as well as the family relation nouns list are available in supplemental section A.4.

Sieve	Example
Trigram Matching	“They have none of them much to recommend them,” replied <b>he</b> .
Dependency Parses	<b>Mrs. Bennet</b> said only, “Nonsense, nonsense!”
Single Mention Detection	... <b>Elizabeth</b> impatiently. “There has been many a one, I fancy, overcome in the same way. I wonder who first discovered the efficacy of poetry in driving away love!”
Vocative Detection	“My dear <b>Mr. Bennet</b> ,...” “Is that his design in settling here?”
Paragraph Final Mention Linking	After a silence of several minutes, <b>he</b> came towards her in an agitated manner, and thus began, “In vain have I struggled...”
Supervised Sieve	–
Conversation Detection	“Aye, so it is,” cried <b>her mother</b> ... “Then, my dear, you may have the advantage of your friend, and introduce Mr. Bingley to her.” “Impossible, Mr. Bennet, impossible, when I am not acquainted with him myself; how can you be so teasing?”
Loose Conversation Detection	“I will not trust myself on the subject,” replied <b>Wickham</b> ; “I can hardly be just to him.” Elizabeth was again deep in thought, and after a time exclaimed, “To treat in ... the favourite of his father!” She could have added, “A young man, too,... being amiable”– but she contented herself with, “and one, too, ... in the closest manner!” “We were born in the same parish, within the same park; the greatest part of our youth was passed together;...”

Table 5: Quote→Mention sieves and example quotes that they apply to.

Sieve	Example
Exact Name Match	“ <i>Do you really think so?</i> ” cried <b>Elizabeth</b> , brightening up for a moment.
Coreference Disambiguation	“ <i>You are uniformly charming!</i> ” cried <b>he</b> , with an air of awkward gallantry;
Conversational Pattern	“ <i>Impossible, Mr. Bennet, impossible ...</i> ” (Mrs. Bennet) “I honour your circumspection...I will take it on myself.” (Mr. Bennet) The girls stared at their father. Mrs. Bennet said only, “Nonsense, nonsense!” (Mrs. Bennet)
Family Noun Vocative Disambiguation	“...You know, <b>sister</b> , we agreed long ago never to mention a word about it. And so, is it quite certain he is coming?” “ <i>You may depend on it,</i> ” replied the other ...
Majority Speaker	–

Table 6: Mention→Speaker Sieves and example quotes that they apply to. Bold text indicates where the speaker information comes from while italic text indicates the target quote being labeled.

character name, a pronoun, or an animate noun,<sup>9</sup> we assign the quote to the target mention.

**Single Mention Detection** If there is only a single mention in the non-quote text in the paragraph of the target quote, link the quote to that mention.

**Vocative Detection** If the preceding quote contains a vocative pattern (see supplemental section A.2), link the target quote to that mention. Vocative detection only matches character names and animate nouns.

**Paragraph Final Mention Linking** If the target quote occurs at the end of a paragraph, link it to the final mention occurring in the preceding sentence.

**Conversational Pattern** If a quote in paragraph  $n$  has been linked to mention  $m_n$ , then this sieve links an unattributed quote two paragraphs ahead,  $n + 2$ , to mention  $m_n$  if they appear to be in conversation. We consider two quotes “in conversation” if the paragraph between is also a quote, and

<sup>9</sup>The list of animate nouns is from Ji and Lin (2009).

the quote in paragraph  $n + 2$  appears without additional (non-quote) text.

**Loose Conversational Pattern** We include a looser form of the previous sieve as a final, high-recall, step. If a quote in paragraph  $n$  has been linked to mention  $m_n$ , then this sieve links quotes in paragraph  $n + 2$  to  $m_n$  without restriction.

## 5.2 Mention→Speaker

The second stage of our system involves linking the mentions identified in the first stage to a speaker entity. We again use several simple, deterministic sieves to determine the entity that each mention and quote should be linked to. A description of these sieves and example mentions and quotes that they are applied to appears in Table 6.

For the following sieves, we construct an ordered list of *top\_speakers* by counting proper name and pronoun mentions around the target quote. If gender for the target quote’s speaker can be determined either by the gender of a pronoun mention or the gender of an animate noun (Bergsma and

Lin, 2006), this information is used to filter the candidate speakers in the *top\_speakers* list.

We use a window size from 2000 tokens before the target quote to 500 tokens after the target quote. If no speakers matching in gender can be found in this window, it is expanded by 2000 tokens on both sides.

**Exact Name Match** If the mention that a quote is linked to matches a character name or alias in our character list, label the quote with that speaker.

**Coreference Disambiguation** If the mention is a pronoun, we attempt to disambiguate it to a specific character using the coreference labels provided by BookNLP (Bamman et al., 2014).

**Conversational Pattern** Similarly as in the quote→mention section, we match a target quote to the same speaker as a quote in paragraph  $n + 2$ , if they are in the same conversation and it is labeled. Next, we match it to the quote in paragraph  $n - 2$  if they are in the same conversation and it is labeled. This sieve receives gender information from the mention that the target quote is linked to.

**Family Noun Vocative Disambiguation** If the target quote is linked to a vocative in the list of family relations (e.g. “papa”), pick the first speaker in *top\_speakers* that matches the last name of the speaker of the quote containing the vocative.

**Majority Speaker** If none of the previous sieves identified a speaker for the quote, label the quote with the first speaker in the *top\_speakers* list.

## 6 Experiments

In all experiments, we divide the data as follows: *Pride and Prejudice* is split as in He et al. (2013) with chapters 19-26 as the test set, 27-33 as the development set, and all others as training. *Emma* and *The Steppe* are not used for training.

### 6.1 Baseline

As a baseline, for the quote→mention stage we choose the mention that is closest to the quote in terms of token distance. This is similar to the approach taken in BookNLP (Bamman et al., 2014), in which quotes are attributed to a mention by first looking for the closest mention in the same sentence to the left and right of the quote, then before a hard stop or another quote to the left and right of the target quote. For the mention→speaker stage,

Test	ES	AS(p)	AS(o)	IS	All
<i>P &amp; P</i>	98.4	77.3	42.9	82.3	85.1
<i>Emma</i>	92.1	62.5	35.0	71.5	75.9
<i>The Steppe</i>	97.5	67.0	14.9	60.4	72.7

Table 9: Breakdown of the accuracy of our system per type of quote (see Table 3) in each test set.

we use the Exact Name Match and Coreference Disambiguation sieves.

### 6.2 Comparison to Previous Work

Table 7 shows a direct comparison of our work versus the previous systems. We replicate the test conditions used by He et al. (2013) as closely as possible in this comparison.

In this comparison, the evaluations based on CQSC are of non-contiguous subsets of the quotes that are also not necessarily the same between our work and the previous work. As discussed in section 3, CQSC provides an incomplete set of quote-speaker labels. In this work we follow the same methodology as He et al. (2013) to extract a test set of unambiguously labeled quotes by using a list of character names to identify those that are unambiguously labeled. In section 7, we analyze *The Steppe* and *Emma* more thoroughly, showing that this method results in an easier subset of the quotes in these novels.

Our preferred evaluation, shown in Table 8, differs from previous evaluations in four important ways. We hope that this work can establish consistent guidelines for attributing quotes and evaluating system performance to encourage future work.

- Each quote is attributed separately.<sup>10</sup>
- The test sets are composed of every quote from the test portion of each novel, no subsets are used because of incomplete annotations.<sup>11</sup>
- No gold data is used at test time.<sup>12</sup>
- Precision and recall are reported in preference to accuracy for a more fine-grained understanding of the underlying system.

<sup>10</sup>This is in contrast to the work of He et al. (2013)

<sup>11</sup>This is in contrast to the work of Elson and McKeown (2010) and He et al. (2013). The work of O’Keefe et al. (2012) is the only previous work to augment the unlabeled portions of CQSC. They achieved 53.3% accuracy on CQSC from a rule-based system similar to our baseline. This data is not available.

<sup>12</sup>Gold data was used at test time by Elson and McKeown (2010) who achieved 83.0% accuracy on the CQSC.

Test	He et al.	Baseline	This work	+ supervised
<i>Pride and Prejudice</i>	82.5	45.3	83.6	<b>85.2</b>
<i>Emma</i>	74.8*	40.7*	75.3*	<b>76.1*</b>
<i>The Steppe</i>	80.3*	66.7*	81.8*	<b>83.8*</b>

Table 7: Comparison with previous work. This table reports accuracy and comes with some caveats: \* indicates that a non-contiguous subset of the quotations were used (not all subsets are guaranteed to be the same as described in section 6.2), and all quotes within the same paragraph were collapsed. *Emma* and *The Steppe* come from CQSC. All systems are trained on *Pride and Prejudice*.

System	Test	Quote→Mention			Mention→Speaker			Accuracy
		P	R	F1	P	R	F1	
+supervised	<i>Pride and Prejudice</i>	86.7	93.5	89.9	85.1	100	92.0	85.1
+supervised	<i>Emma</i>	75.2	85.2	79.9	75.9	100	86.3	75.9
+supervised	<i>The Steppe</i>	81.7	88.6	85.0	72.7	100	84.2	72.7
	Average	81.2	89.1	84.9	77.9	100	87.5	
+precision	<i>Pride and Prejudice</i>	90.2	80.1	84.9	92.1	70.9	80.1	
+precision	<i>Emma</i>	84.6	68.3	75.6	85.7	59.0	69.9	
+precision	<i>The Steppe</i>	92.5	75.3	83.0	93.3	65.5	77.0	
	Average	89.1	74.6	81.2	90.4	65.1	75.7	

Table 8: Precision, recall, and F-Score of our systems on un-collapsed quotations and the fully annotated test sets from the QuoteLi3 dataset.

### 6.3 Adding a Supervised Component

To test how orthogonal our two-stage approach is to previous systems, we experiment by adding a supervised sieve to the quote→mention stage. We train a binary classifier, using a maxent model to distinguish between the correct and incorrect candidate mentions.

**Candidate Mentions** We take as candidate mentions all token spans corresponding to names, pronouns, and animate nouns in a one-paragraph range on either side of the quote. Names are determined by scanning for matches to the character list. We restrict pronouns to singular gendered pronouns, i.e. ‘he’ or ‘she’.

**Features** We featurize each (quote, mention) pair based on attributes of the quote, mention, and how far apart they are from one another. These features largely align with previous work and can be found in supplemental section A.3 (Elson and McKeown, 2010; He et al., 2013).

**Prediction** At test time our model predicts for each quote whether each candidate mention is or is not the correct mention to pair with that quote. If the model predicts more than one mention to be correct, we take the most confident result.

This sieve goes just before the conversation pat-

tern detection sieves in the quote→mention stage (see Table 5). This forms our +*supervised* system.

### 6.4 Creating a High-Precision System

One advantage of our sieve design is that we can easily add and remove sieves from our pipeline. This means that we can determine the combination of sieves that result in the system that achieves the highest precision with respect to the final speaker label. We use an ablation test to find the combination of sieves with the highest precision (95.6%) for speaker labels on the development set from *Pride and Prejudice*. These results are achieved by removing the Loose Conversation Detection sieve for the quote→mention stage and keeping only the Exact Name Match and Coreference Disambiguation sieves for the mention→speaker stage.

Together, these sieves create a system that we call +*precision* that emphasizes overall precision rather than F-score or accuracy.

## 7 Results

We show that a simple deterministic system can achieve state-of-the-art results. Adding a lightweight supervised component improves the system across all test sets. The sieve design allows us to create a high precision system that might be more appropriate for real-world applications that

value precision over recall.

The results in Table 8 confirm that the subset of test quotes from *Emma* and *The Steppe* used in previous work were an easier subset of the whole set of quotations. When evaluating based off of the whole set of quotations, we lose 0.2 and 11.1 points of accuracy for *Emma* and *The Steppe*, respectively. As we show in Table 4, *The Steppe* is missing a significant portion (50.9%) of the annotations whereas *Emma* is missing 28.6%. Our error analysis shows us that *The Steppe* features more complicated conversation patterns than the novels of Jane Austen, which makes the task of quote attribution more difficult.

One type of error analysis we performed was inspecting the accuracy of our system by quote type. As seen in Table 9, the main challenge lies in identifying anaphoric and implicit speakers. We find that resolving non-pronoun anaphora is much more challenging for our system than pronouns. This is because the only mechanism for dealing with these mentions is the Family Noun Vocative Disambiguation sieve; otherwise, the only information we gather from them is gender information. This indicates that adding information about the social network of a novel and attributes of each character (such as job and relationships to other characters) would further increase system performance.

## 8 Conclusion

In this paper, we provided an improved, consistently annotated dataset for quote attribution with both quote-mention and quote-speaker annotations. We described a two-stage quote attribution system that first links quotes to mentions and then mentions to speakers, and showed that it outperforms the existing state-of-the-art. We established a thorough evaluation and showed how our system can be tweaked for higher precision or refined with a supervised sieve for better overall performance.

A clear direction for future work is to expand the dataset to a more diverse set of novels by leveraging our annotation tool on Mechanical Turk or other crowdsourcing platforms. This work has also provided the background to see the pitfalls that a dataset produced in such a way might encounter. For example, annotators could label mentions and speakers separately, and examples with high uncertainty could be transferred to expert annotators. An expanded dataset would allow us to

evaluate how well our system generalizes to other novels and also allow us to train better models. Another interesting direction is to eliminate the use of predefined character lists by automatically extracting the list of characters (Vala et al., 2015).

## A Supplemental Material

### A.1 Nested Conversation Example

Figure 2: An example paragraph that contains multiple speakers from *The Steppe*

Figure 2 shows a screen shot of our annotation tool displaying a paragraph with a complex conversational structure from *The Steppe*.

### A.2 Vocative Patterns

Pattern	Example
between , and !	, Nastasya!
between , and ?	, Mr. Bennet?
between , and .	, Yegorushka.
between , and ;	, papa;
between , and ,	, Emma,
between “ and ,	“Father Christopher,
between , and ”	, mother”
after the word “dear”	Dear Lydia
between “oh” and !	Oh Henry!

Table 10: Vocative patterns for extracting mentions.

### A.3 Supervised Classifier Features

We used the following features in our supervised classifier:

- *Distance*: token distance, ranked distance (relative to mentions), paragraph distance (left paragraph and right paragraph separate)
- *Mention*: Number of quotes in the mention paragraph, number of words in mention paragraph, the order of the mention within the paragraph (compared to other mentions), whether the mention is within conversation

(i.e. no non-quote text in the same paragraph), whether the mention is within a quote, POS of the previous and next words.

- *Quote*: the length of the quote, the order of the quote (i.e. whether it is the first or second quote in a paragraph), the number of words in the paragraph, number of names in the paragraph, whether the quote contains text in it, whether the present quote contains the name of the mention (if mention is a name).

### A.4 Words Lists

**Common Speech Verbs** Similar to He et al. (2013), we use *say*, *cry*, *reply*, *add*, *think*, *observe*, *call*, and *answer*, present in the training data from *Pride and Prejudice*.

**Family Relation Nouns** ancestor aunt bride bridegroom brother brother-in-law child children dad daddy daughter daughter-in-law father father-in-law fiancée grampa gramps grandchild grandchildren granddaughter grandfather grandma grandmother grandpa grandparent grandson granny great-granddaughter great-grandfather great-grandmother great-grandparent great-grandson great-aunt great-uncle groom half-brother half-sister heir heiress husband mama mom mommy mother mother-in-law nana nephew niece pa papa parent pop second cousin sister sister-in-law son son-in-law stepbrother stepchild stepchildren stepdad stepdaughter stepfather stepmom stepmother stepsister stepson uncle wife

### A.5 Annotation Guidelines

- Each quote should be annotated with the character that is that quote’s speaker.
- Each quote should be linked to a mention that is the most obvious indication of that quote’s speaker.
  - Quotes can be linked to mentions inside other quotes.
  - Multiple quotes may be linked to the same mention.
- Mentions should also be annotated with the character that they refer to.
  - If a character’s name is meaningfully associated with an article (e.g. “...,” said *the Bear*), include that article in the mention.

# Out-of-domain FrameNet Semantic Role Labeling

## Abstract

Domain dependence of NLP systems is one of the major obstacles to their application in large-scale text analysis, also restricting the applicability of FrameNet semantic role labeling (SRL) systems. Yet, current FrameNet SRL systems are still only evaluated on a single in-domain test set. For the first time, we study the domain dependence of FrameNet SRL on a wide range of benchmark sets. We create a novel test set for FrameNet SRL based on user-generated web text and find that the major bottleneck for out-of-domain FrameNet SRL is the frame identification step. To address this problem, we develop a simple, yet efficient system based on distributed word representations. Our system closely approaches the state-of-the-art in-domain while outperforming the best available frame identification system out-of-domain. We publish our system and test data for research purposes.<sup>1</sup>

## 1 Introduction

Domain dependence is a major problem for supervised NLP tasks such as FrameNet semantic role labeling (SRL): systems generally exhibit a strong performance drop when applied to test data from a different distribution than the training data. This prohibits their large-scale use in language technology applications.

The same problems are expected for FrameNet SRL, but due to a lack of datasets, state-of-the-art FrameNet SRL is only evaluated on a single in-domain test set, see e.g. Das et al. (2014) and FitzGerald et al. (2015).

In this work, we present the first comprehensive study of the domain dependence of FrameNet SRL

on a range of benchmark datasets. This is crucial as the demand for semantic textual analysis of large-scale web data keeps growing.

Based on FrameNet (Fillmore et al., 2003), FrameNet SRL extracts frame-semantic structures on the sentence level that describe a specific situation centered around a semantic predicate, often a verb, and its participants, typically syntactic arguments or adjuncts of the predicate. The predicate is assigned a *frame* label, essentially a word sense label, that defines the situation and determines the *semantic roles* of the participants. The following sentence from FrameNet provides an example of the *Grinding* frame and its roles:

[The mill]<sub>Grinding\_cause</sub> **grinds**<sub>Grinding</sub> [the malt]<sub>Patient</sub> [to grist]<sub>Result</sub>.

FrameNet SRL consists of two steps, frame identification (frameId), assigning a frame to the current predicate, and role labeling (roleId), identifying the participants and assigning them role labels licensed by the frame. The frameId step reduces the hundreds of role labels in FrameNet to a manageable set of up to 30 roles. Thus, FrameNet SRL differs from PropBank SRL (Carreras and Màrquez, 2005), that only uses a small set of 26 syntactically motivated role labels and puts less weight on the predicate sense. The advantage of FrameNet SRL is that it results in a more fine-grained and rich interpretation of the input sentences which is crucial for many applications, e.g. reasoning in online debates (Berant et al., 2014).

Domain dependence is a well-studied topic for PropBank SRL. However, to the best of our knowledge, there exists no analysis of the performance of modern FrameNet SRL systems when applied to data from new domains.

In this work, we address this problem as follows: we introduce a new benchmark dataset YAGS

<sup>1</sup>[www.ukp.tu-darmstadt.de/ood-fn-srl](http://www.ukp.tu-darmstadt.de/ood-fn-srl)

(Yahoo! Answers Gold Standard), which is based on user-generated questions and answers and exemplifies an out-of-domain application use case. We use YAGS, along with other out-of-domain test sets, to perform a detailed analysis of the domain dependence of FrameNet SRL using *Semafor* (Das et al., 2014; Kshirsagar et al., 2015) to identify which of the stages of FrameNet SRL, *frameId* or *roleId*, is particularly sensitive to domain shifts. Our results confirm that the major bottleneck in FrameNet SRL is the frame identification step. Motivated by that, we develop a simple, yet efficient frame identification method based on distributed word representations that promise better domain generalization. Our system’s performance matches the state-of-the-art in-domain (Hermann et al., 2014), despite using a simpler model, and improves on the out-of-domain performance of *Semafor*.

The contributions of the present work are two-fold: 1) we perform the first comprehensive study of the domain generalization capabilities of open-source FrameNet SRL, and 2) we propose a new frame identification method based on distributed word representations that enhances out-of-domain performance of frame identification. To enable our study, we created YAGS, a new, substantially-sized benchmark dataset for the out-of-domain testing of FrameNet SRL; we publish the annotations for the YAGS benchmark set and our frame identification system for research purposes.

## 2 Related work

The domain dependence of FrameNet SRL systems has been only studied sparsely, however, there exists a large body of work on out-of-domain PropBank SRL, as well as on general domain adaptation methods for NLP. This section briefly introduces some of the relevant approaches in these areas, and then summarizes the state-of-the-art in FrameNet frame identification.

**Domain adaptation in NLP** Low out-of-domain performance is a problem common to many supervised machine learning tasks. The goal of domain adaptation is to improve model performance on the test data originating from a different distribution than the training data (Søgaard, 2013). For NLP, domain adaptation has been studied for various tasks such as POS-tagging and syntactic parsing (Daumé III, 2007; Blitzer et al., 2006). For the complex task of SRL, it is strongly associated with PropBank, because

the corresponding CoNLL shared tasks promote out-of-domain evaluation (Surdeanu et al., 2008; Hajič et al., 2009). In the shared tasks, in-domain newspaper text from the WSJ Corpus is contrasted to out-of-domain data from fiction texts in the Brown Corpus. Most of the participants in the shared tasks do not consider domain adaptation and report systematically lower scores for the out-of-domain data (Hajič et al., 2009).

Representation learning has been successfully used to improve on the CoNLL shared task results (Huang and Yates, 2010; FitzGerald et al., 2015; Yang et al., 2015). Yang et al. (2015) report the smallest performance difference (5.5 points in  $F_1$ ) between in-domain and out-of-domain test data, leading to the best results to date on the CoNLL 2009 out-of-domain test. Their system learns common representations for in-domain and out-of-domain data based on deep belief networks.

**Domain dependence of FrameNet SRL** The FrameNet 1.5 fulltext corpus, used as a standard dataset for training and evaluating FrameNet SRL systems, contains texts from several domains (Ruppenhofer et al., 2010). However, the standard data split used to evaluate modern systems (Das and Smith, 2011) ensures the presence of all domains in the training as well as test data and cannot be used to assess the systems’ ability to generalize. Moreover, all the texts in the FrameNet fulltext corpus, based on newspaper and literary texts, are post-edited and linguistically well-formed. The FrameNet test setup thus cannot provide information on SRL performance on less edited out-of-domain data, e.g. user-generated web data.

There are few studies related to the out-of-domain generalization of FrameNet SRL. Johansson and Nugues (2008) evaluate the impact of different parsers on FrameNet SRL using the Nuclear Threats Initiative (NTI) data as an out-of-domain test set. They observe low domain generalization abilities of their supervised system, but find that using dependency parsers instead of constituency parsers is beneficial in the out-of-domain scenario. Croce et al. (2010) use a similar in-domain/out-of-domain split to evaluate their approach to open-domain FrameNet SRL. They integrate a distributional model into their SRL system to generalize lexicalized features to previously unseen arguments and thus create an SRL system with a smaller performance gap between in-domain and out-of-domain test data (only 4.5 percentage points  $F_1$ ).

Note that they only evaluate the role labeling step. It is not transparent how their results would transfer to the current state-of-the-art SRL systems that already integrate methods to improve generalization, for instance using distributed representations.

Palmer and Sporleder (2010) analyze the FrameNet 1.3 training data coverage and the performance of the Shalmaneser SRL system (Erk and Padó, 2006) for frame identification on several test sets across domains, i.e. the PropBank and NTI parts of the FrameNet fulltext corpus and the fictional texts from the SemEval-2007 shared task (Baker et al., 2007). Having observed that the majority of errors results from coverage gaps in FrameNet, they suggest to focus on developing frame identification systems that generalize well to new domains. Our observations support their findings and show that the problem still persists even when modern SRL methods and the extended FrameNet 1.5 lexicon are used.

Søgaard et al. (2015) annotate 236 tweets with FrameNet labels to apply SRL to knowledge extraction from Twitter. They report that the frameId performance of `Semafor 2.1` (Das et al., 2010) on the new test set is similar to its performance on the SemEval-2007 newswire test set (Baker et al., 2007). For full SRL, there are large differences:  $F_1$  reaches only 25.96% on the Twitter set compared to the 46.5% reported by Das et al. (2010) on the in-domain set. These results show that there is ample room for improvement for SRL on Twitter data.

Recent FrameNet SRL systems are not evaluated in the context of their domain dependence: Kshirsagar et al. (2015) use the domain adaptation approach from Daumé III (2007) to augment the feature space for FrameNet SRL with FrameNet example sentences; FitzGerald et al. (2015) and Hermann et al. (2014) adopt deep learning methods, including learning representations that may generalize better to unseen data, to present state-of-the-art results for FrameNet SRL. All of the former only use the already introduced split of the FrameNet fulltext corpus for testing, as does the long-time state-of-the-art system `Semafor` (Das et al., 2014). Out-of-domain evaluation is lacking, as are datasets that enable this kind of evaluation.

**Frame identification** Current state of the art in frame identification is the approach by Hermann et al. (2014), further referred to as `Hermann-14`, followed by the previous state-of-the-art model `Semafor` (Das et al., 2014).

The frame identification system of `Semafor` relies on an elaborate feature set based on syntactic and lexical features, using the WordNet hierarchy as a source of lexical information, and a label propagation-based approach to take unknown predicates into account. `Semafor` is not specifically designed for out-of-domain use: the WordNet coverage is limited, and the quality of syntactic parsing might drop when the system is applied to out-of-domain data, especially in case of non-standard user-generated texts.

`Hermann-14` uses distributed word representations augmented by syntactic information. General-purpose distributed word representations (such as `word2vec` (Mikolov et al., 2013) and `GloVe` (Pennington et al., 2014)) are beneficial for many NLP tasks: word representations are calculated on a large unlabeled corpus, and then used as input for high-level tasks for which training data is scarce, such as syntactic parsing, word sense disambiguation, and SRL. In the syntax-augmented representations of `Hermann-14`, a region of the input vector, a *container*, is reserved for each syntactic path that can connect predicates to their arguments. This container is populated with a corresponding argument word representation, if the argument on this path is found in the training data. `Hermann-14` uses the WSABIE algorithm (Weston et al., 2011) to map input and frame representations to a common latent space. WSABIE uses WARP loss and gradient-based updates to minimize the distance between the latent representations of the predicate target and the correct frame, while maximizing the distance to all the other irrelevant frames. During testing, cosine similarity is used to find the closest frame given the input. One advantage of this approach is that similar frames are positioned close to each other in the latent space which allows information to be shared between similar predicates and similar frames. This system is the current state-of-the-art for in-domain frame identification, but has not been applied in an out-of-domain setting.

### 3 Out-of-domain FrameNet test data

This section describes available in-domain and out-of-domain FrameNet test sets and the creation of YAGS, a new out-of-domain FrameNet test set.

**FrameNet test sets** FrameNet SRL is typically evaluated on **das-test**, the test set first introduced by Das and Smith (2011). It is a held-out set randomly sampled from the FrameNet 1.5 fulltext cor-

If [you]<sub>Grinder</sub> have a [mortal and pestle]<sub>Grinding\_instrument</sub>, **grind**<sub>Grinding.head</sub> **up**<sub>Grinding.satellite</sub>  
 [all the ingredients]<sub>Undergoer</sub> [in the order above] <sub>Manner</sub> [with it]<sub>Instrument</sub>.

Figure 1: Example sentence from YAGS with multiword predicate and typo (*mortal* vs. *mortar*).

pus. While the FrameNet fulltext corpus contains data from various sources, we consider das-test an *in-domain* test set: all data sources of the test set are also represented in the training set.

There are two additional datasets from other domains that we use in our study on domain generalization: The MASC word sense sentences corpus contains FrameNet annotations for a lexical sample of roughly 100 lemmas from ANC (Passonneau et al., 2012). The Twitter-based dataset from Søggaard et al. (2015), henceforth TW, has some very distinctive properties: it does not provide a gold standard, but annotations by three annotators. This leads to a high variance in role annotations: the annotator TW<sub>3</sub> annotated only 82% of the number of roles annotated by TW<sub>1</sub>, see Table 1. Like Søggaard et al. (2015), we report SRL results as averages over the three annotations (TW-av).
